This pattern is an emergent behavior of the ant colony, that is ordered and is robust against the uncertainty and the complexity of the environment. Although information about the presence of food is made available locally, it affects the global behavior of the colony and the state of the environment.

In order to integrate this behavior within the holonic architecture, the deposit of pheromones can be translated into order holons reserving time slots in these local schedules. In other words, "ant agents" travel virtually and execute virtually what an order holon might do for real. Finally, the order holon picks out the best solution among available alternatives. This architectural pattern is represented as Delegate MultiAgent System (DMAS), and is sketched in Figure 2. According to this pattern, the DMAS allows a holon to delegate a swarm of lightweight agents to perform an action to support the issuing holon in fulfilling its functions.

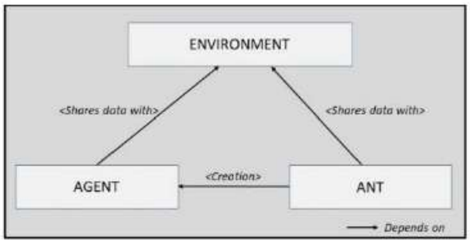

Figure 2. Delegate MultiAgent System (adapted from [7])

In the application reported in this paper, we developed a model involving resource, order and product holons (Figure 3), where the product holon exposes attributes that can be retrieved directly from a BIM model, and the holon order applies the ant-colony optimization algorithm described in the next sub-section to find out the optimal schedule. The architecture depicted in Figure 3 was built according to the PROSA reference architecture, which was successfully applied in manufacturing. The order holon is in charge of managing the schedule. It commits resources, both those ones which are in charge of executing the tasks and the resources that are consumed by construction works (e.g. excavated or drilled soil). To be noticed that there are several instances of "product holons", because each of them includes information about a possible technology for constructing the several types of piles that can reasonably be found in a building detailed design. Resources are sized according to the specific technology and to parameters, which can be inputted directly from the BIM model.

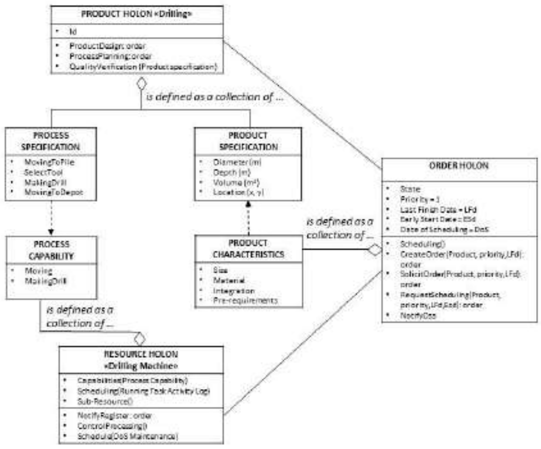

Figure 3. Suggested UML architecture for pile construction (adapted from PROSA)

3.2.2 Multi-objective Optimization Algorithm

As the case study analysed in this paper is the first task of bored piles execution (i.e. drilling), optimization was performed by means of vehicle routing problems. Indeed, driving drilling machines along the most cost-effective path recalls problems about routing optimization. More specifically, we refer to the multiple ant colony system for vehicle routing problems with time windows (MACS-VRPTW), which performs ant colony optimization [20]. Basically MACS-VRPTW is organized with a hierarchy of artificial ant colonies designed to successively optimize a multiple objective function: the first colony minimizes the number of vehicles while the second colony minimized the travelled distance. Basically, a VRP is composed of n customers served from a unique depot. Each customer asks for a quantity q_i of goods and a vehicle capacity Q is available for delivery. Each delivery cannot be split and the vehicle has to periodically return to the depot for reloading. On the overall, the problem is represented as a graph made of a node set $C = \{c_0, c_1, \dots, c_n\}$ and arcs $L=\{c_i, c_j\}$ to which a matrix of travel time values t_{ij} is associated. The goal is to find a set of tours of minimum total travel time, where each tour starts and ends at the depot c_0. Extensions to the basic problem include: service time for each customer; duration limit of each tour. But in this paper we applied the VRP with time windows, i.e. VRPTW. This problem includes for the depot and each customer c_i a time window [b_i, e_i], during which the customer has to be served between starting time b_i and end time e_i. The tours are performed by a fleet of identical vehicles. This approach is applied to the case study presented in this paper, and optimization is performed by means of ant colony optimization (ACS), and both the number of vehicles and travel time are to be minimized (i.e. multi-objective). To this purpose, two measures (i.e. heuristics) are associated to each arc: closeness (η_{ij}) and pheromone trail (τ_{ij}). The first is the inverse of the distance, the second one is dynamically changed by ants at runtime. Pheromone trails are used in conjunction with the objective function to construct new solutions: a higher probability is given to elements with a strong pheromone trails. Pheromone levels give a measure of how desirable it is to insert a given arc in a solution. At runtime, m ants build tours in parallel. Each ant is randomly assigned to a starting node and has to build a solution, by adding iteratively new nodes until all nodes have been visited. When ant k is located at node i, it chooses the next node j probabilistically in the set of feasible (i.e. have not been visited, yet) nodes N_i^k. The probabilistic rule is defined by Equation 1:

$$p_{ij} = \begin{cases} \dfrac{\tau_{ij} \cdot [\eta_{ij}]^{\beta}}{\sum_{l \in N_l^k} \tau_{il} \cdot [\eta_{il}]^{\beta}} & if\ \ j \in N_i^k \\ 0 & otherwise \end{cases} \qquad (1)$$

In fact, the process goes through two steps: exploration and exploitation. During exploration, with probability q_0 a node with the highest $\tau_{ij}[\eta_{ij}]^{\beta}$ is chosen, with the purpose of selecting the components to be used to construct a solution. During exploitation, the next components is chosen by maximizing a blend of pheromone trail values and heuristic evaluations. More specifically, with probability (1- q_0) the node j is chosen with a probability p_{ij} (Eq. 1). The procedure exploits two parameters: β weighs the relative importance of the heuristic value, while q_0 determines the relative importance of exploration versus exploitation. Once each ant has built a complete solution, this is tentatively improved using a local search procedure. Next, the best solution found from the beginning of the trial is used to update the pheromone trails. Then, the process is iterated starting again m ants until a termination condition is met. The best solution is used to modify the pheromone trail matrix (τ_{ij}), future ants will use this information to generate new solutions in the neighborhood of the best solution, as follows:

$$\tau_{ij} = (1-\rho) \cdot \tau_{ij} + \frac{\rho}{J_{\Psi}^{gb}}, \qquad \forall\ (i,j) \epsilon \Psi^{gb} \qquad (2)$$

Where $0<\rho<1$ and J_{Ψ}^{gb} is the length of J^{gb}, i.e. the shortest path generated by ants since the beginning of computation. Locally, when an ant moves from node i to node j, the amount of pheromone trail on arc (i, j) is decreased by the amount:

$$\tau_{ij} = (1-\rho) \cdot \tau_{ij} + \rho \cdot \tau_0 \qquad (3)$$

Where τ_0 is the initial value of trails. This algorithm was used with two objective functions: minimization of the number of tours and minimization of the total travel time. To this purpose, two independent colonies are used, one per each objective, but both share the variable Ψ^{gb}. Finally, time windows are used to limit the duration of the path. To this purpose, an active procedure is inserted in the algorithm, which, at every step when and ant moves between nodes i and j, it checks whether the movement violates time window constraints. Optionally, even vehicle capacities (i.e. payload) can be checked for violation, but it was not used in the application that will be shown in this paper.

3.3 Implementation of the Holonic Execution System

The MACS-VRPTW algorithm detailed in sub-section 3.2.2 was integrated in the DMAS architecture (Figure 3), as depicted in Figure 4. The order holon gets an order from the master schedule with task description, start and end dates. At time step t_0, the order holon delegates ant colonies to search for the best path. After the drilling process starts and disturbances or unexpected occurrences can take place changing boundary conditions, the order holon runs more simulations and performs on-line planning, i.e. continuous improvement of the initial work plan. The resources in charge of drilling piles were committed according to the best solution found out by the holon order itself. The algorithm was implemented in Matlab™ environment, because it facilitates the prototyping of the code. In the near future, integration within a multi-agent simulation environment (e.g. Anylogic) will be carried out. The main boundary conditions were:

- no maximum payload was assigned to drill resources, in fact assuming that they never come back to the depot until they finish their tasks;
- drills were not allowed to follow a path overlapping the nodes were piles had already been drilled; this was done by using a dynamic cost matrix;
- As all the parameters are dynamic (e.g. time window, cost matrix) when the algorithm updates the current best solution with a new one, the cost of the current solution is re-computed at each iteration.

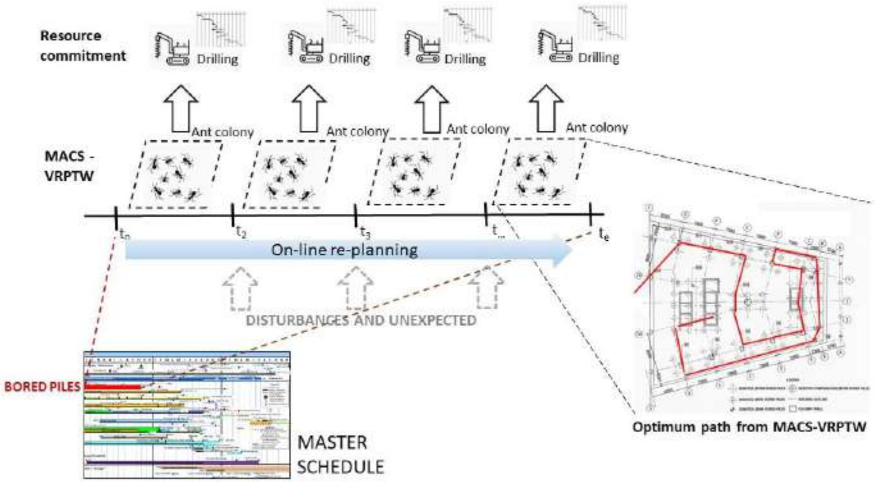

Figure 4. Sketch of the overall logic underlying the MACS-VRPTW algorithm.

The termination condition was set at 300 iterations. The main outputs provided by the algorithm are: sequence of nodes forming the best solution; overall cost of the solution; service (i.e. delivery) time to perform each pile drilling.

4 Testing of the Holonic Execution System

4.1 On-line Planning of Construction Works

4.1.1 The Case Study

Pile construction was chosen as the test case for our proof of concept, because it poses several challenges: uncertainty generated by soil type, equipment efficiency and weather conditions; again, unexpected occurrences like site restriction and disposal of excavated soil ask for the application of a reliable on-line planning scheduling [18]. The drilling task only was simulated (excluding rebar cage positioning and concrete pouring). The resource holon assigned to each pile contained information about the volume, type of concrete, soil type, location, that were used by drills to estimate their task duration. This information was used as input for the application of the MACS-VRPTW algorithm. The set of piles was assumed to be arranged as shown in Figure 5.

4.1.2 Simulation of Scenarios

Two scenarios were simulated:

1. The site is initially fully available for drilling and there are no space restrictions; then, due to interferences with other crews, part of the site is restricted to access, so re-planning is necessary; after some time, the site becomes fully available again and the task is accomplished.
2. Drilling starts when the previous task is not finished, yet. So, just a portion of the site is available for drilling. After a while, the previous task gets accomplished and the whole site becomes fully available again and the drilling task can be accomplished, too.

Before starting the drilling process, the HES finds that the path marked on Figure 5-a and superimposed to the foundation plan is the best one, where the red squared node is the depot and the yellow circle nodes are the piles. In all figures, black lines form the path to be executed, whereas red lines form the accomplished path. While pile no. 16 is in progress (marked in a blue-coloured circle in Figures 5-a and 5-b), the site area within the boundaries of the blue dashed rectangular shaped area marked on Figure 5-b becomes restricted. As a result, the best path is re-planned, whose outcome is shown on Figure 5-b (piles between no. 1 and no. 13) and the drilling machine continues working according to this second work plan. The restricted area becomes available again while the drilling machine is doing pile no. 53 (blue-coloured marked circle on Figure 5-c). Hence, the on-line planning system computes again a new solution for the best path and the whole job is accomplished. In the second scenario, the site area included within the boundaries marked by the blue dotted polygon (Figure 6-a) is restricted due to the previously scheduled task. So the drilling machine is sent into the left side area of the site. Such a site area becomes unrestricted while the machine is drilling pile no. 4 (blue circled on Figure 6-b). As a result, the best solution is promptly updated and changes as shown on Figure 6-b. Also, the overall cost is updated as shown on Figure 6-c. Until the restricted area was not accessible, the best solution found was as costly as shown by the plot at iteration no. 150. But, on-line re-planning, which involved the second block made up of 150 iterations, caused the overall cost to decrease down to the value $1.8 \cdot 10^4$, which corresponds to iteration no. 300.

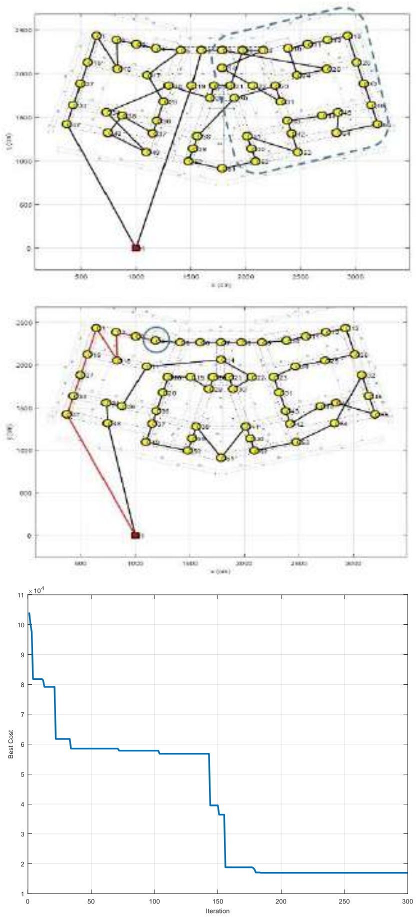
b)

c)

Figure 5: on-line re-planning relative to the Scenario no. 1.

4.2 Results and Discussion

This paper focused on the preliminary development of a holonic execution system (HEM) to implement on-line re-planning of construction activities.



a)

b)

c)

Figure 6: on-line re-planning relative to the Scenario no. 2.

The architecture used in this paper was adapted from the PROSA approach and the ACS-VRPTW algorithm was integrated to simulate the DMAS pattern. Simulation results are referred to the case of pile construction in the foundation of a building. It was shown that the HES is highly resilient to uncertainty and can cope with unexpected events, while minimizing the overall cost function. Thus, it is a good candidate for the implementation of lean management policies. In addition, the proposed architecture defines a valid general framework, based on which system frameworks specialized to several tasks can be developed. Further research will focus on the extension of the proposed architecture towards the realization of different construction tasks, for its enhancement and generalization. Finally, this approach is capable of facilitating the development of simulation scenarios relative to construction tasks, thanks to the reusability of the components forming the overall system architecture.

Abstract –

Building Information Modeling (BIM) represents a procedural and technological transition that emerges as a change agent in the Architecture, Engineering and Construction (AEC) industry. 4D modeling refers to a BIM dimension that associates the 3D model of an enterprise with the planning schedule information, providing the visualization of the actual sequence of construction activity. Interactions with 3D models are discussed and debated extensively in research, when in fact, 4D modeling is less discussed, thus there is a knowledge gap that can be explored. In this way, this article aims to know the current scenario of the studies that approach the 4D modeling theme in an international context. For this, a systematic mapping study was performed, covering only the researches in scientific paper format published between the years of 2006 and 2016. After establishing inclusion and exclusion criteria, a total of 148 articles were analyzed in this study. In the logical organization of the subject phase, bibliometric indicators were applied for analysis of the sample regarding the temporal evolution of the publications, publications by country, institution and author, and most commonly used keywords. Finally, the articles were also classified as to their content, and 10 categories were identified for them. The category containing the highest number of articles refers to the barriers, opportunities and impacts observed in the implementation of BIM 4D. It also includes surveys that measure the 4D BIM utilization rate by professionals, companies and countries. The results show that the number of studies published on 4D BIM has grown over the years, with the United States being the country that produces the most in the area. This fact suggests that US policies to encourage the adoption of BIM have been providing positive effects, serving as an example for other countries.

Keywords –

Building Information Modeling; BIM; 4D Modeling; Systematic Mapping Study; Scientific Production.

1 Introduction

Building Information Modeling (BIM) means a procedural and technological change that is considered a very promising evolution in the Architecture, Engineering and Construction (AEC) industry [1]. BIM is disseminated as a broad process of improving the techniques of designing, planning, constructing, occupying/using and maintaining a building throughout its life cycle, based on a data model that contains all the necessary information to stakeholders [2]. BIM is a digital representation of the physical and functional characteristics of a building [3].

Therefore, Building Information Modeling can be understood as a process that uses a variety of tools capable of generating and sharing information about a given construction, which will help in decision making during its life cycle. In this way, BIM is evident from project conception to demolition of the construction. It is noteworthy that the AEC industry is increasingly open to approaches that associate elements of 3D BIM (geometric shapes in three dimensions) with time and programming information, aiming to improve Integrated Project Delivery [4].

One of the biggest problems in construction projects is that their increasing complexity has made it difficult to accurately predict some extremely important performance indicators, for example, the project schedule. 4D models allow project participants to communicate performance deviations based on commitments from coordination sessions, measure readiness of the upcoming tasks based on inter-dependencies of current schedule tasks and their constraints, and highlight locations that are at-risk of potential performance problems [5].

While interactions with 3D models are widely addressed and discussed in surveys, the uses of 4D modeling are less debated, so there is an "urgent need to explore and evaluate these models" [6]. According to There is a need for an improved interoperability between BIM and softwares of scheduling. Their related research efforts in this field have demonstrated advancements in utilizing 4D models, but remains to be done comprehensively leveraging of the intelligence of BIM for automated scheduling generation. To reach this purpose, a systematic mapping of the literature is done in relation to 4D BIM, involving only the works published in scientific paper format [7].

Thus, this research focuses on the study of only one of the areas of scope attributed to BIM, which is the effective planning of the construction. Hence, it is important to inform that a 4D model (3D model plus time dimension) is a powerful and effective tool in planning, capable of exposing the sequence of construction phases linked to a three-dimensional model of the building. Therefore, the visualization of the elements is tied to the exact time (phase) in which they are to be constructed. This allows an effective and tangible communication between the professionals involved in the construction, and with the client, improving the understanding of the project's lifecycle and its construction strategies.

2 Previous Studies

The authors haven't found any previous studies involving this kind of approach in the context of the international production of 4D BIM. However, it should be noted that the authors Pérez, Fernandes and Costa [8] have reviewed the literature on BIM 4D studies, focusing on logistics operations and workspace management (construction sites). For the accomplishment of the mentioned research, only 20 articles, published in the period from 2005 to 2015, were selected for use. The articles were classified according to their respective vehicle of publication, year and subject.

Although it contributes to the understanding of the production of articles on the mentioned theme, there is not the required deeping for the characterization of this production due to the low number of analyzed works. In contrast, the present study mapped 148 articles, classifying them into fourteen different categories and analyzing a series of indicators. It's important to highlight that the articles were searched in both Portuguese and English languages, and the period of coverage selected includes the years from 2006 to 2016.

3 Research Method

A Systematic Mapping Study was developed in order to obtain an overview of the publications about the uses of 4D BIM. By presenting a detailed and explained approach, the chosen method aims the future repetition of this work in a more comprehensive way by other researchers or the authors themselves. The starting point of this search was the selection of journals and databases that publish or store contents related to architecture, civil engineering, construction, planning and management methods, technologies and software related to 4D BIM. It seeks to identify the articles of greater relevance to the proposed mapping. The research design is illustrated in Figure 1.

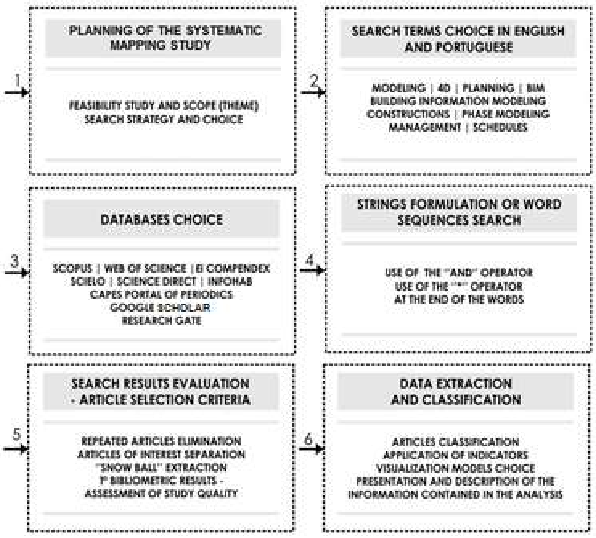

Figure 1. Methodological research steps

After the keywords were defined, the source search step was performed in two moments. In the first one, the publications were searched in the following digital databases: Scopus, Ei Compendex, SciELO, Science Direct, Web of Science, Google Scholar, the Capes portal of periodics and brazilian's Infohab (Centro de Referência e Informação em Habitação). Papers found in the ResearchGate social network were also tabbed. They led to a new search, characterizing the second moment, in which were included the collection of articles from the International Group for Lean Construction and electronic journals related to the industry of the AEC, as some of the Elsevier (Automation in Construction, Computers in Industry, Journal of Occupational Accidents, Advanced Engineering Informatics and Procedia Engineering), the EmeraldInsight (Construction Innovation, International Journal of Innovation Science, The International Journal of Logistics Management, International Journal of Operations & Production Management; International

Journal of Physical Distribution & Logistics Management, Journal of Engineering, Construction and Architectural Management) and the ASCE Library (Journal of Computing in Civil Engineering and Journal of Construction Engineering and Management). Other journals were found in the digital databases. Then, the Snowball Sampling mapping was carried out, in order to identify pertinent articles that were not previously selected. Snowball Sampling is a non-probability sampling technique that investigates the hidden population, which in this case refers to the papers that are not found in the search step [9].

At the end of this procedure, 314 articles were selected. Beyond the interval of time that was initially established, other criteria for the inclusion and exclusion of the data obtained were defined. It was necessary to have at least one keyword in the title, abstract, or keywords; and the access to the full text should be available for electronic consultation. Finally, articles that appeared in more than one base were eliminated, leaving a total of 148 articles.

The search results were moved to a Microsoft Excel spreadsheet and sorted according to their main subject. In the phase of logical organization of the subject, the following indicators were applied for the sample analysis: (i) time evolution of publications; (ii) publications by country, institution and author; (iii) most commonly used keywords; (iv) most used publication vehicles; (v) main subject.

4 Results and Discussions

In this section, the results of the international and national databases are summarized. Following the methodological procedures described in section 3, the search step resulted in a sample of 148 articles, in which 78 are from journals, and 74 from conferences.

4.1 Indicators

4.1.1 Time evolution of the publications

The evolution of the annual publication of the selected articles in the international search is showed in Figure 2, where it's possible to notice that all articles were published in a maximum of one decade. It is emphasized that there a considerable increase in publications happened after the year of 2014. The peak of the publications is marked by the year of 2015, with 33 articles published. In view of this, it is noted that the 4D BIM subject is recent and has not been much explored.

4.1.2 Publications per country, institution and author

The distribution of countries with more publications regarding 4D BIM, following the methodological procedures described in section 3, is presented in Figure 3. The most prominent country is the United States of America, with 40 articles, a value that is higher than the double of papers from the country in second place, which is Brazil. This result reinforces the SmartMarket Report study on the use of BIM in the United States, where it jumped from 40% in 2009 to 71% in 2012 [10]. The increase in the adoption of BIM is related to a national program called the 3D-4D-BIM Program, created in 2003 by the General Services Administration (GSA) in the USA. Subsequently, in 2006, the GSA decreed that all the new projected public buildings should use BIM at the conception stage, which also positively influenced the adoption of the technology [11].

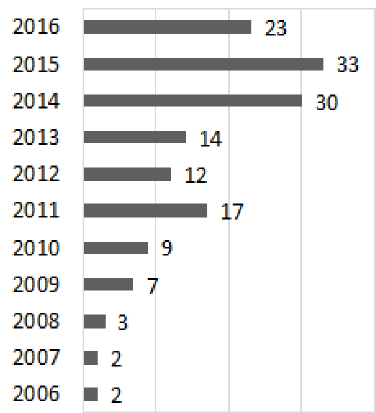

Figure 2. Articles published per year

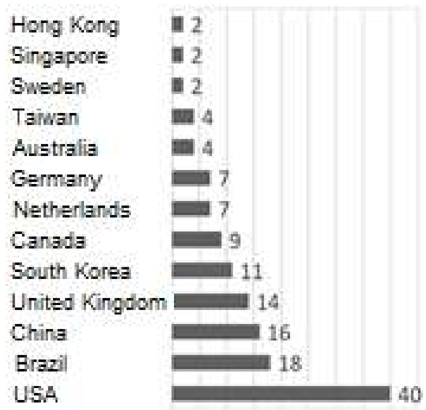

Figure 3. Articles published per country

The Figure 4 shows the number of institutions with more publications per country. Again, the United States of America appears in first place, with 15 institutions on the list, more than twice as many as the second, a position occupied by both China, South Korea and the United Kingdom, with 7 institutions on the listo of selected articles.

Figure 4. Institutions per country

Figure 5, however, represents the number of publications per institution. The university that publishes the most about 4D BIM is the University of Illinois, in the United States, with 11 articles, accounting for 27.5% of all publications in this country. Then, with 7 publications, are tied the institutions University of Twente, in the Netherlands, and Tsinghua University, in China.

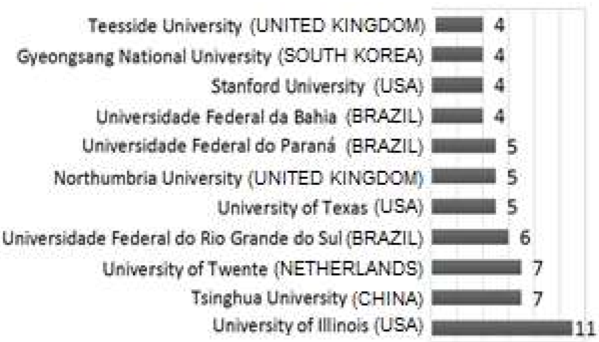

Figure 5. Publications per institution

Figure 6 shows the number of publications per author, but only those who collaborated in 3 or more articles on the subject, totaling 38 authors. In addition to these, 264 are present in the final sample of articles. The author with highest number of publications is Mani Golparvar-Fard, an assistant professor at the University of Illinois, in the United States. The second author on the list is Timo Hartmann, an assistant professor at the University of Twente, in the Netherlands. In the third place, two assistant professors are tied. They are LeenSeok Kang, from Gyeongsang National University, in South Korea, and Jianping Zhang, from the Chinese institution named as Tsinghua University.

4.1.3 Most used keywords

It is important to note that keywords represent the main subjects addressed in articles objectively, and are essential for tracking jobs quickly and accurately in a search. Thus, it's crucial for authors to choose the keywords of their articles carefully, otherwise it can hinder their propagation and the dissemination of their ideas. Figure 7 shows that the most used keyword in the articles was "4D", with 60 applications. Soon after, the word "BIM" comes up with 56 uses. In the third position comes the word "construction", with 48 uses.

Figure 6. Publications per author

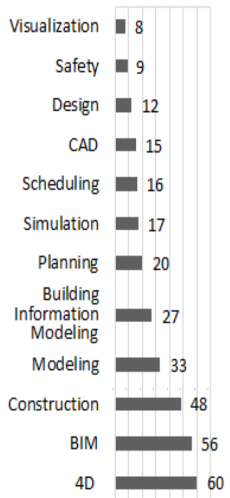

Figure 7. Publications per keyword

4.1.4 Most used publication vehicles

The journals in which it was possible to find the largest number of publications related to 4D BIM are those presented in Figure 8. "Automation in Construction" is highlighted, with 24 articles, followed by the "Journal of Construction Engineering and Management", with 11 publications.

Figure 8. Publications per Journal

The conferences (Figure 9) that concentrate more publications were two, the "International Conference on Computing in Civil and Building Engineering" and the "Conference of the International Group for Lean Construction", both with 12 articles. Soon thereafter, the event titled "Construction Research Congress" appears with 11 publications.

Figure 9. Publications per Conference

4.1.5 Main subject

In regard to identify he topics covered in the 148 articles chosen, a classification was made with 14 items. For a better understanding of the main subject categories, a brief explanation will be given on each one of them, in descending order of number of published articles.

The categorization generated Table 1, in which can be observed that the subject "Implementation of 4D BIM" was the most treated in the articles, with 51 apparitions. This category refers to research efforts that seek to identify challenges and opportunities encountered in the adoption of BIM 4D, at both organizational and governmental levels. In general, questionnaires are applied, and interviews are conducted to obtain insights from the AEC industry professionals. This classification also includes the growth rate in the adoption of 4D BIM by companies.

Implementation of 4D BIM	51
Logistics operations and workspace management	30
Dynamic planning - comparison between the as-planned and the as-built	23
Risk management in construction using 4D BIM	14
Management of space-time conflicts in projects	11
Integration between physical schedile and cost	6
Construction quality control through the integration of 4D BIM and other methods	5
Development and improvement of 4D BIM softwares	4
Comparison between different planning methods and 4D BIM	3
Development of components libraries	1

Table 1. Publications per main subject

Secondly, with 30 articles, is the "Logistics operations and workspace management" subject. The planning of logistics in a construction is fundamental to avoid waiting time, to manage the transportation of materials and waste, people movements and workflow of the various activities. Some problems such as lack of workspace, competing and restricted areas cause significant loss of time, thus being essential for construction planning.

The "Dynamic planning - comparison between the as-planned and the as-built" category, with 23 articles, is an actual performance analysis compared to the planned model for an early detection of initially idealized project designs.

In "Risk management in construction using 4D BIM", containing 14 articles, it refers to the evaluation of risks related to the safety and health of construction professionals associated with the work environment through BIM 4D.

The "Management of space-time conflicts in projects using 4D BIM " category has 11 articles. It refers to the the generation of modeling for the detection of conflicts between time, space and the 3D elements of projects, aiming the resolution of interferences before the beginning of construction. These problems can occur between the overlapping of activities in the schedule or different components of the building, such as, structure and installations, frames and sanitary pieces, among others.

The category named as “Integration between physical schedule and cost planning” contains 6 articles. It consists in papers that report the simultaneous use of 4D and 5D BIM softwares.

5 articles were put in the category called "Construction quality control through the integration of 4D BIM and other methods". It basically consists of integrating or comparing the use of BIM 4D with other methods, such as the Last Planner System (LPS). 4D scheduling is one example of synergy where BIM can be used to achieve lean effects.

The category "Development and improvement of BIM 4D tools" has 4 articles of the sample. With the increasing adoption of BIM, many tools are being developed and it is normal for existing ones to undergo improvement processes. As inherent in new technologies, one of the challenges related to 4D modeling tools is the lack of visualization patterns to represent construction elements and tasks, since each tool typically has its own standards.

With 3 articles in its sample, the ninth category is “Comparison between different planning methods and 4D BIM”. It’s a comparison of the acceptance of construction scheduling visualizations in 4D BIM and traditional planning tools, such as bar-charts and flowline-charts.

Lastly, only 1 article was found to the category named as “Development of a components library” category. It refers to the use of 4D BIM simulations to help in the creation of components libraries for projects.

5 Conclusions

This study aimed to characterize the international production of scientific articles in the area of 4D modeling. A sample of 148 papers was obtained in a time span from 2006 to 2016. The pioneering of this detailed research makes an important contribution to the identification of the subtopics related to 4D BIM.

This paper did not analyze the articles published in congresses related to 4D BIM, since most of them are not accessible to the researchers, unless they have participated in the events. The difficulty of finding conferences publications evidences the need to disseminate the articles produced by the students and professionals that make up the AEC industry. This may have caused a distortion in the search results, which identified that 49% of the publications came from events, while 51% were from journals. For this reason, it is recommended that other systematic mapping studies of the literature be done, including this kind of papers. It is noteworthy that articles of congresses contained in the research bases were counted in the present study.

The results show that the number of studies published on 4D BIM has been increasing over the years. It was also observed that the largest volume of publications occurred in 2015, with a slight decrease in 2016. The journal that most generated publications in the studied subject was the “Automation in Construction”, with 24 titles. The United States of America was the most representative country, with 40 publications. It also has the institution with the highest number of articles published, the University of Illinois, with 11 papers in its domain. This indicates that USA policies to encourage the adoption of BIM in public works have had positive effects.

Regarding the main subject of the articles, the fact that 51 of them approached the implementation of BIM 4D, totaling about 32% of the total sample, in which almost all of them are case studies, shows that the BIM methodology for planning is not only being studied in Academic world, but is also being applied in real construction projects.

Abstract

Pipe spool fabrication is still highly dependent on skilled craft labour and thus is subjected to the productivity issues, such as rework, that plague the construction industry. Rework is a major challenge and is estimated to account for up to 12% of the total cost of a major project. Identifying geometric non-conformance that requires rework is done by pipe fitters and inspectors and its impact is commensurate with the stage in the assembly process at which the non-conformance is detected. Thus, improving the frequency and effectiveness of this process can reduce rework and help mitigate its impact. It is proposed to replace the traditional process with an augmented reality process, where a 3D as-built point cloud can be superimposed on the 3D BIM model of the design, facilitating the communication of rework information. An experiment was conducted to compare the time required to convey rework information using an augmented reality feedback process compared to a traditional feedback system. Participants were given a PVC pipe spool to assemble with either the augmented reality process or with a two-sided isometric drawing. The time spent conveying the rework and the iterations of rework that were completed in each instance were evaluated to compare how the use of visualization technology affects the communication of rework.

Keywords –
Rework; Pipe fitting; Augmented Reality; point cloud; 3D BIM; modular

1 Introduction

Modular construction has become an increasingly popular means of construction as it allows for greater automation and allows for more work to be completed in a controlled fabrication shop environment as opposed to on a construction site. Shifting construction from an exterior activity where it is impacted by the elements to an interior activity has helped reduce rework. Currently, rework is believed to account for 6 to 12% of the cost of a typical construction project [1]–[3]. However, not every task can be automated. This is particularly true for the piping industry, leaving it susceptible to project delays and cost overruns caused by rework.

The focus of this work is on piping elements, since they can account for up to 50% of the total cost of an industrial construction project and of module fabrication [4]. This is largely due to the nature of piping work and its dependence on skilled craft workers, as most components in a piping project are custom-made based on the design, by cutting and welding sections of pipe, elbows, reducers and tees. The raw materials coupled with the extensive hands-on time from craft workers makes piping portions of projects costly to complete and critical with respect to the project schedule. Additionally, current quality control methods for piping are time consuming, requiring use of conventional measuring tools and utilize traditional paper based drawings to convey information. This method is inefficient, as it is not conducive to the sharing of information regarding an assembly's fit for use amongst project stakeholders [5]. While this study is focusing on pipe elements, the general concept could be applied to other construction project components.

Craft workers conduct routine checks as they assemble to verify their progress thus far. The technology traditionally used to complete this work consists of hand tools tailored to measure the geometry of the pipe assembly. These include callipers, measuring tapes and spirit levels. Following the completion of an assembly, quality control personnel complete a final check before the assembly is deemed complete. Should an instance of non-conformance requiring rework be detected, the quality control personnel must take note of the issues and explain them to the craft worker. The craft worker will be responsible for remedying the situation through interpreting the information presented by the quality control person and comparing it with the design information presented on the isometric drawing. The work proposed in this study would facilitate the self-checking during the assembly process by the craft workers by providing them with quick visual feedback regarding their work in addition to assisting quality control personnel with conveying information to craft workers.

In a traditional industrial project, pipe fitters are given isometric drawings containing all the information pertaining to the assembly they are fabricating. These drawings represent the pipes as a single straight line using a 45°, 90°, 45° projection system [6]. These drawings provide information about assembly geometry, welds and components such as elbows and flanges. Isometric drawings can be hard to interpret depending on the geometric complexity of the assembly and the worker's experience and level of comfort with the drawing format. Studies have found that using a two-sided isometric drawing, one which contains a traditional isometric drawing on one side and then a two dimensional (2D) projected rendering of a three dimensional (3D) model increases productivity by making the design easier to interpret [4]. Studies have also shown that providing a worker with a 3D model has a similar effect [6], [7]. With the technology used to acquire 3D spatial data becoming increasingly more affordable, and the ubiquity of 3D models for construction projects, it is now possible to show craft workers the rework that needs to be completed by overlaying the 3D as-built scan over the 3D design model, simplifying the process of conveying this information.

2 Literature Review

2.1 Rework

Rework is responsible for losses of both resources and time in the construction industry and is a major contributor to projects being completed behind schedule and over budget. In an industrial project, measured rework is believed to be approximately 2.4% of the contract value, representing millions of dollars in losses [8]. Normal process iteration is not considered part of rework. In general, minimizing rework and its impact on a project's ability to meet its budget and schedule is viewed as the key in improving construction productivity [9].

It has been found that craft workers believe that 32% of their negative productivity is caused by the insufficient quality of the information they are provided, and this insufficient quality of information was deemed to contribute to reduced morale within the group of workers [10].

In addition to the direct costs of rework in construction, which may total up to 25% of the contract value, rework has an impact valued at 3 to 6 times its direct cost given the impact it has on workers and the decreased site moral experienced when workers are asked to redo work that was previously completed [11].

2.2 Augmented Reality

In recent years, enhanced digital reality has become increasingly prevalent as technological advances allow for higher quality digital environments at lower price points. There are two areas of enhanced digital reality: virtual reality and augmented reality. Virtual reality consists of an immersive environment while augmented reality is an enhancement of the existing surroundings by overlaying digital information [7]. Augmented reality is preferable to virtual reality for applications in the construction industry as it does not inhibit a user's awareness of their physical environment in the way that virtual reality does, making it a safer option for hazardous construction sites.

2.3 Information Formats

A number of studies have been conducted showing the impact of different information formats on the productivity and quality of work performed by craft workers.

In 2015, Hou et all [7] focused on improving productivity and performance through lowering the cognitive load experienced by craft workers using augmented reality. The study was executed on graduate students in construction, computer science, architecture and engineering. Students were tasked with assembling a PVC pipe system. Half of the students were given a 2D isometric drawing while the other were given a 3D model on a TV display. The model could be rotated by moving a hand-held remote sensor in the direction they wanted to move the model. This study found that the use of 3D models reduced the cognitive load experienced by the participants and reduced the time required to complete the assembly by 50%

In 2016, Goodrum et al [4] completed a study in which 54 pipe fitters were given different formats of information to assemble a pipe assembly. One group was given a traditional 2D isometric drawing. The second group was given a two-sided isometric drawing, which consists of a 2D isometric drawing with a 2D projection of the corresponding 3D model on the back. The third group was given a 2D drawing with a 3D printed model of the assembly. The latter two groups both benefitted from the additional information; however, the second group, the one with the two-sided isometric drawing, was the fasted group. The results of this study were the main motivation behind providing the participants who did not use the augmented reality application with a two-sided isometric instead of a standard isometric drawing in the current study as two-sided isometrics are now an industry best-practice.

In 2014, Dadi et al [6], recruited 26 individuals, both engineering professionals and craft workers to assemble a 3D structure. The individuals were separated into three groups and each group was given the design in a different format. One group had a 2D set of drawings, the second a 3D computer model of the assembly and the third had a 3D printed model of the assembly. The study found that 3D printed models increased direct work and lowered the required mental work load more than 3D computer models and 2D drawings.

While studies focused on the impact of information formats on a craft worker's ability to complete an assembly have been completed, this study will instead focus on how the information format affects a craft worker's ability to identify and correct errors in their own work.

2.4 3D BIM

The increased prevalence of 3D Building Information Modeling (BIM) over the last two decades is a major contributor to the feasibility of the process being investigated in this work, as the process is contingent on having access to accurate, updated 3D models. Utilizing BIM offers many benefits to project stakeholders. Projects that utilize BIM are able to achieve increases in productivity of up to 30% while reducing the Requests for Information and Change Orders by a factor of 10 [12]. With design errors and omissions having the highest impact on the project cost for industrial projects, adopting 3D models to better integrate the different aspects of the design can help reduce the cost of a major industrial project [13]. Project managers believe that 3D modeling is a worthwhile investment and, specifically for the piping industry, that failing to create a model will increase the cost of piping project by 10% [14].

2.5 3D Spatial Data Acquisition

The use of laser scanners to acquire 3D spatial data is well established in construction management [15]. Laser scanners have been used for automated progress tracking [16], [17] and for compliance checking of fabricated elements [18], [19].

While laser scanners are able to provide highly accurate and broad range data, the data requires processing to be used, often requiring that multiple scans be stitched together, making it difficult to incorporate the technology into real time processes. For this reason, portable structured light scanners present a unique opportunity to acquire 3D spatial data that does not require processing and can thus be used in real time. For this reason, a structured light scanner is being utilized in this work.

2.6 Research Motivation

In countries with high labour costs, it is imperative to incorporate new technologies to maximize productivity. With the strict tolerances provided on most projects and the lack of skilled labour in countries like Canada and the United States [20], finding the means to minimize the impact of rework once it is encountered on a project is critical.

While work has been done to assess the impact of rework on a project's schedule and budge, and studies have been competed to determine how the format used to convey design information impacts productivity, there has been no work done in assessing how the communication of rework helps reduce the impact of rework on a construction project.

3 Methodology

As part of a larger study being conducted by the University of Waterloo and Aecon Industrial West, an application was developed with the aim of increasing productivity and reducing rework in pipe spool assembly through the use of augmented reality. This same application was utilized to assess how using an augmented reality process assists quality control personnel in conveying information pertaining to rework that must be completed on an assembly to the craft worker creating the assembly.

3.1 Participants

Currently, the recruited participants are all engineering students. Participants were split into two groups, with one completing the experiment with a two-sided isometric drawing and having corrections verbally conveyed. The other group utilized the augmented reality process to complete the assembly and were actively involved in the quality control, utilizing the augmented reality process to obtain feedback on their work. As such, a total of 2 groups of participants were utilized in the experiment: engineers with drawings and engineers with the application.

A total of 30 students were used, 15 in each subcategory. There are plans in place to recruit craft workers to further this study and this effort is currently in the coordination stage.

3.2 Experiment Assembly

It was deemed infeasible from a financial, logistical and safety perspective to conduct the experiment using a welded metal pipe assembly as would be the normal use scenario for the augmented reality process once it is deployed. Thus, a spool utilizing 1.5" diameter black PVC pipes was designed for this experiment. To help simulate the act of tack welding, the team purchased flexible couplings shown in Figure 2. The connections require the participant to use a screwdriver to tighten the metal connector. This penalizes a participant for creating an incorrect assembly since the connection must be loosened, the components moved and then the connection reconnected.

The nature of these socket-based connections prevents some of the challenges pipe fitters typically experience in assembling components to be flush with one another. This prompted the design of a spool with a more challenging geometry than normally experienced in an industrial piping project to help create an assembly that requires the level of planning and attention to detail that assembling a proper metal pipe spool would require. This design was then shown to an engineer at Aecon Inc. who said that while the spool was more complicated than a typical spool assembly seen in their shop, it was not an unreasonable design.

The two-sided isometric drawing that was given to participants to convey design information is shown in Figure 1.

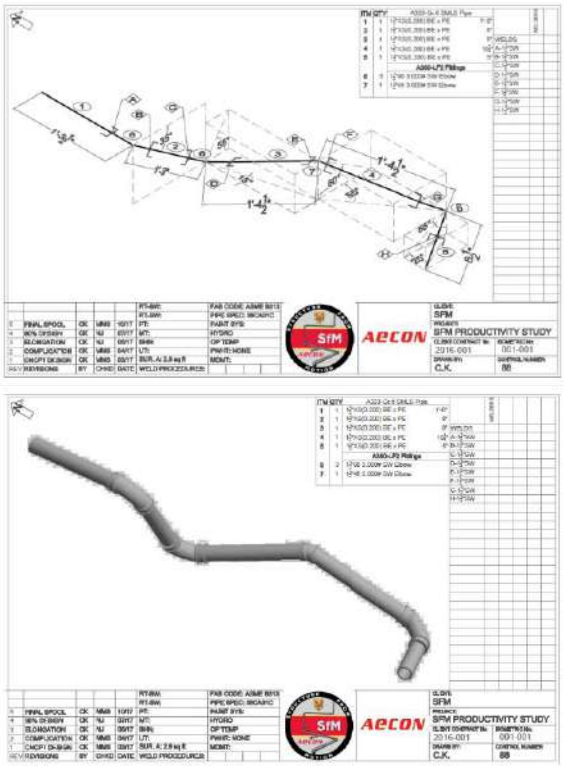

Figure 1. Both sides of the two-sided iso used in the experiment

Figure 2. Flexible elbow coupling used to simulate socket welds

3.3 Experiment Process

The participants were divided into two groups: one group working with a standard two sided isometric drawing and the other group working with the augmented reality process. Both groups were instructed to complete the same assembly. Figure 3 shows the set-up participants who used the augmented reality process were given to begin the experiment.

Figure 3. Initial set up of experiment

Figure 4. Structure IO, structured light scanner used for experiment mounted on an iPad

The workflow associated with both iterations of the experiment is shown in Figure 5. The steps enclosed in the red boxes are the main focus of this work. Both groups were given the same two-sided isometric drawing and assembled the same PVC pipe spool, however, the augmented reality group had rework identified by showing errors through overlaying a scan of the as-built assembly over the 3D design model while the group working with only the two-sided isometric drawing had their rework identified without the aid of the visual contrast comparing their erroneous assembly with the design model.

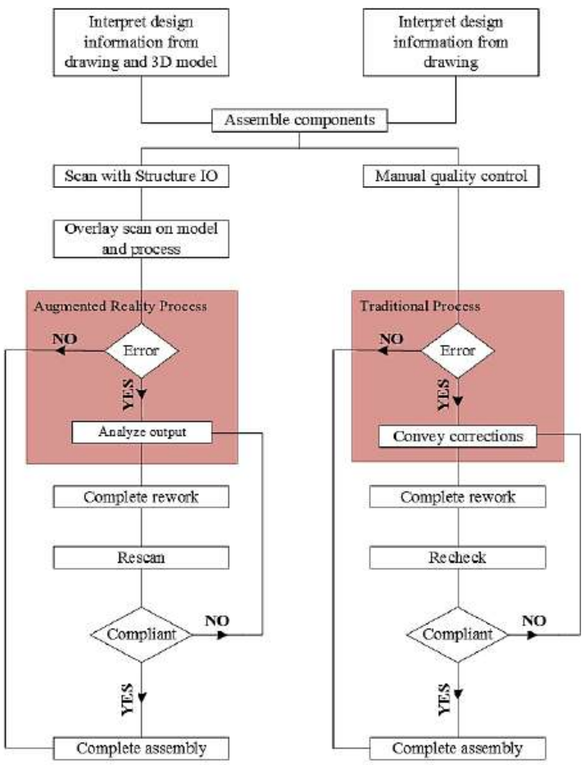

Figure 5. The workflows associate with both iterations of the experiment

Both groups were given the same traditional measuring tools and the same two-sided isometric drawing. In addition to the resources given to the participants who had information presented on only a static drawing, the participants using the augmented reality process had access to the 3D design model during the assembly process and were able to use a structured light scanner shown in Figure 4 to scan the assembly as they build it. This scanner is accurate up to 0.5 millimetres (mm) depending on how close the scanner is to the object being scanned [21]. A tolerance of 5 mm was set as the threshold for acceptance through multiple trials of scanning prefabricated components and comparing the scans to their actual dimensions. These participants were able to overlay the assembly, as they completed it, on the 3D design model to verify that what they had completed to that point was correct. These participants were also actively involved in the quality control process as they were the ones scanning the assembly, overlaying it on the model and doing the processing required to check if their assembly was compliant.

For participants using the static drawing, required rework was articulated and gestured to the participant by the experiment administrator who completed the quality control on the assembly.

3.4 Participant Assessment

Participants were administered two spatial cognition tests: a Card Rotation Test and a Cube Rotation Test created by Educational Testing Service (ETS) in 1976 [22]. This was done primarily to ensure that participants with higher spatial cognitive skills were not all grouped into the same category and inflating the results by comparing a group with higher spatial cognition against a group with lower spatial cognition. Participants were then grouped into 3 groups: having either low, medium or high spatial cognition. The groupings were determined by averaging the scores of the two tests. A fairly even distribution of scores was found across all the participant groups as is shown in Table 1.

Table 1. Distribution of spatial scores of participants

Score	App Participants	Drawing Participants
High (0.8-1.0)	3	3
Med. (0.6-0.79)	6	4
Low (0-0.59)	6	6

3.5 Data Analysis

Participants were filmed while assembling the pipe spool. The videos were watched and segmented into activities and durations to assess the participants' progress during the experiment. Figure 6 illustrates the average time spent on each activity for experiment participants who only had the drawing. Figure 7 shows the average time sent on each activity for participants who used the app.

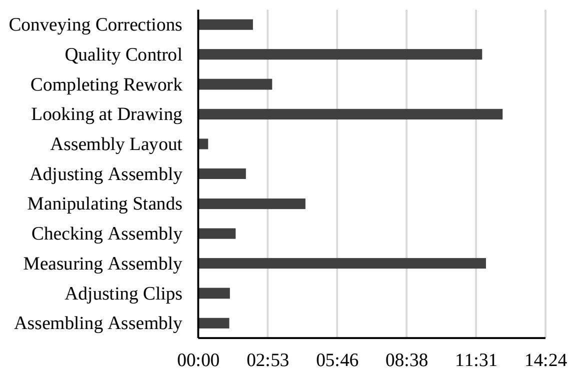

Figure 6. Average time spent on each activity for experiment participants using only the drawing

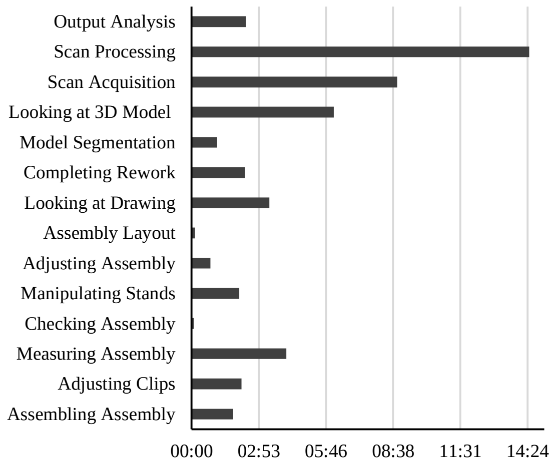

Figure 7. Average time spent on each activity for experiment participants using the app

In evaluating the videos, emphasis was placed primarily on tracking the activities of conveying the rework to be done and completing rework. Conveying rework was deemed to be any time where the administrator explained to the participant how their assembly failed to meet the required specifications in the case of participants using a traditional assembly and the time the participant spent assessing their own mistakes based on the overlay of the as built scan on the 3D model for a participant using the application. In both cases completing rework was deemed to be any time where the participants were modifying components that failed to meet the required specifications.

For both activities the time and cycle count were tracked. In the case of conveying rework, cycle count referred to the number of cycles of feedback that were completed. In the case of completing rework, cycle count considered the total number of times a participant modified an assembly component based on the feedback they were given regarding the work that had been completed thus far.

4 Results

The participant categories were divided into three clusters based on spatial cognition: low, medium and high spatial cognition as shown in Table 1 to compare how using the augmented reality application to convey rework affected participants of varying levels of spatial cognition. A total of 30 trials were run on engineers, 15 using the augmented reality process and 15 using the traditional drawing. Two participants had to be remove from the data pool that used the drawing as those two did not have any rework associated with their trials.

4.1 Conveying Rework

The times that were spent conveying the errors to the participants were totaled. An average of 2:26 was spent conveying corrections to participants with traditional formats while an average of 1:50 was spent conveying corrections to participants with the augmented reality process, a 25% reduction in the time required. Table 2 shows a summary of the time spent conveying corrections to the three groups. The use of the augmented reality process seemed to have the biggest impact on participants who fell into the medium spatial skills category. A number of the participants who fell in the low spatial skills category were unable to complete the assembly and eventually gave up, meaning that the times spent conveying corrections to them are lower than they should be as they do not represent the total time required.

Table 2. Average times spent conveying rework to participants based on spatial skill groups

Cognition Score	App Participants	Drawing Participants
High (0.8-1.0)	2:01	2:14
Med. (0.6-0.79)	1:47	3:07
Low (0-0.59)	1:33	1:54

4.2 Completing Rework

The time spent by participants completing rework was computed. The average time spent by participants using only the drawing and traditional quality control practices was 4:21 compared to 2:09 for participants who used the augmented reality process to assess their correctness. Using the technology led to a 50% decrease in time spent completing rework. Table 3 presents a summary of the time taken by each spatial group to complete the rework required for their assembly.

Table 3. A summary of the time taken to complete rework by both groups of participants

Cognition Score	App Participants	Drawing Participants
High (0.8-1.0)	1:27	4:30
Med. (0.6-0.79)	1:17	4:33
Low (0-0.59)	3:21	3:58

The number of rework cycles completed by each participant was also totaled. It was found that the average person using the augmented reality application had 11.73 cycles of rework while the average person using the drawing had 18.77 cycles of rework, a decrease of 37% when the augmented reality process was used. Table 4 presents a summary of the number of rework cycles by each group.

Table 4. Average number of rework cycles by both groups of participants

Cognition Score	App Participants	Drawing Participants
High (0.8-1.0)	10	13
Med. (0.6-0.79)	7.33	15.25
Low (0-0.59)	17	24

5 Conclusions and Discussion

It was found that using the augmented reality process reduced the time required to convey the required rework to participants by 25% and that it reduced the time they required to complete the rework by 50% with a 37% reduction in the number of rework cycles needed.

The data samples collected thus far were all using engineers, many of whom lacked experience working with hand tools and assembling products based on drawings. While their spatial skills and ability to interpret information was a factor in their work, the rework cycles could have likely been reduced if the participants were more experienced with working with the hand tools they were presented.

Somewhat surprisingly, the augmented reality process seemed to have the greatest impact on the group with medium spatial skills. From a qualitative assessment of the participants, the reason appears to be that the medium spatial skills participants were more likely to confuse themselves. They were fairly confident in their own interpretation of the information and were noticeably flustered when presented with information that did not align with their expectations. Participants with low spatial skills were more likely to accept what the experiment administrator told them at face value and didn't question the rework they were told to complete. The augmented reality process had the lowest impact on participants who had high spatial skills, likely because most of the rework these participants had was linked to their ability to perform the tasks of assembling and measuring the assembly, that is their ability to complete craft work, and was not as dependent on their ability to have the general correct assembly shape.

5.1 Participant Habits

It was observed that participants who had access to the augmented reality app utilized the app as a measuring tool in favor of actually measuring. It appears that participants realized that they would be able to verify the assembly with the application quicker than they would be able to actually perform the measurements with traditional measuring tools.

Participants with the application also appeared more comfortable checking assemblies they were less confident in. Participants with the drawing were more inclined to spend time checking the assembly before telling the experiment administrator that it was complete, whereas participants using the application were more likely to check it and modify the same piece multiple times. This may be because for the participants using the application the feedback on the rework to be done was self-given whereas the participants who had only the drawing to complete the assembly were being told by someone else that their work was wrong, lowering their morale.

5.2 Feedback from Participants

At the end of the experiment, participants were briefly presented the format of the other version of the experiment. Participants with the drawing often expressed that they would have found the visualization of the rework to be more conducive to their ability to complete it while several participants who used the augmented reality process expressed that they did not think they would be able to complete the assembly without the aid of the 3D model.

6 Future Work

At this time, experiment trials still need to be completed, particularly with craft workers. The intention was to evaluate 40 engineering students and 40 craft workers. At this time 30 engineering students and 4 craft workers were recruited. The sample of 4 craft workers was deemed too small to include in the work at this time.

The participants' skills working with their hands must also be taken into account. Additional trials could be conducted with engineering students who were more experienced working with their hands or they could be evaluated in groups based on their experience working with hand tools and assembling things. To help offset the impact of participants' skills, the participants could be recruited to complete a second spool of comparable difficulty with the alternate experimental procedure. Participants who used the traditional methodology could use the augmented reality process and those who used the augmented reality process could use the traditional methodology.

Additionally, using a more realistic spool could give participants a greater sense of purpose in completing the assembly. Finally, statistical analysis of the significance of the variance must be completed.

7 Acknowledgements

The authors would like to acknowledge the experiment participants for their willingness to participate in this study and their industrial partner, Aecon Industrial West for their support and providing access to craft workers. The authors would also like to acknowledge NSERC for their continued support of this research.

Abstract -

Recently, facilities that are a foundation of industries such as roads, water pipes, and tunnels are getting old. Along with this, the demand on inspection in the decrepit facilities is increasing. The robots are introduced to inspection in these facilities. It is required that the operators can control the robots easily when facilities are inspected using the robots. However, the control device which the operators can operate the robots easily is different depending on the robots which are controlled and the inspection task. Therefore, a control device which enables us to control various robots is developed by us. The device can represent various operation manners by changing the shape. In this paper, a method of device control with a virtual configuration is described. A joystick is represented using the virtual configuration. The torques to be outputted to each joint of the joystick are calculated using the forces and moments which applied to the grip of the device by the operators. The calculated forces and torques are distributed to the torques which drive each joint in the device. Therefore, the joystick using the virtual configuration is represented. The usability of the proposed method is shown by verification experiments.

1 Introduction

Recently, facilities that are the foundation of industries such as roads, water pipes, and tunnels are getting old. In this paper, these facilities are called the social infrastructures from now on. The demand on inspection in the social infrastructures are increasing along with the increase of the decrepit social infrastructure. There are many scenes where a judgment by humans is required in the inspection task of the social infrastructures. However, there are some situations that are difficult for humans to enter depending on the environment where the inspection task is performed. Therefore, it is desired to assist the inspection task is performed by humans with controlling the robots remotely. Against this backdrop, development and introduction of next generation robots for the social infrastructures are done in Japan since 2013[1]. On the other hand, the number of experts who inspect the social infrastructures is decreasing. Therefore, it is demanded to inspect efficiently even if an operator is not used to controlling the robots. Various robots which inspect the social infrastructures is developed[2][3]. Also, a hexapod robot for inspection in narrow environment is developed by us[4]. It is required that the operators can control the robots easily when the social infrastructures are inspected using these robots. On the othe hand, a control device and an operation manner are different depending on the robots which are controlled and the inspection task.

A cockpit and a control device which enables us to control various robots are developed by us (Figure 1). The control device has a virtual configuration represented by using a multiple virtual axes of rotation. A virtual axis of rotation which does not exist in the actual configuration is represented by combining multiple axis of rotation as shown in Figure 2. In this paper, a representation of a joystick using the virtual configuration is described. Hereinafter, The joystick which is represented using the virtual configuration is called the virtual joystick.

Overview of the virtual axis of rotation is described. In the case of the actual axis of rotation, the moments applied to the axis of rotation can be divided into a moment about the axis of rotation and others. Object rotates about

Figure 1. The cockpit which is developed by us.

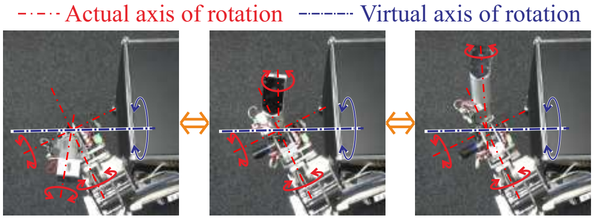

Figure 2. The actual axis of rotation and the virtual axis of rotation.

the axis of rotation by the moment about the axis of rotation. Hereafter, the moment about the axis of rotation is called the unconstrained force. On the other hand, the moments and forces other than the unconstrained force applied to the axis of rotation is received by the structure of the axis of rotation. The forces which received the moments and forces by the structure of the axis of rotation is called the mechanically constrained forces from now on. However, in the case of the virtual axis of rotation, the mechanically constrained forces cannot be achieved by the structure of axis of rotation. Therefore, the mechanically constrained forces are achieved by position control if the virtual axis of rotation is represented. On the other hand, control to achieve the mechanical behavior which want to be represented is performed about unconstrained force. The virtual axis of rotation is represented by the unconstrained force and the mechanically constrained forces. The unconstrained force is a spring force if the joystick is represented. The representation of the virtual axis of rotation is performed as follows. First, a coordinate system of the virtual axis of rotation Σ_V is fixed at a position where the virtual axis of rotation is represented. Then, the unconstrained force and the mechanically constrained forces required to represent the virtual axis of rotation are calculated. The unconstrained force and the mechanically constrained forces are represented by the forces which in each coordinate axis direction in Σ_V and the torques which about each coordinate axis in Σ_V to be outputted to Σ_V. The forces and torques are distributed to the torques which drive each joint in the device. The virtual axis of rotation is represented by the torques which drive each joint in the device.

The structure of this paper is as follows. First, related work is described in section 2. The control device which is developed by us is described in section 3. The methods of representing the virtual joystick and the virtual axis of rotation are described at the beginning of section 4. Then, the method of calculating the forces and torques to be outputted to Σ_V using the forces applied to the grip of the control device by the operators is indicated. The method of distributing the calculated forces and torques to the torques which drive each joint in the actual device is shown at the end of section 4. The usability of the proposed method is shown by verification experiments in section 5. Finally, conclusion is described in section 6.

2 Related Work

A lot of devices for controlling robots are studied. An equipment for controlling a mobile robot is developed by Yamazawa et al.[5]. Locomotion interface and immersive projection display are used in the equipment. The robot is controlled using the walking information of a operator. A cockpit for controlling humanoids is developed by Tachi et al.[6]. An equipment for controlling humanoids in the cockpit has the same configuration as the arm of humanoids. Humanoids are controlled by using the master-slave control system. These equipment enables us to control the robots intuitively. However, these equipment has only one operation target. Using a motion capture to control humanoids is studied. A system that control humanoids using optical motion capture is developed by Kurihara et al.[7]. Using the motion capture enables us to control humanoids intuitively. However, the equipment becomes large scale in the case of using motion capture. Hull which is a cockpit for controlling robots is developed by Institute Future Robotics Technology Center, Chiba Institute of Technology [8]. Hull has haptic interface. It is able to present the forces applied to the robot to the operator by using the haptic interface. Bilateral master-slave control is proposed for force feedback control to the operators[9][10] [11]. Among them, a bilateral master-slave control with different configuration is proposed by Arai et al.[12]. It is possible to combine the slave with high workability and the master with high operability by using the proposed method in document [12]. Further, there is an advantage that general versatility is enhanced and modularization is easy to perform. The master is given the torque which drive each joint of the master as the commanded value in the bilateral master-slave control with different configuration. Applying the bilateral master-slave control with different configuration to the device which is developed by us is considering.

3 The Control Device Which is Developed by Us

The control device which enables us to control various robots is developed by us. The device is shown in Figure 3. The device is composed with one prismatic joint and five revolute joints. A DC motor and a rotary encoder are installed on each joint to use the device as a haptic interface. An angle of each joint is acquired by the rotary encoder. A 6-axis force sensor is installed between 5th axis and 6th axis of the device. It is possible to measure the forces and moments which applied to the grip of the device by the operators using the force sensor.

The device can represent various operation manners by changing the shape. The operation manners that can be represented at present is shown in Figure 4. Joystick Mode in Figure 4(a) is a mode that represents a joystick on the market. 3D Input Mode in Figure 4(b) is a mode that represents the gaming device "*Falcon*" sold by Novint company. Any point on the three-dimensional space can be designated by 3D Input Mode. Dedicated Input Mode in Figure 4(c) is a mode exclusive to the hexapod robot which is developed by us. The configuration of the device in Dedicated Input Mode is the same as that of a limb of the hexapod robot. Therefore, it is possible to perform an intuitive control like actually grasping the limb of hexapod robot. Please refer to document [4] for details of the hexapod robot.

4 Representation of the Joystick Using the Virtual Configuration.

4.1 The Virtual Joystick

The control device which is developed by us can be represented various operation manners by changing the shape. However, the movable axes installed on the actual device may not be orthogonal in some cases. In that case, it cannot represent the joystick by using only axes of rotation installed on the device. Therefore, the virtual axis of rotation different from the actual axis of rotation as shown in Figure 2 is used. The joystick is represented using three virtual axes of rotation orthogonal to one another. The method of representing the virtual joystick is described below. First, a coordinate system of the virtual axis of rotation is fixed newly at a position where the virtual axis of rotation is represented as shown in Figure 5. The coordinate system is denoted as Σ_V. One of the coordinate axes in Σ_V is made to overlap with the virtual axis of rotation. In this example, Y-axis in Σ_V is made to overlap the virtual axis of rotation. The position of Σ_V is fixed. Further, only rotation about Y-axis in Σ_V is performed, thereby the virtual axis of rotation is represented.

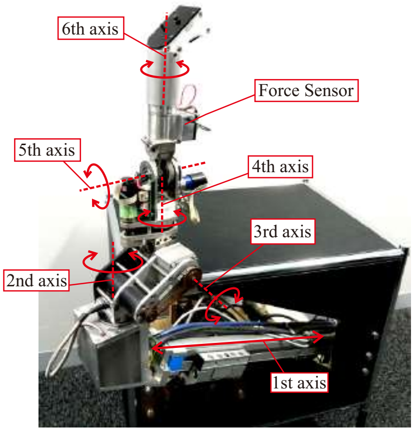

Figure 3. The control device which is developed by us.

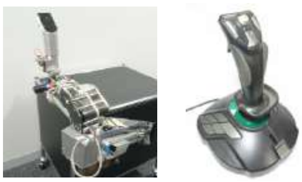
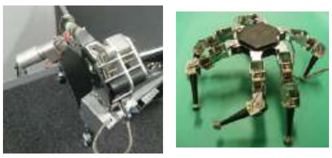


(a) Joystick Mode

(b) 3D Input Mode



(c) Dedicated Input Mode

Figure 4. The operation manners that can be represented at present.

The forces in each coordinate axis direction in Σ_V to be outputted to Σ_V is denoted as ${}^V\boldsymbol{f}_v = [{}^V f_x, {}^V f_y, {}^V f_z]^T$. The torques about each coordinate axis in Σ_V to be outputted to Σ_V is denoted as ${}^V\boldsymbol{\tau}_v = [{}^V\tau_x, {}^V\tau_y, {}^V\tau_z]^T$. The unconstrained force and the mechanically constrained forces for representing the virtual axis of rotation are represented by ${}^V\boldsymbol{f}_v$ and ${}^V\boldsymbol{\tau}_v$. In this example, only rotation about the Y-axis in Σ_V is performed. Therefore, ${}^V\tau_x$, ${}^V\tau_z$, and ${}^V\boldsymbol{f}_v$ are the mechanically constrained forces. Also, ${}^V\tau_y$ is the unconstrained force. Since the joystick is represented this time, the unconstrained force is spring force. Also, the mechanically constrained forces are represented by position control. ${}^V\boldsymbol{f}_v$ and ${}^V\boldsymbol{\tau}_v$ are calculated using the forces and moments which applied to the grip of the device by the operators. It is impossible to directly output ${}^V\boldsymbol{f}_v$ and ${}^V\boldsymbol{\tau}_v$ to the virtual axis of rotation because the virtual axis of rotation does not exist in the actual configuration of the device. ${}^V\boldsymbol{f}_v$ and ${}^V\boldsymbol{\tau}_v$ are distributed to the torques which drive each joint in the device. The equilibrium of the force and moment in static mechanics is used for the distribution. The details are described below.

4.2 Each Coordinate System Used for Calculation.

Each coordinate system used for calculation is as follows. The coordinate systems of each joint and the force sensor are assigned as shown in Figure 6. A world coordinate system is denoted as Σ_W. The positive direction of

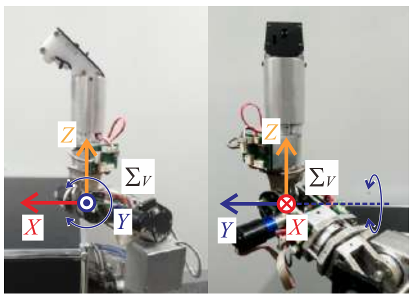


Figure 5. The position where the coordinate system of the virtual axis of rotation is fixed.

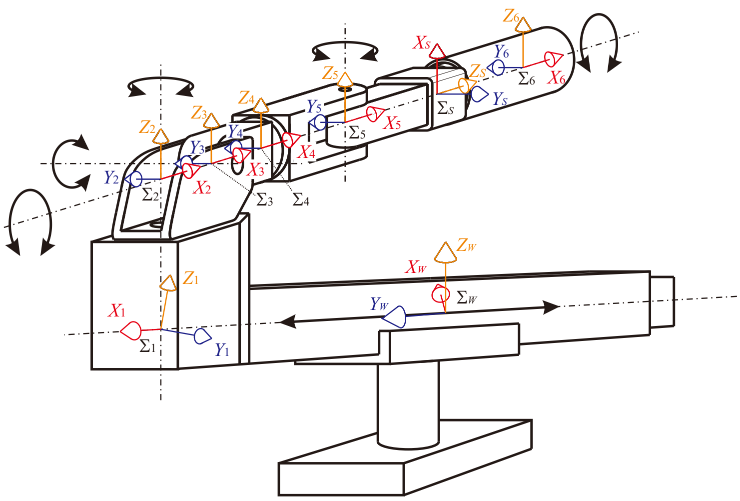

Figure 6. The position where each coordinate system is fixed on the device.

the X-axis in Σ_W is assigned in the same direction as the front direction of the operator. Also, the positive direction of the Z-axis in Σ_W is assigned as the upward direction perpendicular to the ground. The coordinate system of i-th axis is denoted as $\Sigma_i (i = 1, 2, \ldots, 6)$. Σ_1 is fixed at the intersection of 1st axis and 2nd axis. The X-axis in Σ_1 is the same direction as a movable axis of the prismatic joint. All $\Sigma_i (i = 2, 3, \ldots, 6)$ are the same posture in the case of the device is the initial posture. A coordinate system of the 6-axis force sensor is denoted as Σ_S. The origin of Σ_V is fixed to the same position as the origin of Σ_5 at this time. Also, the initial posture of Σ_V is the same as that of Σ_W.

4.3 Calculations of the Forces and Torques to Be Outputted to Σ_V.

${}^V\boldsymbol{f}_v$ is outputted to the origin of Σ_V as the mechanically constrained forces. Since the mechanically constrained forces are achieved by position control, ${}^V\boldsymbol{f}_v$ is calculated using Equation(1).

$$ {}^V\boldsymbol{f}_v = -\boldsymbol{K}_p \Delta\boldsymbol{p} + \boldsymbol{K}_d(\boldsymbol{0} - \dot{\boldsymbol{p}}) \quad (1) $$

${}^V\boldsymbol{f}_v (\in R^{3\times1})$: The forces in X-axis, Y-axis, and Z-axis direction in Σ_V to be outputted to the origin of Σ_V[N].
$\boldsymbol{K}_p (\in R^{3\times3})$: Proportional gain matrix.
$\Delta\boldsymbol{p} (\in R^{3\times1})$: Deviations of Position in X-axis, Y-axis, and Z-axis direction in Σ_V from the initial position of the origin of Σ_V[m].
$\boldsymbol{K}_d (\in R^{3\times3})$: Differential gain matrix.

${}^V\boldsymbol{\tau}_v = [{}^V\tau_x, {}^V\tau_y, {}^V\tau_z]^T$ are calculated as follows. Since ${}^V\tau_x$ and ${}^V\tau_z$ are the mechanically constrained forces, these are achieved by position control in the same way as ${}^V\boldsymbol{f}_v$. Therefore, ${}^V\tau_x$ and ${}^V\tau_z$ are calculated using Equation(2).

$$ {}^V\tau_i = -k_p \Delta q_i + k_d(0 - \dot{q}_i) \quad (i = x, z) \quad (2) $$

${}^V\tau_i$: The torque about i-axis in Σ_V to be outputted to Σ_V[N·m] $(i = x, z)$.
k_p: Proportional gain.
Δq_i: Angular displacement about i-axis in Σ_V[rad] $(i = x, z)$.
k_d: Differential gain.

On the other hand, ${}^V\tau_y$ is the unconstrained force. Since the joystick is represented by using the virtual axis, the unconstrained force is spring force. Therefore, ${}^V\tau_y$ is calculated using Equation(3). The forces and moments which applied to the grip of the device by the operators acquired from the force sensor are used for the calculations.

$$ {}^V\tau_y = {}^V F_x \, l - k_{pj} \Delta q_y \quad (3) $$

${}^V\tau_y$: The torque about Y-axis in Σ_V to be outputted to Σ_V[N·m].
${}^V F_x$: The force in X-axis direction in Σ_V applied to grip of the device by the operators[N].
l: Length from the origin of Σ_S to the origin of Σ_V[m].
k_{pj}: Proportional gain used for representation of the joystick.
Δq_y: Angular displacement about Y-axis in Σ_V[rad].

It is possible to represent the virtual axis of rotation about the X-axis in Σ_V by using Equation(4) instead of Equation(3). Also, it is possible to represent the virtual axis of rotation about the Z-axis in Σ_V by using Equation(5) instead of Equation(3). In that case, ${}^V\tau_y$ is calculated using Equation(2) as $i = y$.

$$ {}^V\tau_x = -{}^V F_y \, l - k_{pj} \Delta q_x \quad (4) $$

$$ {}^V\tau_z = {}^V M_z - k_{pj} \Delta q_z \quad (5) $$

${}^{V}\tau_i$: The torque about i-axis in Σ_V to be outputted to Σ_V[N·m] ($i = x, z$).
${}^{V}F_y$: The force in Y-axis direction in Σ_V applied to grip of the device by the operators[N].
${}^{V}M_z$: The moment about Z-axis direction in Σ_V applied to grip of the device by the operators[N·m].
l: Length from the origin of Σ_S to the origin of Σ_V[m].
k_{pj}: Proportional gain used for representation of the joystick.
Δq_i: Angular displacement about i-axis in Σ_V[rad] ($i = x, z$).

4.4 Calculation of the Angular Displacement About Each Coordinate Axis in Σ_V.

The angular displacement about each coordinate axis in Σ_V are necessary to calculate ${}^{V}\boldsymbol{\tau}_v$ using Equation(2)-(5). However, the virtual configuration is different from the actual configuration. Therefore, the angular displacement cannot be gotten directly using the rotary encoder installed on each joint of the device. The calculations of the angular displacement about each coordinate axis in Σ_V are performed as follows.

A initial coordinate system of the virtual axis of rotation is denoted as Σ_{V_0}. It is supposed that Σ_{V_0} becomes Σ_V by operating the device. The positions of the origin of Σ_{V_0} and Σ_V don't be changed. It is supposed that ${}^{V_0}\boldsymbol{R}_V$ can be calculated by forward kinematics at this time. A rotation matrix from Σ_{V_0} to Σ_V is denoted as ${}^{V_0}\boldsymbol{R}_V$. Then, ${}^{V_0}\boldsymbol{R}_V$ is expressed by Equation(6) using R_{ij} $(i, j = 1, 2, 3)$ that are known parameters.

$$ {}^{V_0}\boldsymbol{R}_V = \begin{bmatrix} R_{11} & R_{12} & R_{13} \\ R_{21} & R_{22} & R_{23} \\ R_{31} & R_{32} & R_{33} \end{bmatrix} \tag{6} $$

On the other hand, the angular displacement about each coordinate axis in Σ_V can be represented by the roll, pitch, and yaw angles because the joystick is represented. Therefore, the rotation matrix can be calculated using a representation by the roll, pitch, and yaw angles. The roll, pitch, and yaw angles are denoted as ϕ, θ, and ψ. The rotation matrix ${}^{V_0}\boldsymbol{R}_V$ from Σ_{V_0} to Σ_V is given by Equation(7) using ϕ, θ, and ψ.

$$ {}^{V_0}\boldsymbol{R}_V = \begin{bmatrix} C_\theta C_\psi & -C_\theta S_\psi + S_\phi S_\theta C_\psi & S_\theta S_\psi + C_\phi S_\theta C_\psi \\ C_\theta S_\psi & C_\theta C_\psi + S_\phi S_\theta S_\psi & -S_\phi C_\psi + C_\phi S_\theta S_\psi \\ -S_\theta & S_\phi C_\theta & C_\phi C_\theta \end{bmatrix} \tag{7} $$

Here, $S_\phi = \sin\phi$ and $C_\phi = \cos\phi$. The same applies to θ and ψ. Equation(8) is obtained from Equation(6) and (7).

$$ \begin{aligned} &\text{if } \sin(\theta) = 1 && \begin{cases} \phi = 0 \\ \theta = \dfrac{\pi}{2} \\ \psi = \operatorname{atan2}(R_{23}, R_{22}) \end{cases} \\ &\text{if } \sin(\theta) = -1 && \begin{cases} \phi = 0 \\ \theta = -\dfrac{\pi}{2} \\ \psi = -\operatorname{atan2}(R_{23}, R_{22}) \end{cases} \\ &\text{otherwise} && \begin{cases} \phi = \operatorname{atan2}(R_{32}, R_{33}) \\ \theta = -\operatorname{asin}(R_{31}) \\ \psi = \operatorname{atan2}(R_{21}, R_{11}) \end{cases} \end{aligned} \tag{8} $$

However, the values of ϕ and ψ can not be uniquely decided in the case of $\sin(\theta) = \pm 1$. In this case, it is assumed that $\phi = 0$. From the above, ϕ, θ, and ψ are calculated.

For example, the case of applying to the our device is described. Σ_{V_0} is fixed by us so that the postures of Σ_{V_0} and Σ_W are the same. Therefore, ${}^{V_0}\boldsymbol{R}_V$ can be expressed as Equation(9).

$$ {}^{V_0}\boldsymbol{R}_V = {}^{W}\boldsymbol{R}_V = {}^{W}\boldsymbol{R}_6\,{}^{6}\boldsymbol{R}_V \tag{9} $$

Here, a rotation matrix from Σ_W to Σ_6 is denoted as ${}^{W}\boldsymbol{R}_6$. A rotation matrix from Σ_6 to Σ_V is denoted as ${}^{6}\boldsymbol{R}_V$. Σ_V always follows the movement of Σ_6. Also, the posture of Σ_6 becomes the same as that of Σ_V when rotated only $\pi/2$ about Y-axis in Σ_6. Therefore, ${}^{6}\boldsymbol{R}_V$ is always given by Equation(10).

$$ {}^{6}\boldsymbol{R}_V = \begin{bmatrix} \cos(\pi/2) & 0 & \sin(\pi/2) \\ 0 & 1 & 0 \\ -\sin(\pi/2) & 0 & \cos(\pi/2) \end{bmatrix} = \begin{bmatrix} 0 & 0 & 1 \\ 0 & 1 & 0 \\ -1 & 0 & 0 \end{bmatrix} \tag{10} $$

On the other hand, ${}^{W}\boldsymbol{R}_6$ can be calculated by using forward kinematics, thereby R_{ij} $(i, j = 1, 2, 3)$ in Equation(6) are obtained. ϕ, θ, and ψ are calculated using R_{ij} $(i, j = 1, 2, 3)$ and Equation(8).

4.5 Distribution of the Calculated Forces and Torques to the Torques Which Drive Each Joint in the Device.

In this section, the method of distributing ${}^{V}\boldsymbol{f}_v$ and ${}^{V}\boldsymbol{\tau}_v$ to the torques which drive each joint in the device is described. The same idea as calculations of the each joint torques which are balanced with the forces and moments applied to the end effector in the robot manipulators is used[13]. ${}^{V}\boldsymbol{f}_v$ corresponds to the forces which applied to the end effector of the robot manipulators. Also, ${}^{V}\boldsymbol{\tau}_v$ corresponds to the moments which applied to the end effector of the robot manipulators. The each joint torques which are balanced with the forces and moments applied to the end effector are calculated in the case of a robot manipulators. However, ${}^{V}\boldsymbol{f}_v$ and ${}^{V}\boldsymbol{\tau}_v$ are outputted to Σ_V by using the torques which drive each joint in the device in the case of the virtual axis of rotation. Therefore, keep in mind that signs are different when calculating the torques of the robot manipulators and the virtual configuration.

${}^{V}\boldsymbol{f}_v$ and ${}^{V}\boldsymbol{\tau}_v$ which are calculated using Equation(1)-(5) are the forces and torques expressed in Σ_V. ${}^{W}\boldsymbol{f}_v$ and ${}^{W}\boldsymbol{\tau}_v$ which are ${}^{V}\boldsymbol{f}_v$ and ${}^{V}\boldsymbol{\tau}_v$ expressed in Σ_W are given by Equation(11) and (12) by the equilibrium of force and moment in static mechanics.

$$ {}^{W}\boldsymbol{f}_v = {}^{W}\boldsymbol{R}_V {}^{V}\boldsymbol{f}_v \tag{11} $$

$$ {}^{W}\boldsymbol{\tau}_v = {}^{W}\boldsymbol{R}_V \, {}^{V}\boldsymbol{\tau}_v + {}^{W}\boldsymbol{p}_V \times ({}^{W}\boldsymbol{R}_V {}^{V}\boldsymbol{f}_v) \tag{12} $$

The position vector of Σ_V expressed in Σ_W is denoted as ${}^{W}\boldsymbol{p}_V$. Cross product of vectors is denoted as "×". ${}^{W}\boldsymbol{p}_V = [{}^{W}p_x, {}^{W}p_y, {}^{W}p_z]^T$ and Equation(13) are defined by us.

$$ [{}^{W}\boldsymbol{p}_V\times] = \begin{bmatrix} 0 & -{}^{W}p_z & {}^{W}p_y \\ {}^{W}p_z & 0 & -{}^{W}p_x \\ -{}^{W}p_y & {}^{W}p_x & 0 \end{bmatrix} \tag{13} $$

Accordingly, Equation(11) and (12) are expressed by Equation(14).

$$ \begin{bmatrix} {}^{W}\boldsymbol{f}_v \\ {}^{W}\boldsymbol{\tau}_v \end{bmatrix} = \begin{bmatrix} {}^{W}\boldsymbol{R}_V & \boldsymbol{0} \\ [{}^{W}\boldsymbol{p}_V\times]{}^{W}\boldsymbol{R}_V & {}^{W}\boldsymbol{R}_V \end{bmatrix} \begin{bmatrix} {}^{V}\boldsymbol{f}_v \\ {}^{V}\boldsymbol{\tau}_v \end{bmatrix} \tag{14} $$

The relationship between the torques which drive each joint $\boldsymbol{\tau}(\in R^{6\times1})$, ${}^{W}\boldsymbol{f}_v$, and ${}^{W}\boldsymbol{\tau}_v$ is expressed by Equation(15) using Jacobian matrix $\boldsymbol{J}(\in R^{6\times6})$.

$$ \boldsymbol{\tau} = -\boldsymbol{J}^T \begin{bmatrix} {}^{W}\boldsymbol{f}_v \\ {}^{W}\boldsymbol{\tau}_v \end{bmatrix} \tag{15} $$

Therefore, the relationship between ${}^{V}\boldsymbol{f}_v$, ${}^{V}\boldsymbol{\tau}_v$, and $\boldsymbol{\tau}$ is expressed by Equation(16) from Equation(14) and (15).

$$ \boldsymbol{\tau} = -\boldsymbol{J}^T \begin{bmatrix} {}^{W}\boldsymbol{R}_V & \boldsymbol{0} \\ [{}^{W}\boldsymbol{p}_V\times]{}^{W}\boldsymbol{R}_V & {}^{W}\boldsymbol{R}_V \end{bmatrix} \begin{bmatrix} {}^{V}\boldsymbol{f}_v \\ {}^{V}\boldsymbol{\tau}_v \end{bmatrix} \tag{16} $$

${}^{V}\boldsymbol{f}_v$ and ${}^{V}\boldsymbol{\tau}_v$ are distributed to the torques which drive each joint in the actual device using Equation(16).

5 Verification Experiments

5.1 The Representation of the Virtual Joystick

A experiment is performed, thereby it is confirmed that the virtual joystick is represented by using the proposed method. The joystick with one virtual axis of rotation is represented in the experiment. The virtual axis of rotation is installed as shown in Figure 7. The forces in lateral direction and longitudinal direction against the virtual axis of rotation are applied to the grip of the device and a behavior of the device is observed. The spring scale is used to understand easily and visually the forces that applied to the grip of the device. Measurable range of the spring scale is 0 to 2 kgf. The behavior of the device in the case of the virtual axis of rotation is not represented is also observed for purposes of comparison. The device is only performed gravity compensation when the virtual axis of rotation is not represented.

The top-view of the device is shown in Figure 8 as the experiment result. The result in the case of performing only gravity compensation without the virtual axis of rotation is indicated by a red frame in Figure 8. Also, the result in the case of the virtual axis of rotation is represented is indicated by a blue frame in Figure 8. Small red triangles are put in Figure 8 in order to easily understand elongation of the spring scale. The grip of the device should move on the red dashed line in Figure 8 if the virtual axis is installed as shown in Figure 7.

The grip of the device is leaning in the direction to which the forces were applied in the case of the virtual axis of rotation was not represented. And the grip of the device is moving away from the red dashed line. On the other hand, the following results were obtained in the case of the virtual axis of rotation was represented. The grip is rotating about the virtual axis of rotation when the forces were applied in lateral direction against the virtual axis of rotation. And the grip of the device is moving on the red dashed line. Also, it is confirmed by looking at the spring scale that the forces applied to the grip of the device are increasing as angular displacement from initial posture is increasing.The grip is not leaning even if the forces which applied to the grip increased when the forces were applied in lateral direction against the virtual axis of rotation. From the above results, it is considered that the virtual joystick has been represented by using the proposed method.

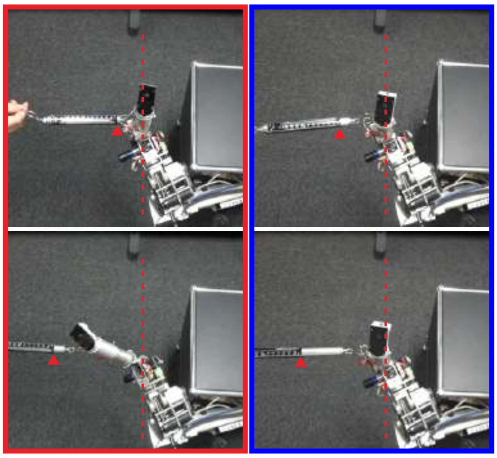
(a) lateral direction



(b) longitudinal direction

Figure 8. The behavior of the device when forces are applied in lateral direction and longitudinal direction against the virtual axis of rotation (Red frame:Without virtual axis of rotation, Blue frame:With virtual axis of rotation).

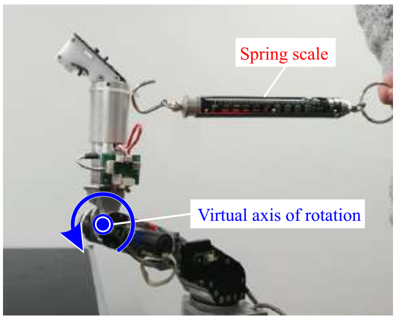


Figure 9. The environment in which the experiment is performed.

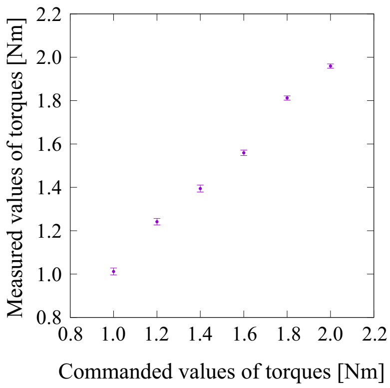

Figure 10. The relationship between the commanded values of torques and the measured values of torques.

5.2 The Torques Outputted to the Virtual Axis of Rotation.

The torques to be outputted to the virtual axis of rotation are distributed to the torques which drive each joint in the device by using Equation(16). A experiment is performed, thereby it is confirmed whether the required torques are actually outputted to the virtual axis of rotation by the torques which drive each joint in the device. The experiment is performed as follows. The environment in which the experiment is performed is shown in Figure 9. A commanded torques to the virtual axis of rotation are given. The commanded torques are distributed to the torques which drive each joint in the device by using Equation(16). The forces outputted to the grip of the device at this time are measured using the spring scale. The torques actually being outputted to the virtual axis of rotation are calculated. The measured values of the forces and the distance from the point where the forces were measured to the virtual axis of rotation are used for the calculation. The measured values of torques and the commanded values of torques are compared. 1.0, 1.2, 1.4, 1.6, 1.8, and 2.0 N are given five times respectively as the commanded torque.

The relationship between the commanded values of torques and the measured values of torques obtained from the experiment is shown in Figure 10. The horizontal line is the commanded values of torques, and the vertical line is the measured values of torques. The points are the mean values of the measured values of torques. The error bars are standard deviation. Figure 10 shows that the ratio between the commanded values of torques and the measured values of torques is about 1 : 1. Also, the standard deviation is small. Therefore, it is considered that the required torques are actually outputted to the virtual axis of rotation by the torques which drive each joint in the device.

The above results show that it is possible to output the torques commanded by us to the virtual axis of rotation. Therefore, it is considered that the bilateral master-slave control with different configuration proposed in document [12] can be applied to the device with the virtual configuration.

6 Conclusion

In this paper, the representation of the joystick using the virtual configuration was described. The coordinate system of the virtual axis of rotation was fixed. The virtual axis of rotation was represented with performing only rotation about one coordinate axis of the coordinate system. The method of calculating the forces and torques to be outputted to the coordinate system using the forces moments applied to the grip of the control device by the operators was shown. Then, the method for obtain the angular displacement about each coordinate axis in the coordinate system required for the calculations of the forces and torques was shown. In addition, the method of distributing the calculated forces and torques to the torques which drive each joint in the device was shown. The virtual axis of rotation was represented using the above methods. Finally, the usability of the proposed method was verified by performing the verification experiments.

On the other hand, there are two problems in the proposed method. First, the equation in static mechanics is used when the forces and torques are distributed. Therefore, the movement with large inertial force is not considered. Then, the virtual axis of rotation was represented in only one position. It is thought that the representation of more operation manners becomes possible by representing virtual axes of rotation at multiple position. The future task of this study is to deal with these problems and further extend the representation of the control device with the virtual configuration.

Abstract –

With a scenario of intense difficulties faced by the construction industry, improvements of the productive processes are demanded in order to make them more efficient, optimizing resources such as human, materials and financial ones, aggregating quality to the delivered product. Thus, this study aims the application of a methodology of improvement in the design process, under the lean approach, in a design-build firm, including the usage of the tool Value Stream Mapping (VSM). The VSM is initiated from the first contact with the customer to the final design and construction documents delivery. As a result, high levels of interruption and waiting for information have been detected. It has been verified a total lead time of 50 days, with only 21.28% corresponding to the effective execution time of activities. The analysis of the negotiation phase indicates a consumption of 32% of the total cycle time and in the design phase it was observed that just 30.68% of the time is utilized on activities which generate value for the customer. Besides, there is a loss of €84.93 in materials and services. With the implantation of kaizens, it is proposed to lower the total lead time in half of the initial amount. Therefore, the simple usage of lean tools contributes to reduce waste.

1 Introduction

Low productivity is one of the biggest challenges facing the construction industry in the world economy. Brazil and the European Union, for example, play about 15% and 75% of United States productivity respectively, indicating that there is a gap between them (Mello and Amorim [1]).

Therefore, it is more and more necessary the adaptation to new technologies and way of production from the industry making the processes more efficient, increasing in the optimization of human resources, materials and financial, but also aggregating quality to the delivered product.

In this context, there are some studies that aim to improve construction processes. Generally, these researches seek to adapt theories, methods and tools originated from manufacture to the construction sector. Lean Construction, originated from the Lean Thinking, which aims to gain quality and productivity through the reduction of waste in the construction sector. This approach has generated positive results and stabilization of the constructive processes, but there are not many studies on the application of the Lean within the administrative scope of the design firms. Thus, the gap of the knowledge that this paper seeks to fill is the application of the VSM tool in a design firm.

Studies like Lima et al. [2], Tilley [3] e Melo et al. [4] prove that problems with the design quality and documentation in the construction industry have a significant impact on the efficiency of the construction sector and are the main factors for the rework in design and projects phase.

This paper consists on the application of a methodology of improvement of the design process, adapted from Freire and Alarcón [5], in a design firm based in Natal, Brazil. The firm develops design activities, budgets, licensing and consults. The team is composed by two engineers and an intern, being this one responsible for aiding the engineers.

2 Theoretical reference

2.1 Lean Thinking

The Lean Thinking is a generalization of the Toyota Production System (TPS) (Womack et al. [6]). Idealized by the engineer Taiichi Ohno, the TPS emerges as an application of a new manufacturing technology at the Toyota Motor Company, automobile industry, after the Second World War. Its principle is based on increasing the productivity through the complete elimination of waste, defined as everything that does not aggregate value, structured in two pillars: The Just in Time and Autonomation. In this system one item is only produced when it is necessary and in the correct amount (Ohno [7]).

In the battle against the waste, main principle of the Lean Thinking, Rother and Shook [8] created the Value Stream Mapping (VSM), based on the maps of material flows and on information utilized by Toyota. The VSM is considered the most important tool in the fight against waste.

2.2 Lean Thinking Application

Freire e Alarcón [5] proposed a methodology to improve the design process and applied on 4 designs of a design firm specialized in the civil engineering, mining and industrial area. The suggested methodology by the authors is based on the Lean Design approach, which considers the application of the conversion models, flow and value to the processes of design elaboration, seeking to identify and eliminate the waste and activities which do not aggregate value.

Tilley [3] analyzed, through a literature review, that if the implementation of the Lean Design has the potential to reach the necessary quality improvements. He concluded that a Lean Design Approach has the potential to improve significantly the way the design process is managed, aggregate value to the internal customers and to the final customer and minimize the waste in the construction process through designs and documentation of better quality.

Koskela et al. [9] points out that the design management is chaotic and improvised. The authors applied the Lean approach in the design management of construction of a building with 7.600 m^2 in Finland, through the usage of the Last Planner system, method that used to be applied only in construction phase. The design was compared to another similar design, previously carried out by the same planners and at the same location using the conventional way of planning. The results indicated a decrease of 30% in the design time comparing to the traditional planning method, the process of the design as a whole was more disciplined in comparison with the design managed in the conventional way. Koskela et al. (1997) observed that the application of the Last Planner generated a superior process of design in all aspects and that all the involved parties saw the approach as something really positive and everybody wanted to use the method in future designs.

Lee et al. (2010) proposed the application of Lean concepts in the elaboration of proposals of megaprojects of infrastructure. The research is a case study concerning the development of a proposal of a Design-Build-Operate-and-Maintain (design, construction, operation and maintenance) project of US$ 500 million in the public sector. The study discusses the concepts of Design Constraint Analysis Choosing by Advantages (CBA), set-based design, cross functional teaming, colocation, and Target Value Design (TVD). The results indicated improvements in the collaboration between teams and in the integration between the process of design and cost estimate, and by consequence, a better performance on the conception of megaprojects and delivery of a more competitive proposal.

3 Research Method

The research method used in this paper is an adaptation from the method used by Freire and Alarcón [5] to achieve improvements in the design process. Based on concepts and Lean Design principles, the authors consider the design process composed of three models: conversion, flow and value. According to the researchers 4 stages are necessary, such as:

1. **Diagnosis and evaluation**: It aims to determine the current conditions of the process under the perspective of flow and value. At this stage Freire and Alarcón (2002) consider necessary and complementary the application of five actions to a complete comprehension of the design process. They are: the obtainment of performance indicators, the value mapping stream, execution of interviews, the achievement of the time distribution in the process, the identification of waste and opportunities of improvement.
   In this research the utilized performance indicators are based on Lima et al. [2]: Processing Time (PT), Lead Time (LT) and PT/LT percentage. Adapted from Freire and Alarcón [5] the time percentages are defined according to the distribution of activities in the process: Data collection, design, consultations, exception or rupture, time of waiting for information and time of inactivity. The study also proposes indicators for the analysis of the negotiation time compared to the time of project and to the total time.
   The Value Stream Mapping (VSM) was performed according to Tapping and Shuker [11], focusing on the information flows. The data utilized to produce the map were obtained from direct observation,

interviews and analysis of documents (through the observation of the date and time of emails and app messages, and the notes from the team's reports as well) within 3 months of follow up. Divided in 5 meetings which add up approximately 13 hours of data collection with the team of the design-build firm. It has been obtained the time distribution in the process by the VSM interpretation and analysis, the identification of waste and opportunities for improvement. Through the interpretation and VSM analysis it was obtained the time distribution in the process, the identification of waste and opportunities of improvement.

2. **Implementation of changes:** based on the stage of diagnosis and evaluation it suggests the implementation of changes in the process depending on the types of waste and problems found. In this stage the authors proposed the usage of 7 tools of improvement, classified according to the 5 areas of improvement (customer, administration, design, resources and information - CAPRI): interactive coordination; intranet; checklists before the design; checklists after the design; Quality Function Deployment (QFD); value stream mapping and training.

   It is not mandatory the application of all suggested tools by Freire and Alarcón [5], but those compatible with the company's necessities, according to the areas of improvement (CAPRI). In this study just some of the aforementioned tools were adopted.
3. **Control:** It aims to control and assess the effects of the changes made in the process. It consists on following control measures such as the time distribution and performance indicators, verifying the effectiveness of the improvements.
4. **Standardization:** It aims to introduce permanent improvements on the working methods of the company, through the formalization of changes, as well as implementing the ongoing improvement to design process through the reapplication of the methodology.

   In this study the stages 3 and 4 will not be applied because they do not fit the purpose of the research.

4 Findings and Discussions

4.1 VSM Current state

This phase comprehends the diagnosis of the current situation of a design-build firm which has as an external customer an owner of a supermarket with 382.50 m^2 of built area. Figure 1 illustrates the value stream mapping of the design package and complementary documents for purposes of legalization, atypical situation of the firm. The initial contact with the customer was via an instantaneous message app with the engineer, followed by a visit to the site. Next, due to the need to consult the appropriate procedures to legalize the project after built it, it is done a visit to SEMURB (Environment and Urbanism Department). From that, it is set up and proposal and sent to the customer.

After waiting some time for the customer to reach out, there is the negotiation phase, with adjustments of the values, payment method and, lastly, contract signing at the supermarket. The team visits the project to data collection for the architectural executive design (AED) sketch, after some mishaps. Ultimately, with all the measures of the building collected in the field, the intern begins the digitalization of the data collected and the location of the points for the drainage design. When the file is received, there is the first review of the architectural executive design.

In the next phase, there is the sewage and drainage design sizing and respective specifications. In the drainage design some doubts about the position of the water tank on the roof came up. Therefore, there is a waiting time for information, due to other ongoing activities and the engineer just reaches out on the next day to obtain the answer from the customer and next, an interruption of a working day because of external factors not related to this VSM. The architectural executive design is resumed, followed by another interruption.

The engineer starts the draft of the drainage design from the data collected during the technical visit and, once it is concluded, it goes to the intern in order to finalize the design. For the execution of the RIV (Neighborhood Impact Report), the engineer consults with the SEMURB to eliminate doubts and requests the customer data such as: Schedule of the garbage truck, data of the sanitation in the area and public transportation; and, the property title. After receiving them, they can be included in the RIV.

The team schedules another technical visit for the approval of the architectural executive design, with a wait of 2 days due to incompatibilities of schedules among the team, and other data for the RIV: working schedule of the supermarket, number of employees, way of solid waste packaging and water table level. On this visit, the customer decides to incorporate one more floor in the architectural executive design. Afterwards, there are two working days with no activities connected to the customer's design. Coming back, the team works in parallel: the intern proceeds with the architectural executive design, the engineer works on the elaboration of the schedule and the other engineer finishes the RIV, designs the fire design and continues the architectural design from the last update from the intern.

The intern includes some architectural design changes demanded by the customer, corrections on the

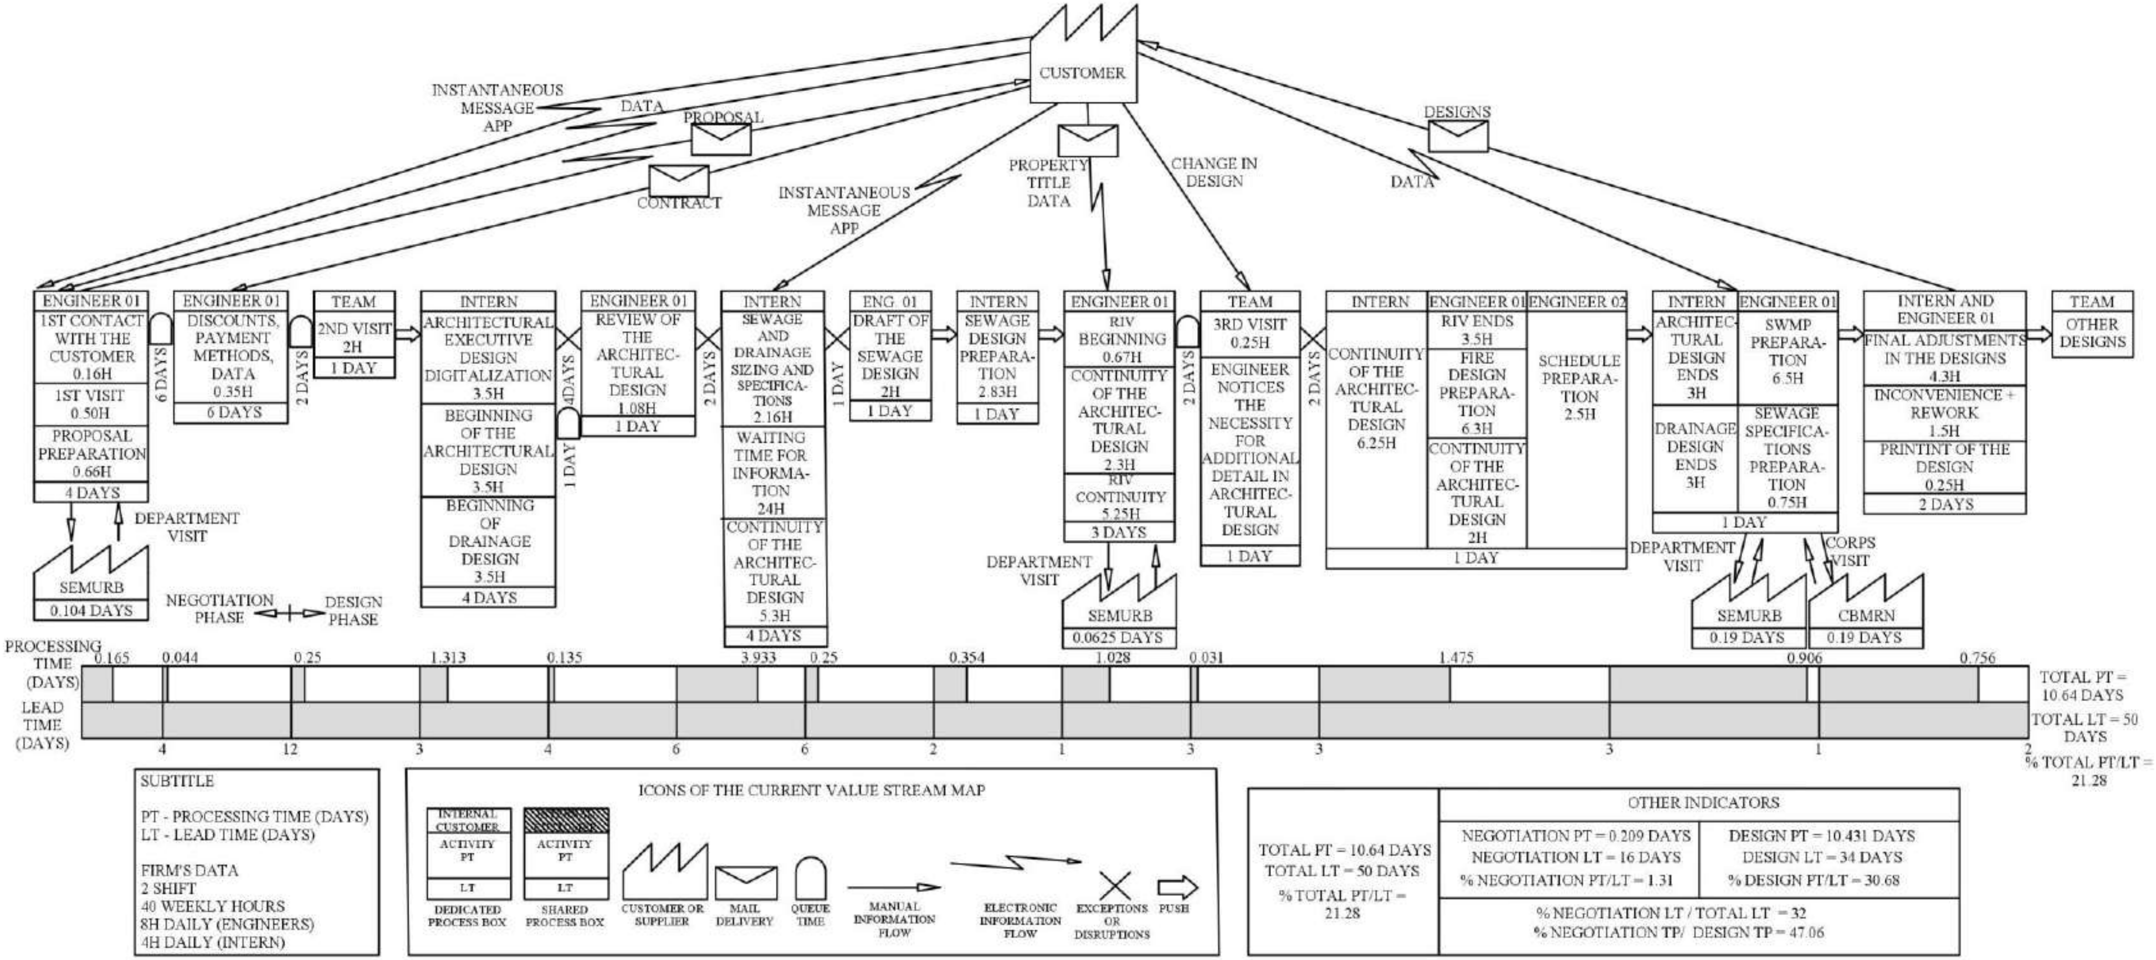

Figure 1. Current State Map.

drainage design, then conclusion and organizes the layout of printing of the architectural design. In parallel, the engineer consults with SEMURB and the CBMRN (Military Firefighter Corps of Rio Grande do Norte State), through the Engineering Technical Service (SERTEN) about the access stair on the fire design of the first floor. With the data which were requested from the customer, it is done the solid waste management plan (SWMP). The engineer requests the sewage memorial already finalized by the intern, but to avoid the waiting for information, elaborates a new sewage memorial.

Together, the engineer and the intern make final adjustments on the designs and plot the boards and reports, but because of the lack of colorful printer cartridge ink, the boards of AED are not printed and because of this they decide to send them to a print shop. Having the printed designs, the engineer delivers to the customer, however noticing some flaws on the printing of the architectural boards, this is corrected and plotted again by the print shop. Lastly, the designs, reports and specifications are delivered in person to the customer.

Summing up the lead time of each activity results in the total lead time of the process. In the study, it was verified a lead time of 50 days, from which only 10.64 days correspond to a processing time. Therefore, the activities do not aggregate value correspond to a total of 78.72% of the process.

The process can also be divided in two sub processes: the negotiation phase and the design phase, after getting the contract signature from the customer. The negotiation phase presents a lead time of 16 days, from which just 1.31% represent the actual time of value aggregation. In the design phase, the lead time corresponds to 34 days. From these days, only 10.431 equals the lead time of each activity. In other words, the only activity which adds value to the process is the design process, but only 30.68% of the cycle time is used for that. It is important to point out that the established deadline by the parties on the contract for execution of the activities was 30 days, surpassing in 4 days what had been previously defined. On the feedback the design-build firm cites modification in the architectural executive design as a motive.

Facing the expressive time of lead time negotiation, this value was compared to the total LT and design LT. As a result, it was obtained 32% and 47% of the time, respectively, indicate the negotiation percentage. This shows the high time consumption with the customer, which could have been done by another professional.

There were identified activities which do not aggregate value to the process: Wait of information from external or internal customers, wait for updated designs and documents

On the system, computer lagging, interruptions due to other customers (conversions of the digital file versions or plotting). And routine tasks of the technical room such as: plotting, folding the site plans, signature collections, stamps, answering the telephones (Lima et al. [2]). It also identified how much cost the wastes indicated in Table 1 and Table 2.

Table 1. The cost of the 3rd technical visitation (unnecessary)

Waste	Cost (€)
Transportation	5.14
Hourly cost of team work (1h25)	30.78

Table 2. The cost of the printings with errors

Waste	Cost (€)
Material	14.80
Transportation	5.14
Engineer’s rework cost (1,5h)	17.44
Engineer’s work hourly cost (1h)	11.63

The total cost of these wastes result in € 84.93 (Adjusted according to the currency exchange rates on January 7th, 2018), the current year.

By the time this research was conducted, the design team had other 7 ongoing designs, shifting the priority of other activities between parallel designs.

4.2 Future state map

Aiming to reduce the waste, the suggested value stream modifications are next, illustrated on the map of Figure 2.

1. **Technician assistant of engineering:** The time wasted by the engineer could be minimized if the first contact with the customer for negotiation goals (such as visits and elaboration of proposals) were through a technician assistant of engineering. Besides, the technician would be responsible by the consults with external institutions, when requested.
2. **Reducing the validity of the proposal:** The reduction of the validity of the proposal from 30 to 10 working days pressures the customer to return to contacting the firm as fast as possible, reducing the answer time from the customer.
3. **Communication optimization:** In the negotiation phase, it is suggested the contact from a phone call and confirmation via email with the with a deadline established in the proposal.
4. **Interactive coordination:** It is proposed the possibility that many subjects are designed simultaneously, providing more interaction among the team, in order to avoid interferences as much as possible, allowing a parallel correction, reducing

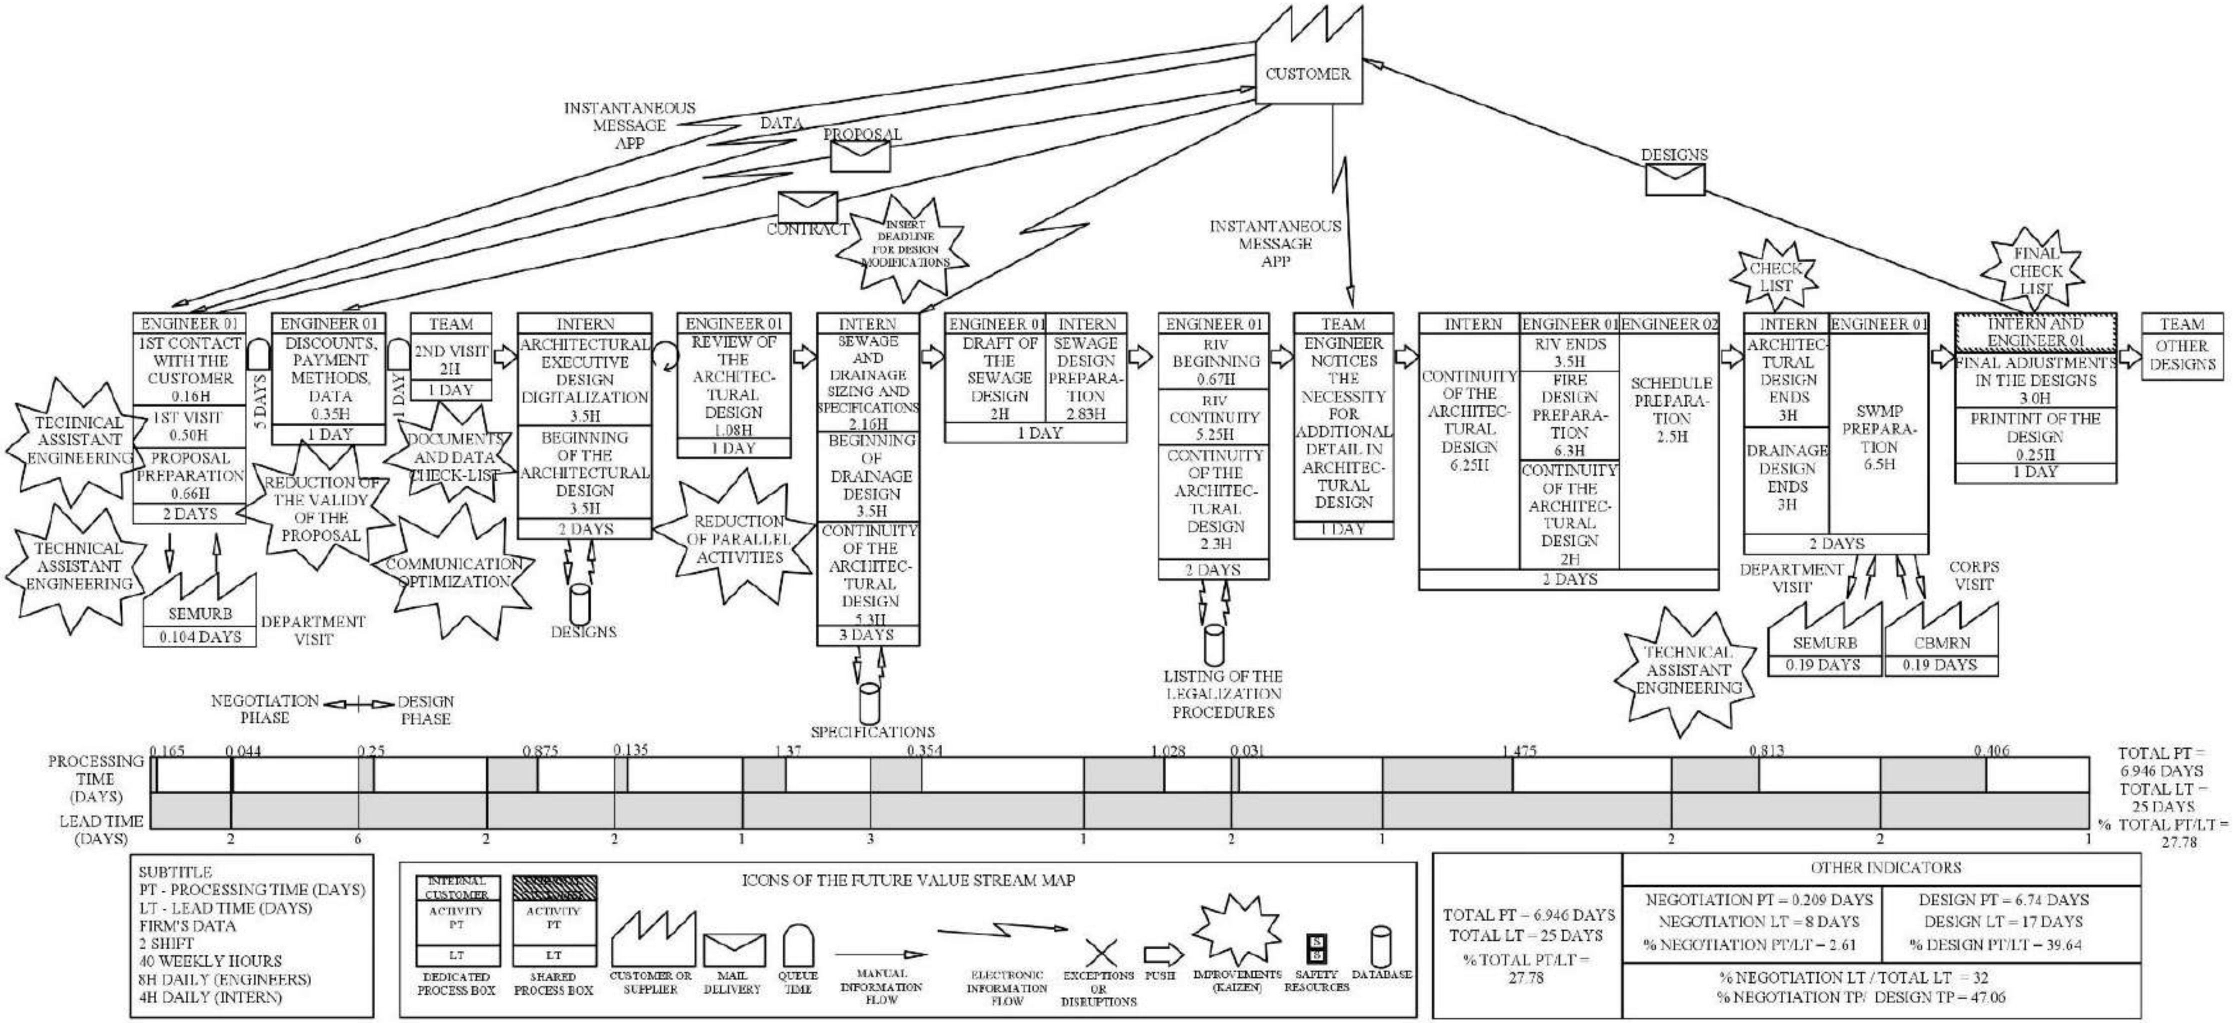

Figure 2. Future State Map.

the time of wait for information and reducing the cycle time of the drawings. It can be adopted through the implementation of auxiliary software, in BIM platform.

5. **Creation of a database (designs, sizing spreadsheets, memorials, legalization procedures and checklists):** The use of a database, with designs and documents templates, speeds up the process of digitalization and helps to reduce the PT. Analogously, it is suggested the creation of pre-programmed sizing spreadsheets, calculation specifications and legalization procedures for the daily situations. It is also proposed the usage of checklists to verify which documents and data will be necessary throughout the design process, as well as a final verification after the project is finished.
6. **Reduction of parallel activities:** It is suggested to prioritize the current design, avoiding this way the interruptions in the elaboration and corresponding documents.
7. **Use of task manager:** The software aids in the analysis of invested time in the performance of the activities. It is possible to create tasks, attribute tasks and count automatically the time effectively used in each activity. This way the team can oversee itself.

As a result of a future VSM, the total lead time of the process is reduced in half, 25 days. The total PT is also reduced, 6.946 days. In other words, the activities which do not aggregate value correspond to 72.22% of the total process time.

The negotiation phase presents a lead time of 8 days, being less than the proposed time of 10 days. In the design phase, the lead time corresponds to 17 days, from which 6.74 represents the time of execution of each activity. Thus, it is reduced the time of waste on activities that do not aggregate value in 8.96%, resulting in 60.36%. This change contributes to deliver the design within the deadline. Regarding the indicators related to the negotiation time percentage, it was kept constant in 32% of the total PT and was elevated to 47.06% the design PT. The time spent per discipline is illustrated in Figure 3, before kaizens.

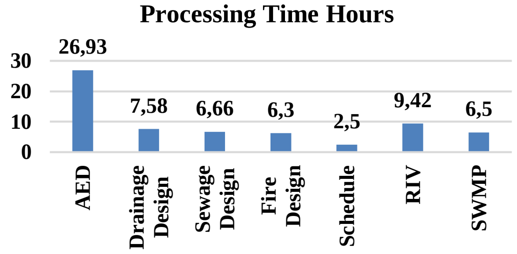

Figure 3. Processing Time Hours per discipline.

4.3 Implementation Plan

Many improvements were suggested to the design-build firm in study, and with the intention of applying the same, a plan of implementation was created. This plan targets the gradual integration of changes to the work procedures, providing the best way of team adaptation to the new techniques.

Under the supervision of the engineer, the insertion of the interactive Coordination through the use of BIM tools is divided in two stages: acquisition of the computational tool and team training. It is estimated a duration of 1 month for the first stage, which involves a cost-benefit research to choose the *software* and purchase. The team training stage lasts 3 months, divided in 1 month for each member of the team. This one was escalated in a way that the activities of the firm were not interrupted.

The *checklists* can be elaborated in 1 month, being 15 days for each list. It is necessary, for this activity, the internal data gathering of the firm about essential information for the elaboration of documents and designs of recurrent typologies at the company, under the shared responsibility between the engineer and the intern. The modifications of the proposal validity and insertion of deadlines in the contract must be done within 10 days by the engineer.

Concerning the creation of a database (designs, memorials and legalization procedures) it is expected 2 months of activity, assigned to an external consultant (a *freelancer* engineer). Regarding the hiring of a technician assistant of engineering it has been established a deadline of 6 months to the engineers. This extended time is due to the priority of the aforementioned improvements, besides the current limitation of physical space and the company’s budget organization.

Among the suggested changes, just the alteration of the validity date and the hiring of a *freelancer* engineer were not deemed valid by the firm’s engineers. Some of the attributions that were suggested to the technician were vetoed, as well as negotiation and elaboration of proposals.

5 Conclusions

The use of the VSM *lean* tool is essential in the identification of value adding and non-value adding activities to the selected processes flow. In this study, the VSM indicated that the lead time in the activities is fairly elevated if compared to the execution time, for the total cycle time as well for the negotiation and design phases. The study points out as reasons the long waiting time for information from the external and internal customers and interruption of the activities to deal with activities related to other customers. To minimize or eliminate the waste is did a plan of implementation of improvements and just part of it is validated by the firm, due to costs originated from these changes.

The biggest obstacle reported by the engineer to count the time spent by the team members on the execution of the design. On the one hand, they not only worked in the design-build firm, but also on the outside, making it harder to establish the actual time spent on the design-build project. On the other hand, there is no linearity in the activities due to other needs: technical visits, consultation with public institutions, possible future clients and reception of phone calls regarding the projects of the company (clients and others), shifting the focus of the ongoing activities. Another important reported challenge is to make the team adopt the changes made, despite the results and observations from this study. The fact that the team is neither Lean nor expert at this philosophy imposes difficulties to the adoption of new techniques and mainly the change of attitude in the organization. The engineer notices not only the need to show the losses and offer solutions, but also to transform the culture and organizational thinking of the company; the training of the current and the new members about the Lean approach also stands out.

At first the firm was reluctant to recognize that the design lead time surpassed the established deadline of 30 days. Thus, the results of the VSMs were eye opening so the team could accept that there was room for improvement in their production process. As future perspectives, the engineers decided to hire an intern of engineering and initiate a software course to BIM architecture concept. Due to the fact of not being a lean firm, the suggested changes have some barriers at first, but ones that decrease as long as the team lives their benefits (Leite and Neto [12]).

Overall, the Lean Design approach provides gains of quality to the design process. With proven improvements in the reduction of the cycle time, waste and rework, besides the delivery of more value to the customer in less time and with less cost if compared to the current design techniques.

As a limitation of the paper, there is not a mapping of activities done during the interruptions of the studied flow and other current processes in the firm in the same period of this research. For future studies, the paper suggests executing the same method of research at other bigger firms, with the performance of similar activities and mapping the current state, developing the future VSM and comparing the results.

Abstract –

There are approximately 10,000 road tunnels in Japan. Human visual inspections of the tunnels must be conducted once every five years. However, presently, the number of inspection engineers is insufficient and the cost incurred for the inspection is significantly high. In conventional crack inspection methods based on an image processing, inspection engineers process many images off site. However, these methods require a lot of effort to identify the cracks and dirt manually.

We have studied a brand-new robotic inspection method to measure the crack positions automatically by using high-resolution texture/depth images that are acquired based on the light-section method. In this report, we present the study outline and introduce the devices developed. Furthermore, we present the inspection results of tunnel lining concretes by using our method in contrast with both an actual road tunnel made by the conventional piling method and a simulated actual-size tunnel we made by the NATM method.

Keywords –

Tunnel inspection; Crack detection; Depth-image

1 Introduction

The Japanese government decided to periodically inspection the road tunnel once every five years since 2014. In principle, the inspection should be performed by near visual inspection to the tunnel overall length. The results of the inspection and diagnosis were recorded and saved, and a decision was made to classify the diagnostic results of soundness on a unified basis. Against such a background, issues such as a shortage of engineers and lack of budget to inspect road tunnels are becoming apparent [1].

Close visual inspection of a road tunnel is conducted by inspection experts, who observes the surface of the lining concrete in the vicinity using an aerial work platform or the like. The experts measured and recorded the degree of the changes in the cracks, floats, steps, efflorescence, honeycombs, water leakage and the like. The representative method to support the experts is based on an image processing [2]. Often, the method requires off-line image process for a large amount of image data of the concrete lining surface. Because the common method of the image processing recognizes dark pixels with cord-like arrange as the cracks, a dirt or the like can be erroneously detected as a crack. Various methods have been made to prevent these false detections, but some challenges still remain for completely automatic crack detection.

In order to solve these problems, the automatic crack inspection device based on the light-section method have proposed and developed to support close visual inspection [3]. The device is the one of the component of our robot system shown in Figure 1, called “Variable guide frame vehicle” developed for traffic-free tunnel inspection [4]. In this paper, we describe an outline of the device, and the results of the performance validation experiments of the device in contrast with both an actual road tunnel made by the conventional piling method and a simulated actual-size tunnel we made by the NATM method.

2 Mobile Light-section Device Developed

The authors have made it possible to distinguish between cracks and dirt by obtaining depth images as a three-dimensional shape of the concrete surface. In various methods to acquire the three-dimensional shape, a light-section method was adopted considering both the high resolution with 0.1 millimeter/pixel order and the portability for wide area inspection over kilometer order.

The light-section method acquires a three-dimensional shape by causing the slit-light and the area camera to move relative to an object for scanning, while maintaining a certain angle. It is based on the property that the slit-light deforms accordingly. By using the slit-light of a white LED, a color image (visible image) whose coordinates are coincident with the three-dimensional information can be obtained.

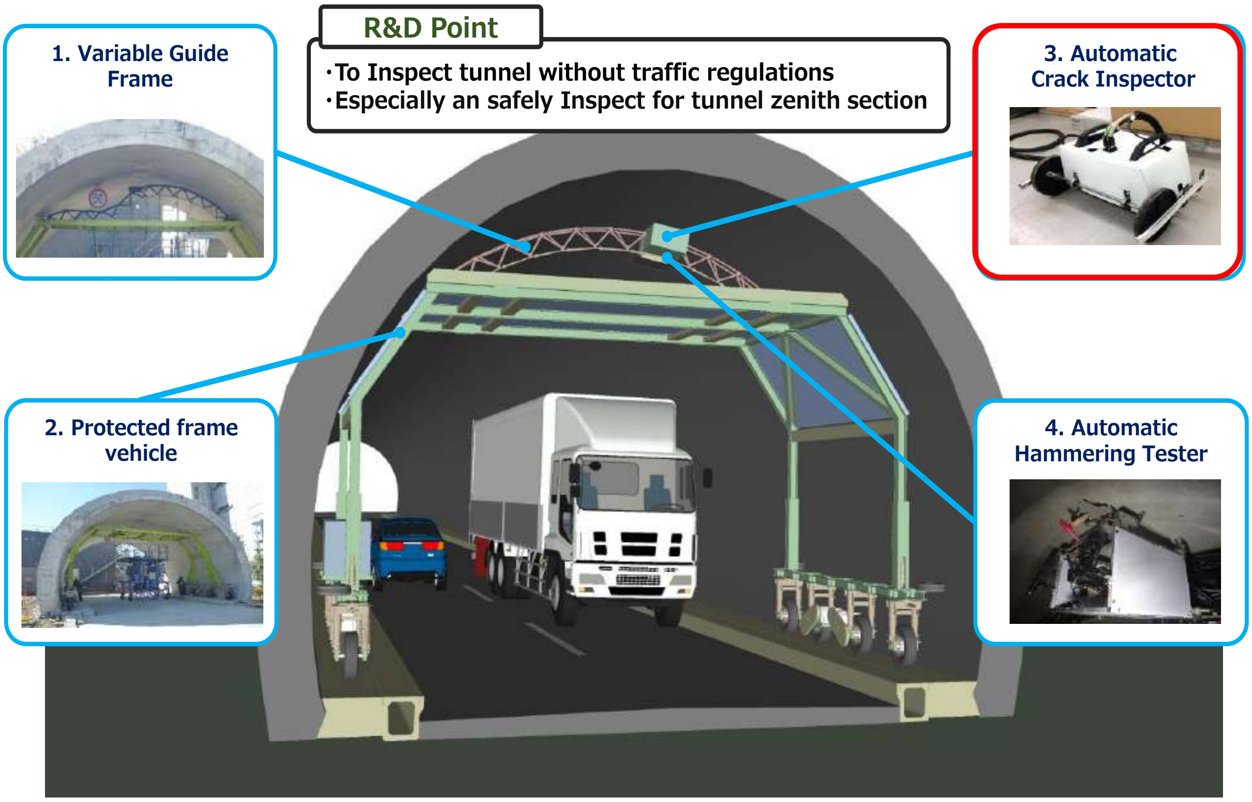

Fig. 3 Concept of our method of tunnel inspection (mobile light-section device is in red square at upper right)

The authors made the device for an automatic concrete crack inspection that can implement the mobile light-section method by combining the wheel and encoder, and robotic scanning of the lining concrete surface (Figure 2). Our image processing software for the device was configured as shown in Figure 3. An image is photographed according to the scanning distance, and the light-section processing is performed when the images are accumulated. Based on the generated depth image and color image, the cracks are automatically detected (see [3] for more details). The detection results are integrated on a stitched image with about 10 square meters, and are used for the measurement of the crack length and the investigation of the closed cracks that has a risk of chip out to a road. Our system could be performed these processes onsite.

Figure 4 shows an example of a color image and a depth image obtained by scanning the same object. In the depth image, it is possible to distinguish between real cracks and simulated cracks drawn with felt pen (black, brown and green) and chalk (white) near the actual cracks. In order to verify the performance of the automatic inspection of cracks by this device, for each of the 10 concrete test samples, the detection rate (the detected crack length dividing by the actual crack length) and the false detection rate (the number of erroneously detected pixels divided by the total number of detected

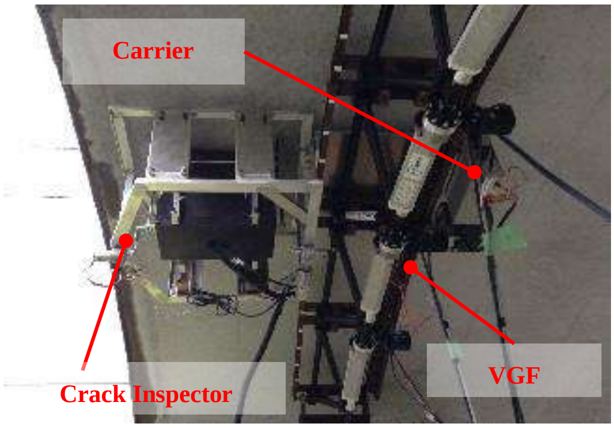

Figure 1. Our light-section device prototype

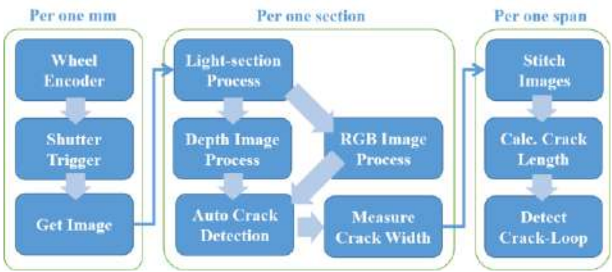

Figure 2. Crack inspection flow by our device

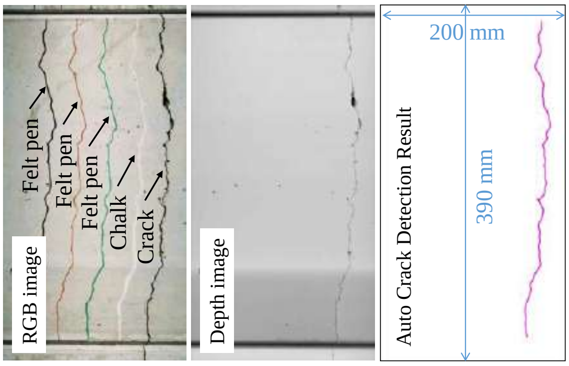

Figure 4. Automatic crack detection result example by using a concrete test sample with simulated dirt lines and a chalk line

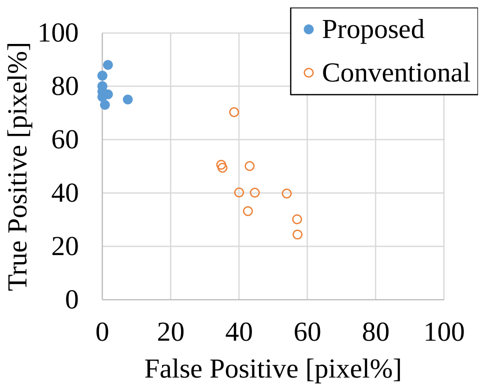

Figure 5. Automatic Crack detection accuracy by using 10 concrete test samples

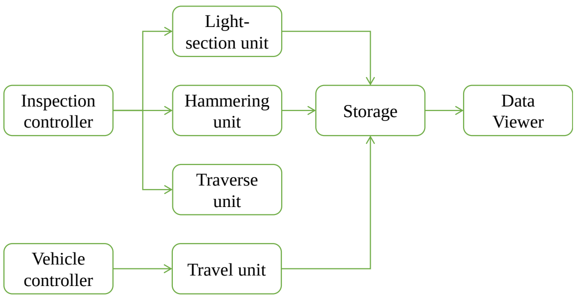

Figure 6. Inspection process by VGF vehicle

pixels) was evaluated and plotted as shown in Figure 5. The cracks were detected by using only the depth image. On the other hand, for comparison, the detection rate by a commercial software and the color images was also shown in the figure. The crack detection rate by our method was greater than 73% and the false detection rate was less than 8%, both of which were confirmed to be superior to those of the conventional method. The main cause of false detection was surface bubbles near the cracks. However, the misdetection of felt pen or chalk was 0%.

Figure 6 shows an inspection process for our system. The variable guide frame vehicle has 4 features. The 1st is a variable guide frame. It enables avoidance of speed signs and luminance and so on. The 2nd is a protected frame vehicle. It enables traffic-free inspection and ensures safety of road users. He 3rd is the mobile light-section device. The 4th is the robotic hammering device (see [5] for the details). These features enables robotic tunnel inspection method we have proposed.

3 Test on NATM simulated tunnel

The depth image and color image were obtained by scanning the lining concrete surface using the light-section method on the actual-size simulated tunnel made by NATM method. The scan range was ~5.4 m in the circumferential direction of the arch part, as shown in Figure 9, and ~10.3 m in the axial direction. Considering the overlapping portion in the short axis direction, the effective scan width was 400 mm. 26 strips of image were taken and stitched as Figure 7 and 8. A white part on these figures is a place of speed sign.

Based on the obtained texture/depth images, crack detection software is used to automatically detect the cracked parts from the images of each scan; the width and length of the crack are obtained by counting the detected pixels semi-automatically as shown in Figure 9. This was done by an operator specifying two points on the screen and automatically counting the pixels in a straight line connecting the two points. The width and length of the cracks thus obtained were compared with those obtained using the conventional method (close visual observation) by a skilled checker.

The measurement results of the crack length are shown in Figure 9. The upper numbers on the side of the cracks are crack width. The lower ones are crack length ratio against with the close visual inspection results obtained by skilled workers as shown in Figure 10. When comparing the measured value by our method with the value by skilled workers, it was found that the crack length shorter than the values obtained by a skilled worker, however, bold cracks (width >= 0.5) in results are almost same.

4 Test on tunnel made by piling method

The depth image and texture (color) image were also obtained on an actual road tunnel made by conventional piling method. The scan range was ~3.4 m in the circumferential direction of the arch part, and ~3.7 m in the axial direction. The effective scan width was 400 mm. 10 strips of image were taken and stitched as Figure 11 and 12. A white part on these figures is a place of speed sign.

Based on the obtained texture/depth images, crack detection is used to automatically. The length of the

Figure 7. Panoramic texture image of a tunnel lining concrete made by NATM method

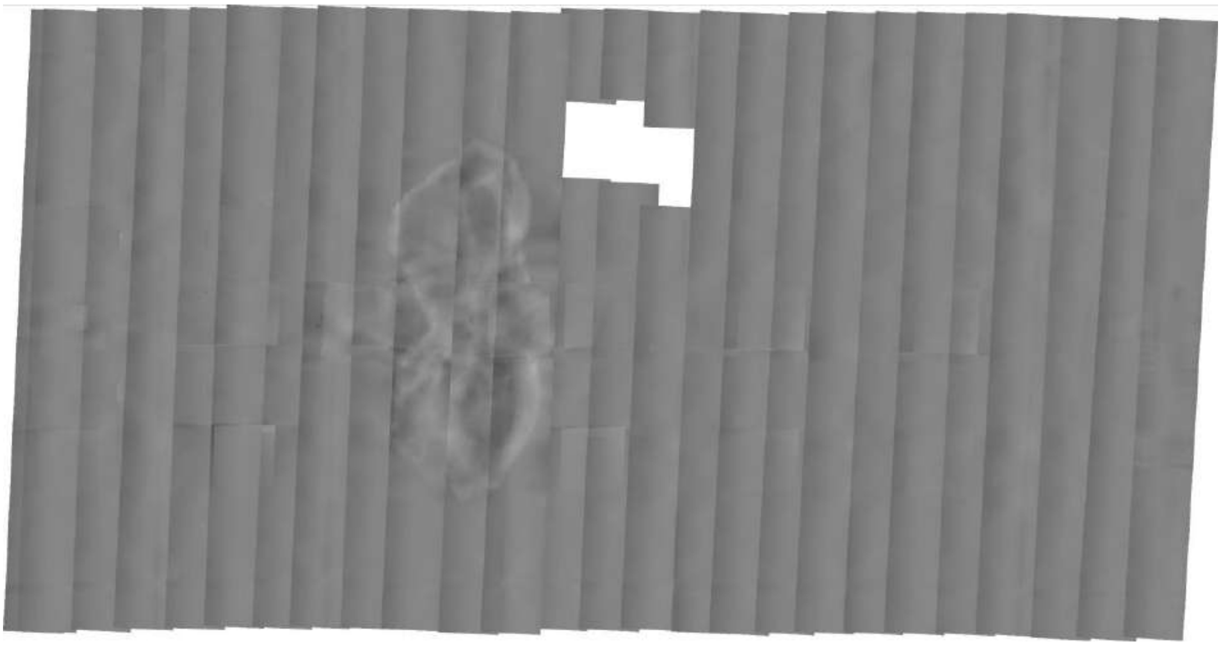

Figure 8. Panoramic depth image of a tunnel lining concrete made by NATM method

crack are obtained by the same way as shown in Figure 12. The values on the figure means the same parameters of the Figure 9.

The crack detection rates of the above two tunnels and CMI tunnel results (reported in [3]) are shown in Figure 13. The rate was over 90% when excluding the cracks with a width of less than 0.5 mm and with an efflorescence. The false-negative of the detection especially occurred for the crack with an efflorescence. The most of the false-positive occurred at the bug-holes in concrete near the cracks or the construction joints. Currently, we are investigating ways to distinguish the cracks and the bug-holes more clearly using a cord-like structure of the cracks and a circularity of the bug-holes.

5 Conclusions

We developed an automatic crack detection method by using both depth and texture images. In order to obtain these images in about 0.1 mm/pix resolution

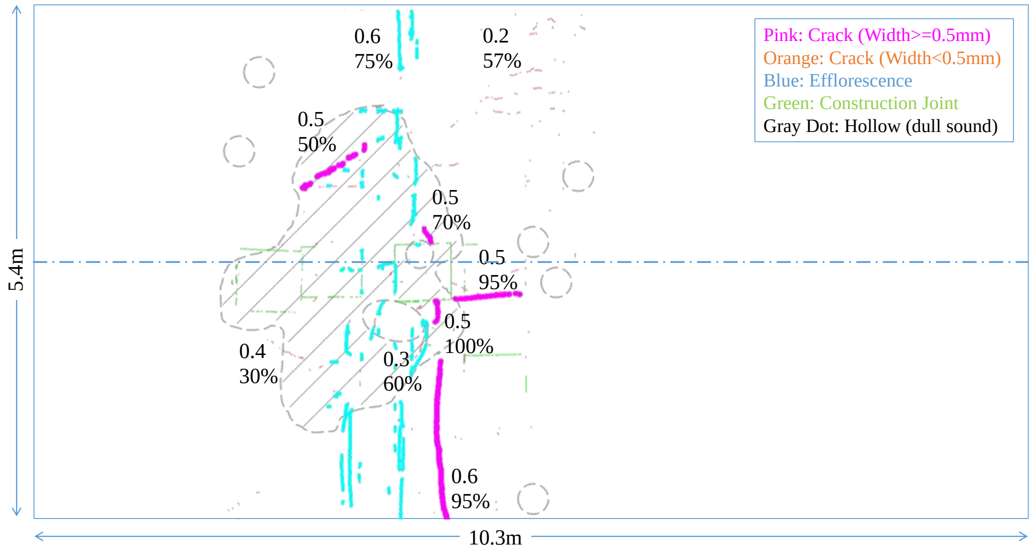

Figure 9. Inspection result by our method with crack width and crack detection rate

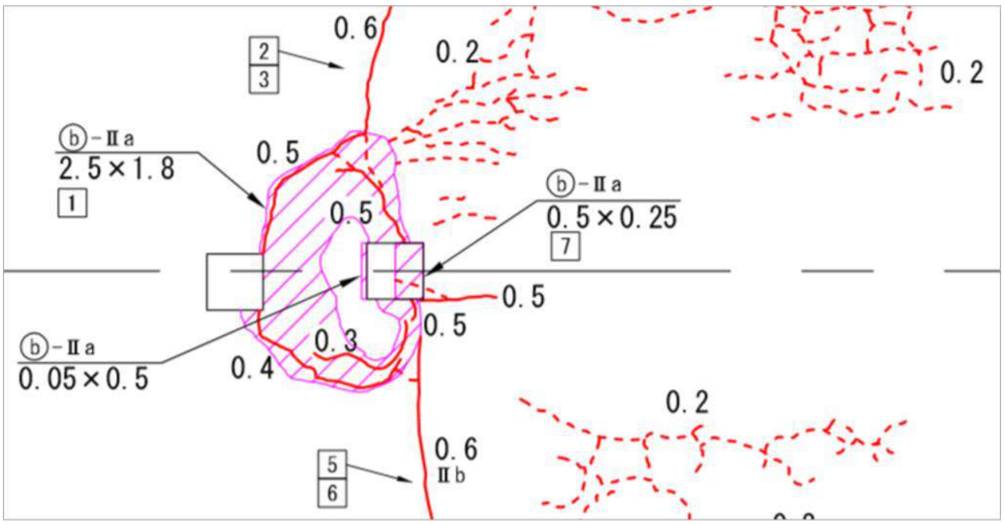

Figure 10. Inspection result by conventional method by inspection experts

quickly, we developed crack inspection device based on the light-section method. We inspect two type of tunnel ceilings by our device equipped with the variable guide frame vehicle. These results showed that the proposed technique has a crack detection performance equivalent to that of humans.

Currently, the authors are brushing-up the tunnel inspection method using this device for improving the detection accuracy of crack detection software.

Generative Architectural Design and Build Strategies based on the Mapping of Human Behaviour

J.B. van Ameijde[a]

[a]Architectural Association School of Architecture, London, United Kingdom
E-mail: ameijde_je@aaschool.ac.uk

Abstract –

The introduction of robotics in construction offers the possibility of implementing design processes that incorporate unforeseen levels of complexity. Not only does this allow for the construction of high degrees of formal differentiation, but for the conception of projects with a high-resolution integration of performative qualities. These performance aspects can include environmental and economical properties but also social and cultural mechanisms, which can be monitored through the tracing of human activities within architectural and urban spaces.

This research presented here focuses on technologies and work flows that enable on-site data collection and construction implementation, in separated design and build phases or in an integrated process with continuous feedback. It discusses a series of small projects that explore new scenarios for the creation of architectural structures, experimenting with mobile and low-cost fabrication devices, connected to generative design algorithms driven by sensory technologies. These projects show that instead of working directly with the geometry of the final outcome, architects can begin to script individual and unique processes for generating structures, using rule-sets that capture the intelligence and underlying logic of materiality, organisation and spatial performance.

We advocate a new paradigm where the architect is a 'process designer', aiming to generate emergent outcomes where the inherent complexity of the project is generated towards specific performance criteria related to human activities and inhabitation.

On-site sensing and construction technologies; Human Activities Monitoring; Computational design; Emergent design; Custom robotic devices; Digital construction;

1 Introduction

As robotic fabrication and assembly devices are being introduced to construction sites, it becomes possible to re-think the entire process of how architectural projects are materialised. Construction processes no longer rely on inefficient communication protocols towards manual workers and manual tools but can directly be connected to digital 3D models created by the design team. This could increase quality, reduce errors and cost, and potentially reduce construction time. It could also be used to deliver projects of increased complexity, due to the system's ability to perform large amounts of operations at high precision. As robotic devices are becoming mobile and able to work collaboratively, this paradigm can be applied to the scale of the building site instead of being limited to the working envelope of a single device.

The direct communication between design software and construction technologies signifies a fundamental shift in the possibilities of design, as projects can potentially be conceived and built with a much higher resolution of material properties and with a high degree of internal differentiation rather than repetition. Instead of applying robotic tools to the production of sculptural or decorative complex geometries, there is the much more radical opportunity that presents itself: the incorporation and integration of several layers of functional complexity.

The architectural design, and therefore the design process as well, could start to incorporate complex properties of a building's performance within its environment, generated through detailed simulations and real-world data gathered through sensors, measurement and mapping processes. Performance could be understood within the context of physical environmental and climatic conditions such as sunlight, wind, temperature and noise and this is indeed one of the great potentials of digital design processes, to deliver increased building quality, efficiency and improved spaces designed around human comfort. But performance analysis can also be applied to how buildings perform within their socio-political context, from an economical perspective or as an environment for human circulation and inhabitation. Within the practice of planning office layouts for instance, it is already commonplace to consider the interplay between the comfort, psychology and productivity of employees and the arrangement of furniture can directly influence the economic success of a company. The layout of shelves and the product placement in supermarkets is designed to increase sales of the most profitable items, taking into account the visual navigation and behavioural psychology of the customers. Through increasingly precise monitoring systems that build up large data-sets of statistical analysis of human activities, the design processes that optimise spatial layouts are increasingly being automated, informed by semi-intelligent processes such as machine learning.

While commercial applications might be the driving force behind the rapid development of data-driven design, there is an opportunity and arguable an obligation of academics and practitioners within the architectural discourse to critically examine the possible positive and negative consequences of these new processes. The monitoring of people's behaviour through CCTV, online communication and mobile devices might have a potential dystopian dimension, but if done in an appropriate and acceptable manner, this could offer a wealth of knowledge to architectural and urban design processes. Instead of focusing on the commodification of user data for profit driven operations, architects and planners could calibrate their designs towards social interaction, human comfort and health. Where architectural and urban spaces are required to house social activities and community formation, generative design processes can be used to monitor human behaviour and define the properties and organisation of spaces to stimulate this in the most effective way. Data-driven processes could be used in the design stage of a project, as well as for the continuous management or adaptation of the project throughout its life.

2 Precedents: Mapping human behaviour

One example of research into the social dynamics of public spaces is the work by sociologist William H. Whyte, who's publications include The Social Life of Small Urban Spaces (Whyte 1980). His aim was to understand why certain plazas remain empty and unused, while others were well loved and heavily used as leisure spaces and social condensors within the city. He used manual techniques of measuring, counting, mapping and other forms of direct observation to understand the relationships between specific physical characteristics of the space, and the human activities that would occur. His work resulted in design guidelines on principles such as visibility, accessibility, seating, greenery and environmental conditions such as sun and wind, many of which were consequently applied by municipal governments in different cities in the United States. Whyte served as a mentor to Jane Jacobs, who wrote The Death and Life of Great American Cities (Jacobs 1961), which famously argued for the conservation of organically grown neighbourhood qualities, recognising the value of the rich mix of complementary programs that emerge around walkable neighbourhoods.

A continuation of research into the underlying principles of human decision making within urban environments can be found amongst the highly varied initiatives that can be considered part of the 'smart city' movement, that has been referenced by academic and professionals in various locations in recent time. The idea of a ‘Smart City’ was first introduced in the 1990’s but has recently attracted more high-profile projects and attention, resulting in several projects and policies that are being executed around the world today. The goal of a Smart City is to use technology to create economic, social and environmental improvements. This challenge is not only related to design and planning issues but is also aimed at the economic and political frameworks that guide urban development. ‘Smart City’ projects aim to understand the urban ecologies - the invisible networks of human activities that drive the materialisation of the city.

The sociologist Jennifer Gabrys has written about the "new wave of smart-city projects that deploy sensor-based ubiquitous computing across urban infrastructures and mobile devices" (Gabrys 2014). She notes the potential positive ambitions of these project to improve sustainability but also warns of the potential dangers of monitoring and managing data on citizens. Referencing the French philosopher Michel Foucault (1926 – 1984) who has written extensively about mechanisms of power and control exercised by the state, and how its manifestations in the structures of buildings and the city can be understood as a 'bio-political machine'. Gabrys argues that smart-city design processes should focus on the performance of urban environments as demonstrated through the behaviour of people within them rather than collecting data on citizens and populations. The sensitive subject of monitoring human activity should be approached with the necessary safeguards to ensure privacy and data protection of individuals and allow for open-endedness towards behavioural patterns and demographics.

3 Methodology: Generative Design

This paper will present a series of small projects undertaken in the context of various academic research and teaching programs at the Architectural Association in London, organised under a larger research agenda into generative design and build processes based on the mapping of human activities.

The practice of generative design is well established within multiple design and engineering disciplines and can be defined as a computational design process aimed at creating the best possible solution towards specific performance criteria. It can be considered a sub-category of the larger field of parametric design, which is a terminology that merely indicates that certain parameters or relational modelling techniques are considered during a design process. The practice of generative design assumes that there are clear goals for the design solution which makes it particularly suited to be conceived as data-driven design, evaluating potential design options against detailed contextual information.

The potential role of generative design processes has been identified early on by Mitchell and McCullough (1991), who contemplated the implications of computational processes being able to address a complexity of parameters and interactions, much greater than could be handled by human cognitive processes alone. They emphasized however that instead of promoting 'automated design procedures', there remains a central role of the designer's intellectual capacity, using critical judgement towards the employment of algorithms, the input of data parameters and the definition of the evaluation criteria. Generative design in this context is employed as operating on the underlying relationships rather than formal characteristics of the built environment. As Lima and Kós write, "this form of algorithmic or parametric modelling transcends the understanding of the computational paradigm as a mere promoter of complex forms, and contributes to processes capable of forming models that contemplate several parameters involved in the functional, environmental and of the cities and the buildings they contain" (Lima and Kós 2014).

Within our research, we interpret the practice of generative design as a methodology that has a clear logic and consistent step-by-step translation of design information over time. This allows for the design process to ‘generate’ traceable solutions which can be evaluated against the performance criteria that informed the design process in the first place. This approach to the use of rule-sets allows us to generate site-specific outcomes within the limitations of a particular context, allowing projects to take full advantage of and contribute to environmental, programmatic and connectivity characteristics of the surroundings.

3.1 Project 1: 'Point-Cloud'

The first project that was undertaken to test rule-based design methods and in-situ digital fabrication and construction technologies, was a small experimental

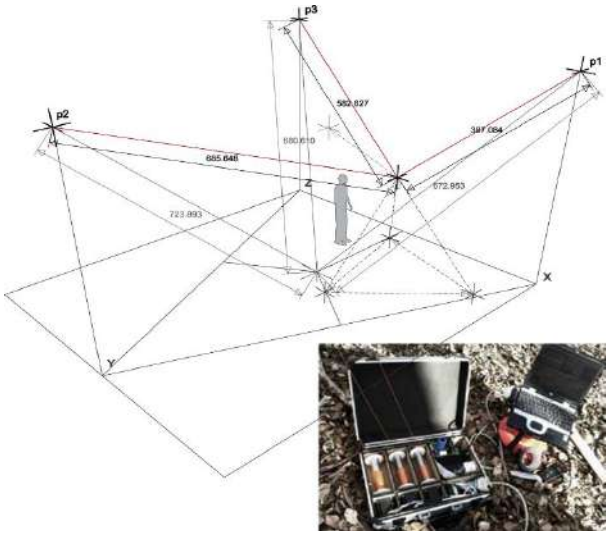

Figure 1. CNC cable robot, used as point indication device

structure situated within the forest of the Dorset campus of the Architectural Association.

The project used a custom-built cable robot device, designed to act as a 3D location point indication device on site. It functioned through a computer numerically control (CNC) protocol to manipulate the length of three wires on spindles attached to stepper motors. The wires were installed in a site by attaching three pulleys to existing trees or buildings around an empty area. This system is adaptable and scalable: a wide range of sites can be turned into a CNC working envelope. The CNC machine was connected to a laptop with the widely used G-Code control software Mach 3, allowing to move the wire pointer to a specific coordinate in 3D space similar to how the cutting head is moved around on a three axis CNC milling machine (Figure 1).

The project explored a digital work-flow which translated 3D scanned data of people movements and densities towards a corresponding cellular structure to be built on site. The movement data was collected by using a KINECT 3D camera to gather point cloud data of human bodies within the site over a time period of 10 minutes. A semi-automated design work flow was set up to handle the translation of the point cloud information from the 3D scans to the specific geometry to be built, using cell-packing and tessellation algorithms (Figure 2). The design method was calibrated to translate higher intensities of movement into increased densities within the structure, visualising previously invisible qualities on site and guiding subsequent visitor movements along specific paths.

The construction system was deliberately designed as part of a human-machine collaboration, envisioning a scenario in which the device is only used for its most important task: the translation of detailed construction

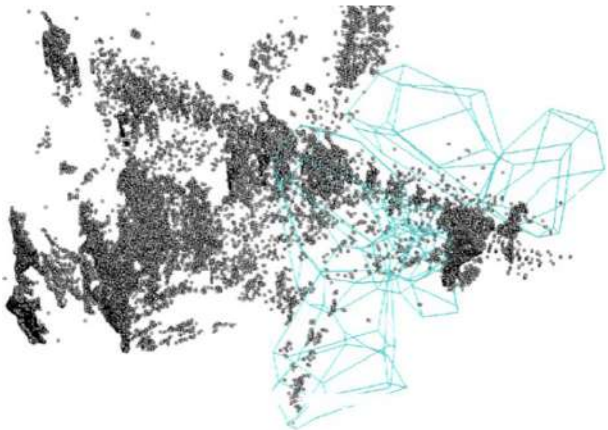

Figure 2. 3D scans of people movements through the site, translated into a triangulated structure through a generative design process

information from a digital model containing three-dimensional point locations onto a 1:1 building site. The human collaborators did tasks which they can do better than machines, such as the manual handling and connecting of building elements (Figures 3 and 4).

Figure 3 and 4. Human collaborators installing timber elements guided by the cable robot pointer, resulting in a variable density triangulated structure

The 'Point-Cloud' project demonstrated the potential of a generative design process based on site-specific data, however the design properties of the physical structure did not attempt to change or contribute additional functionalities related to the movement within the site. Successive projects have been set up to incorporate this ambition, not just responding passively to the data gathered on site but aiming to introduce improvements to the conditions found.

3.2 Project 2: 'Emergent Constructions'

The second project within our line of research consisted of a medium sized architectural pavilion designed to offer a temporary cluster of spaces and seating elements to visitors of a large shopping mall in Kuwait. Using digital cameras to record the movement of people through a central atrium space, the prevailing pattern of visitor flows was mapped in relation to the entrances and attraction points within the mall. Data regarding user density and sight lines between the pavilion location and the surrounding amenities was translated into the design of a pavilion that would create an intervention on the existing site. This intervention would generate activity, intervene with general paths of circulation, and create a louvre effect between the internal spaces and the context to offer varying degrees of privacy for the people inside (Figure 5).

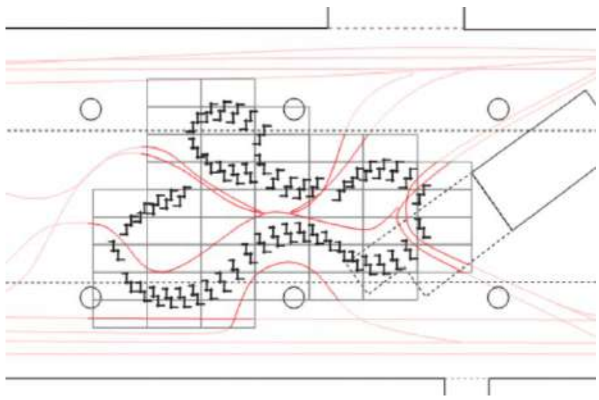

Figure 5. Pavilion space constructed through louvre walls that mediate privacy

The qualities of space that result cover a range of social interactivity scenarios including private space for a single occupant, and larger group spaces for dynamic social interaction and play. The programmatic possibilities were further enhanced through the incorporation of furniture elements such as benches and stools. The result of the generative design and construction exercise was a pavilion that manifest itself as a field condition, distributing a large amount of self-similar elements with varying properties and relationships within the circulation space of the mall to intensify and enrich its spatial and programmatic possibilities (Figure 6).

The pavilion as a field of elements with different heights, density and functions created a varied architectural landscape that has specific intentions for

Figure 6. Pavilion spaces designed to separate visitors from the surroundings and stimulate social interaction

stimulating social interaction built into it. The multiple possibilities of use and interpretation however allowed the users to create their own social patterns and interactions, exploring unforeseen modes of engagement with the design at the many in-between spaces of the pavilion. The role of the architecture was conceived as creating a stimulating environment with a strategic purpose and agenda, without being over-prescriptive or inflexible but instead creating an open-ended system for appropriation by the users of the mall.

The principle of feedback between architecture and users is something that is explored further in the subsequent projects. This research follows on from an important precedent titled "Seek", exhibited in Jewish Museum in New York in 1970 by Nicholas Negroponte.

This installation consisted of a glass display case filled with small cubes that could be rearranged by a robotic arm connected to a camera and computer system. The display was inhabited by gerbils, who continuously moved the cubes around. The robotic arm was used to help organise the arrangement of the cubes, not according to a fixed blueprint but based on rules that tried to interpret the preferences of the gerbils. Throughout this process over time, the aim was to let an ideal inhabitable landscape design emerge out of the negotiation between the inhabitants and their environment.

3.3 Project 3: 'Emergent Field'

The third project titled 'Emergent Field' explored a similar generative, rule-based design strategy that monitored people movement through a particular forest site and materialised this as a field of timber sticks placed vertically within the terrain. This material system was chosen for its ease of construction and the compatibility of the geometries with the CNC controlled device that was going to be used, which was the same cable robot device as introduced in project 1, described previously. The vertical nature of the sticks would allow the wires of the cable robot to be moved in between the elements, if the movements of the pointer were choreographed to drop down vertically each time it would indicate a new location point. This characteristic would enable the system to build additional pieces inside areas that had already been populated with sticks.

The project explored a process where the final formation was not known at the beginning of the construction process but was allowed to emerge throughout a series of iterations consisting of movement tracking, generative design translation and construction. A digital camera facing vertically downwards towards the build area was used to take snapshots over a period of time of people locations. A simple piece of software was used to process the images, selecting areas of red colour as all people in the experiment were asked to wear red head coverings. The recorded site occupation density patterns were automatically translated into geometrical patterns for the timber stick formations using a generative design process based on simple rules (Figure 7). The movements were recorded during breaks in between the building activities, when people were asked to freely pass through, explore or inhabit the forest site.

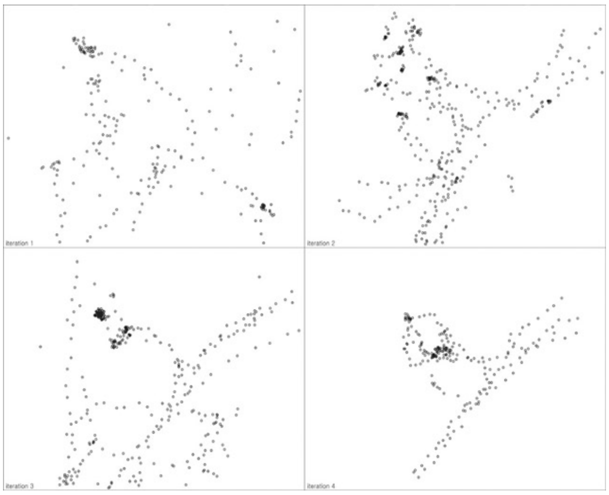

Figure 7. Density maps generated by web-cam monitoring of people, showing the iterative refinement of pathways and hangout spaces

Each iteration resulted in a construction pattern that added additional density in areas which the people hadn't occupied, gradually articulating the edges around movement pathways and inhabitation spaces with rows of vertical sticks. The initial layers of elements within the site were placed with a generous spacing, in order to allow users to move in between the sticks that were

Figure 8. Final installation of the field of elements on site, using a web-cam suspended from the trees and a cable robot pointer device

placed, still suggesting adjustments to the patterns that was gradually emerging. The gradual refinement and articulation of circulation and inhabitation areas occurred within both the digital design model and the physical space, thus allowing the final design to informed through the active negotiation between material and users around the real experience of the installation in the site (Figure 8).

The outcomes of the project might seem abstract and show a significant reduction in the amount of functionality compared to the previous project, yet the iterative design and build process signifies a radical improvement in the process of design conception and data management. Instead of 'friezing' a data-set containing site information, the relevant parameters are continued to be monitored throughout the construction process, allowing to building design to keep adjusting to new information from the site caused by the intervention being placed. The feedback loop between a structure on site and the resulting user activities around it, allows for a design process to continuously monitor the performance of its output and learn how to make improvements within it.

3.4 Project 4: 'Public Space Furniture'

The fourth project continued to build on to a series of experiments inspired by Negroponte's 'Architecture Machine'. It was executed with help of several students and used the terrace of the Architectural Association as a testing ground. A web-cam pointing towards the space was used to record people inhabiting the terrace, documenting their position, duration of stay and distance to others (Figure 9). A set of computational rules was then applied on to these maps, instructing the human assistants in the project to place furniture elements around the site. Specific rules and policies were explored to award or discourage certain behaviours, for instance place furniture in positions that would encourage social interaction between people or instead create separations in between different people. The experiments produced emergent outcomes where an architectural structure would grow over time without predetermined design. Users interacted with the structure through sitting, leaning, placing coffee cups, etc. and generally staying longer and engaging in different activities than they would have normally done within this site.

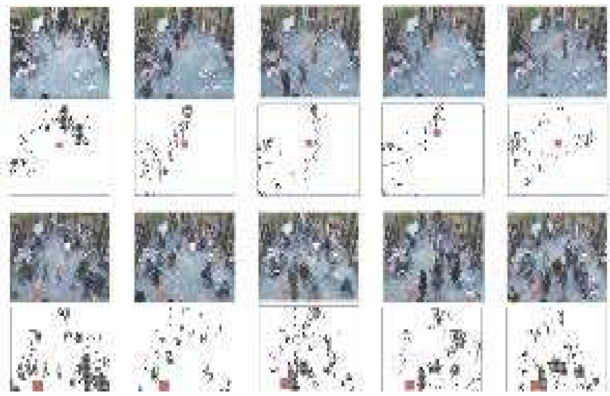

Figure 9. Snapshots of people monitoring as seen through the web cam and as analysed by blob-tracking algorithms

An initial furniture system was implemented using plastic crates, which led to increased social interaction within the site and engagement of the visitors with the experiment. In the second phase, a custom designed CNC fabricated furniture system was deployed that allowed for cantilevering elements and incorporated open and closed panels to be able to block sight lines and create privacy (Figure 10).

Figure 10. Sequence of iterative furniture placements and usage based on people monitoring and specific response policies

The experiments conducted as part of this project added yet another level of complexity to the body of research, testing specific reactionary social policies as part of an iterative scan and build process that incorporates feedback loops. The high amount of variables in the experiments makes it difficult to evaluate with precision which rule-sets or furniture configurations are more effective than others, and the project was mainly intended as a proof of concept that this type of process could be built.

3.5 Project 5: 'Data-Space'

The fifth and most recent project in the series is by no means a final development as it was intended to offer even a higher degree of speculation and open up additional avenues of contemplation about continuous monitoring and feedback systems embedded within the built environment. Titled 'Data-Space', it was developed by the author in collaboration with faculty and students specialised in interaction design from the ArtEZ University of the Arts in Arnhem, The Netherlands, as well as with collaborators from within the Architectural Association. The project explored the use of a field of nodes that each incorporate a sensor and LED lighting, allowing monitoring and communication with people within the site in a distributed and scalable way, as opposed to the previous projects which were limited by the use of a digital camera. The nodes were arranged in a gridded field and suspended above the ground, creating a virtual ceiling embedded with infra-red sensors to create a real-time data stream of user locations. The data was collected via wireless communication in a central computer, that was able to determine the speed, duration of stay and distance in between people. A series of evaluation algorithms were paired with rules for analysis and implementation of certain feedback action, in the form of animated lighting patterns that were displayed around the visitor location(s) (Figure 11).

The additional complexity in this project lies in its capacity to collect data over longer periods of time and communicate not just passive reactions that directly translate sensor input, but instead send out intelligent signals. Protocols that were tested in the project were for instance to entice users to move along light pathways or to reward desirable behaviours such as closeness between two people. When the site was occupied by too many people at once, the system would display 'angry' ripple patterns to indicate to people that it wanted them to leave. There is significant potential in the further development of these systems and an intended provocation towards observers, as the system acts as a metaphor for new types of surveillance systems that are gradually being implemented within society. The scalable nature of these systems both in area size and time allows them to be applied to a range of applications including office layout optimisation, public space furniture, shopping mall design and the planning of services and infrastructure at the city scale. The output would not have to be constrained to electronic communication but can be connected to construction methodologies as discussed in the previous projects. The high complexity of the system and limited time and means for our experiments allowed only initial testing rather than a methodical exploration of the wide range of possibilities.

Figure 11. 'Data-Space' – field of nodes containing infra-red sensors and LED's, tracking human activities and communicating intelligent signals.

4 Conclusions and Future Research

The research presented in this paper explores the conceptual opportunities found within the integration of sensors, material growth systems and robotic devices into generative on-site design and construction strategies. It has focused in particular on the conceptual implications of the introduction of new technologies for the nature of the design process itself, the changing role of the architect and the potential attitude towards processes of negation between inhabitants and their built environment.

It has shown how the monitoring of human activities can be used to inform consequential design adjustments that can be implemented right away, adapting the final outcomes better towards the intended functionalities. By creating feedback loops between the mapping of human behaviour and construction implementation, it is possible to explore strategies for fabrication where the final construction is not predetermined, but instead is producing emergent qualities based on the decisions and desires of human agency within society.

There are several key potentials of this new approach towards design and construction:

Design decisions may be taken in relation to a detailed understanding of a site and context, where the detailed and multi-faceted performance of a building within its environment can be experienced and tested rather than speculated upon from behind the screen of a computer. This should allow buildings to become be better adapted to perform within their context, with high-resolution integrated functionalities and environment-specific, performance-based features.

The increased control over production offers a democratisation of design decision making and facilitates negotiation between different parties in the design process. The role of the architect using these methodologies may shift from controlling the end result to designing a process-based, quality driven generative method, allowing successful methodologies to be implemented towards a range of programs and sites.

The research may increasingly incorporate intelligent behaviours, mimicking processes of self-organisation as observed within nature or in the growth and adaptation of cities. Providing an alternative vision to static and idealised architectural solutions, these methodologies are able to deal with the contingencies and complexities of dynamic social, cultural, economic processes and other forms of human interaction that drive the materialisation of our architectural and urban environments.

Abstract –

Virtual reality (VR) is becoming common in the AEC/FM industry, closely linked to BIM implementation. VR tools can be used to anticipate operational issues, simulating them in a virtual prototype since early design. The paper investigates such a topic in relation to access, space and use performance of an existing hospital facility. A case study has been developed considering a pavilion where both medical and food spaces are located, causing a clash between flows of end-users in critical time-slots. Crowd simulations and immersive virtual environments have been tested as occupancy evaluation tools. Post-occupancy evaluation (POE) data have been translated into a dynamic simulation of the existing occupancy conditions within the BIModel of the pavilion and considering various profiles of end-users. Subsequently, both the BIModel and the crowd simulation have been imported into a game engine to be visualised and experienced in a VR-headset, switching from the analysis of flows to the perspective of end-users (i.e. able-bodied users, person in a wheelchair, visually-impaired person). The use of VR enables a clear visualisation and communication of the existing conditions. Moreover, POE data translated into a dynamic simulation of the building use scenario could be applied for the pre-occupancy evaluation of internal layout reconfigurations. Finally, the combined use of crowd simulation and immersive VR enables the users to perceive crowding in the occupancy evaluation and adds the user experience as design input, representing an innovative approach that goes beyond traditional resources such as personal experience and regulations.

Occupancy evaluation; Virtual reality; Crowd simulation; Immersive virtual environment; Building performance

1 Introduction

The use of Virtual Reality (VR) is becoming common in the Architecture, Engineering, Construction and Facility Management (AEC/FM) industry, closely linked to the implementation of Building Information Modelling (BIM) tools and processes. VR tools (e.g. game engine, immersive virtual environment, crowd simulation) can be used with different purposes, such as visualisation, communication, analysis, design optioneering and training [1] [2] [3]. For example, they can be implemented to analyse the eventual possibility of construction and operational issues in design proposals, simulating them into a virtual prototype since early design. A virtual prototype is, in fact, a digital representation of a design proposal that can be explored, tested and evaluated before being physically realised [4] [5]. Moreover, VR can be applied to evaluate if a design proposal satisfies a performance-based requirement. For example, considering operational outcomes, a pre-occupancy simulation can be applied as evaluation method in order to simulate how the space will be used by the end-users during their activities and, at the same time, improving the understanding of the client about the design proposal [6]; in this way, the human experience is added to the project before it is built [1] [7] [8]. For example, compliance of a design proposal with requirements that relate to access for people with disabilities could be demonstrated by simulating their movements within a virtual space [9]. In the case of an existing building, a virtual simulation can be developed based on Post Occupancy Evaluation (POE) data related to the current in-use condition to provide feedback about how the building is used and produce a benchmark for the possible need for renovation. Furthermore, several examples of immersive VR applied to the iterative design review and feedback process exist in literature. For example, immersive VR can be effectively applied as a communication tool in user-centred design processes based on the feedback of stakeholders [10]. Virtual prototypes developed in immersive environments can support collaborative design review sessions since early design stages, improving the communication among stakeholders [11] and allowing the evaluation of behaviours and preferences of end-users, given different design scenarios [12].

In the following paragraphs, a case study is described in which VR has been applied to the simulation of operational issues in an existing building with communication and analysis purposes. The implemented method and the obtained results are illustrated. Further considerations for future works are also introduced.

2 Case Study

A case study has been developed to test the implementation of two different types of VR technologies (i.e. crowd simulation and immersive virtual environment), regarding communication and analysis of access, space and use performance of the current in-use scenario of an existing hospital facility. The VR-aided analysis has been performed in collaboration with the contracting entity (CE), who wanted to evaluate the benefits of digital approaches to reconfigure spaces and services offered in the asset. In order to narrow the scope of the case study, a VR concept has been developed to communicate and analyse a specific critical in-use condition considering a pavilion where both medical (i.e. emergency entrance from the ambulance parking, elevators to the wards located at the upper floors) and food spaces (i.e. hospital canteen, cafeteria) are located (Figure 1). In critical time-slots (i.e. lunch time, 11:45 am – 2:45 pm) the access to the hospital canteen is likely to cause major queues (Figure 2). This increases the waiting time for the personnel, which has a limited amount of time to have lunch, and interferes with the access of internal and external users (e.g. personnel, patients, visitors), who head towards the elevator to go to the wards in the upper floors of the pavilion. The result of that current use scenario is a clash between flows of end-users.

The CE conducted a traditional POE to collect data for investigating such critical situations. Resulting data have been attached to a public call for feasibility studies to improve the current service response to the needs of end-users, while considering the possibility for a low-budget internal layout reconfiguration of the pavilion at ground-floor, among other solutions. The research group started from this specific case to experimentally evaluate (1) how VR could support the CE in communicating its needs, effectively considering the perspective of end-users and (2) how VR could support the CE in evaluating design proposals.

Figure 1 Ground-floor of the analysed hospital pavilion. Main entrances, wheeled-bed elevator and hospital canteen are highlighted

Figure 2 The queue in front of the elevators during the critical time-slot with people arriving from the emergency entrance

3 Crowd simulation of the existing building use scenario

A crowd simulation tool has been used to represent and simulate the existing building use scenario based on the POE integrated with additional data sources. The aim is to understand if such a simulation could support the CE to answer the following questions: how do the access, space and use scenarios perform in the existing hospital pavilion? Are the needs of end-users satisfied in using spaces and services?

3.1 Data collection regarding the current in-use condition

The case study integrates three data sources, which have been used to evaluate the current building use scenario:

1. existing surveys and building use data collected during the POE by the CE have been analysed
2. focus groups and thematic tables have been

organised with the CE, when critical issues have been discussed in detail, as well as the possibility of introducing a digital approach to the problem evaluation

3. further on-site surveys and walkthroughs have been carried out in order to (1) understand usual movement paths walked by the various profiles of end-users moving and using services in the pavilion (e.g. technical operators, healthcare personnel, administrative staff, medical staff, patients and external users); (2) have occupancy data on narrower time ranges than the ones provided by the CE with the POE. A mobile application was used to collect the number of end-users moving in the pavilion in the critical time-slot according to users profiles; these data, elaborated in percentages, was used as input for simulating the current building use scenario within a BIM-based crowd simulation tool.

Available as-built documents have been reviewed and translated into a BIModel in Autodesk Revit. The level of definition of the BIModel was established according to the model use defined for this case study, which is the translation of POE data into a dynamic simulation able to support the communication and analysis of existing occupancy conditions. Spaces, circulation paths, external and internal walls have been modelled to simulate the flows of end-users. Other elements (e.g. ceilings, windows, furniture) and attention to the lighting of the spaces guarantee a greater sense of presence during the immersive experience, which will be described in the next paragraphs.

The existing building use scenario of the pavilion, related to the critical time-slot (i.e. activities, end-users, circulation paths, spaces), has been formalised by the BPMN graphical modelling approach for processes [13] to be organised and used as a reference framework for the simulation.

3.2 Occupancy data as input for the crowd simulation

Occupancy data have been used as input to a crowd simulation tool (i.e. Oasys MassMotion), where the agents have been customised based on the profiles of end-users acting in the analysed pavilion. Various agents have been created to represent technical operators, healthcare personnel, administrative staff, medical staff, patients and external users (Figure 3). Their profiles have been parametrised considering geometrical data (e.g. range of action) and behavioural data (e.g. circulation paths, speed of movement). The number of agents for each type of profiles of end-users have been set according to the POE data integrated with on-site surveys and measurements organised in 15-minute time ranges during the critical slot.

The BIModel has been imported into MassMotion, which is able to parse the Industry Foundation Classes (IFC) data format and automatically recognise the elements that hinder the movement of people (e.g. doors, walls).

Finally, the simulation has been run according to the scenario described in the BPMN (i.e. critical time-slot), with the collected data used as simulation parameters and the geometrical constraints of the BIModel.

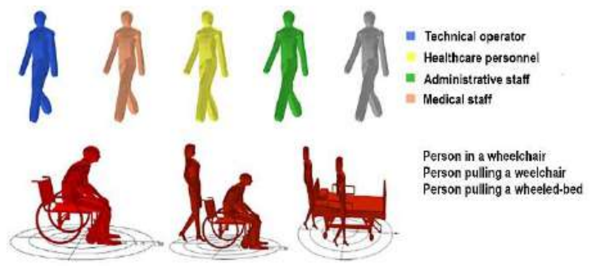

Figure 3 Agents set for the simulation

3.3 The BIM-based crowd simulation as communication tool

The result of the crowd simulation has been optimised by an iterative review process with additional on-site surveys and focus groups with the CE. Such an optimisation has allowed the simulation to be representative for the current in-use condition and related critical issues in the access of the end-users to the services offered in the analysed hospital pavilion. For example, the simulation has highlighted the problem of clashes between the two flows of end-users (i.e. users of the hospital canteen and users entering the building and going towards the elevator) in the hall of the pavilion in the critical time-slot (lunch time). Based on that, it has been possible to share with the CE and a representative group of stakeholders:

- a clear visualisation of the problem and communication of the issue to people that usually do not experience the critical time-slot in the pavilion, but that may be required to take decisions and develop strategies about it (e.g. define the available budget for the reconfiguration of the internal layout) (Figure 4);
- a definition of the profiles of end-users that access the services provided in the analysed pavilion (e.g. personnel, visitors, patients, disabled people using wheelchairs, patients transported on hospital beds) (Figure 5);
- a density map of the pavilion at the critical time-slot, useful to understand which services are the most used ones during the critical time-slot and support future design and decision processes regarding the

reconfiguration of the internal spatial layout (Figure 6).

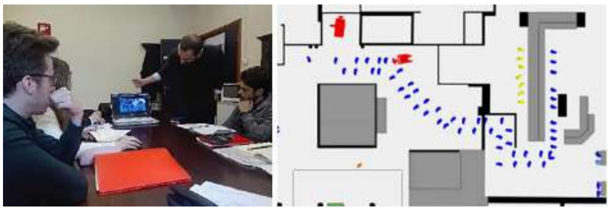

Figure 4 Results from the crowd simulation have been used to support focus groups with the client

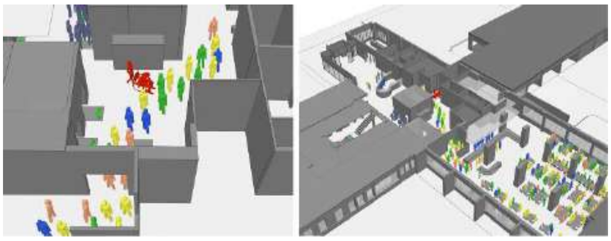

Figure 5 Crowd simulation of the current condition

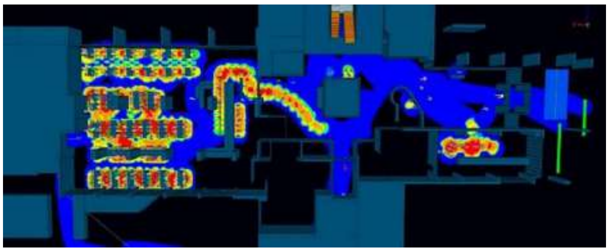

Figure 6 Density map of the pavilion at the critical time-slot

3.4 The BIM-based crowd simulation as Pre-Occupancy Evaluation tool

Occupancy data, collected during the POE and organised in traditional paper-based documents by the CE have been digitised. Once integrated with on-site surveys, they have been used as input for the simulation, becoming a dynamic representation of the current building use scenario and critical issues. The possibility to use the same simulation data and formalised building use scenario for evaluating design options for the layout reconfiguration of internal spaces has been discussed with the CE. In this way, the simulation would not be just the result of the Post Occupancy Evaluation and the picture of the current asset performance, but it would become the tool for an effective Pre Occupancy Evaluation of design proposals [14]. This hypothesis has been tested by proposing low-budget internal layout reconfigurations. The related BIModels have been imported in MassMotion, where the simulation, based on the same data as the existing in-use condition, has been executed again (Figure 7). In this way, it is possible to evaluate how, without changing the current building use scenario, it would be possible to (1) create a pre-occupancy simulation of access, space and use performance of the building according to various design proposals and (2) eventually select one of those options based on the results of this simulation.

Figure 7 Crowd simulation of the current in-use scenario applied to low-budget reconfigurations

4 Immersive Virtual Environment

Subsequently, both the BIModel and the crowd simulation have been imported into a game engine (i.e. Unity3D) to be visualised and experienced in an immersive VR headset (i.e. HTC Vive), with communication and analysis purposes in mind. The aim of this second part of the case study consists of the possibility to switch from the analysis of flows to the perspective of the end-users, who are part of those flows. Immersive VR has been used to evaluate the building spaces from various points of view, simulating four different scenarios:

- able-bodied users (scenario 0 and 1);
- person in a wheelchair (scenario 2);
- person pulling a wheelchair (scenario 3);
- visually-impaired person (scenario 4).

Unity3D was used to build the immersive environment with accurate lighting, a locomotion system and creation of various profiles of end-users to be simulated (e.g. viewpoint height), supporting the VR-headset natively. Moreover, the game engine was first used to import and visualise in the immersive VR both geometrical and non-geometrical attributes of BIM objects: this was necessary to be able to select and visualise information related to building objects while navigating the virtual scene. An interoperable data flow is not possible between Unity3D and a BIM authoring platform by default. The BIModel has been imported in Unity3D through the *.fbx data format and C# scripts have been used to import the non-geometric attributes embedded in BIM objects to be visualised when selecting them with one of the controllers. A teleporting system has been also integrated to navigate the BIModel.

In order to add the "occupancy" variable in the interaction with the building, while navigating in the virtual environment and experiencing the spaces as crowded as in the current building use scenario of the hospital pavilion, the crowd simulation developed in MassMotion has been also imported into Unity3D. This data flow has been managed by an Alembic (ABC) file exported from MassMotion to Autodesk 3ds Max, where an *.fbx file has been then created to be used in Unity3D (Figure 8). Once imported into the game engine, the crowd simulation maintains the number of agents and their speed of movement as defined in MassMotion and compliant to the POE data.

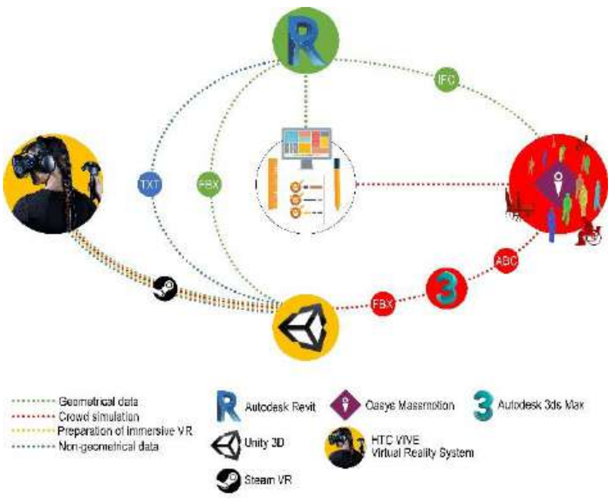

Figure 8 Data flow from the BIM authoring platform to crowd simulation and the immersive virtual environment

4.1 Simulation from the prospective of various end-users

Four scenarios have been created to experience the hospital pavilion and the crowd simulation from the perspective of as many profiles of end-users. The benefits of VR have been evaluated, highlighting its role as occupancy evaluation tool, its use for training purposes and to better understand how various profiles of end-users perceive the space. A modified first-person camera in Unity3D supports changing the perspective of the end-users according to the various scenarios.

4.1.1 Scenario 0: able-bodied users

Scenario 0 represents the point of view of an able-bodied user, a person of average height without disabilities and able to walk within the building spaces. The crowd simulation was not enabled in this scenario (Figure 9).

Figure 9 Internal spaces as visualised in the immersive virtual environment

4.1.2 Scenario 1: able-bodied users with the crowd simulation

Scenario 1 differs from the previous one because the crowd simulation has been imported in the immersive virtual environment and the user can evaluate how the feeling in using the building spaces changes when a crowded situation occurs (Figure 10).

Figure 10 Internal spaces as visualised by an able-bodied person, including the crowd simulation based on POE data

4.1.3 Scenario 2: person in a wheelchair

Scenario 2 represents the perspective of a person in a wheelchair: the movement of an electric wheelchair has been programmed in Unity3D to be controlled in VR by using the HTC Vive 3D-joysticks. The wheelchair user may represent either an employee on a wheelchair or an external visitor. A script has been created to visualise the walking (simulated) end-users via a red highlight when they are within the range of action of the wheelchair user. According to the CE, hospital employees with disabilities do not use the canteen service because of the current issue, optioning for other food services. This scenario aims to allow the CE to better understand the perspective of a person in a wheelchair using the building spaces and the problem that he/she must face in a day-to-day situation (Figure 11).

Figure 11 Simulation of a wheelchair user experiencing a crowded situation based on POE data. The accessibility of internal spaces can be tested and evaluated

4.1.4 Scenario 3: person pulling a wheelchair

Scenario 3 has been created to simulate an end-user pushing a wheelchair, which may be the case for medical staff that accompanies a patient from the ambulance parking to the hospital wards by the emergency entrance (Figure 12). In the current building use scenario, this situation is the one that causes major issues during the critical time-slot, because end-users entering from the emergency entrance and going to the elevator must cross the queue of end-users waiting to enter to the hospital canteen. The immersive simulation allows who usually do not experience that scenario to feel the actual discomfort of this implication.

Figure 12 Circulation path from the emergency entrance and the elevators is simulated from the perspective of a person pushing a wheelchair

4.1.5 Scenario 4: visually-impaired person

Scenario 4 simulates the viewpoint of a visually-impaired person. The rendered view in the HTC Vive has been partially obscured to reproduce the view of a visually impaired person (Figure 13). Sensitive paths have been modelled in the BIM authoring platform. A virtual cane, attached to the HTC Vive controller, enables users to follow the paths, while walking in the displayed building spaces. The cane/controller has been programmed to vibrate when touching sensitive paths during the navigation in VR. For example, such a scenario could be used (1) to validate the design of sensitive paths and internal spaces also in new design proposals acting as a Pre Occupancy Evaluation tool; (2) with training purposes; (3) to better understand how visually-impaired person perceive the space.

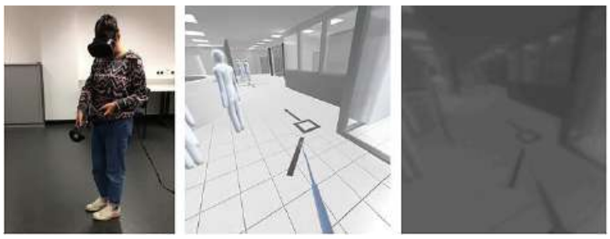

Figure 13 How a visually impaired user follows the sensitive paths with a simulated cane

4.2 Feedback collection

Feedbacks on the VR-aided scenarios previously described have been collected from people with various backgrounds and experience in the use of VR (i.e.

computer science, civil engineering, humanist disciplines, architecture, building accessibility, CEs). Fifteen users have been asked to navigate within the model, testing the proposed scenarios. It has been required for them to move through the spaces according to the actual circulation paths of employees, visitors and patients to experience the same crowded situation as detected during the POE and simulated in MassMotion. Despite the various backgrounds and experience in VR technology, users provided similar comments (excerpt):

- when switching from scenario 0 to scenario 1 it has been noted that spatial dimensions, even if compliant to building codes, may not be sufficient in a crowded situation as the experienced one
- the perception of the actual discomfort due to the occupancy simulation is realistic
- the crowd simulation, which is compliant with POE data, provides an added value to the implementation of immersive virtual environments as evaluation tools
- CEs have highlighted the possibility to experience building spaces from the perspective of the end-users as positive input in the decision-making process
- the possibility to support user-centred design processes and stakeholder engagement by immersive technology has been considered
- immersive VR could be an effective tool to analyse the accessibility of building spaces, going beyond codes, regulations and computable parameters and implementing the dynamic simulation of how the building is/will be used
- immersive VR could be used as a training tool to learn how a person with disabilities moves and acts within the space

5 Results

The paper describes the implementation of crowd simulation and immersive VR in the communication and analysis of access, space and use performance of an existing building. A case study has been developed testing VR implementation in an hospital pavilion where both medical and food spaces are located, causing a clash between flows of end-users in critical time-slots.

Crowd simulation has been used to integrate a multitude of paper-based POE data and translate them into a dynamic representation of the critical in-use condition; the case study has allowed the research team and the CE to understand which type of POE data are needed to create a reliable simulation of the in-use condition. Such a simulation allowed a clear visualisation and communication of current issues to people that usually do not experience them but who are involved in taking decisions related to the asset management. Moreover, POE data digitally simulated have been also applied to the pre-occupancy evaluation of design proposals for the low-budget reconfiguration of the internal layout.

Immersive VR shown the possibility to switch from the analysis of flows to the evaluation of the perspective of the end-users, simulating their point of view in a day-to-day situation. The combined use of crowd simulation and immersive VR, in fact, enables the users to perceive crowding in the occupancy evaluation and adds the user experience as a design input, representing an innovative approach that goes beyond traditional resources such as personal experience and regulations. This application may support the validation of design proposals, the evaluation of current in-use scenarios and a better understanding of how end-users perceive the space and its performance in meeting their needs.

A data flow has been proposed and tested to connect the BIM authoring platform, the crowd simulation tool and the immersive virtual environment. Moreover, the CE has started to consider the possibility to attach the outputs of a similar simulation (e.g. a video) to the traditional paper-based documents for better communicating needs and requirements to the suppliers.

6 Conclusion

The case study described in this paper aims to evaluate how VR technologies may be used to communicate and analyse the current in-use condition of an existing building as far as access, space and use performance are concerned. It conceptually connects the iterative review and feedback process (e.g. Post Occupancy Evaluation) to the briefing one (e.g. restate a need for action, evaluate lessons learnt, needs and expectations).

Some aspects should be further considered and researched about the implementation of VR in AEC/FM processes: technological, procedural and contractual aspects should be integrated into a single implementation framework. In particular:

- the suitability of various VR technologies should be considered according to different processes (e.g. collaborative design review, user involvement, building code checking) [11]
- process phases, users to be involved, related responsibilities and requirements to be analysed should be deeply evaluated before implementing VR
- contractual aspects related to the implementation of VR-aided simulations in AEC/FM processes should be investigated (e.g. consequences if a gap between simulated and actual performance occurs)

Moreover, the novelty effect of VR technologies in the AEC/FM industry should be considered: the case study described in this paper lasted for five months during which the CE has been iteratively involved to validate the simulation and evaluate the possible benefits of such an approach. The CE took a considerable amount of time before switching from considering the simulation as a fancy video to deeper understand its communication and analysis benefits. As a first attempt, this case study has been affected by the novelty effect, but final results suggest for a possible effective implementation of VR technologies, as well as BIM methodology, in future actions.

Acknowledgments

The case study has been developed with experimental purposes in collaboration with Marco Storchi and his team at the Policlinico Sant'Orsola-Malpighi of Bologna (Italy). The authors would like to acknowledge Prof. Markus König for his contribution to the project. Research activities have been sponsored by the Construction Technology Institute of the Italian National Research Council and by the MIUR-DAAD Joint Mobility Program that has been awarded to University of Brescia and Ruhr-Universität Bochum in 2015.

Abstract –

This paper presents the general aim of the research at the Institute of Structural Design (ITE) at Braunschweig University of Technology to bring digital design and digital fabrication together to develop resource efficient construction elements, manufacturing processes and building systems.

Basis of research at ITE is the so-called Digital Building Fabrication Laboratory (DBFL). The paper gives an overview of machine design, the technical parameters and its basic abilities of subtractive and additive processes e.g. milling, printing and scanning.

Based on the combined use of these digital fabrication processes and in cooperation with high-performance materials such as ultra-high performance concrete (UHPC), different research projects are being performed at the ITE. To explain the possibilities of the DBFL, the paper will present the results of two different – additive and subtractive - research projects to develop fabrication techniques for the building industry.

The first project is dealing with the development of "digitally fabricated high precision Non-Waste-Wax-Formwork for innovative UHPC structures" and the second project is investigating "Additive manufacturing of free-form concrete elements using Shotcrete 3D Printing (SC3DP) technology".

Finally, the paper will highlight the possibilities of combining these technologies and transferring them to industry 4.0.

1 Introduction

Concrete has been continuously developed in recent years into a high-performance material with a variety of different features. Nowadays we have the knowledge and the technology to cast self-compacting concrete, with the compressive strength similar to steel, into complex formwork or to modify the rheology of the concrete to the point where it is keeping its stability after pumping and spraying.

On the other hand, as the digitalization reached the building industry, it provided us with powerful calculation and planning tools, which liberated architects and engineers from restrictions concerning the geometric design of objects. This new freedom is still restricted by the available industrial standard of manufacturing technologies.

For example, the standardized, commercially available formwork systems for concrete components are optimized with regard to simple geometric shapes and joining principles. As a result, concrete structures are still composed of predominantly bending-stressed mass-intensive components. Although there are occasional attempts to realize free form, "non-standard" concrete architectures - such as the "Phaeno" in Wolfsburg by Zaha Hadid Architects - the challenge for the engineers is essentially to translate the architectural shape into reality. Nevertheless, light weighted and highly efficient structures, such as Heinz Isler's shell buildings, are barely to be found anymore [1].

Today, with the help of high-performance building materials, robotic automation and digital tools, we have all the instruments for fundamental developments in building construction. In 2002, Khoshnevis et al. [2] provided a concept how an automated approach to construction could look like, called "Contour Crafting" (CC). CC is extruding concrete and using trowels to create smooth and accurate planar surfaces. Another extrusion based process, called "Concrete Printing" (CP), was developed by Lim et al. [3] in 2011 at the Loughborough University. CP is not using trowels to achieve the surfaces quality needed, but a smaller resolution of deposition. Combining the advantages of all these technological developments, it is possible to build lightweight, efficient and therefore resource-saving structures.

With the research of the Institute of Structural Design (ITE) at TU Braunschweig, we want to develop digital fabrication methods to transfer innovative technology of computational design, automation and materials into building construction industry.

Application processes always depend on the materials used. In order to redefine the traditional manufacturing method, it is often necessary to rethink the entire fabrication process and adapt it to existing technologies and materials. Based on what the process offers the design space is stretched out. Our aim is to enlarge the architectural design space by providing new digitally controlled fabrication processes, see Figure 1.

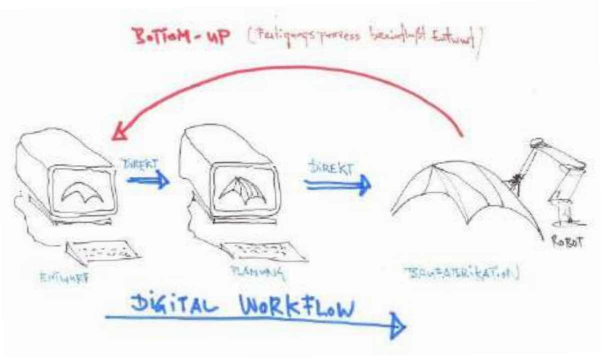

Figure 1. Design process turns into digital bottom-up workflow

2 Digital Building Fabrication Laboratory

The DBFL in its design and capabilities is unique and is the focus point of future research in the field of digital building manufacturing at the ITE. The focus is on combining latest technological developments from car and plane manufacturing with new high performance materials in order to fabricate material efficient structures for the building industry. By combining flexible robotic components with precise and robust machining systems, a huge bandwidth of applications will become available.

The DBFL operating range is almost 7 meter in width, 15 meter in length and more than 3 meter in height. A 6-axis Stäubli robot connected to a 3-axis portal is the core of the additive manufacturing unit in the DBFL (Figure 2). The robot can carry up to 200 kg and move freely in the entire working area. The end effector can be equipped with various attachments, depending on the examined process. The second portal is carrying a 5-axis CNC milling and sawing machine. It represents the subtractive part of the DBFL and has been designed for low tolerance and high precision milling jobs. It also has the ability to process high-density materials like granite and ultra-high performance concrete (UHPC).

Both units can operate individually or in a synchronized cycle. By combining the additive and subtractive abilities of both portals, complex process chains, in order to fabricate efficient and graduated building elements, can be established without moving the element.

As an example, the DBFL is capable of spraying and printing concrete, milling, scanning objects and connect these features. Its two portals can operate synchronously or simultaneously in order to investigate a majority of different manufacturing processes. Based on these possible digital fabrication processes and available high-performance materials like the ultra-high performance concrete (UHPC), different research projects are being performed at the ITE involving the DBFL.

Figure 2. Digital Building Fabrication Laboratory at ITE TU Braunschweig

3 Digitally subtractive fabricated high precision Non-Waste-Wax-Formwork for innovative UHPC structures

UHPC can generally be cast in any shape, assuming the right additives were used. Depending on the complexity of the required form, the main effort and cost is to build the formwork. The formwork systems, which are mainly used in the building industry today, can only produce geometrically simple basic forms and allow deviations within the range of centimeters.

To produce concrete parts that differ from these common straight and rectangular basic shapes, various 3D free-form formwork principles have been established in the construction industry. Primarily CNC-machined wooden formworks or epoxy resin coated foaming polystyrene (EPS) are used for these geometrically high complex free-form geometries. These CNC-milled formworks have high production costs and the disadvantage of not being recyclable due to the coating. In summary, it can be said that almost all 3D free-form formwork systems currently available on the market are usually expensive custom-made products, which cannot be reused for variable geometries. In addition, the currently permissible tolerance deviations of system formwork for high-precision precast UHPC elements are not acceptable. Precise and free-form shuttering is therefore a decisive factor in the production of UHPC constructions.

Due to this need and inspired by the research of Gramazio & Kohler [2] of ETH Zürich a research approach for free-form concrete formwork by CNC-milling industrial waxes was developed by the ITE.

In contrast, to the research approaches of Gramazio & Kohler, based on an adjustable formwork shell on which liquid wax is cast to preserve the form and the "FreeFAB ™" research approach of the Australian Dr. James B. Gardiner et. al. [4] using hot liquid wax to 3D printed free-form formworks, the ITE approach is based on the use of large cooled down wax blocks that are fast and precisely shaped into form by subtractive CNC-milling to robust Non-Waste-Wax-Formwork with nearly any geometrical shape.

Based on these developed approach, the technical applicability of industrial waxes for the fabrication of free-form formwork elements was investigate at the ITE within the joint research project: “Non-Waste-Wax-Formwork-technology: Innovative precision formwork on basis of CNC milled recyclable industrial waxes for the casting of geometrically complex concrete elements” [5] in the years 2014-2016. In addition to the prevention of waste, the complete recycling of the wax results in low formwork costs, as the material investment can be allocated to the number of applications. The industrial wax used has similar strength properties compared to polyurethanes with the same density, although the material costs per application are significantly lower than those of polyurethanes.

3.1 Material properties of the selected industrial waxes and production of large wax blocks

Since industrial waxes have not been used as concrete formwork material until now, a suitable wax had to be found. Therefore, a technical wax requirement profile for the application as formwork material regarding the technical properties was specified. Based on this profile different waxes were selected and tested regarding their general machinability (millability) and their different physically mechanical properties for example: compressive, bending and tensile strength, elastic modulus, temperature-dependant strain or volume change, Differential scanning calorimetry (DSC) and thermal conductivity.

As a result of the tests and investigations of the research project, an industrial wax titled “ConFormWax” with a melting point of around 60°C, a (elastic) compressive strength of around 2,5 N/mm² (at 20°C) and an elastic modulus of 1923 N/mm² was selected as most suitable wax for the developed Non-Waste-Wax-Formwork technology [6].

As Dr. Gardiner [7] also mentioned, wax is very difficult to melt and pour into large blocks. Big molten wax blocks contain a considerable amount of latent heat, due to their insulating thermal conductivity they only cool down slowly. Cooling results in thermal shrinkage, which leads to high internal stresses that cause deformations or cracks. If these internal stresses are too high, the wax blocks also deform during CNC milling, which leads to an insufficient dimensional accuracy and precision.

An important part of the investigations within the research project was therefore the development of a process for the production of large-format, low-tension wax blocks for CNC milling. The procedure which turned out to be the most suitable to minimize these effects was to use smaller, tension free, planed cold wax tablets as filler. These wax tablets can be placed in a rectangular shape at regular intervals and can be grouted together with hot liquid wax in almost any dimension of wax blocks, as seen in Figure 3.

Figure 3. Grouting of cold wax tablets with hot wax to wax blocks (left) Cooled off wax block (right)

3.2 Verification of selected wax and developed formwork process

To verify the selected wax, the wax block production and the wax milling process, wax formwork panels, with dimensions of 500 mm x 500 mm x 120 mm where produced. The wax formwork panels were digitally composed of different geometric elements as grousers and grooves, round and pyramidal stubs, uni- and multidirectional curved surfaces. After milling these geometries into the blocks, ultra-high performance concrete were then cast on the resulting wax formwork panels. The aim was to analyse the influence of the aspect ratio and structural refinement as well as the separating properties of the concrete (Figure 4).

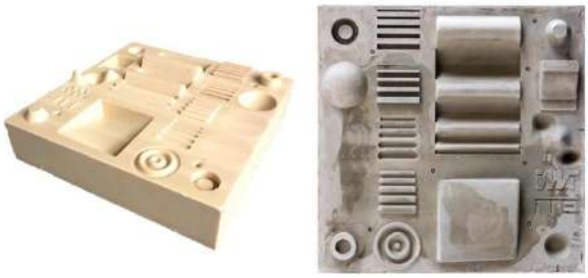

Figure 4. Wax formwork panel A after stripping of the UHPC (left); UHPC cast of panel A (right)

Hereafter the wax formwork panels and the UHPC casts were digitalised at GOM (company of industrial and automated 3D coordinate measuring technology) [8] with a standard 3D scanner (type ATOS). The digital 3D-scan data were used to conduct a volumetric form analysis in comparison to the original CAD data.

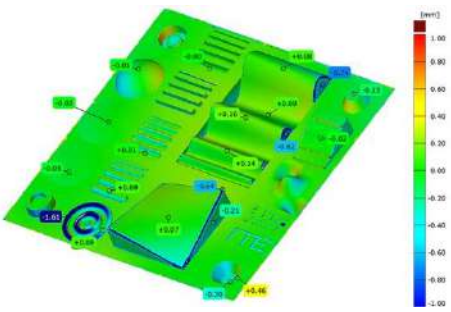

Figure 5. Comparison between the scan data of the UHPC cast (panel A) and the original CAD data

As shown in Figure 5, the UHPC casting of the wax formwork achieves very high precision over the entire area compared to the original CAD data.

The results of the research project have shown that the selected industrial waxes are suitable for the fabrication of precise formwork for complex, free-form concrete, and in particular UHPC, members. The technical properties of the used waxes, as the elastic modulus and compressive strength, are within a favourable range for concrete formwork construction rigid enough to withstand the fresh concrete pressure and soft enough for an efficient milling.

The volume analysis showed that not only the wax formwork, but also the cast concrete components have a high degree of precision for the construction industry. Apart from some production-related deviations, the measured tolerance is only in the tenth of a millimetre range. Due to the possibility of recycling the wax chips and wax formwork elements by re-melting, the Non-Waste-Wax-Formwork technology provides an ecologically and economically viable alternative to modern free-form formwork made of EPS and PU.

The technical foundations of the developed Non-Waste-Wax-Formwork therefore provide a technology and an industrial wax that enables the production of concrete and especially ultra-high performance concrete (UHPC) elements. The wax can be cast with adjustable surface qualities, with an accuracy in the tenth of a millimetre range and in almost any geometric form with sharp edges and very small curvature radii. A further advantage is the achieved sustainable closed loop recycling process, since the recycling (melting) of the wax chips and the disused wax formwork elements does not produce any waste in the process. This not only makes the wax formwork technology ecologically interesting, but also offers an economical alternative to modern free-form formwork made of epoxy resin-coated foam polystyrene (EPS) and polyurethane (PU). By reusing wax, material costs per application can be reduced to a comparable EPS level, while at the same time achieving better material properties - comparable to those of medium-density PU [5].

3.3 Transferring the Non-Waste-Wax-Formwork technology to the industry

Based on these good results and the industry's need for sustainable free-form formworks, the Non-Waste-Wax-Formwork technology was awarded with the German Innovation Prize of the Supplier Industry for Structural Concrete Products 2017 and is now being converted into industrial applications. The challenge of transferring the technology into an industrial process lies in the fulfilment of the respective user-specific requirements and the associated adaptation and optimization of the individual process steps, such as the production of the wax blocks.

To do so, two actual research projects are currently being carried out at the ITE together with industrial partners following different requirements and approaches.

The first project entitled "Development of a modular and fully automatic production process for free-form concrete formwork in building construction based on technical wax" is funded by the German Federal Ministry of Economics and Technology (BMWi). The focus of this research is the fast and fully automated production of modular expandable wax formwork, with a low demand on the achievable precision (Figure 6). The concept is to replace the disposable CNC milled eps formwork used today. In this project, the strategy of producing wax blocks by pressing cold wax chips into form is tracked. These pressed wax blocks have a four times lower compressive strength than cast blocks of wax (Figure 7) but their production is significantly faster and does not require any melting energy.

The second project entitled "Innovative Non-Waste-Wax-Formwork for the Fabrication of High-Precision Machine Frames made by UHPC", funded by the German

Research Foundation (DFG), focuses on the development of a precise and robust wax formwork (replacement of PU / Steel / timber "multiple formwork"). Therefore, wax blocks are made by casting filler-added wax. These wax blocks have shown a higher compressive strength (Figure 7) than compressed or cast wax blocks without filler. Their production is also less complicated, since the thermal shrinkage and the high melting energy are reduced.

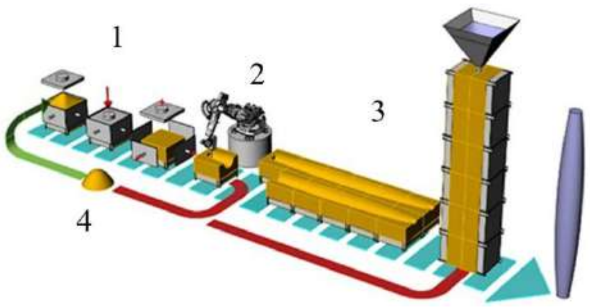

Figure 6. Principle of automated modular wax formwork: (1) compression of chips to blocks, (2) CNC-milling, (3) assembly of modular formwork, (4) closed loop recycling

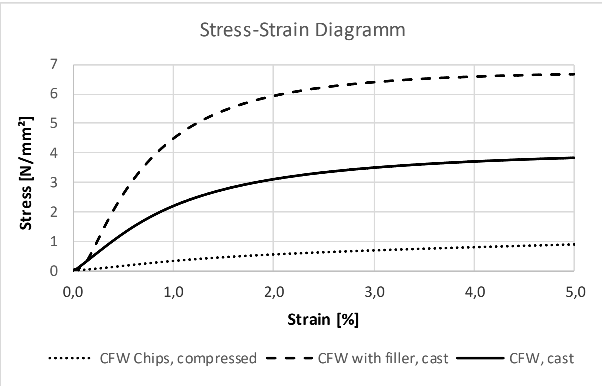

Figure 7. Stress-Strain Diagram of ConFormWax (CFW) samples produced by: cast (a), cast with 20% filler content (c) and compressed chips (b)

The aim of both projects is to make wax accessible for a variety of industrial applications. The fields, which both projects cover, makes it possible to use the wax, for example in precast factories, which then are able to react flexibly to requested free-forms.

4 Additive manufacturing of free-form concrete elements using Shotcrete 3D Printing (SC3DP)

For over 100 years, shotcrete has been used to spray reinforcement and produce lightweight and efficient structures. This technology is supposed to be transferred with the help of a robot into a digital, formwork-free and automated fabrication process. To achieve this goal a major collaborative research project of the Universities of Braunschweig, Hannover and Clausthal is carried out. Under the direction of the ITE, researchers from the fields of material science, mechanical engineering and computer science are developing a "robot-assisted shotcrete technology for generative manufacturing of complex concrete structures without formwork". The developed robot-controlled process is called "Shotcrete 3D printing" (SC3DP) see Figure 8. In addition to the development of a process technology, it is also necessary to develop a suitable shotcrete whose properties can be adapted to the respective components and the production process [9].

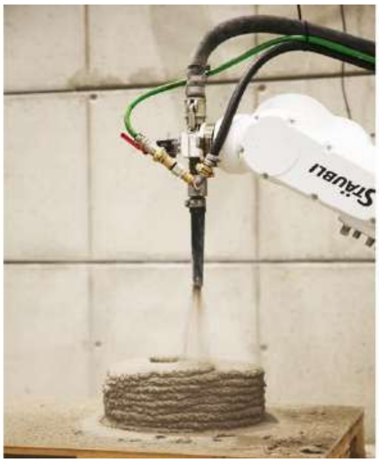

Figure 8. Application process of the new developed Shotcrete 3D Printing technology

Within the conventional Additive Manufacturing methods, the production of concrete elements is limited due to the layered application. Since no formwork is used for the 3D Printing process, the production process relies on self-supporting of the material. The material has to be applied on top of already printed material and overhangs as well as thin-walled elements are hard to realize. The use of the SCP3D method in additive manufacturing makes it possible to vary the application angle in contrast to the extrusion process. This opens up new possibilities in terms of geometric freedom. The material no longer simply has to be "deposited", but can be applied spatially to an already sprayed layer. In addition to a better surface bond, the resulting degrees of freedom can lead to a new surface quality and offer approaches for the integration of reinforcement in 3D printing with concrete. While the composite zone, according to Le T. T, et al [10], in extruded concrete components, from a mechanical point of view, is to be regarded as a weak point, this problem could not be observed using the shotcrete method [9]. In order to demonstrate the possibilities of robotic, generative manufacturing, it is planned to produce a single curved and a double curved wall without the use of formwork at the end of the project. In particular, curvature in two axes cannot be realized with current standard formwork systems.

4.1 Application parameters

One of the biggest disadvantages of the shotcrete process is also one of the biggest advantages. For example, the SCP3D process and the sprayed geometry depends on a many parameters, such as air pressure, concrete volume flow rate, robot speed and the distance of the nozzle to the target (see Figure 9). All these parameters must be controllable by the program in order to realize the desired application. Furthermore, the computer has to get real-time information about all parameters and the resulting geometry in order to control the shotcrete 3D printing. However, if you manage to regulate the parameters and adapt them to the application strategy, there are many possibilities for the shotcrete process.

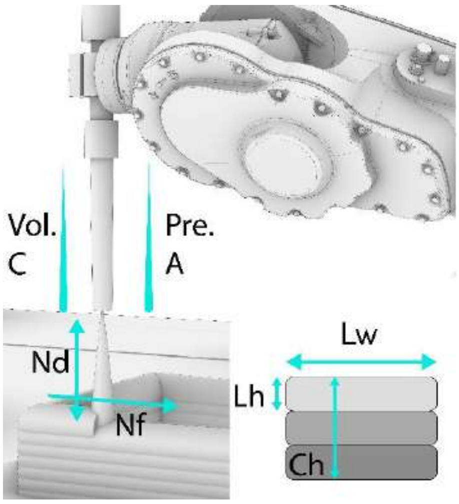

Figure 9. Overview of important parameters: Nd=Nozzle distance, Nf= Nozzle feedrate, Vol.C=Volume flow concrete, Pre.A=Pressure air, Lw=Layer width, Lh=Layer height, Ch=Concrete hardening

As the ITE has already been able to show, the control of these parameters is currently possible [11]. However, research is still in progress on the measurement technology for this complicated process. Currently, the focus of the integration is on a laser and a camera for in situ measurement of the sprayed geometry. This enables measurement of the width and height of the layer as well as the distance between the nozzle and the surface. This information is used to readjust the robots speed to either increase or decrease the thickness of the applied material.

4.2 Integrate reinforcement into the printing process

The manually spraying of steel and textile reinforcement was approved in different construction projects over the last years with great success.

The first studies at the DBFL to integrate reinforcement into the automated shotcrete process were performed in early 2018. It has been shown that it is possible to integrate textile and steel reinforcement without major problems. Although the reinforcement was still inserted manually, it can be assumed that a robot arm could perform this work even more precisely. Figure 11 shows a curved wall produced with the "Shotcrete 3D Printing" method. The wall is about 1.0 meters high and was reinforced at the backside with a textile (Figure 10, left). The smooth surface also on the backside was post processed manually by a trowel, based on Khoshnevis et al. [2]. Because the concrete hardens from the inside to the outside, it is already stable in the middle, but the outside is still soft enough to be processed. Therefore, the processing of the concrete with a trowel succeeds well. In preliminary tests with small robots [12], it could be shown that different surface qualities can be achieved in an automated process using trowels, rammers and scoops. However, the next experiments are intended to show that subsequent processing of the surface can also be carried out in real scale by a bigger robot.

On the frontside, a steel-reinforced console was added (Figure 10, right). To show the position of the reinforcement in the console, two reinforcement bars were not sprayed, as shown in Figure 11, left. The reinforcement is placed in the middle of the console and not in the upper part where it would statically belong, due to an easier integration process of the bars.

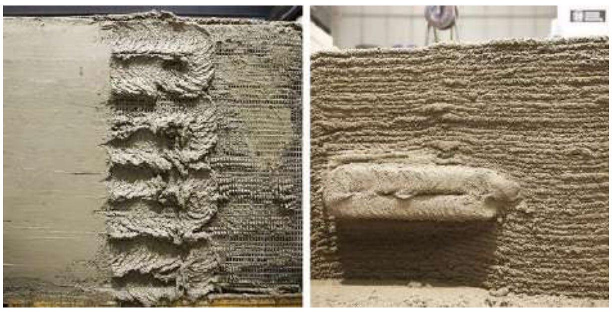

Figure 10. Wall produced with Shotcrete 3D Printing; backside smoothed and with implemented textile reinforcement (left); frontside with steel reinforced sprayed console (right)

Figure 11. Wall produced with Shotcrete 3D Printing; Detail of the console, with 2 reinforcement bars left blank (left); top view of the wall (right)

5 Summary and Outlook

In order to build concrete structures and elements more efficiently to save resources by making them lighter, alternative construction techniques to today's standard techniques are needed. With the development of the Non-Waste-Wax-Formwork technology, it is possible to realize a multitude of individual free-form concrete forms. Thereby the wax can be reused, which is not only ecologically but also economically reasonable. Further, the achieved surface quality can be utilized for high-precision components, which opens up new ways of use. But also low surface qualities and the associated rapid production of wax blocks is yet being applied in industry.

The next steps on the way to industrial use are the improvement of the wax by using fillers and the wax block production. This would reduce the energy absorption to melt the wax and increase its strength. Improving the material will always improve the process itself, which in return could reveal new fields of application.

In contrast, the Shotcrete 3D Printing requires no formwork at all, by assembling layers to bigger elements. This saves the intermediate step of producing a formwork and the time and cost associated with it. In this way, a complex curved shape could be produced without formwork. As the first tests showed, it is also possible to integrate reinforcement (textile or steel) without any major effort and to apply concrete horizontal up to a thickness of about 16 cm. As Hack and Lauer [12] stated it is possible to print a mesh-mould by a robot. This mesh could be sprayed with concrete, which would fully automate the building process. Upcoming experiments using meshes and more complex reinforcement structures will investigate the opportunities of the SC3DP to produce viable real scale structures.

Going along with these experiments, the integration of a closed control loop is prepared. This will push the method ahead by getting more control of the spraying process and the sprayed structures.

Strongly connected to the process is the used material. Just as with other additive manufacturing strategies, a high-performance concrete material, which meets the requirements, must be developed for this process. This is currently carried out at the Inst. of Building Materials, Concrete Construction and Fire protection (IBMB) of the TU Braunschweig in cooperation with the ITE. The objective is to create an adjustable concrete that can be adapted to the printing process in terms of rheology, mechanical properties and hardening [9].

In the future, the possibility of combining these two methods, described in this paper, will also be explored. This means that the concrete can be sprayed onto a single-face wax formwork and thus be graduated over its thickness. It would be possible to integrate reinforcement, other components or to leave out areas and have a precise and free-from single-side surface.

To produce load-bearing components for the use on construction sites it is necessary to implement reinforcement on an affordable level. This will be one of the next challenges for the 3D printing techniques. Using the DBFL, the ITE has the opportunity to address these challenges and enhance digital fabrication.

Proposal for a discipline-specific open exchange framework

G. Sibenik[a] and I. Kovacic[a]

E-mail: goran.sibenik@tuwien.ac.at, iva.kovacic@tuwien.ac.at

Abstract –

Several data exchange standards support the open exchange of building data. Industry Foundation Classes (IFC) standard is the most widely implemented within software solutions and the most used in practice. This standard is developed by buildingSMART International and describes a schema defined with EXPRESS data modelling language also including the data validation rules.

Because of its richness and redundancy, inadequate support of specific disciplines, but also its variable application within software solutions, open data exchange has not achieved a satisfying level of reliability. To transfer building data, actors that exchange information turn to various alternative data exchange possibilities like other open exchange formats, software specific data exchange software solutions, and workarounds.

This paper aims at analysing the problem of data exchange among disciplines with varying exchange requirements. Depending on the discipline and its specific requirements, data exchange potentials with IFC differ largely. Overcoming the interoperability problems are often discipline-specific: providing new schemas, incorporating strict workflows (for native and receiving application), or using 2D drawing - based exchange, physically or digitally.

In this paper, two workflows that follow BIM modelling process are examined. The first step in both workflows is the creation of architectural BIM model. Consequently, two data transfers are considered: to structural analysis and to life cycle analysis (LCA) software tools. The actors' exchange requirements are identified, as well as their description through the data flow.

Thereby, the adequacy of a predefined set of exchange requirements in the construction industry is assessed. Results show that IFC schema, or any other schema defined in the same way, is not an optimal answer to the end user needs. An improved open exchange based framework is proposed with a data management concept that supports it. Finally, the implementation of the new concept aims to enhance the technological development of open standards and draw it towards the seamless exchange.

1 Introduction

1.1 Current Modelling Framework

Construction industry practices differ worldwide. The role of an architect in Europe frequently overlaps or overtakes project manager roles, especially in small offices. An architect is the first actor in the planning process that defines geometrical and non-geometrical data of the object to be built. In BIM workflow, architect models a building using 3D objects representing the digital versions of building elements. These objects can be defined either within an architectural BIM modelling software or taken from the external sources. Besides that, architect produces drawings as planning documentation and provides other actors with the necessary information about building elements for further design, analysis, calculation, validation by authorities, etc.

Created geometric and non-geometric data is required by the other actors in the process, belonging to both design and non-design disciplines. The exchange processes in most cases are still performed using paper documents or 2D digital drawings. BIM workflow aims to change that. Open BIM initiative from software producers and buildingSMART [1] suggests the use of the same information by different disciplines. This workflow neglects the need for standardization of integrated model interpretation for different construction industry domains. However, exchange using the open exchange format is still the most promising way of exchanging information in the industry with numerous actors and disciplines involved, where each takes part in the planning process with their specific requirements.

1.2 IFC Open Exchange

Several standards define the open exchange. One of them is the IFC schema standard that specifies a building data model to be used for the data exchange. IFC schema describes the integrated building model representing some disciplines in the industry. The first actor providing data for an integrated model is most often an architect. Other actors who are part of the planning process use data that architects provide, and in the follow up enrich and change it. They contribute by introducing the new and modified information to the integrated model. Differences that exist in the disciplines are managed by different subschemas called Model View Definition (MVD). The latest version of IFC schema is IFC4. It includes two MVDs - Reference View and Design Transfer View. Software solution certification is only provided for Reference View. This MVD tends to provide the IFC building data model as a reference only [2]. It is not supposed to be used for further data editing. For Design Transfer View, that exists since July 2015 and should serve for further editing of the building model, the certification is still not launched. On the list of certified software solutions [3], there are currently no tools certified with IFC4 MVDs. Because of the inexistent formal practical implementation, a widely used IFC2x3 schema will be tested in this proposal. Software solutions that implement IFC 2x3 are officially certified only for MVD Coordination View version 2.0 (CV V2.0). CV V2.0 is used for three different disciplines: architecture, structural analysis, and building services. In this open exchange workflow, these three disciplines use the same subschema. However, implementation of MVD differs greatly between the software solutions. If open exchange workflow with IFC schema is used, all the involved construction industry disciplines must conform to the same schema and use specific parts of it with MVDs (Figure 1).

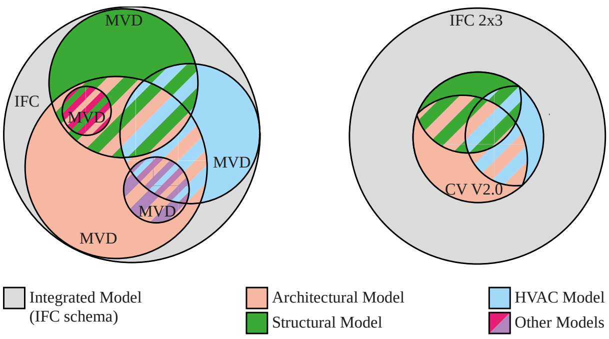

Figure 1 Concept of open data exchange with IFC schema and IFC2x3 with MVD CV V2.0

1.3 Asset Hierarchy

There is a strict asset hierarchy between geospatial industry, construction industry, and manufacturing industry. While the geospatial industry deals with the elements on the environmental scale and uses geographic information system (GIS) for its needs, manufacturing industry is on the product (or component) scale and uses product lifecycle management (PLM), construction industry deals with the products on the building scale [4]. There is an overlapping between the assets where GIS is interested in the data of a built facility as well as where the construction industry is interested in the components. Construction industry assets using BIM are represented through the IFC schema that defines the digital representation of building elements. However, the assets in the construction industry are getting evermore present within the other two industries. Architectural BIM software is mostly able to create product models as well (*.rvf files for Revit, *.gsm for Archicad or *.nmk for Allplan) and in that way, they are becoming part of the architectural model. Despite the fact that the product manufacturers are also interested in providing the digital content describing their product, its use within BIM workflow seems to be a gap in knowledge [5]. This field also lacks standards that relate it to open exchange. For instance, comparing to *.gsm and *.rvf files respectively, there are only 32% and 10% of digital objects provided in *.ifc format on one of the biggest online libraries for digital objects [6]. It is clear that product models are still generally exchanged with native software solution formats. These digital products are mainly developed to be used with software solutions in the construction industry. The new version of IFC5 [7] defines infrastructure elements which bring the schema closer to GIS. In other words, in the future, it will share more assets with geospatial industry. The schema provided by buildingSMART is in that way increasing its complexity and size, while the currently implemented MVD version is not sufficiently supported by software developers to achieve seamless exchange for most of the construction disciplines.

2 Background

2.1 STEP

Aspiration for standardisation of data for exchange purposes is present in all industries using digital models. STEP (Standard for the Exchange of Product Model Data) initially aimed to unify different national industry standards. It is widely implemented in the manufacturing industry, and it is the biggest standard of all ISO standards. It defines the way to exchange digital information about a product. Instead of defining an integrated model, its definition started by defining several part models called Application Protocols (APs) [8]. AP 225 called “Building elements using explicit shape representation” was a starting point for defining an IFC schema.

What construction industry lacks comparing to other industries is inter-firm adaptations. The construction industry represents loosely coupled system where every product is unique. For those reasons it is difficult, or maybe even inadequate to implement principles from other industries in the construction industry [9].

Actors involved in the planning process perform different actions that involve using different models of the same real-world product. Processes are complex and independent for each building in particular. Models of different domains differ from each other, where not only different data scope is used, but it also needs to be interpreted for a specific use (Figure 2).

If compared with the STEP standard, the whole range of disciplines that are used in the construction industry is reduced to a single Application Protocol that is later accepted as a starting point for the IFC standard. However, the construction industry with all its domains more resembles the STEP standard itself with multiple APs.

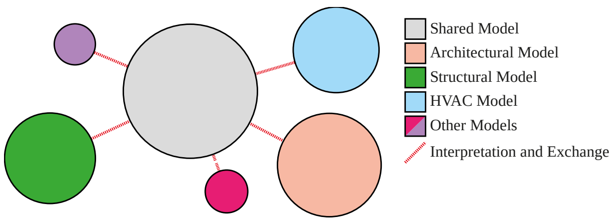

Figure 2 Concept of data exchange with domain specific models

2.2 Other work regarding structure

Two ISO standards are a base for the structure of building data model. Those are ISO 12006 "Building construction – an organization of information about construction works" Part 2 "Framework for classification" [10] and Part 3 "Framework for object-oriented information" [11]. IFC schema is based on 12006-3 addressing it as International Framework for Dictionaries (IFD). ISO 12006-2 is developed to standardise different national classification standards in construction and does not contain geometry information. Differences between IFC and 12006-2 are explained in [12]. IFC documentation does not state where the structure or model classes originate from.

Several works already described the necessity to expand the IFC schema to be able to support for instance structural analysis [13] or energy simulation [14]. buidlingSMART plans to involve several new disciplines in the future IFC editions [15]. The original plan is to create a steadily growing model that will eventually support all the involved disciplines. IFC2x3 covers eight domains including architecture and structural analysis. However, many problems are detected also in the domains supported by the schema [16]. A file-based data exchange is not a solution that has potential in the future [17]. Research by Lee et al. [18] states that schematic design is not enough for all the information needed for cost estimation. A necessity to bring the IFC schemas to an ontological level [19] describes transforming the IFC schema to ifcOWL, a terminology box definition using Web Ontology Language (OWL). For that reason, they propose to use semantic technology, where the IFC building data model is converted to RDF data.

The modularization of the ifcOWL ontology is suggested by Pauwels et al. [20] with the aim to use only the filtered model data. For that purpose, the particular modules need to be defined or the existing ones significantly redefined. Cost Estimation (CE) and Quantity Takeoff (QTO) framework by Aram et al. [21] suggests a knowledge-based system for using implicit besides explicit information in these two disciplines. Venugopal et al. [22] describe general schema structure reconsideration with MVD concepts to achieve a working modular exchange framework. The importing software needs to interpret the geometry and associate the meaning to the native objects for every discipline except simple geometry clash check. The mentioned research shows that the problems with the existing schema are detected in many disciplines. The focus is set on reaching the integrated model that will satisfy the requirements of more actors than the current open schema. On the other hand, the size of the current schema is also recognized as a problem, where data needs to be extracted, modularised and interpreted for specific applications.

3 Methodology

In this work, data transfers from architectural model to structural analysis and LCA using open exchange are reviewed. They both require specific geometric and non-geometric information about the building that is provided by the architect. Two workflows are depicted in Figure 3. The IFC data is considered for import into domain-specific software solutions. IFC2x3 with MVD CV V2.0 is used because of the lack of support for IFC4 in software tools, and because the certification of Design Transfer View MVD is still not taking place.

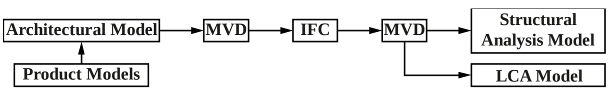

Figure 3 Two workflows considered in the study

Import exchange requirements are defined for each of the disciplines. These requirements are predefined with MVD concept list in the case of an open exchange. A simple case study model of door and wall is modelled in the architectural software [23]. Based on the previous research [16] [24], exports from the software solutions were generally using valid concepts of MVD, and therefore the exported model is considered valid.

Exchange requirements for two different imports that can be transferred from the native model to the exported model are identified and presented in Table 1. The structure of exchange requirements presented in the table is described from the end-user conception.

Table 1 Exchange requirements in the analysed case study model (SA = Structural Analysis)

Exchange Requirements			SA	LCA
wall	layer1	geometry	✓	✓
		material	✓	✓
		Load bearing	✓	×
	layer2	geometry	×	✓
		material	×	✓
		Load bearing	✓	×
door	handle		×	×
	panel	geometry	×	✓
		material	×	✓
	frame	geometry	×	✓
		material	×	✓
void		geometry	✓	×

The required data is allocated to the exported building data model and the structure of the export is analysed. Some special cases require additional information, but they are not considered in this work. The main aim is to describe various differences in exchange requirements, and how heterogeneity of disciplines and used software solutions require different ways of data exchange since it cannot be achieved with the current state of open exchange and MVD.

The presented case study questions if using an open exchange workflow with a predefined integrated schema answers the needs of actors in the construction industry. An open exchange framework allowing inclusion of more actors in the planning processes and bringing the digital building model closer to the real product is defined. With the results obtained from the case study and the related detected flaws, a new data managing structure is defined supporting the proposed framework.

4 Results

4.1 Geometrical Data

In this example (Figure 4) a wall consists of two layers, where one is load bearing. In IFC building data model it is represented as an entity IfcWallStandardCase. Its geometry definition is contained within the entity IfcProductDefinitionShape, where two different IfcShapeRepresentation entities are defined. First one is ‘Axis’ ‘Curve2D’ representation that is used for aligning material layer sets. Second is the ‘Body’ ‘Model’ representing the wall as a single homogeneous geometry, and not as a combination of two layers. Layer geometries are not specified separately. For structural analysis only the layer with load-bearing properties is relevant. That layer needs to be interpreted as a 2D element (with its axis and height). A common interpretation where a wall axis is placed in the central plane of the entire wall geometry creates an incorrect structural analysis element in this case.

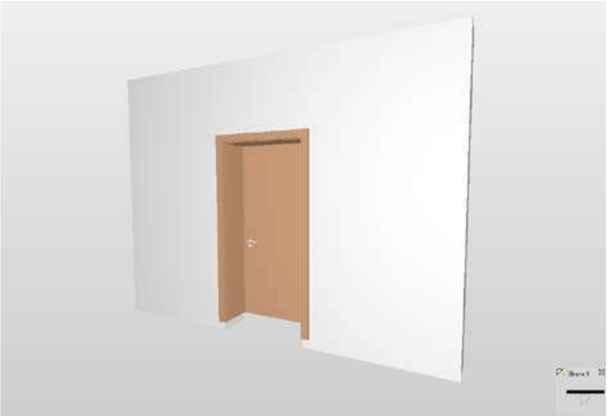

Figure 4 Screenshot from a viewer [25] of the

A door is represented by IfcDoor entity in IFC schema. There are two IfcShapeRepresentation that define its geometrical properties. This is ‘FootPrint’ ‘MappedRepresentation’ that defines an element representation in a 2D drawing, and ‘Body’ ‘MappedRepresentation’. Within the second one, geometry is represented using a boundary representation (‘Brep’) including all its parts. That means that a door handle, a door frame, and a door panel are creating a single geometry even though they are conceptually separate elements. For structural analysis the door does not represent an important element, only the void it creates in the wall. For LCA, a door panel and a door frame geometries are required. From these two geometries, the total width and height of the door information need to be extracted. In the IFC schema, the door total height and width are defined as attributes specific to the IfcDoor entity. In that way, it is easy to extract this information for LCA from individually defined attributes and not from its geometry, which makes redundant data.

The void is defined as IfcOpeningElement and its geometry is defined as ‘Body’ ‘SweptSolid’. It clearly specifies the cubic element that creates an opening in the wall.

Parameters that exist within the native model are generally lost during the mapping. This means that an ‘intelligent’ digital building model from the native software solution becomes a 'dumb' model [26]. For that reason, it is hard to interpret the future editing possibilities and constraints in the receiving applications. The details concerning the shape modelling aspects of the IFC models are not part of this work.

4.2 Non-geometrical Data

Non-geometrical data describing building element models, or attributes that represent them are mapped in three ways. They are declared as direct, inverse or derived attributes. In the study, all the analysed attributes are either direct or inverse ones. Direct attributes are attached to the model of interest, while the inverse ones are assigned through a relationship.

The structural analysis model requires the information about load-bearing properties for specific layers of the wall. The importing software tool only needs the load-bearing layers and to place the axis plane in the correct way. In the architectural software solution, the load-bearing properties of the layers are defined by an architect. In the IFC model, this is an inverse attribute defined through IfcRelDefinesByProperties. Property 'LoadBearing' is defined, but only for the wall as an entity, not for the specific layers within it. This property is not standardised and therefore not understandable by other software applications. Even if the load-bearing property can be successfully interpreted by an importing application, the specific layer cannot be extracted from the element. Another attribute necessary for proper interpretation is the information about the material. Materials are required by many disciplines and in this case both by LCA and structural analysis. For LCA materials of all layers are required. For structural analysis, it is necessary to import only the load bearing material information. Through IfcRelAssociateMaterial, IfcMaterialLayerSetUsage, and IfcMaterialLayerSet, materials are assigned to the wall. IfcMaterialLayer contains information about the layer thickness that could be used to extract information about the volume of a specific layer even if its geometry is not separately specified.

Data from the object IfcDoor is not required for structural analysis. For LCA calculation, it is necessary to have the total area of the door (including the frame) and materials of the door panel and the frame [27]. Materials are assigned with the relation IfcRel-AssociatesMaterial and IfcMaterialList to the door. There are three materials assigned to the whole element but without the details which specific parts of the geometry they describe. However, through IfcStyledItem, the geometry elements like the door panel, the handle, and the frame have different visual representation in IFC imports. These representations are defined using the inverse relations for geometry elements because objects like the door frame or the panel are not separately defined.

Most of the non-geometrical attributes are not standardised. In this case study, materials are mapped with the same names as in the native software solution. In the schema, there are some attempts to standardise attributes as IfcThermalTransmittanceMeasure, but that is not the case for any of the examined exchange requirements. In that way, the properties end up being machine unreadable and not relevant for future applications.

4.3 Data structure

The IFC schema structure, defined with the EXPRESS schema definition language, is rich and redundant. Attributes that can be optional or mandatory are inherited from the 'Supertype' of the entity or defined within it. In that way, entities are connected with the other types of entities. They can have simple or complex entities as attributes. That multiplies the possible definitions of the object. There are 812 optional and 625 mandatory attributes within IFC 2x3 schema. The mandatory attributes are often left as empty strings and not defined in the IFC building data model. Besides the hierarchically clear concepts, there are inverse relations that define inverse attributes. They act like containers of specific entities. This number of interrelated entities results with an extremely rich schema, which on the other side does not satisfy the needs of many actors involved in the industry. A simplified part of the case study model with the analysed exchange requirements is illustrated in Figure 5.

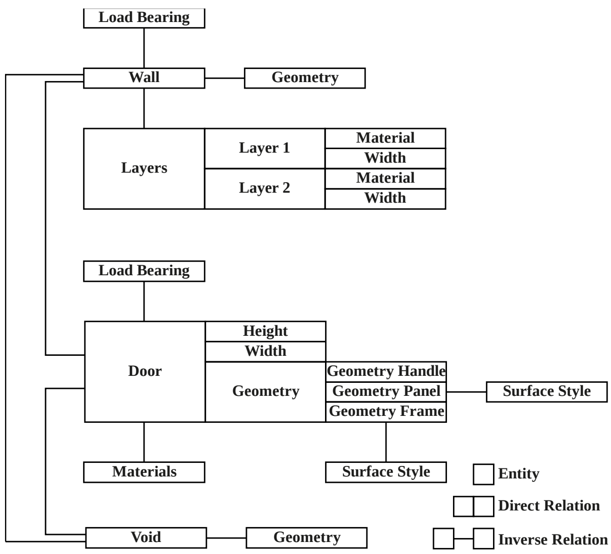

Figure 5 A simplified representation of the analysed case study building data model

A void element is connected to IfcWallStandardType with IfcRelVoidsElement which makes an opening in the wall and IfcRelFillsElement to IfcDoor that places the door in the opening element. The door and the wall are connected with IfcRelContainedInSpatialStructure to IfcBuildingStorey. For IfcDoor there are 7 different property sets connected with IfcRelDefinesByProperties, and 6 for IfcWall. Besides that, there are also IfcRelDefinesByType relations for defining IfcWallType and IfcDoorType for wall and door respectively. In total, for the door 45 IfcPropertySingleValue entities are defined, and for the wall 52, of which the majority is not standardised, machine-readable or required by the other software solutions.

5 Discussion

The intentions to use a single schema for a shared model in construction industry has not met user expectations yet. The history of IFC reaches back to 1994, but its main goal, achieving interoperability across the industry is still not achieved. In this paper, this schema is thoroughly analysed. The problems commonly occur due to three reasons: schema elements do not adequately represent the end user conceptions, some disciplines involved in the planning process and their requirements are not considered, and the schema implementation in software solutions is not trustworthy. To address these issues, a new concept for a schema is proposed followed by a framework that could result with an integrated building data schema definition.

A problem found in the case study is the lack of real-world object definitions that are required by the actors in the process. In the conducted analysis that problem is clearly presented with the door elements and wall layers. Upon the examined exchange requirements we propose a new structure from the end user perspective (Figure 6). The main property of the structure is to separate geometrical and non-geometrical data. Problems occurring within the geometry mapping are generally the problems of using different geometry kernels from the different software solution. The non-geometrical properties of objects belong rather to the standardisation category. Another advantage of this concept is that the end users can easily understand its structure. Thereby these two types of properties should be separated in the building data model (Figure 7).

The integrated data building model needs to support all the data exchanged in the planning process. The framework suggested in STEP standards, with different APs that would eventually form an integrated model, could deliver a functioning integrated schema. Due to numerous optional attributes that are left for users to define, the software solutions are already not able to follow with the support of the schema. Introducing new attributes and more possibilities to define the elements are not going to simplify its implementation and improve the interoperability without greater efforts by software developers. Mandatory attributes describing an entity are not necessarily a requirement for each discipline in practice. The planning processes differ between the countries and can be project-specific. Therefore the exact data exchange scenarios cannot always be predefined.

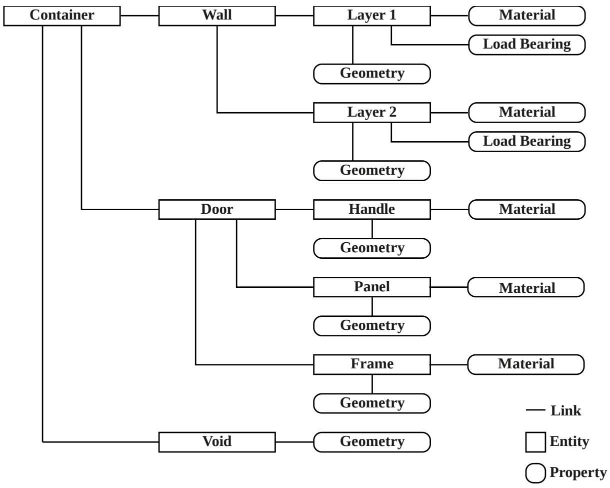

Figure 6 Schema proposal for easier implementation and validation

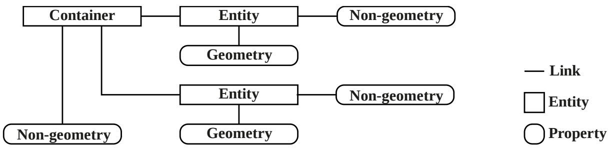

Figure 7 Basic part of the proposed structure

The attributes describing an object need to be defined as discipline-specific requirements, sometimes even software-specific requirements. Only after they are clearly stated, the schema definition can take place for the specific discipline. The limited integrated schema that cannot cover all the disciplines does not provide an answer. An integrated model can only exist with all the necessary requirements of every actor being supported. It can result from the coordinated unification of discipline-specific requirements across the industry. Following this concept, a base for an integrated schema would be a result of the specific disciplines' exchange requirements intersection. In this way, an extensive single schema is not avoided, but its definition is focused on the data exchange.

Implementation of the schema within software solutions, and especially software solution certification, is another obstacle for data exchange. This problem is extensively described in [24]. The idea of having different MVDs is still not implemented in practice since there is only one certified MVD used for data transfer between different disciplines (building service, structural planning, and architecture) that supports further planning tasks. Certification process of buildingSMART defines one concept list for import exchange requirements of all three disciplines. Software solutions certified without being able to support all the specified exchange requirements do not satisfy end-user expectations in practice. In order to achieve that, MVDs and the belonging concept lists need to reflect the discipline or software solution requirements.

When an integrated schema is defined as a product of discipline-specific schemas, a software solution does not need to support the integrated schema as a whole, or a single MVD, which is currently the case. Software solutions can in this way be tested for a specific purpose. Tools that are currently BIM capable would be BIM capable of a specific discipline, or more of them. It would be possible to measure which amount of relevant data a software solution is able to use based on the clearly defined end-user requirements. This concept can serve as a base for a metrics system for a discipline-specific certification process. The competitiveness of the software developers regarding the implementation of open exchange schema could improve the quality of its implementation. Defining a general metrics system and a certification that would provide end users with credible interoperability information can speed up a process of its implementation.

The analysis in this work is limited to three mentioned disciplines and a simple case study model. Analysis of a bigger example and its application in additional disciplines would surely address more issues regarding the schema. However, even this simple model demonstrates many problems that exist within an integrated schema currently used for open exchange. A more complex case study is avoided so the results could be presented as clearly as possible. Only one-way data exchange is considered.

The proposed structure concept is based on the end user conception of examined elements. The complete schema using the proposed structure would drastically increase in complexity, but comparing to the existing schema it would create a significant simplification of the integrated model. A software solution can only be certified for a domain specific or federative parts of an integrated schema, since there are no software solutions used for all the involved disciplines. The integrated model should support all actors involved in the process, without limitations and workarounds. Since there is a long way to achieve it, the focus can be set on the unification of federated models where the integrated model would be flexible enough and allow new concepts to become part of it. Its structure must, however, be clearly defined and validated. Another aspect of open exchange that needs to be standardised are interpretations for a specific domain and object properties. The uncertainties that occur during the mapping to the receiving application are one more thing that keeps the end users from using the schema. The same approach of filtering and interpretation must be applied in the other direction, federative or domain model to the integrated model. The future work regarding this topic is going to focus on the detailed structure development with a proof of concept to follow.

6 Conclusion

An integrated schema as a data managing concept in the construction industry was not able to provide satisfying results for many disciplines in the planning process. Processes like data filtering and interpretation are neglected in the general framework with the current IFC schema-based data exchange. Some disciplines can make use of the existing model only by filtering the information. However, the majority of actors involved find it easier not to use open exchange and to use other schemas, strict workflows that often include various workarounds and non-intuitive practices, and 2D drawing based exchange. Mapping processes are not standardised and clearly defined whereas many decisions are left to software producers. Viewers that are specifically made for the IFC schema are the most compliant with the integrated model. To solve the interoperability problems, schema has to cover the needs of all the software solutions involved in the exchange, and thereby consider all exchange requirements. Until then, all the disciplines that are not considered will turn to other options.

The required flexibility among the disciplines in the construction industry is not supported within the current open exchange schema. The taxonomy model defining exchange requirements could be a good start for the integrated schema. However, the schema that is limited does not satisfy the needs of the industry. The integrated schema must be complete and support all the product and project data from all the involved disciplines. For software solutions implementation, the focus needs to be set on filtering and interpretation processes. They need to support clearly defined subschemas similar to MVDs that are the answers for real end-user needs. Discipline-specific subschemas that represent exchange requirements are the key to achieving a working data exchange. The integrated schema unifying the discipline-specific requirements can offer answer to the interoperability problems in the construction industry.

Abstract–

This paper addresses the problem of explaining the reason for mixed assessment results in comparing cost performance of project delivery systems (PDS). In particular, we focus on mediator effects for the explanation that would traditionally not be handled by project performance evaluation disciplines. Previous studies revealed that two kinds of disciplines deal with change orders from different points of view. Evaluating PDS by project owners uses change order as a cost performance metric, whereas contractors consider it as a method to increase project cost for their own profit. A Path Analysis model was established by integrating these viewpoints to explain the discrepancy in assessment of PDS. It describes the process how PDS impact on change orders. For the path model, 234 public sector projects completed between 1998 and 2013 in Korea were collected and analyzed. The dataset consists of both Design-Build and Design-Bid-Build projects which are the most prevalent delivery systems. While examining the total effect of PDS on cost performance using the path analysis, mediator effects were significant in building construction project type. This study fills the gap between the successful performance result and the failed adoption of PDS using causal relationship as explanation. The intervention of procurement methods between PDS and their cost performance may provide the clue that project decision makers should consider mediator effects and project characteristics when they select and assess PDS.

1 Introduction

1.1 Background

When project owners decide on a project delivery system (PDS) that will carry out their project within budget, it is important to consider related project and bidding characteristics. From the point of view of the project owner, the cost performance assessment of PDS is as important as the type of PDS used, because an inappropriate selection of PDS based on mistaken assessments may lead to considerable cost overruns and cause confusion throughout the project.

In order to assess PDS, most research compares the two prevalent methods, Design-Build (DB) and Design-Bid-Build (DBB) [1-5]. Research in this area mostly shows that the cost performance of the DB system is regarded as better than the DBB system [1-3, 6]. However, some studies have displayed negative results for the performance of DB against that of DBB depending on project characteristics and different datasets [4, 5, 7, 8]. These inconsistent results could stem from different measurement according to point of view. To measure the cost performance of PDS, various performance metrics such as unit cost, cost growth, intensity (cost/time) are used [1]. The cost growth from contract amount to completion amount is widely used as the cost performance metric. It mostly adopts change order as its operational definition of measurement index by owner's viewpoint [9-12] (Detailed explanation is provided in Section 2.3).

On the other hand, some studies consider change order as a method to preserve or increase contractor's profit during the construction phase [13]. Construction projects where there are significant differences between the selected bid price and the pre-bid estimate of the owner (hereinafter referred to as "bid to estimate ratio") have higher change orders [14-17]. Bid to estimate ratio and change orders are often influenced by the number of bidders depending on PDS in bidding stage [9, 10, 13, 18]. When the number of bidders is large, bid to estimate ratio is lower than a smaller number of bidders due to excessive competition. DB has usually small number of bidders than that of DBB, which can easily increase bid price. That is, DBB has lower bid price than DB, and in case that the bid to estimate ratio of DBB is significant lower than average, the contractors often try to increase change order during construction phase to preserve their profit. These bidding characteristics from contractors' viewpoint, bid to estimate ratio, and the number of bidders affect change orders during the construction phase. Those situations yield that DBB has generally higher change orders than DB. Higher change orders is welcomed by the contractor's viewpoint in those cases. However, from owner's point of view, fewer change order is known as superior in terms of assessment of PDS. From the point of view between owner and contractor, there two types of conflicting studies coexist for the purposes of using change orders.

Consequently, change orders should be understood with two different perspectives between owner and contractor (Figure 1). Owners use change orders to measure project cost performance, while contractors often consider it as a method to increase project cost for their own profit.

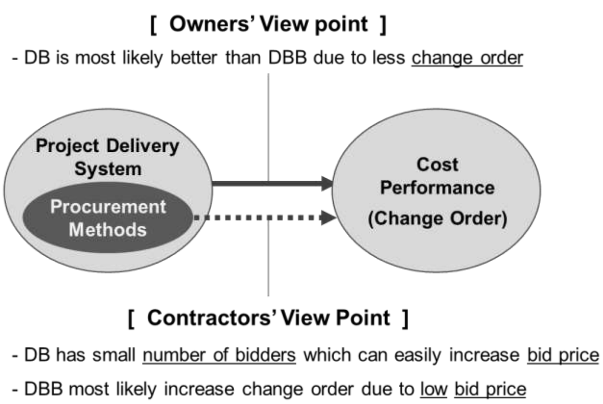

Figure1. Different perspectives between owner and contractor on change order

1.2 Problem Statements

As Figure 1 shows, this issue may lead to debates on cost performance between DB and DBB. Numerous studies have been conducted on each of these topics. However, the methodologies of both studies are limited to correlation or regression models, which can only analyze the dependent relationships of PDS, bid characteristics and change orders, respectively. Because, those methods analyze only direct effects between independent and dependent variables (Figure 2).

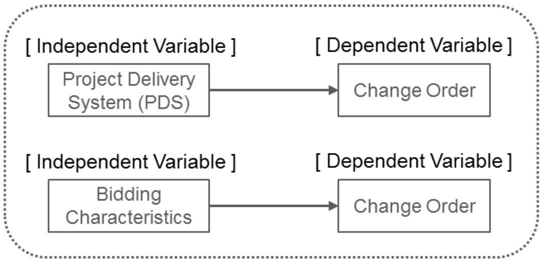

Figure 2. Different viewpoints of studies and their direct relationships

If other factors intervene between independent and dependent variables, they would act as mediator, which means indirect effects occur. Therefore, another method is needed to compare the size of the effects and to identify stronger factors that impact on change orders. To deal with this problem statement, we need to build a single model that combines the different purposes of both the owner's and contractor's viewpoints as influential factors (independent variables). Figure 3 shows the combined model, adopted a Path Analysis method.

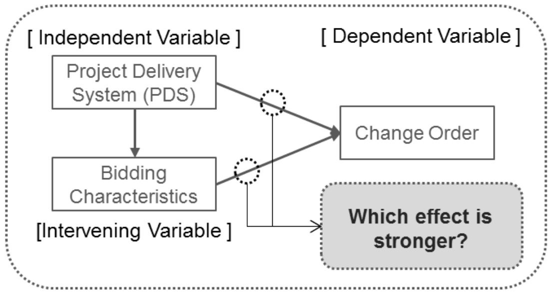

Figure 3. Integrated model of different view points

1.3 Adoption of Path Analysis Method

To deal with the aforementioned problem statements, we adopted a Path Analysis method. It performs causal analysis using a theoretically grounded model and covariance (or correlation) matrix. Compared to system dynamics models, it examines a hypothetical test using empirical data, while system dynamics build a more theoretical model that has difficulty validating the model. Path analysis makes it possible to identify both direct and indirect effects that are otherwise difficult to detect in multiple regression analysis. Path Analysis is a technique that can analyze not only the influence relationship between independent and dependent variables but also the influence relationship between independent variables at the same time [19, 20].

Let us compare path analysis models with multiple regression models. For instance, we can analyze the multiple regression model Y ~ X1 + X2. The regression coefficients are interpreted as how much Y would increase when we increase X1 by 1 and fix X2 at constant value. However, this assumption could be counterfactual if X1 has a causative influence on X2. If X1 increases X2 and X2 increases Y in succession, the regression coefficients of X1 underestimate the causal influence of X1 on Y. Path analysis incorporates the causal influence of X1 on X2 and successfully estimates the causal influence of X1 on Y.

In this paper, the Path Analysis model integrates the factors attributed to the two stakeholders. There is an influential relationship between PDS and bidding characteristics. Both are independent variables that affect change orders in a multiple regression model. The model will identify the relationships and estimate the effect of PDS on cost growth from change orders.

It combines the theory and the data to estimate the causal effects of variables. For the theory, we built a theoretical model through research hypothesis and literature survey, then the path model and real world data were combined and examined.

1.4 Research Objectives and Hypothesis

The objective of this study is to build a Path Analysis model that identifies mediator effects and describe the process of the causal relationship between PDS and cost performance. A database of 234 public sector construction projects completed between 1998~2013 in South Korea was examined for the path model. This study made an effort to explain the cost performance of PDS by illustrating the process of the contractor's impact on change orders by considering the different viewpoints of owners and contractors.

The research hypothesis is that the contractor's intention impacts on change orders that are measured for the cost performance of PDS by owners (Figure 4).

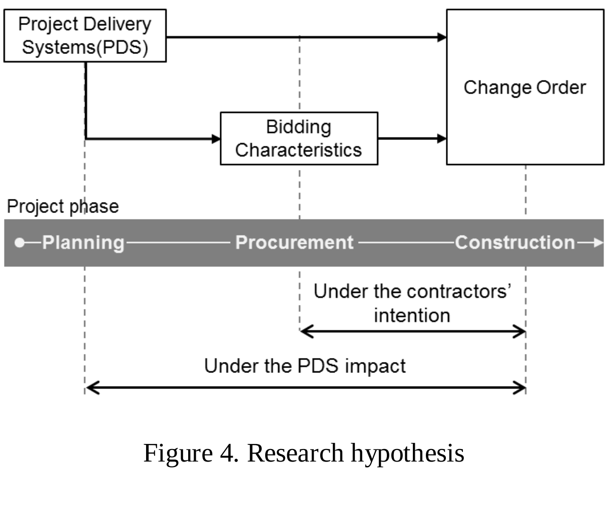

Figure 4. Research hypothesis

The intention will be identified as the mediator effect working between PDS and cost performance.

2 Methods

As described in section 1.3, we built a theoretical model. The data collected was analyzed to establish suitable Path Analysis models and the model that was supported by the data was examined.

2.1 Building a Theoretical Model

Moon [12] studied a mediator effect of bid price to estimate the ratio between PDS and change orders. However, more features can be uncovered and categorized as bidding characteristics that may be part of the contractor's intention. We examined the previous studies on which variables affect the change orders and hypothesized processes regarding how these variables affect the outcome (Figure 5).

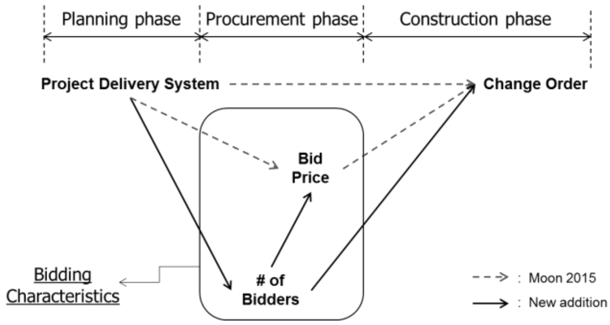

Figure 5. Theoretical path model

2.2 Data Collection and Analysis

This study utilized a database of 234 public sector projects that were completed in South Korea between 1998~2013. Each project awarded by the city of Seoul cost more than five million dollars. Nine project types were constructed and categorized to four types: civil, building, facilities, and landscaping. The sample size of DB and DBB projects are similarly distributed where DB is 97 samples (41.5%) and DBB accounts for 137 samples (58.5%). Figure 6 shows the sample size of each PDS according to project type. Building projects and civil projects were selected for the analysis as each project type has a similar distribution as well as sufficient number of samples for both DB and DBB. In addition, according to reports by the city of Seoul authorities, excessive change orders due to governmental policy and social conditions in four projects were assumed to be outliers and these were removed from the dataset.

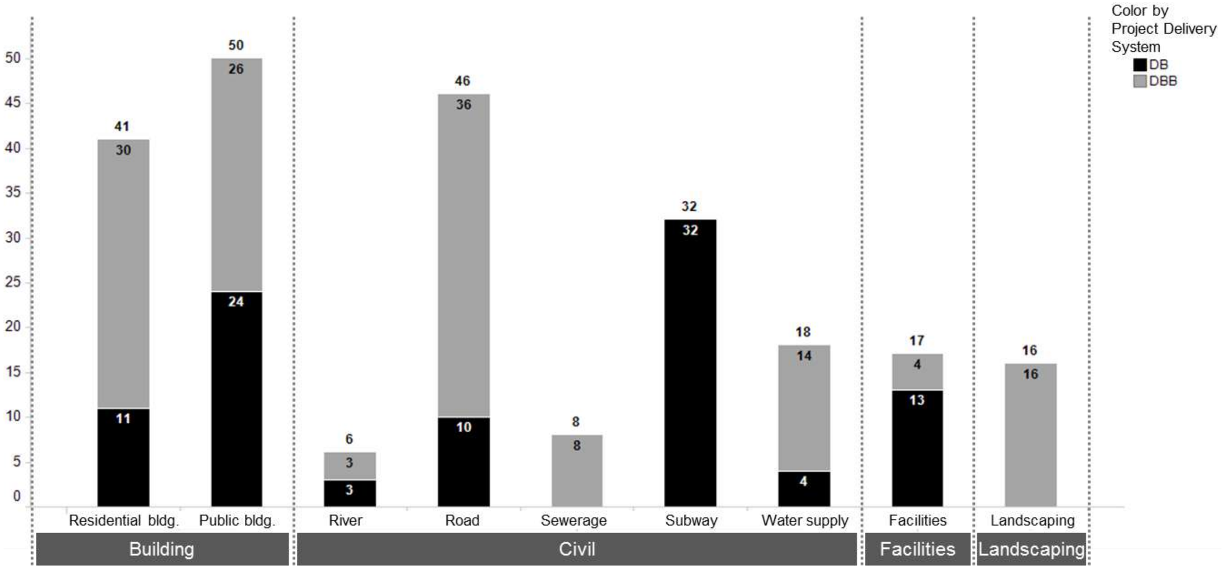

Figure 6. Sample size and project type

2.3 Cost Performance Metric

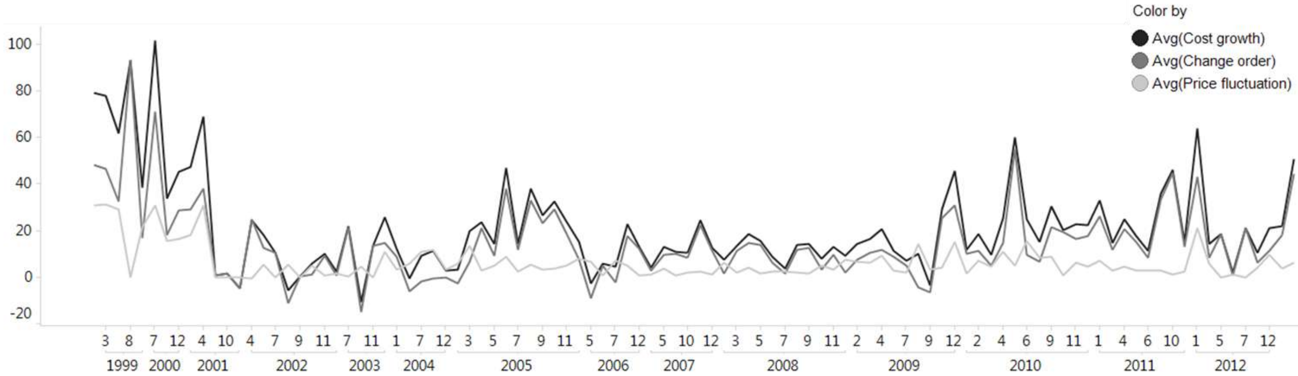

Figure 7. Change order as a cost performance metric

To address cost performance metrics, we analyzed the dataset. A line chart of cost growth rate was projected according to the actual date of project completions. Cost growth rate of the dataset consists of escalation (price fluctuation) and change order rate. Figure 7 shows that both cost growth and change order rates have similar rise and fall curves, but the price fluctuation rate is projected far from the both lines. The cost performance is dominated by change order rather than price fluctuation in the case of the present dataset. Finally, we adopted change order rate as the cost performance metric based on the metrics included in the previous studies [9-12] and data analysis. As operational definition, change order is represented in percentages by comparing the final construction costs which is subtracted fluctuation price to the initial contract cost.

2.4 Path Analysis Model

Unlike independent multiple regressions, path analysis simultaneously estimates the parameters and can estimate the indirect effects (mediator effects) of certain variables. Based on the theoretical model, we postulated the process model of how PDS affects the change order. Figure 8 shows two proposed path models. In the first (Figure 8(a)), PDS has a direct effect on change order and indirect effects through the number of bidders and bid price. In Figure 8(b), PDS has direct and indirect effects on change order, but the indirect effects have different paths. We assumed the number of bidders cannot have direct effects on change order but it has an indirect effect through the bid price. Some studies examined the effect of the number of bidders on change orders [10, 18]. However, we provide statistical evidence that these can be explained via the causal effect model.

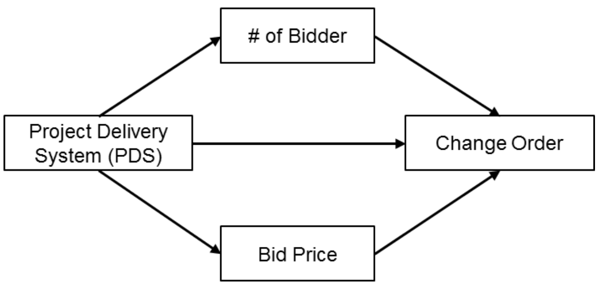

Figure 8(a). The path model-1

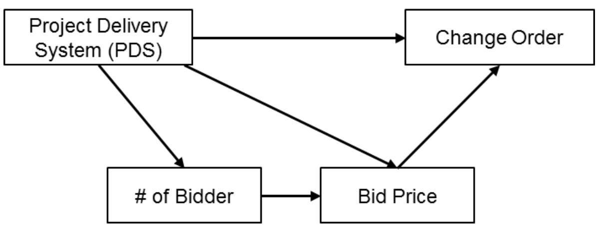

Figure 8(b). The path model-2

We analyzed the data using model described above and used multi-group analysis to incorporate the fact that the process of determining the change order might be different according to project type. We used Full Information Maximum Likelihood (FIML) to utilize the missing data fully. FIML is recommended by several methodologists since it is unbiased even when the missing mechanism is Missing at Random (MAR) rather than Missing Completely at Random (MCAR) [21, 22].

3 Results and Discussion

First of all, we examined the fit of both models to see how probable it is that the proposed models were true. It is advisable to check the fitness of a model before interpreting any coefficients from it [19, 20]. Since the proposed models are only one parameter short of being a saturated model per group, we used the chi-square test to see if the coefficient can be assumed to be 0. The scaled chi-square test [23] of the first model versus the saturated model resulted against the null hypothesis (chi-sq difference (df = 2) 17.56, p-value = 0.0002), meaning that the first model cannot adequately fit to the data. The scaled chi-square test of the second model resulted in a chi-squared difference of 3.4149 with a degree of freedom of 2. P-value was 0.1813 indicating that the second model has adequate fit. Therefore, we used the second model to estimate the effects of PDS.

Since we use multiple group analysis, the first thing to check was whether the coefficients were the same across the groups. We compared the multiple group model with the same coefficients between groups and the model with the different coefficients for each group. We used the chi-square test and the assumption of the same coefficients across groups that could not be justified by the data (chi-square difference = 19.513, df = 5, p-value = 0.002). We also tested if the error variance could be assumed to be the same across the group (allowing the coefficients to be the same for different group) and it was not supported (chi-square difference 46.305, df = 3, p-value = 0.000).

As a result of the aforementioned outcomes, we used models with the different coefficients and different error variance for each group. For powerful analysis, we used bootstrap method to estimate the direct and indirect effects and the standard error of these. We analyzed the data with path model-2.

The fit was adequate with chi-square p-value 0.352, RMSE 0.021(0, 00-0.20), CFI 0.99 and P-value for RMSEA being less than 0.05, 0.439 [24]. Estimated coefficients for building construction projects are in Table 2. In the building construction projects, the direct effect of PDS on change order was not significantly different from 0, but the indirect effect was found to be significant. Table 1 shows the two specific indirect effects of PDS on change order.

Table 1. Effects of PDS on change orders via different paths for building construction projects

Effect	Path	Estimate (Bootstrap confidence interval)	SE	P-value	Standardized
Specific indirect	PDS → # of bidders → bid price → change order	-0.97 (-2.13 ~ -0.12)	0.53	0.067	-0.079
Specific indirect	PDS → bid price → change order	8.65 (1.26 ~ 16.46)	3.94	0.028	0.705
Direct	PDS → change order	-2.91 (-13.93 ~ 6.49)	5.09	0.567	-0.238
Total	Sum of the above	4.76 (-0.86 ~ 10.24)	2.76	0.084	0.388

The results of Table 1 show that both of the specific indirect effects of PDS on change order are significant (Column Estimate shows the estimated coefficients and the .95 confidence interval from bootstrapping. Values in column SE and P-value are results from normal theory). But the sign of the effects is the opposite. Table 1 shows the complicated process of determining change order. Total effect of PDS on change order was insignificant but the indirect effect through the ratio of bid to estimate was significant and the estimate was quite large (8.65 with confidence interval from 1.26 to 16.46).

Table 2 shows all the estimated coefficients from the proposed model for building construction projects. In the results, PDS had significant effects on the number of bidders and bid price. Since the model is causative, we can analyze the causal relationship between variables. For instance, we can figure out what will happen when the number of bidders does not increase for PDS. The first specific indirect effect in Table 1 will be blocked and the effect will disappear so the change order will increase by 0.97 on average.

Table 2. Building construction projects

Antecedent	Consequent								
	M1(# of bidders)			M2(bid price)			Y(change orders)		
	Coefficient	SE	P-value	Coefficient	SE	P-value	Coefficient	SE	P-value
X(PDS)	70.38	13.2	0.00	-15.6	1.55	0.00	-2.91	5.09	0.57
M1(# of bidders)				0.03	0.01	0.00			
M2(bid price)							-0.55	0.26	0.03
Constant	-68.76	13.80	0.00	108.81	2.35	0.00	64.30	29.62	0.03
	R^2 = 0.191			R^2 = 0.562			R^2 = 0.119		

The model appears to be quite reasonable. In particular, the causal chain of PDS on number of bidders, the number of bidders on the ratio of bid to estimate, and the bid to estimate on the change order appears reasonable. As Hume [25] indicated, temporal priority is a necessary condition for causality.

Even though the model showed adequate fit, we could not be sure that the model is true of reality. As

Bollen [26] mentioned, researchers can only say their causal model is consistent with the data in hand and there may be other models that show adequate or better fit. For instance, causal relations can be nonlinear or there might be confounding variables in the causal relationships we hypothesized.

4 Conclusions

Based on previous studies, it is concluded that the DB system outperforms the DBB delivery system due to fewer change orders. This result is from the owner's perspectives in terms of assessment of PDS. However, according to different studies, the number of bidders and bid price during procurement phase also impact on change orders in construction phase. Change orders are often welcomed by contractors to preserve or increase their profit. These two types of research with mixed results were combined and the theoretical model that included PDS, the number of bidders, bid price, and change orders, was developed and tested statistically using Path Analysis method. In a specific project type, the mediator effects of bidding characteristics between PDS and cost performance were validated. In that case, we should not conclude that DB is superior to DBB only due to fewer changes.

This study made an effort to provide a better understanding of the mechanism of PDS impact on cost performance through intervening factors. This research is expected to help project decision makers in selecting a PDS by considering mediator effects of specific projects and bidding characteristics.

More data analysis techniques are needed to gain insight from real world data and for this data to be examined by the Path Analysis method.

Abstract –

This paper aims to describe a natural language processing (NLP) and deep learning-based approach for supporting automated rule checking system. Automated rule checking has been developed in various ways and enhanced the efficiency of building design review process. Converting human-readable building regulations to computer-readable format is, however, still time-consuming and error-prone due to the nature of human languages. Several domain-independent efforts have been made for NLP, and this paper focuses on how computers can be able to understand semantic meaning of building regulations to intelligently automate rule interpretation process. This paper proposes a semantic analysis process of regulatory sentences and its utilization for rule checking system. The proposed process is composed of following steps: 1) learning semantics of words and sentences, 2) utilization of semantic analysis. For semantic analysis, we use word embedding technique which converts meaning of words in numerical values. By using those values, computers can extract related words and classify the topic of sentences. The results of the semantic analysis can elaborate the interpretation with domain-specific knowledge. This paper also shows a demonstration of the proposed approach.

Keywords –

Automated rule checking; Natural language processing; Deep learning; Semantic analysis; Building information modeling (BIM)

1 Introduction

As BIM (Building information modeling) has increasingly used in architecture, engineering, construction (AEC) industry, there are many efforts to develop BIM applications to use rich building information. The role of automated rule checking has been recognized before the use of BIM [1]. As BIM provides computer interpretable building model, many researchers reported that BIM can improve efficiency and accuracy of design assessment [2]. The main components of rule checking consist of 1) rule interpretation and logical structuring, 2) building model preparation, 3) rule execution, and 4) reporting of the checking results [3]. Compared to other phases, rule interpretation task needs a lot of manual efforts. For automated rule checking, regulatory information must be expressed in an explicit format which computers can execute. Extracting and structuring required data from sentence is time-consuming and error-prone due to the vagueness of natural language. Therefore, to intelligently automate rule interpretation, computers should understand the semantics of the regulatory sentence.

Deep learning-based NLP (Natural language processing) enables the computers to learn the semantics of natural language from raw text data. Unlike conventional method, deep learning model extracts training features from raw text and adjusts the weight without human's intervention. It can alleviate the manual efforts to interpret regulation sentences which required for automated rule checking. In this regards, the objective of this research is to apply deep learning-based NLP for translating building regulations into a computer-readable format. As an early stage of research, this paper proposes a semantic analysis process to support rule checking, focusing on rule interpretation.

The scope of this paper is the approach to analyzing the semantic data of Korean building regulation sentences with NLP and deep learning. We analyzed 5 Korean building regulations: Building Act, Enforcement Decree of Building Act, Regulation of the building Structure criteria, Regulation of the building facility criteria, and Regulation of the evacuation and fireproof construction criteria. 3504 training sentences are derived from 5 building regulations. Steps of the proposed analysis are summarized as follows.

1. Learning step: Decompose training sentences in word-level and learn semantic of words and sentences by using NLP and deep learning model
2. Utilization step: Automatically inference the related word and topic of input sentence, utilizing trained learning model.

After dealing with proposed analysis process, this paper also presents a demonstration of utilization which is associated with domain database.

2 Background

2.1 Rule interpretation for automated rule checking

There have been many efforts to develop automated rule checking. Among the automated rule checking process, rule interpretation is a significant step for automating rule checking. The conventional methodology to translate the building code has been depended on hardcoding or logic rule-based mechanism. The CORENET (COnstruction and Real Estate NETwork) project in Singapore translated building code of Singapore into the programming language by hardcoding [4]. DesignCheck project formalized the building code of Australia and encoded it according to the EDM rule schema based on the EXPRESS language [5]. In GSA project, the courthouse design guide was parameterized and translated into computer-processible format [3]. In case of the Korean building permit research project, they used logic rules and intermediate code to translate Korean building act into the computer-readable format [6]. The conventional rule-based way guarantees the accuracy and reusability. However, establishing the logic rule for interpretation has been done by manual efforts due to ambiguity and vagueness of natural language.

In order to overcome the inefficiency of a manual process, some studies focused on analyzing the semantics of words in regulatory sentences and utilizing NLP. Zhang et al. proposed semantic NLP-based automated compliance checking (SNACC) system [7]. NLP and ontology were applied for extracting the regulatory information from documents. Through the NLP technique and other process, they automated the rule interpretation with semantic information extraction. E.Hjelseth applied RASE methodology to transform normative documents into a single well-defined rule which can be implemented into model checking software [8]. Uhm et al. translated request for proposal (RFP) for public building in South Korea [9]. Sentences in RFP were broken down into morphemes and categorized into four types (object, method, strictness, and others). Context-free grammar approach was deployed for parsing, and the sentences were translated into Semantic Web Rule Language (SWRL). SWRL is translated again into Python script language for implementation. Previous researchers have contributed to capturing the semantics of regulatory documents, but they still need manual effort to interpret patterns of sentences.

2.2 Natural language processing

NLP is a research field of artificial intelligence related to interactions between human and computer. The main research of NLP ranges from understanding human language to making proper responses. Due to the ambiguity of natural languages, it is a challenging process to understand the raw text data. Conventional NLP used logic rule-based or statistical methodology for analyzing natural language. In the rule-based method, the text is analyzed by rules defined with linguistic knowledge. However, the semantic meaning of words is hard to capture since it is hard to be defined by pattern or rules. WordNet is a lexical database for English, which provides sets of synonyms that are in turn linked through semantic relations [10]. This has been widely utilized to present semantic meaning of words but still needs a manual task to build and manage this database.

Development of machine learning and deep learning has changed the methodology of NLP and dramatically improved the accuracy of it [11]. Deploying an extensive amount of data and neural net algorithm, the computer can learn semantics in natural language by itself. As machine learning is processed with numerical vectors, words have to be converted into the computer-interpretable format. Distributed representation in vector space helps to represent words quantitatively. Rumelhart proposed this concept of analysis [12] and recently Mikolov implemented neural net based word embedding model called word2vec [13, 14]. After google opened the word2vec model to the public, many researchers make use of this model for sentiment analysis [15] and information extraction [16].

3 Learning semantic of words and sentences in building regulations

This section describes details of the semantic analysis for building regulations. As shown in Figure 1, proposed process is composed of 2 main steps: Learning semantics and Utilization. Learning step consists of 1) preprocessing, 2) semantic analysis of words and sentences and 3) sentence classification. The process and details about utilization are described in Section 4.

Preprocessing is focused on the grammatical analysis of documents, which is needed for semantic analysis. After the preprocessing, the meaning of words and the topic of sentences are learned by neural net-based word embedding technique. Sentence classification is conducted with deep learning model. In this paper, we used a Python package library KoNLPy [17] for preprocessing, Gensim [18] for word embedding and Tensorflow [19] for establishing classification model.

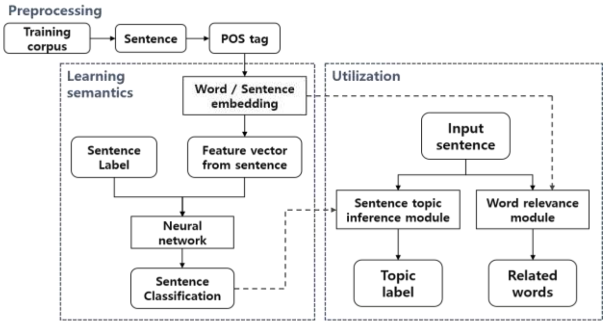

Figure 1. Proposed process of analysis and utilization of building regulations

3.1 Preprocessing

In order to proceed an accurate semantic analysis, raw text data have to be processed in a suitable format. In the Korean language, there are postposition particles which stand for grammatical use. They are attached behind to other words like nouns or adjectives. In the raw text, there are also stop words which disrupt semantic analysis (e.g. punctuation). The sentences should be analyzed in grammatically to exclude these unnecessary part. Preprocessing consists of morpheme analysis, Part-of-Speech (POS) tagging and excluding stop words. Morpheme is the smallest unit which has a specific meaning in a language. By decomposing words in atomic unit, morpheme analysis supports to separate the words from postposition particle. POS tagging assigned the label of grammatical function to each word, such as noun, verb, and adjectives. After POS tagging, we excluded Chinese character, punctuations, and numbers. Figure 2 presents a result of each step of preprocessing.

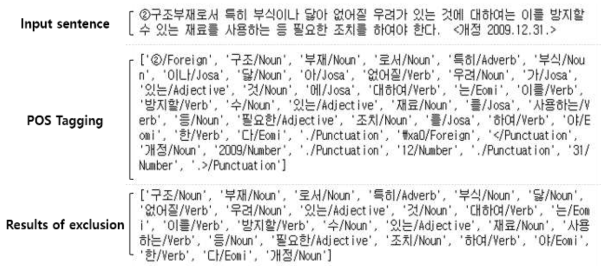

Figure 2. Example of preprocessing result (POS-tagging, Exclude stop words)

3.2 Semantic analysis of words and sentences

This paper uses word2vec model for the semantic analysis of words. Word2vec model is based on the word embedding technique and it learns the semantics of text from co-occurrence information. Some words which appear with target word in the same context are more related to target word than the others. Based on this concept, Mikolov et al. proposed 2 models to learn the word vector 1) CBOW (continuous Bag-of-Words) model and 2) Skip-gram model [14]. Skip-gram model predicts the current word with a certain range before and after the current word, CBOW model is the opposite. By predicting the current or context words, the computer can learn a co-occurrence data of words. Based on the co-occurrence data, the model assigns the high-dimensional vector values for each word. The numerical vector values enable for the computer to calculate a relevance of words. This learning process also can be applied to learning the meaning of sentence [20]. In this paper, the meaning of words and sentences are presented in 400-dimensional vector space, as shown in Figure 3. We set the maximum distance 5 and words with a frequency less than 3 were excluded from the training.

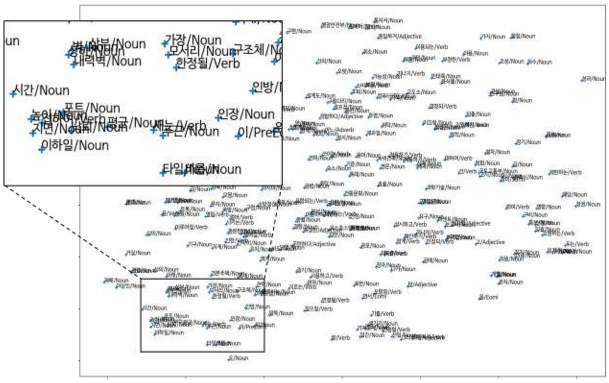

Figure 3. t-SNE Visualization of word distribution

3.3 Sentence classification

Korean building regulations contain not only requirements for building also other rules which are irrelevant to buildings (e.g. administrative procedures, Committees). BIM-based automated rule checking focuses on the requirements for buildings which can be expressed quantitatively. Therefore, computer should classify the sentences according to the content and extract the sentences related to buildings from the raw documents. Furthermore, classifying sentences supports identifying what information has to be extracted. The numerical vector values extracted from semantic analysis facilitate the classification of the sentences.

In this paper, we use deep learning model for classification of sentences. First, we tag the label to each sentence according to its contents. Table 1 shows a classification of content described in building regulations. In this paper, 6 categories are used for classification labels: 1) Non-AEC, 2) Site, 3) Building structure, 4) Facility, 5) Usage of building and 6) Evacuation & Fireproof. We just use Non-AEC category, as we don’t need more detailed for irrelevant sentences in terms of rule checking. Site category covers the regulations for a building site and roads. Facility category includes MEP facilities and Evacuation & Fireproof category is comprehensive of rules for evacuation plan and noncombustible material. For supervised classification learning, we use deep learning model which composed of 4 fully-connected layers and softmax function for multi-class classification. The graph of model and weights are saved for inference model.

Table 1. Classification of contents described in building regulations

Level-1	Level-2	Level-3
Non-AEC	Rule	Amendment
		Delegation, Reference
	Administrative	Procedure
		Committees
		participant
AEC	Site	Site
	Building	Structure
		Facility
		Usage
		Evacuation & Fireproof

4 Utilizing semantic analysis to support automated rule checking system

4.1 Extract related words from input sentence

Extracting related words to target word facilitates understanding of the semantics. Based on the numerical values, the computer can calculate the metric distance between words. The distance between words represent the relevance between them, so we can extract words related to the target word. This features could be used for extract semantic relations of words in a regulatory sentence.

This module extracts words related to a user-input word, using results of the semantic analysis. The given sentence which is selected by users is decomposed to word-level. After decomposition, the relevance of input word and each word from the given sentence is calculated. Through those steps, the computer can get a list of related words, but it has no idea which words are building object or their property. This gap can be decreased by domain knowledge which deals with rule checking data. This paper used the KBimCode database made up of previous work of this research [6]. KBimCode database provides the computer-executable code data and corresponding Korean words. It can be used as a dictionary for translating Korean words into object, property and method data, as shown in Figure 4.

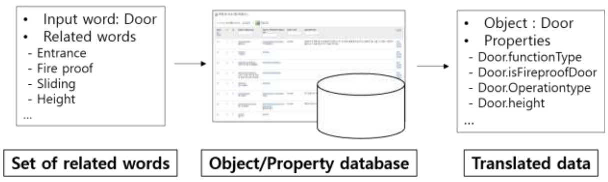

Figure 4. Translating words to corresponding object/property data

4.2 Inference the topic of input sentence

Topic inference module is based on a result of classification learning. The input sentence is also decomposed in a set of words. After preprocessing, inference module infers the vector values of input sentence based on other sentences vector values. In this paper, we assigned the meaning of the sentence in 400-dimensional space, so the inference module also returns the same shape of value. Then, the inferred vector is given as an input for the classification model. It uses a same graph and weights for predicting the topic.

5 Demonstration

The proposed modules described in the previous section are implemented in GUI applications for supporting rule checking process. This section demonstrates the results of implementation. With this application, users can get related words, corresponding KBim data and a predicted topic of the input sentence.

Table 2. An example of word extraction for Korean building regulation

Input Sentence	[Enforcement Decree of Building Act, article 35] Direct stairs installed on the fifth or upper floor or the second or lower underground floor pursuant to Article 49 (1) of the Act, shall be installed as fire escape stairs or special escape stairs in accordance with the standards prescribed by Ordinance of the Ministry of Land, Infrastructure and Transport: Provided, That the same shall not apply where main structural parts are made of a fireproof structure or non-combustible materials and either of the following is applicable
Input word	Stair

Top 5 related word	Direct / Noun Escape / Noun Floor / Noun Underground / Noun Special / Noun
Extracted word	Direct stairs, escape stairs, Special escape stairs, underground floor, fifth floor, second floor
KBim data	-Object: Stair, Floor -Properties : Stair.isDirect, Stair.isEscape, Stair.isSpecialEscape -Method : getFloorNumber()

Table 2 shows a result of extracting related word when "stair" is given as an input word. The result is presented in GUI application as shown in Figure 5. The properties of the stair are also easily found in a lexical level search. However, in the lexical level, floors where stairs are installed or related objects are not searched. The demonstration shows that not only the properties of the stair are suggested, also the related object (Floor) and its properties (Underground), from the semantic analysis.

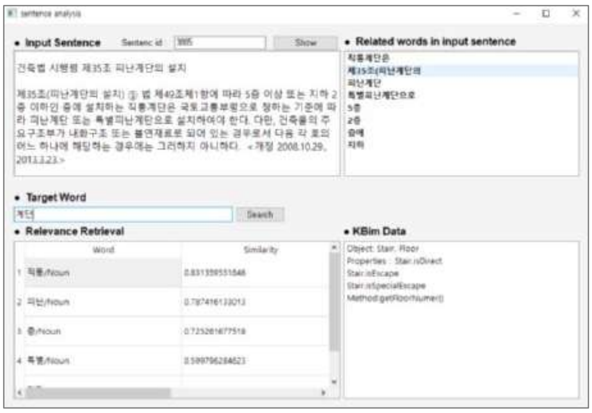

Figure 5. Screenshot of the application for extracting related words in sentence

The topic inference module suggests predicted topic of an input sentence and also similar sentences based on their content. Suggested similar sentences are extracted based on vector representation, calculating the metric distance of each sentence, same process with the word extraction. In terms of extending the scope of rule checking to RFP or other new regulations, this topic prediction makes it easier to classify the sentence whether it deals with content related to BIM-based rule checking. Table 3 shows the examples of topic prediction results. The inference module makes an accurate output in case 1. However, in case 2 and 3 the module make a wrong prediction, as the correct label is predicted in second. The results of prediction are demonstrated in GUI application, as shown in Figure 6.

6 Conclusion

This paper proposes a semantic analysis process and its utilization to support rule interpretation. In this paper, Word embedding model is used for learning the semantics of text. Through the training, the semantic of word and sentences are represented in vector values. The results of the semantic analysis are utilized for extracting related words and classifying the topic of sentences. Sentence classification based on deep learning model enables the computer to classify the regulatory sentence according to its content. Extracting related words helps both human and computer to find semantic information from raw text. Demonstrated implementation shows the possibility of utilizing deep learning and NLP to support rule interpretation process. Leveraging this process can decrease the manual efforts and time for interpreting rules.

This paper also has some limitations. In preprocessing process, there are some errors in morpheme analysis which are done by NLP framework. This causes critical problems for information extraction task and interpretation. And this paper mainly deals with the semantic relation of words. To entirely automate rule interpretation, it needs to be developed to the logical relation. For the future work, it can make a breakthrough to deploy the syntax parsing for capture the logical relations of words. Furthermore, to enhance the accuracy of morpheme analysis and sentence inference, other deep learning models could be applied (e.g. RNN or CNN for sentence classification [21]).

E-mail: fatihk@metu.edu.tr, arzug@metu.edu.tr

Abstract – Unmanned Aerial Vehicles (UAVs) have recently shown great performance collecting visual data through autonomous exploration and mapping in building inspection. Yet, the number of studies is limited considering the post processing of the data and its integration with autonomous UAVs. These will enable huge steps onward into full automation of building inspection. In this regard, this work presents a decision making tool for revisiting tasks in visual building inspection by autonomous UAVs. The tool is an implementation of fine-tuning a pretrained Convolutional Neural Network (CNN) for surface crack detection. It offers an optional mechanism for task planning of revisiting pinpoint locations during inspection. It is integrated to a quadrotor UAV system that can autonomously navigate in GPS-denied environments. The UAV is equipped with onboard sensors and computers for autonomous localization, mapping and motion planning. The integrated system is tested through simulations and real-world experiments. The results show that the system achieves crack detection and autonomous navigation in GPS-denied environments for building inspection.

Keywords –

Unmanned Aerial Vehicle; Building Inspection; Crack Detection; Transfer Learning; Autonomous Navigation

1 Introduction

Inspection of buildings throughout their lifecycle is vital in terms of human safety as the number of structures increases expeditiously. In line with this objective, periodic inspections are essential for residents' safety. For instance, systematic bridge inspections are done periodically in six years to detect structural cracks [1].

In this context, Unmanned Aerial Vehicles (UAVs) have been widely used in inspection operations in the last decade since their workspace is superior than that of ground vehicles. Today, UAVs are employed especially in visual building inspections by utilizing onboard cameras.

Moreover, the robotics community has increased the automated capabilities of the UAVs in terms of data acquisition and processing for inspection. In [1], a micro helicopter using computer vision approaches to be able to inspect bridges is presented. In [2], authors introduced a UAV system for inspecting culverts utilizing GPS, LIDAR and IMU. The data acquired from these sensors are fused to estimate the state enabling autonomous outdoor navigation.

A methodology to monitor the changes due to corrosion damages on industrial plants by using UAV is presented [3]. Images acquired at different instances are aligned through geometric transformation to highlight the changes above a threshold which is automatically determined by assuming damages that have usually different aspects with respect to the surrounding structures. In [4], researchers demonstrated a quadrotor MAV integrated with a stereo camera configuration that can explore GPS-denied indoor environments. They validated the system by autonomous flights inside an industrial boiler.

Recently, a lot of effort is put on crack detection using UAVs. A hybrid image processing technique that estimates crack width while decreasing the loss in crack length information is reported [5]. Another approach for crack detection and mapping using UAVs is presented in [6]. However, the previous works mainly focus on either autonomous navigation or post-processing of the acquired data (i.e. defect detection) by mostly using traditional image processing techniques (as in [7] & [8]) that may fail in different lighting conditions and/or materials.

In this context, the aim of this research is to achieve autonomous navigation and revisit motion planning of UAVs to surface crack locations in order to perform automated building inspection operations since the inspections are generally periodic and requires revisiting for close examination. This revisit task planning strategy enables UAVs to autonomously navigate in different environments while proposing a decision making tool by crack detection. The major contribution of this dissertation can be stated as an implementation of autonomous building inspection considering not only the

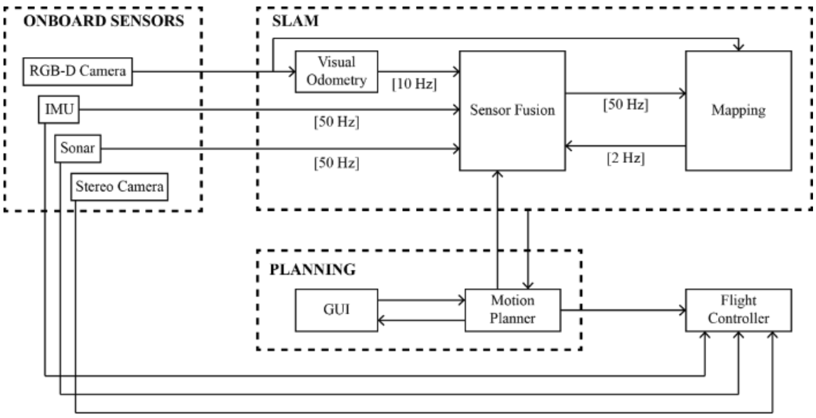

Figure 1. Schematic of the high-level system architecture

data acquisition phase but also revisiting crack locations by transfer learning.

In this regard, an autonomously navigating quadrotor UAV is developed to be able to revisit pinpoint locations. For this purpose, SLAM using onboard visual-inertial localization and mapping to explore the environment in which the UAV is located and motion planning with obstacle avoidance are applied. Transfer learning approach is used to identify surface cracks from images so that possible revisiting locations can be determined for high-level decision making during inspections. Finally, a commercial quadrotor UAV is integrated with onboard sensors and computers in order to validate and verify the methods by testing.

2 System Overview

The necessary software for autonomous navigation and crack detection is both developed and implemented from open source libraries and packages supported by the community in the scope of this study. Figure 1 presents the schema of the software architecture for the overall system. all the computations are done onboard except from GUI and image classifier which runs on a ground station computer. The developed software components for this research is open-source and available online [9].

The flight controller of the quadrotor platform [10] ensures the low-level (attitude and velocity) control of the vehicle. Modified open-source software is implemented for SLAM and motion planning strategies. RGB-D camera is the source for the visual odometry and mapping processes, and it is fused with onboard IMU and ultrasonic sensor for state estimations by an Extended Kalman Filter. Also, a CNN is employed as the image classifier for surface crack detection. It presents an optional support mechanism for task planning of revisiting locations during inspection. It is built on top of autonomous navigation capability of the UAV with a user interface.

A graphical user interface that runs on a ground station computer is developed for high-level planning of the revisiting tasks. The interface wraps the capabilities of the system and enables users to utilize it without a prior knowledge of robotics. Functional callbacks for planning, motion control and other features for visualization purposes such as live video stream are other aspects derived from this interface.

The integrated system aims autonomous navigation with onboard computations. The objectives of autonomous navigation of the UAV in GPS-denied environments are determined as follows:

1. Real-time state estimation of the UAV during flight,
2. Mapping of the environment in which the UAV operates for global localization and motion planning,
3. Motion planning with obstacle avoidance to target locations of revisiting.

In order to achieve these objectives, software is developed and implemented on top of open source software packages and algorithms presented by the robotics community through Robot Operating System (ROS) so that the software can be modular and extendable. Implementation of the software throughout this work is achieved by using ROS framework.

Attitude control is achieved by using velocity control mode of the onboard flight controller in the employed UAV. A graph-based RTAB-MAP [11] ROS node is used both for visual odometry and mapping. A RGB-D camera is integrated with the UAV for visual odometry and onboard IMU is fused with visual odometry with an Extended Kalman Filter [12] at 50 Hz.

Motion planning is achieved with an implementation of MoveIt! [13] ROS node with OMPL [14] backend. A

Universal Robot Description Format (URDF) of the UAV is constructed for collision checking. An algorithm is developed for interoperability of the motion planner and the revisit planner.

3 Revisit Planning

The proposed revisit planning workflow in Figure 3 is demonstrated step-by-step as follow:

1. Images acquired during flight are shown in the GUI for users to pick a revisiting location. Each image corresponds a location (position and orientation) in the algorithm since these images are previously linked with locations.
2. (Optional) A crack detector can step in to process images if a user aims to use the crack detection approach as a support for decision making of locations to revisit.
3. If Step-2 is fulfilled, the GUI visualizes the new cracks on a new set of images.
4. By the corresponding image, a location for revisiting is found. Then, the GUI delivers this goal to the motion planner.
5. The GUI receives an obstacle-free optimal trajectory as the form of waypoints if available.
6. For UAV to cover the path, the required velocities between the waypoints are calculated by an algorithm. In case of being successful or having no feasible motion plan, the GUI reports feedback.

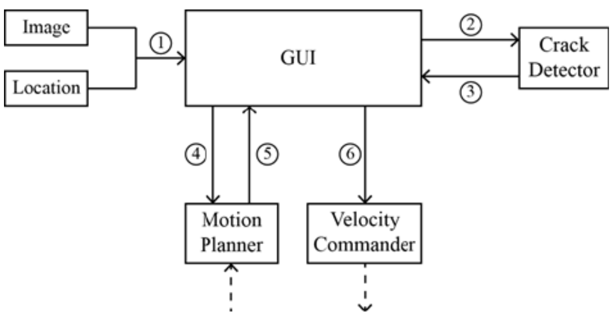

Figure 3. Workflow of the revisit planning strategy

For the step 1, Matching the images with their corresponding locations is essential for this strategy. A ROS node is developed in order to match images with poses (position and orientation) where the UAV had been visited during inspection for possible revisiting in future missions. This algorithm subscribes to both visual-inertial odometry and RGB images. Then, it matches them using Approximate Time Synchronizer message filter of ROS in a predefined period (2 Hz in this implementation). The images saved with their corresponding poses in favor of the revisit planner.

In order to provide the step 4&5, an algorithm is developed using Python interface of MoveIt!. It sends the goal to the motion planner and computes the velocities from the corresponding trajectory. It runs at the backend of the GUI.

4 Crack Detection

Crack detection is one of the most common objectives in building inspection. Increasing efficiency of visual inspection can be achieved by decreasing the time spent for post-processing on captured images during flight.

In this context, Convolutional Neural Networks (CNN) are one of the most commonly used architectures since they can overcome most of the contemporary challenges in crack detection [15]. They are getting more accurate and robust for image classification in recent years.

On the one hand, CNNs are easy to train and can be applied from open source libraries. On the other hand, training an entire CNN from scratch is not preferable for the majority because it is comparatively difficult to have a sufficient amount of data. Transfer Learning has eventually emerged. It uses a pretrained network on a large dataset (e.g. ImageNet which contains 1.2 million images with 1000 categories) as an initialization or a fixed feature extractor for the newly created network. Fine-tuning is one of the methods in Transfer Learning which is used as a complementary of CNN in this study. For working efficiently with small datasets and using a pretrained networks that assures time effectiveness, this approach becomes appropriate in the scope of this research.

4.1 Training the CNN

In this work, InceptionV3 [16] network model with ImageNet weights is fine-tuned since it has relatively high performance in top-1 validation accuracy than most of the top scoring single-model architectures (Figure 4). Keras with TensorFlow backend is used for the implementation. Graphics Processing Units are utilized in training sessions. For this purpose, a modified version of [17] is used.

In the fine-tuning of the CNN, ‘Crack’ and ‘NonCrack’ classes are designated for the image classifier. The training dataset is collected from Middle East Technical University campus buildings. It includes 582 images with cracks, and 458 images without cracks (Figure 5). Since a poor performance was observed on brick wall images in the first implementation, a group of brick wall images are added to the ‘NonCrack’ dataset in order to detect cracks on brick materials. Additionally, data augmentation function is applied to increase the number of the data for greater performance.

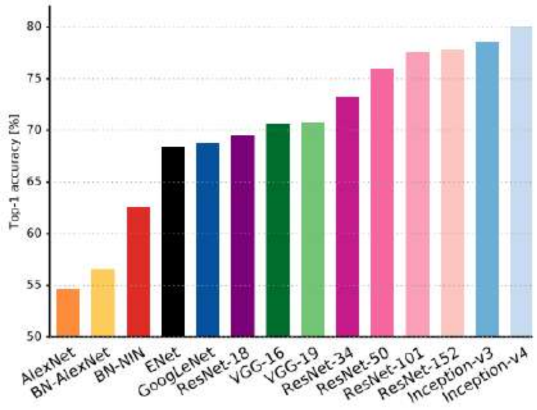

Figure 4. 13 Single-crop top-1 validation accuracies for top scoring single-model architectures [18]

The training and validation accuracies over each epoch are shown in Figure 6. After 5 epochs, the model's training accuracy jumps over 90%. After 20 epochs, the training and validation accuracies attain to approximately 98%. The training and validation losses over each epoch are shown in Figure 7. The losses converge to 0.05 after 20 epochs.

Figure 5. Sample of images used in the training ('Crack' images at left, 'NonCrack' images at right)

4.2 Cross-validation

After the training session, cross validation is done by using a different dataset in terms of image variation. The cross validation dataset consists of 64095 images. 19368 of these have surface cracks while there are no cracks in the rest. The fine-tuned model accurately predicts 62417 from the 64095 image. The accuracy is 97.382% in the cross validation. These results clearly demonstrate the convenience of using an InceptionV3 model as the backbone for transfer learning for such a crack detection application.

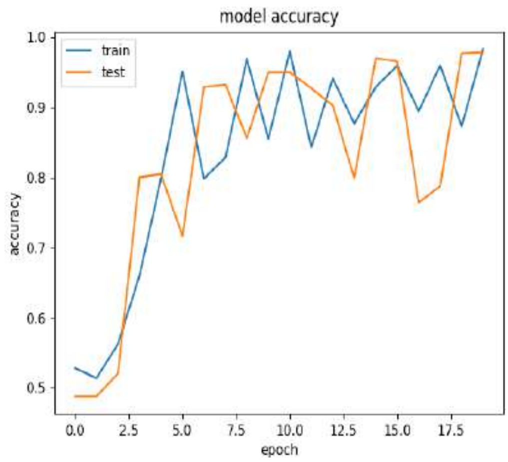

Figure 6. Accuracy vs. epoch number in the training and the validation sets

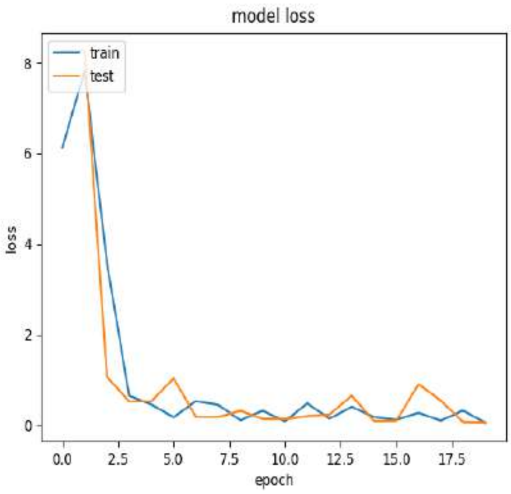

Figure 7. Loss vs. epoch number in the training and the validation sets

5 Experiments

In order to validate the system, autonomous navigation and crack detection capabilities are tested through computer simulations and real-world experiments.

5.1 Simulations

The simulations are performed in order to verify the state estimation performance of the system. For this purpose, a simulated environment is created inside Gazebo simulator. The environment is constructed to mimic an indoor space to be able to verify the performance of visual-inertial navigation of the system in GPS-denied environments. Figure 8 shows the environment used in simulations. Two connected spaces in the environment is enclosed by 3x1x3 m (height x width x length) brick walls. Another wall with relatively monotonous texture is located because identifying loop-closures is harder when repetitive patterns are present in the environment. In this way, the performance of loop closure detection is more indicative since it is a more challenging case.

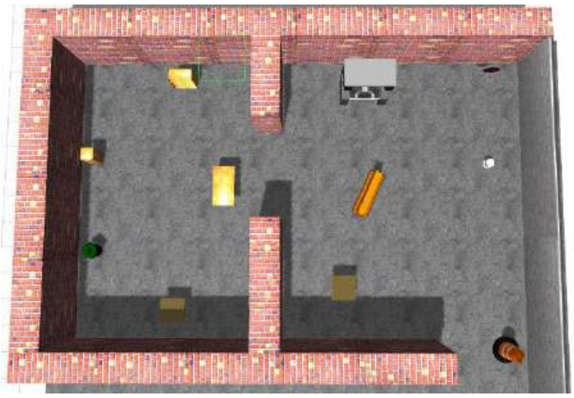

Figure 8. Indoor test environment used in the simulations

5.1.1 Mapping

After the simulation environment is established, the tests are performed to evaluate the performance of the mapping, the state estimation, and planning approaches. First, an exploration (of the environment) session is conducted by manually operating the quadrotor UAV, a 3D voxel grid map is constructed Figure 9. The performance of the mapping is assessed by comparing it with the original environment in the simulations.

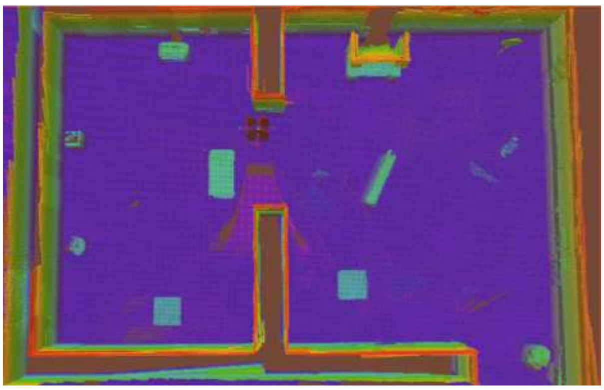

Figure 9. Reconstructed 3D voxel grid map of the environment

5.1.2 State Estimation

In order to evaluate the state estimation performance of the system, the position (global x-y-z) and orientation (yaw) estimates are compared with the corresponding ground truth values. The ground truth values are obtained from the simulation environment. Visual odometry and visual-inertial odometry results are plotted along with ground truth values (Figure 10). The estimates are closely tracking the actual measurements of the trajectory.

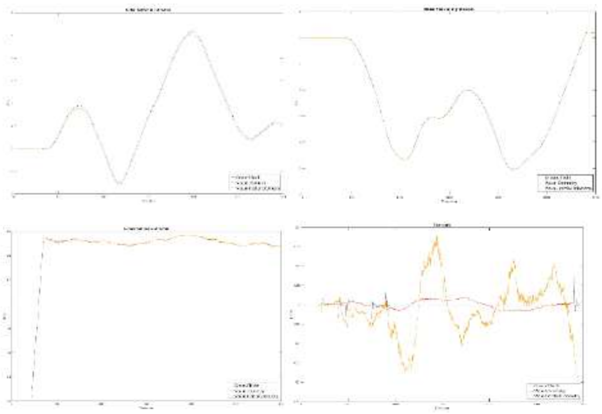

Figure 10. Ground truth vs. Visual-inertial estimations (x-direction at top-left, y-direction at top-right, z-direction at bottom-left, yaw degree at bottom-right)

The maximum deviations (errors) in state estimates are presented in Table 1 in order to comprehend the results in a clearer way. It can be observed that visual-inertial odometry has superior performance than visual odometry as expected. Although the maximum deviations in the x, y and z direction are close to each other, the errors in the yaw angle are slightly dramatic compared to them. This expected behavior shows the importance of fusing inertial measurements with visual odometry since yaw angle of IMUs are generally prone to have error due to the fact that the gravity measured by accelerometers cannot be used to help to estimate it [19]. The values in the table show that the maximum error along the estimated trajectory is in the order of 0.1 m. This value is negligible relative to the building scale so, the performance of the state estimation can be evaluated as sufficient in terms of building inspection.

Table 1. Maximum deviations in the state estimation

	Visual Odometry Max. Deviation	**Visual-Inertial Odometry Max. Deviation**
Global x-direction	0.146157219 m	0.145886557 m
Global y-direction	0.064824391 m	0.052191800 m
Global z-direction	0.058057038 m	0.054663238 m
Yaw Angle	0.23723990 rad	0.02274868 rad

5.2 Indoor Experiment

The second test case is conducted indoor to be able to verify the fully integrated system. After verifying the state estimation and mapping performances in simulations, experiments are performed in a GPS-denied environment for evaluation of the integrated system. The experiments are conducted in the workshop of Design Factory in Middle East Technical University that can be seen in Figure 10.

Figure 11. Indoor experimentation environment

5.2.1 Hardware

In real-world tests, hardware of the system is composed of five components which are an aerial platform, an onboard visual sensing system, a RGB-D camera and an onboard computer. As the aerial platform, DJI Matrice 100 [10] is employed. It is a vertical take-off and landing (VTOL) quadrotor vehicle with reconfigurable hardware installation capability. Matrice 100 is used since it meets the requirements of this research by having onboard low-level flight controller that handles attitude control.

For the onboard visual sensing system, five units of low resolution stereo camera and one processor named Guidance [20] are implemented. Guidance is compatible with the flight controller of the aerial platform, and it fuses stereo camera data for real-time obstacle avoidance in this work.

As the onboard RGB-D sensor, a widely used and open sourced hardware, Microsoft Kinect v1 is used. Having served for the purpose of mapping and localization, it has an RGB camera and infrared depth camera with 43° vertical by 57° horizontal field of view at 30 frames per second.

As the onboard computer of the system, DJI Manifold that has a quad-core, 4-plus-1 ARM processor, NVIDIA Kepler-based GeForce graphics processor, 2GB memory with customized version of Ubuntu 14.04LTS is preferred. Besides, it has a wireless connection chips and antennas for communication purposes.

Figure 12. Integrated quadrotor UAV used in this work

5.2.2 Revisiting a Defected Location

The first phase of this test case is the mapping phase. A low resolution point cloud representation is presented in Figure 13. The environment is partially mapped since it is sufficient for the evaluation of the system. For mapping of the environment, the UAV is covered a trajectory (blue marker in Figure 13). The trajectory contains overlapping positions so that loop closures can be detected.

The test case is demonstration of a revisiting task. For this purpose, the images acquired during the mapping phase are processed with the image classifier developed to detect cracks on walls of the environment.

The algorithm that is developed for matching the images with their corresponding locations acquires 20 images (Figure 14) in the mapping phase. 13 of these images are replaced with images that contain cracks (Figure 15) since there are no surface cracks available in the test environment. The registered locations (positions) are kept same as in mapping but only the images are changed. In this way, the developed task planning pipeline as well as the crack detection approach can be tested.

Then, these 20 images are fed into the CNN in order to identify the cracks. After processing, the CNN classifies 16 of the images as cracks although it should be 13. Several other elements such as windows and radiator mislead the CNN as in the extra 3 images. The other 13 images are those which have cracks. Thus, it can be stated that the crack detection application gives sufficient performance as a decision support tool.

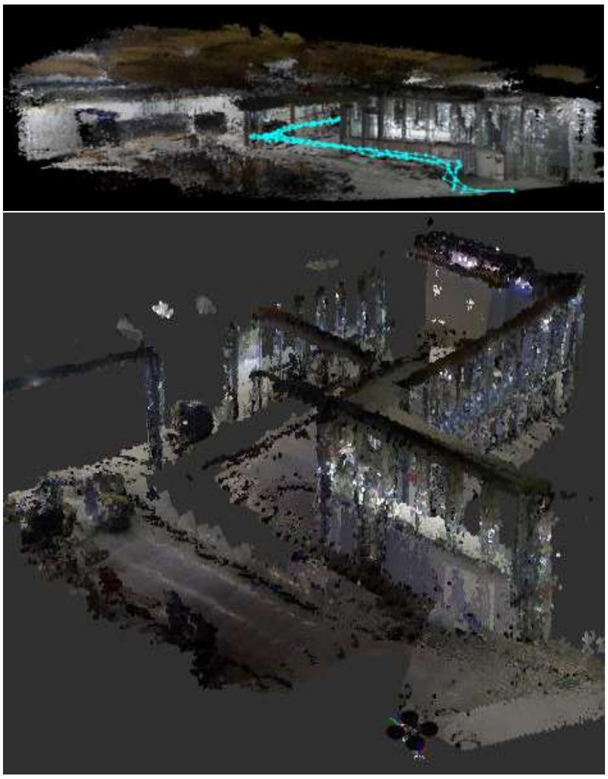

Figure 13. Reconstructed maps of the environment

Figure 14. Sample images acquired during the mapping session

Figure 15. Sample crack images that are replaced with the acquired images

5.2.3 Motion Planning

After the crack detection, one of these crack images that corresponds to a specified location that is selected as the goal position for revisiting. The goal position is selected so that the most complicated motion plan should be achieved in the environment. Thus, the distance between the start and the goal positions is set to be as long as possible in the map. Moreover, the walls and the windows exist between them as obstacles so that the UAV should takeoff and move around the junction of the two walls for obstacle avoidance during motion.

Path planning algorithms that are available in MoveIt! are tested for the motion planning problem between start and goal positions. PRM*, RRT and RRT* algorithms compute solutions while EST, SPL, LBKPIECE, PRM, BKPIECE algorithms are not able to solve the problem. The reason is possibly the sampling strategies of these algorithms. They might not be able to sample the workspace such that the start and the goal positions are covered for a complete solution. The solution of the PRM* algorithm (Figure 16) is not acceptable in terms of both the optimality and the motion constraints since it requires large roll degrees in the motion that may cause overturn. The trajectory planned by RRT (Figure 16) has a sudden jump in the motion which is not possible for the UAV to execute. On the other hand, RRT* computes a trajectory (Figure 16) that satisfies criteria for motion planning. The trajectory is collision-free and smooth as well as optimal in terms of length. Therefore, the motion planner is set to use RRT* as the main algorithm in the motion plans. After the motion is planned, the UAV can be sent to the goal location for revisiting the crack location.

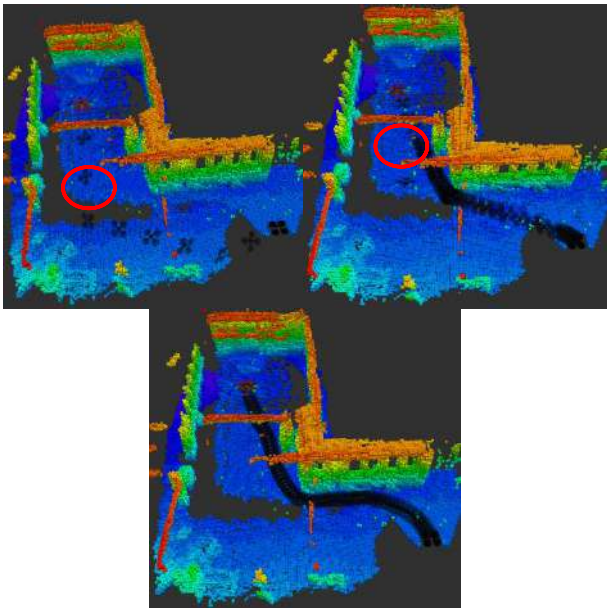

Figure 16. Motion plans (PRM* at top-left, RRT at top-right, RRT* at bottom) Red circles show the motions that violate the planning objectives

6 Conclusion

In this work, an integrated system that enables revisiting crack locations during building inspections by means of a quadrotor UAV is presented. Autonomous navigation of the UAV in GPS-denied environments is achieved by integrating and developing open source software. A task planning strategy is developed in order to revisit defected locations. Transfer learning is used for surface crack detection. Simulations and indoor experiments are conducted for the system verification.

The major contribution of this work can be stated as a application for building inspection by autonomous UAVs considering not only the data acquisition (mapping) phase but also the subsequent close examination (revisiting) of crack locations that are identified by a CNN. Future work will focus on improvements of crack detection on different materials and of crack properties.

Abstract –

Construction in the water is currently under way using an underwater excavator. The underwater excavator is operated by a diver. To reduce the burden on the diver, remote controlled system of underwater excavator is developed, but the current system has poor operability to use. The purpose of this study is to improve operability of remote controlled underwater heavy machine. We considered and proposed the working field condition feedback methods to the remote controlled underwater excavator operator for improving the operability. The methods were evaluated through simulation experiments.

Keywords –

Underwater excavator; Unmanned construction; Teleoperation; Operating Support; Instructions; Input Device

1 Introduction

An underwater excavator is used for constructions in harbors and dams. The underwater excavator is shown in Figure 1. It is remodeled from the land one by reloading the diesel engine to the underwater motor and hydraulic pump, and it can work underwater environment. In the underwater constructions, the excavator is operated by divers riding on it like Figure 2. So, the divers must operate it in the water for a long time. Therefore, remote controlled construction machines are needed for underwater constructions to reduce their burden, and remote controlled underwater excavators and their control systems were developed.

Figure 1. An underwater excavator [1]

Figure 2. An excavator operated by a diver [1]

In the underwater construction using current remote controlled excavator, the operator can get working field conditions only from camera images. The visibility is poor and it is insufficient for the operator to operate the excavator smoothly.

Therefore, operability of the remote control system for underwater excavators should be improved and some improvement methods were proposed [1]. However, the previously proposed remote control system has complex interfaces for showing the environment around the underwater excavator, and its operability improvement is still insufficient.

Then in this study, we propose a simple but efficient method for improving the operability of remote control system for underwater construction machines using vibration of operation lever.

In chapter 2, we analyze the cause of the insufficient operability in the underwater excavator operation. In chapter 3, we propose the simple but efficient working field condition feedback methods to the remote controlled underwater excavator operator. In chapter 4, we evaluated the operability of the proposed methods described in chapter 3 by using our developed simple simulator. In chapter 5, we conclude our study described up to chapter 4.

2 Considering about insufficient operability of underwater excavator

When the diver riding on the underwater excavator operates it, the diver relies on his seeing view, feeling shake of the excavator and hearing sounds. In the water, the diver sometimes cannot see his working field situation because of the rising clouds of dust by the excavator. In this case, the diver must operate the excavator only relying the shake and sounds. This state is shown in Figure 3.

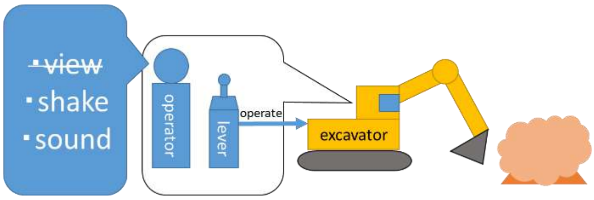

Figure 3. Excavator operated by a diver in the water

Current remote control system has some cameras on the excavator and the working field images are displayed to the operator. But, the operator cannot feel the vibration and sound of the excavator. Additionally, in the underwater work, operators cannot see the field condition when the clouds of dust soar by the operation of the excavator. Then, in the current system, operators cannot rely on not only the vibration and sounds of the excavator but also displayed images of the working field. Therefore, operators cannot operate excavators until the clouds of dust disappear. This state is shown in Figure 4.

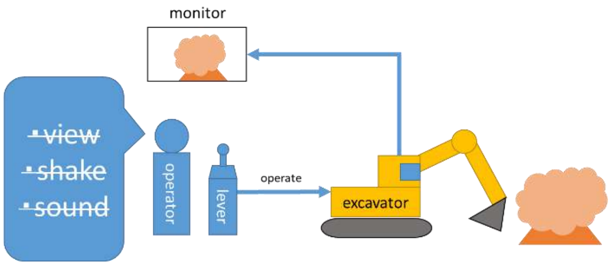

Figure 4. Excavator operated by remote control system from the operation room

3 Considering and proposal of the field condition feedback methods

This study proposes working field condition feedback methods to improve the operability for the remote controlled underwater excavator operators. Necessary information for the excavator remote control was revealed by the interview to the operators who often operate underwater excavators using remote control system. The necessary information is:

- The moment when the excavator starts moving
- The moment when the excavator hits some obstacles
- Whether the excavator reached its moving limits

In the current remote control system, some sensors are attached to the excavator, and their sensor values are sent to the operation monitors and displayed. We considered more intuitive methods are necessary to inform the working field conditions to the operators than using a display monitor. Then, we considered 3 different methods for informing the excavator conditions to the operator based on the sensor values. The methods are as follows:

- Make sounds of different types and patterns for expressing sensor values of the excavator and inform them to the operator
- Move the seat of the operator depend on the sensor values of the excavator
- Apply reaction force or vibration to the control lever of the excavator controller depend on the sensor values of the excavator.

About the first method, some current systems have a function which presents the sounds of working field picked up by a microphone on the excavator. However, further information like presenting many sounds during excavator operation may confuse the operator. About the second method, the already developed system exists [2]. It is shown in Figure 5. Although this system is effective for informing working conditions to the operator directly, it may increase the operator’s burden. Therefore, we considered that the third method, moving control lever depend on sensor values, is the most suitable for informing working conditions to the operator, then we adopted it for our study.

Figure 5. Moving operation seat for the remote control system [2]

We considered 3 methods to move control lever of the excavator controller for showing the sensor values of the excavator and informing working conditions to the operator. The methods are as follows:

- Applying reaction force to the control lever of the excavator controller depend on the sensor values.
- Applying breaking force to the control lever of the excavator controller depend on the sensor values.
- Vibrating the control lever of the excavator controller depend on the sensor values.

The first method was applied to the tele-operated support system of underwater excavator and confirmed that this method is good for tele-operated system when the operator cannot see the surroundings of the excavator [3]. The developed system is shown in Figure 6. Although this method is effective for informing working conditions to the operator when the operator cannot see the surroundings of the excavator, sometimes the operation may become unstable due to the delay of the feedback signal. The second method also seems effective for informing working conditions of the excavator to the operator. But, this is a passive method because breaking force acts only when the operator moves the control lever. Furthermore, the first and second methods may interfere when they are applied to the control lever at the same time. Then, we decided to adopt the third method which is vibrating the control lever depend on the sensor values.

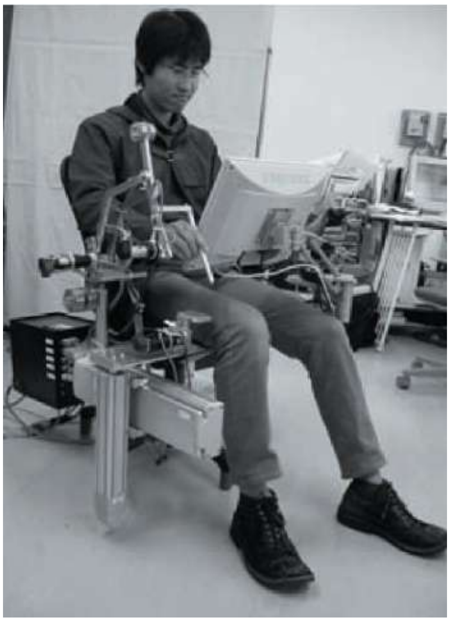

Figure 6. The operation system with force feedback controller [3]

We considered what kinds of vibration patterns of the control lever are good for operators to inform the condition of the excavator, and we proposed some vibration patterns shown in Table 1, Table 2 and Table 3. The proposed vibration patterns shown in Table 1 are for the information to the operator when the excavator starts moving. The vibration patterns in Table 2 are for the information when the excavator hits some obstacles. The vibration patterns in Table 3 are for the information whether the excavator reached its moving limits.

Table 1. Proposed vibration patterns which inform to the operator when the excavator starts moving

Method	Good point	Output
Vibrate only when the excavator starts moving	Can understand the moment when the excavator starts moving	Binary value
Vibrate while the excavator is moving	Can understand the excavator is moving or not	Binary value
Vibrate variably based on the moving speed of the excavator	Can understand the moving speed of the excavator	Analog value

Table 2. Proposed vibration patterns which inform to the operator when the excavator hits some obstacles

Method	Good point	Output
Vibrate while the excavator is loaded	Can understand the excavator is contacting something or not	Binary value
Vibrate variably based on the load of the excavator	Can understand the exerted load to the excavator	Analog value

Table 3. Proposed vibration patterns which inform to the operator whether the excavator reached its moving limits

Method	Good point	Output
Vibrate when the operator tries to move the excavator beyond moving limit	Can understand when the operator tries to move the excavator beyond the moving limit	Binary value
Vibrate variably based on the distance to the moving limit of the excavator	Can understand the distance to the moving limit of the excavator	Analog value

For informing the change of above three excavator conditions to the operator for the excavator remote control, we proposed two types of control lever vibration patterns. One is a constant vibration pattern, and another is a variably vibration pattern. The constant vibration pattern is proposed to detect the moment of condition change when the excavator starts moving or contacts something, etc. And, the variably vibration pattern is proposed to recognize the continuous condition change while the excavator is moving or receiving loads, etc. We evaluated these two types of patters through experiments using a simulator in the next chapter.

4 Evaluation of the proposed condition feedback methods

4.1 Evaluation system and method

We revealed three necessary information for the excavator remote control from the interview of skilled underwater excavator operators, and we proposed 7 vibration patterns of the control lever for informing the condition of the excavator to the operators.

To evaluate the proposed vibration patterns shown in the previous chapter, we developed a simple simulator system and made some experiments.

From the constraints of our experimental system, we evaluated the selected 4 vibration patterns of the control lever for informing the change of excavator conditions to the operator based on the sensor values shown in Table 4.

Table 4. Evaluated vibration patterns by our simple simulator system

Pattern number	Vibration pattern
1	The control lever vibrates while the excavator is moving. *The strength of the vibration changes according to the moving speed.
2	The control lever vibrates only when the excavator starts moving. *The vibration time is 0.2 sec.
3	The control lever vibrates while the excavator is loaded due to the contact of bucket and soil. *The strength of the vibration changes according to the exerted load.
4	The control lever vibrates when the operator tries to move the excavator beyond moving limit. *The vibration continues while the operator tries to move.

We made experiments to evaluate the above proposed 4 vibration patterns of the control lever. A joystick controller with vibration function and our developed simple simulator were used for the experiments. Figure 7 shows the joystick controller and its specifications are shown in Table 5. Our developed simulator is shown in Figure 8.

Figure 7. Joystick controller “PXN Thunder PRO”

Table 5. Specifications of the joystick controller [4]

Product name	PXN Thunder PRO
Model	PXN-2113
Connection	USB cable
Working current	100mA
Dimensions	22.5 x 18.5 x 18.5cm
Product Weight	About 495g

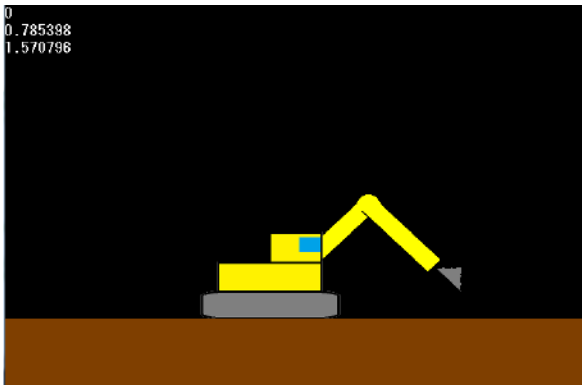

Figure 8. Simulator for the experiments

The simulator was composed of the joystick controller, a computer and a monitor. The connection of these equipment is shown in Figure 9. The computer receives a signal of tilt angle of the joystick controller and sends a signal of strength of the vibration. The monitor displays an image of the excavator like Figure 8. In the simulator, a boom of the excavator moves when the joystick controller is tilted to back or forth, and a bucket of the excavator moves when the joystick controller is tilted to left or right.

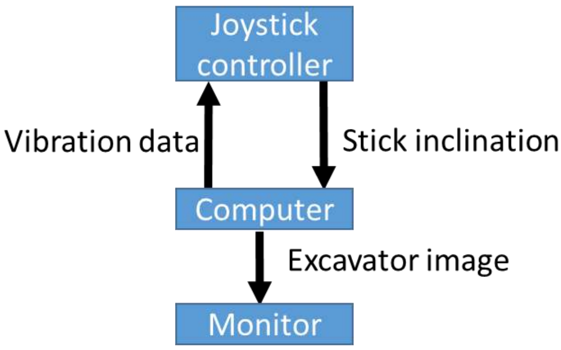

Figure 9. Equipment connection of the simulator

About the vibration pattern 1 in Table 4, the excavator in the simulator moves by tilting the joystick controller, and the moving speed of the excavator changes according to the tilt angle of the joystick controller. The joystick controller vibrates while the excavator is moving, and its vibration strength changes according to the excavator's moving speed. About the vibration pattern 2 in Table 4, the joystick controller vibrates for 0.2 sec. when the excavator starts moving by tilting the joystick controller. About the vibration pattern 3 in Table 4, when the contact of bucket and soil occurs in the simulator while the excavator is moving, the joystick controller vibrates for informing it. The strength of the joystick controller vibration shows the strength of the load exerted to the excavator bucket. About the vibration pattern 4 in Table 4, when the operator tries to move the bucket and the boom of the excavator beyond moving limit in the simulator, the joystick controller vibrates for informing it. The vibration continues until the operator stops moving the excavator to that direction.

Some subjects experienced all vibration patterns by using the simulator. After that, the subjects answered the questions about the impressions of each pattern. The questions are as follows:

- Which vibration pattern was good for operating the excavator?
- How did you feel about using these patterns?

4.2 Evaluation Results by subjects who have no experience operating excavators

Two subjects who don't have experiences operating excavators participated in the experiments. Both subjects answered that the vibration of the joystick controller to inform the collision of the excavator bucket to some obstacles is most useful for recognizing the working field conditions. And, one subject answered that the vibration of the joystick controller during excavator's moving is useful too. The answers of all subjects are shown in Table 6.

Table 6. Evaluation results by the subjects who don't have experiences operating excavators

Vibration pattern number	Evaluation
3	Easy to understand the collision of the excavator bucket to some obstacles, intuitively.
1 and 3	Good for recognizing the excavator and its working field conditions

4.3 Evaluation Results by subjects who have experiences operating excavators

Four subjects who have experiences operating excavators participated in the experiments. All subjects answered that the vibration of the joystick controller to inform the excavator's moving condition is more useful than the vibration which informs the start of moving of the excavator. The answers of all subjects are shown in Table 7.

Table 7. Evaluation results by the subjects who have experiences operating excavators

Vibration pattern number	Evaluation
1 and 3	Good for recognizing the excavator and its working field conditions
1	Vibration pattern 1: Vibration during the movement of the excavator is OK. Vibration pattern 2: It is difficult to understand the excavator's condition only from the vibration which informs the movement start of the excavator. Vibration pattern 3: It is difficult to understand the vibration's differences.
1 and 3	The system should have two different strength of vibration patterns which are strong and weak.
1, 3 and 4	Combining the vibration pattern 1 and 4 will inform us the posture of the excavator. The system should have different types of vibration patterns for presenting different information at the same time.

5 Conclusion

A remote controlled underwater construction machine was developed to reduce the operator's burden. However, current developed system has insufficient operability. This paper revealed the cause of operator's burdens for the operation of the excavator. Furthermore, more intuitive methods to inform the working field conditions to the operators than using a display monitor are considered. And, we proposed the simple but efficient working field condition feedback methods which uses the vibration of the control lever of the excavator for the remote controlled underwater excavator operator.

We considered three necessary information for the excavator remote control, and proposed 7 vibration patterns of the control lever for informing the change of excavator conditions to the operator based on the sensor values. Four different vibration patterns of the control lever were implemented to the simulator and they were evaluated through experiments.

From the results of evaluation experiments, we found that the vibration of the control lever to inform the excavator's moving condition is more useful than the vibration which informs the start of moving of the excavator for all operators. And, the vibration of the control lever to inform the collision of the excavator bucket to some obstacles is useful for recognizing the working field conditions around the excavator for non-skilled operators.

Our study will improve the operability of remote control system for construction machines. In future work, we will evaluate more vibration patterns and some combined vibration patterns using different types of vibration patterns through simulator and actual system experiments. In addition, further study about applying other kinds of feedback methods to the construction machines will be evaluated for the improvement of the system operability.

Abstract

To progress the automated inspection and maintenance of inner wall of tunnel, the advanced inspection system with restricting the traffic regulation was developed. In this inspection system, the guide frame along tunnel wall was installed on the protection unit stepped over the road like gantry crane. The inspection device moved with stability by adopting the guide frame, and the inspection accuracy could be improved. However, when this unit moved along the tunnel, this guide frame should avoid the convex obstacles such as duct fan, lamp and several road traffic sign in the tunnel. Therefore, by composing the entire frame of VGT (Variable geometry Truss), the shape of guide frame was changed flexibly and it could be passed in the tunnel. As a shape control of the guide frame, the inverse analysis method and mathematical interpolation method were applied. The angle of each frame was reversely analysed according to the shape of the obstacle measured with the LMS (Laser Range Finder), and the actuator of the frame was controlled simultaneously. We investigated the construction of a system that can perform a series of tasks such as searching for obstacles and positioning, frame shape simulation, frame shape change, inspection device movement. In this paper, the outline of tunnel wall inspection applied variable guide frame, the structure principle of the guide frame, basic method of shape analysis, the finding of convex obstacles by LMS and the whole inspection system are explained in detail.

1 Introduction

Most of infrastructures for civil engineering structures such as highway roads, bridges, tunnels constructed around the urban region in high-growth era of 1970-1990 begun to reach the life, and it has been the time when large-scale repair and renewal, rebuilding were demanded. Since these structures are difficult to renovate after completion, it is necessary to grasp the progress of deterioration by periodic inspection and to maintain and manage such as repair and renewal on future prediction. Especially, with the collapse accident of the high way tunnel generated some time ago in Japan, the inspection of the superannuated tunnel was requested.

Generally, in the periodic inspection of the road tunnel, by restricting the traffic regulation and the engineers detected the deteriorated wall parts by sighting and hammering sound. To progress the automated inspection and maintenance of inner wall of tunnel, some advanced methods were adopted in the SIP program in Japan of the theme of "Maintenance and management robot". In our proposal of this theme, the inspection system was developed applying the variable guide frame to evade the obstacle in the tunnel without restriction of the traffic regulation as indicating in Fig. 1. In this inspection system, this guide frame was installed on the protection frame with travelling unit. When this unit moved along the tunnel, the guide frame should avoid the obstacles such as traffic plate and lamp in the tunnel. The shape of this frame changing flexibly, the frame was able to pass these obstacles in the tunnel easily [1], [2].

However, since the shape and position of the obstacle on the inner wall of the tunnel are different, it is necessary to change the shape of the guide frame according to each obstacle. In this study, we show the measurement method of the obstacle by the laser sensor and the result and specified the position and shape of the obstacle. As a method of measuring obstacles using laser, we can refer to automatic measurement technology [3], [4], 3-D scanning system [5], [6], [7], tunnel surveying system [8], [9]. On the other hand, as the determination of the guide frame shape, inverse kinematics of the robot mechanism, Spline interpolation which is a mathematical method were applied, assuming that both ends of the guide frame are fixed. By integrating such a series of measurement, analysis and control, it is possible to operate an efficient guide frame.

In this paper, the outline of tunnel wall inspection applied variable guide frame, basic method of shape analysis, the finding of convex obstacles and the whole inspection system are explained in detail.

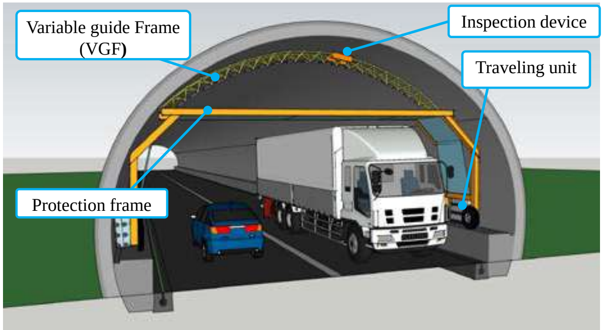

Fig. 1 Variable Guide Frame Vehicle for Inspection of Tunnel

2 Obstacles Detection in Tunnel

Since the positions and shapes of the various obstacles existing in the tunnel are described on the construction drawing of the tunnel, it is possible to change the shape of the frame so as to avoid obstacles. However, the guide frame being on the based truck, it is necessary to accurately measure the relative distance between the based truck and the obstacle. Also, because the movement error of the based truck is actually included, the obstacle search was carried out on the based truck at the site. In this chapter, Stereo measurement system, analysis method of the shape and position of the obstacle, and its measurement results were verified.

2.1 Stereo Measurement System Using Laser Rang Finder

As the base truck on which the guide frame is installed moves along the inner wall of the tunnel, obstacles protruding from the inner wall near the ceiling may come into contact with the guide frame. Here, as shown in Fig.2, two kind of the LRF was installed at the center of the truck beam surface part. LMS-1 is used to measure obstacles of short distance (6 m or less) with high accuracy, and LMS-2 is used to measure the whole area including obstacles at long distances (30 m or less), as shown in Fig. 3. The specification of LRF-1 and LRF-2 are indicated in Table 1.

We connected the LRF to the pan unit and constructed the stereo measurement system giving its inclination angle θ_2 to the plane measurement area angle θ_1 of LRF as indicated in Fig. 4-(a). In this case, if the distance to an obstacle measured by the reflection time of the laser is l, its coordinates (x, y, z) can be expressed by Eq. (1) - (3).

$$x = l \cdot \cos\theta_2 \cdot \cos\theta_1 \quad (1)$$

$$y = l \cdot \cos\theta_2 \cdot \sin\theta_1 \quad (2)$$

$$z = l \cdot \sin\theta_2 \quad (3)$$

The range of measurement is 30[m], the scan time rate is 25[ms] and the resolution angle of rotating laser is 0.25

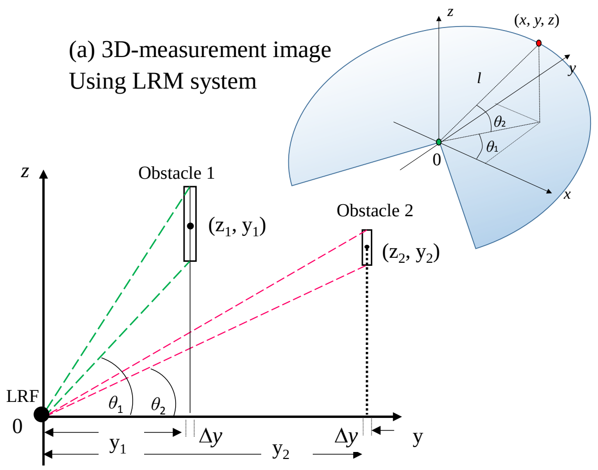
Type	LMS-1	LMS-2
Model Number	UTM-30LX	SICK-LMS511
Light Source	l=870 nm	l=870 nm
Measureable Area	270 deg	190 deg
Accuracy	10-30 mm	25-50 mm
Angular Resolution	0.25 deg	0.166 or 0.25 deg
Scantime	25 ms	10-11.3 ms
Pan unit resolution	0.5 deg	0.5 deg



(b) Objects analysis in x-z coordinate by LRF

Fig.4 Structure of based truck and install of LRF on the truck

[deg]. The angular resolution of pan unit was 1.0 deg. at $\theta_2 \leqslant$ 10 deg. and was 0.5 deg at θ_2 > 10 deg, the measurement precision was increased as it approached the tunnel inner wall. In an actual measurement, the laser irradiated from LRF is reflected to the outer side of the object, and the distances on each object surface were measured from the principle of TOF (Time of flight).

As shown in Fig. 4-(b), to ascertain the cross-sectional shape of the obstacle ahead from the based truck, the laser reflection points existing at the interval of ⊿y (= about 100 mm) with respect to the distance y from the based truck are counted. Then, it estimated that there is an obstacle in a certain y portion where the reflection points are strongly concentrated.

2.2 Position Analysis Method of Obstacles

In order to determine the position of the obstacle in the cross-sectional of tunnel, the center position of the obstacle was analyzed assuming that the shape of the obstacle was a circle from the contour of the point group. By assuming that the obstacle was circular even if it was rectangular, the contour of the obstacle was estimated on the safe side.

Fig. 5 shows the analysis flow for estimating the position and shape of the obstacle.

①: First of all, scanned the inside of the tunnel with LRF and derived and recorded the laser reflection point. However, since the laser reflection points from the inner wall of the tunnel were geometrically known, their reflection points were deleted. As a result, the shape of the obstacle ahead of the truck was extracted.

②: We classified the start position and the end position where the laser reflection point of the obstacle was recorded and extracted the edge of the obstacle.

③: The center position of the circle was estimated using the Constant Distance Method (CDM) [10] and the Least Squares Method (LSM) [11], assuming that the point group constituting the edge was an arc of a circle.

④: Finally, we confirmed the range that the shape change of the guide frame avoids with an extra margin against obstacles.

By repeating the above process, the shape and forward position of the obstacle to be avoided by the guide frame are determined [12].

2.3 Measurement Result of Obstacle

2.3.1 Short Distance Measurement by LRF-1

In short distance measurement using LRF-1, it is necessary to determine the position with an obstacle with high accuracy. Using the real simulated tunnel constructed for the experiment, the obstacles attached to the inner wall of tunnel was measured by LRF-1. Fig. 6 shows the state of the obstacle measured. In the x - y

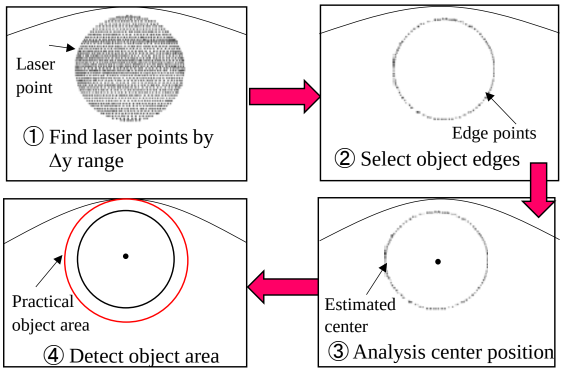


Fig.5 Analysis flow for estimating the position and shape of the obstacle by 3-D Laser Range Finder

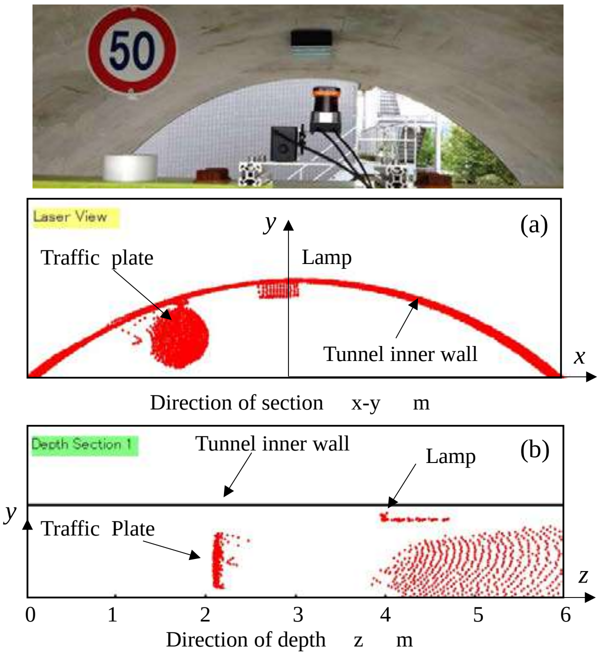

Fig.6 Obstacles state and positions measured by LRF

plane (Fig. 6- (a)), the shape including the traffic signs and the contours of the ceiling lamp in the tunnel is better captured by comparing to the actual picture. In the depth direction z-y plane (Fig.6- (b)), the position of traffic plate and the lamp could be estimated from the portion where the reflection points of the laser are densely concentrated, and it was confirmed that the position was also nearly accurate. In the calculated center position based on the obstacle data in the x - y plane was described in reference [13].

2.3.2 Long Distance Measurement by LRF-2

In order to confirm the long distance measurement using LMS-2, the obstacle was searched using actual tunnel. The radius of the tunnel was about 6 m, and the measuring instrument (LRF-2) was installed at a point of 90 degrees from the horizontal plane was performed at a resolution angle of 0.5 degrees, and the laser reflection distance in the tunnel was acquired. Fig. 7 shows the measurement situation in the tunnel. The lamp protrudes at regular intervals on the side of the ceiling surface of the tunnel, which is expected to become an obstacle when passing through the guide frame. Fig. 8 shows the measurement situation of the obstacle on the x-y plane seen in the entire cross section of the tunnel. When observing on the x-y plane, the obstacles overlap, so it is difficult to determine the exact shape of each obstacle.

On the other hand, the position of the obstacle was analyzed in the depth direction (z axis direction) of the tunnel. Fig.9 shows the shape (y axis direction) of the obstacle with respect to the depth position. Also, it shows the shape of the obstacle in the tunnel cross section with respect to positions ① to ④ where the obstacle was detected. It was confirmed that the lighting at the tunnel ceiling (①, ③, ④was located at regular intervals. As the depth distance became longer, the reflection point spacing of the laser expanded, and the shape of the obstacle became unclear. However, the existence of rough obstacles could each be confirmed. Also, as can be seen in the cross section of ②, obstacles (duct pipe) of a

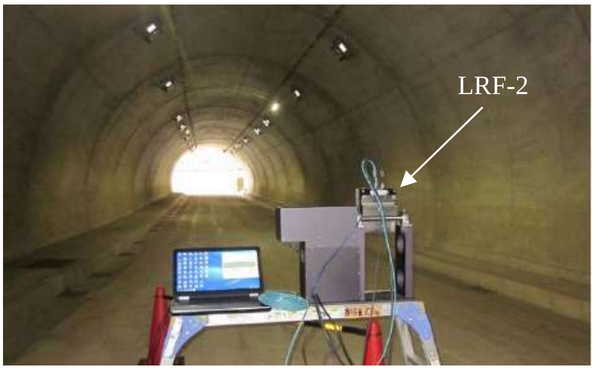

Fig.7 Measurement situation by LRF-2 in the tunnel

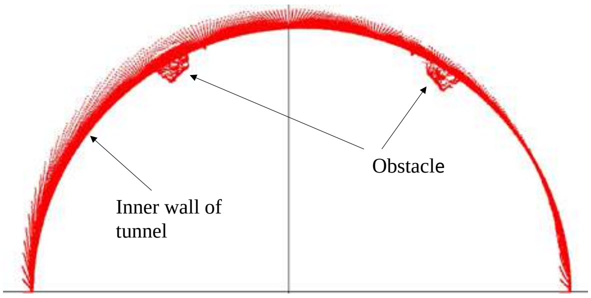

Fig.8 Measurement and shape of obstacles on x-y plane seen in all cross section

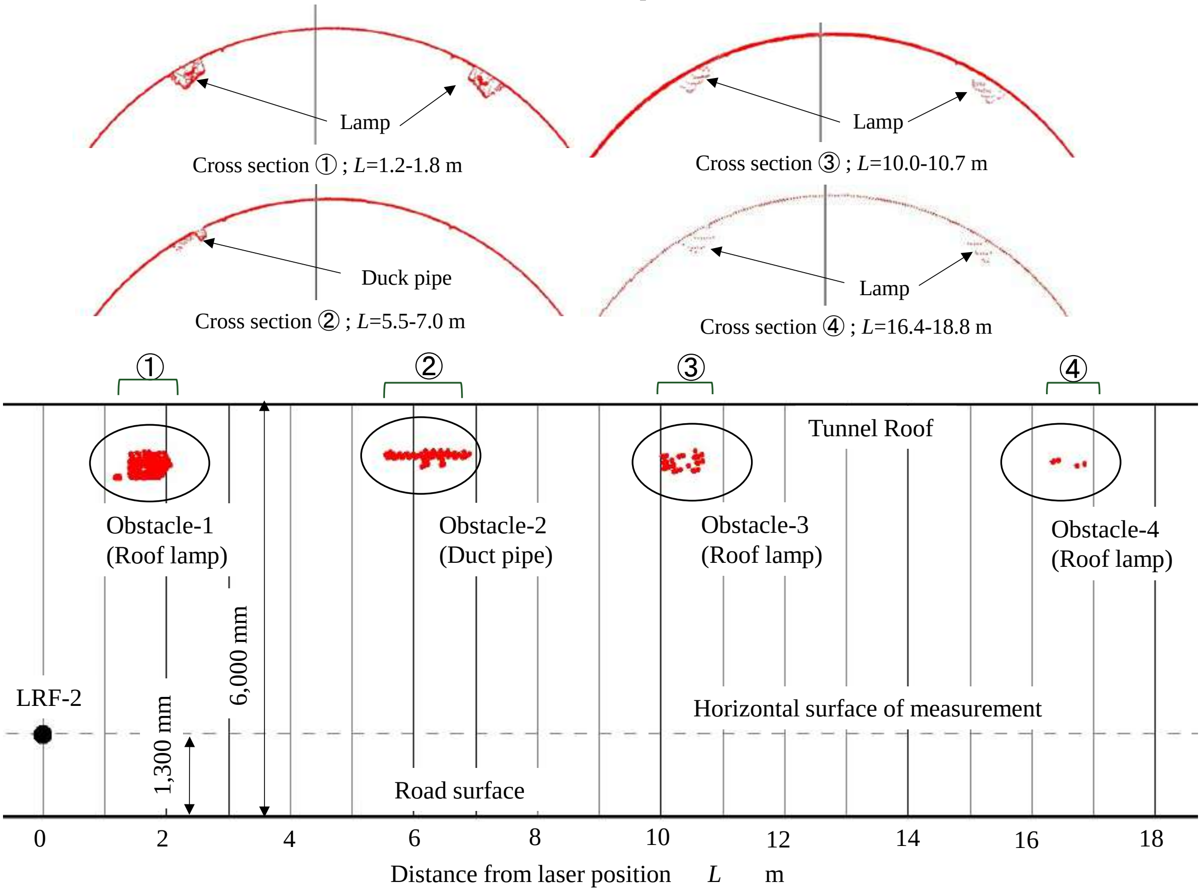

Fig.9 Shape (y axis direction) of the obstacle with respect to the depth position (z axis direction)

shape could be sufficiently confirmed

As described above, by combining the two LRFs methods, it was possible to detect the approximate position and shape of the obstacle at a long distance, and the accurate position and shape at short distance.

3 . Shape Control of Variable Guide Frame

In chapter 3, in order to create a complicated frame shape avoiding any obstacle on the ceiling surface of the tunnel, we simulated the shape of the guide frame by mathematical method and verified the possibility using real guide frame.

3.1 Frame Analysis by Kinematics

As analysing the arch structure composed of VGT, the whole of guide frame was assumed to be a cantilever structure as indicated in Fig.10-(a). The frame can replace a robot manipulator combining two fixed-length members in series. When the supported edge of frame was $q(x_0, y_0)$, the top $q(x, y)$ of the x, y co-ordinates of the frame combined with n (n≧2) VGT sets was given by Eq. (4) and Eq.(5) using each hinge angle θ_j.(j=1, 2, 3, · ·n),

$$q(x,n) = l_0 \cdot \sum_{k=1}^{n} \cos\left\{\sum_{j=1}^{k} \theta_j\right\} \quad (4)$$

$$q(y,n) = l_0 \cdot \sum_{k=1}^{n} \sin\left\{\sum_{j=1}^{k} \theta_j\right\} \quad (5)$$

Where, l_0 was the length of diagonal member of the frame. To transform the shape of arch frame, some hinge positions on the frame only had to change in proportion to target shape. However, for an intended frame shape fixed by equations (4) and (5), it was quite difficult to solve these equations analytically and to decide the angle because the frame was a very highly redundant. In this case, inverse kinematics analysis was applied [14], [15].

Introducing an inverse analysis to avoid the obstacle, first of all, a virtual obstacle was positioned on the perpendicular line of the obstacle as shown in Fig10-(a). The position of a virtual obstacle was gradually lowered, and the frame shape was changed so that surroundings of the obstacle should not come in contact with the frame. As showing the Fig.10-(b) and (c), the arch frame was indicated to change like avoiding the obstacle. Finally, a virtual obstacle came in succession at the position of a real obstacle, and the shape of a final arch frame was decided.

Fig.11 shows the result of experiment in actual model tunnel using variable guide frame. With the real arch frame of 6 m in length, similar shape was able to be also achieved by referring to the simulation result.

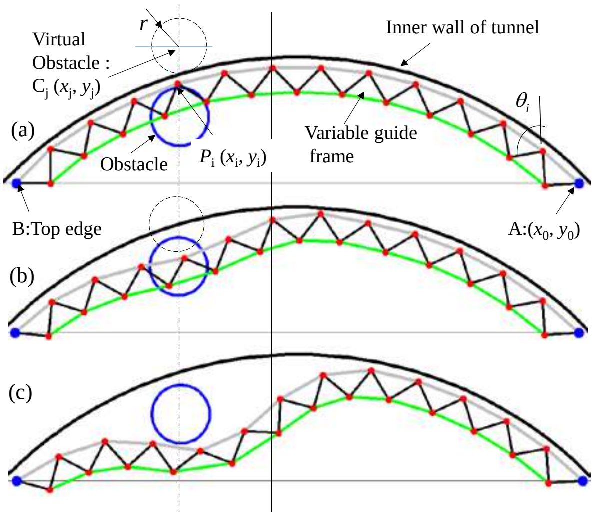

Fig. 10 Shape simulation of VGF to avoid obstacle

Fig11 Shape control of guide frame for traffic plate

3.2 Frame Analysis by Spline Function

In order for the guide frame to avoid obstacles, it is necessary to predict the final shape of the guide frame avoiding obstacles. In this section, the shape of the guide frame was analyzed using a Spline interpolation method and its effectiveness of the method was considered.

3.2.1 Shape Analysis by Spline Interpolation

To the initial guide frame shape, the overall shapes for avoiding obstacles were mathematically combined by the spline interpolation function.

Spline interpolation is a method of combining arbitrary shapes with polynomials to form a continuous shape. Assuming a function that interpolates the section (x_j, x_{j+1}), the piecewise polynomial $S_j(x)$ is expressed by the Equation (6).

$$S_j(x) = a_j(x-x_j)^3 + b_j(x-x_j)^2 + c_j(x-x_j) + d_j \quad (j = 0,1,2\cdots) \quad (6)$$

In order for this cubic equation to be a smooth curve, it is assumed that the value of the first derivative and the second derivative of $S_j(x)$ are equal, and the value of the second derivative at the start point x_0 and the end point x_n is 0. By applying the above conditions to each equation for several interpolation points, the coefficient of function a_j, b_j, c_j, d_j was calculated, and the function

by the spline interpolation was determined.
Here, each coefficient was determined as follows;

$$a_j = \frac{S_j''(x_{j+1}) - S_j''(x_j)}{6(x_{j+1} - x_j)} \quad (7) \qquad b_j = S_j''(x_j)/2 \quad (8)$$

$$c_j = \frac{y_{j+1} - y_j}{(x_{j+1} - x_j)} - \frac{(x_{j+1} - x_j)(2S''(x_j) + S''(x_{j+1}))}{6} \quad (9)$$

$$d_j = y_j \quad (10)$$

3.2.2 Estimation of Guide Frame Shape Avoiding Obstacles

Using the method in the previous section, several interpolation points (x_j, y_j) were determined so as to avoid obstacles, and the constants of the piecewise function were calculated using equation (6). Here, arbitrary six points (including both end points) that avoid obstacles are selected for the shape of the upper chord of the guide frame, and the shape of the new guide frame is analyzed. By constructing a system that can select representative points by touching the tablet screen, we were able to visually show the position to avoid obstacles. Several analysis examples are shown below.

(1) Example of side obstacle

The shape of a circular obstacle suspended from the left side of the tunnel ceiling overlapped the guide frame as shown in Fig.12-(a). We selected 6 optimum interpolation points to avoid obstacles and analyzed the shape of the upper chord by spline interpolation (Fig.12-(b)). A new guide frame was reproduced by configuring the guide frame to conform to the shape of the obtained upper chord member as shown in Fig.12-(c). Based on the above analysis results, the shape of the actual guide frame was observed in Fig.11. It was verified experimentally that the shape of the guide frame analyzed by spline interpolation was a shape that could smoothly obstruct obstacles.

(2) Example of center obstacle

In this case, the shape of the guide frame was analysed assuming an obstacle such as a discharge fan at the center of the tunnel as shown in Fig.13-(a). The interpolation points placing symmetrically at the bottom arc of a circular obstacle, it was possible to determine the shape of the guide frame for avoiding any obstacle (Fig.13-(b)). The shape of the actual guide frame was transformed using data analyzed. The experimental situation is shown in Fig.14. The guide frame was shaped to avoid obstacles, and it was confirmed that there was sufficient margin for structural mechanics.

From the above results, by using Spline interpolation method, it was possible to determine the shape of the guide frame for avoiding any obstacle

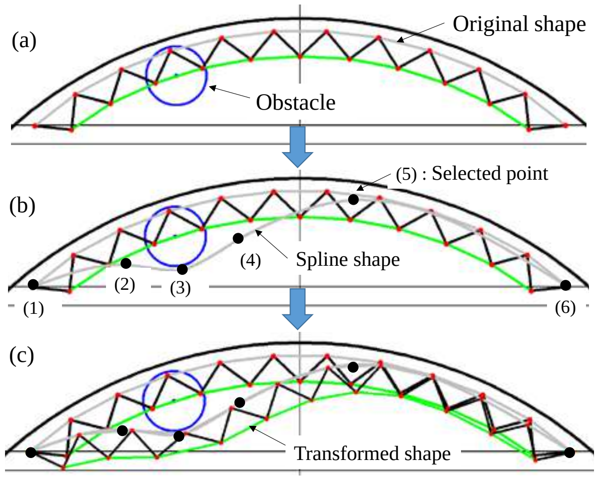

Fig.12 Shape decision of spline function for obstacle

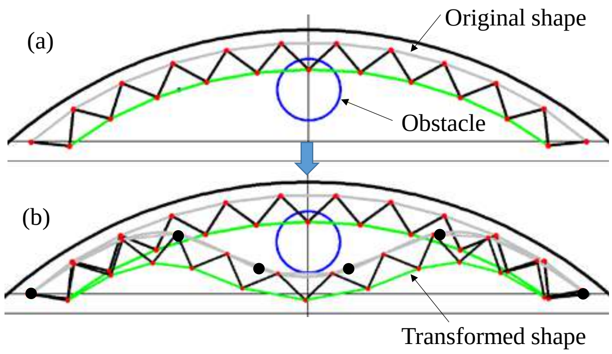

Fig.13 Shape decision of spline function for obstacle

Fig14 Shape control of guide frame for traffic plate

4. Conclusion

The tunnel ceiling area which was an obstacle of the guide frame was searched using two kind of LRF. LMS-1 is used to measure obstacles of short distance with high accuracy, and LMS-2 is used to measure the whole area including obstacles at long distances. By combining the two LRFs methods, it was possible to detect the approximate position and shape of the obstacle at a long distance, and the accurate position and shape at short distance. And also it was expected that it could be applied sufficiently to the actual measurement.

Next, we propose a method to analyzed the shape of the guide frame by inverse analysis and spline interpolation in order to create complicated frame shape avoiding arbitrary obstacles on the tunnel ceiling surface.

When using the inversed analysis, the shape change was created smoothly, however, since each frame undergoes a subordinate change, it is not very effective for complicated shapes. On the other hand, in the case of using spline interpolation method, since the function classification can be divided according to the shape of the obstacle, complicated obstacles can be dealt with.

In the future, we will establish a control method to continuously change the shape of the guide frame from the obstacle search in the tunnel, and to apply it to the actual inspection system.

Finally, the author thanks all who supported the development of the movable arch structure and its accompanying external panel. Further, this work was supported by Council for Science, Technology and Innovation, "Cross-ministerial Strategic Innovation Promotion Program (SIP), Infrastructure Maintenance, Renovation, and Management". Abstract

A comprehensive research has been initiated by Korean government in order to disseminate modernized traditional Korean building (Hanok). Major objectives of this project include reducing construction cost and enhancing performance by developing construction materials and method for modernizing traditional Korean architecture. For example, modern construction methods such as glulam, steel joint, and truss are modified in order to keep the representations of Korean traditional esthetics. As part of this project, seven test-bed projects have been actually built in order to validate the performance of the modernized Hanok, and each project has somewhat different applications depending on its own design requirements.

In order to systematically compare and analyze the different applications of newly developed construction methods, this study proposes an evaluation framework with influencing variables. Firstly, the influencing variables such as different types of floor plan, roof structure and long-span beam of Korean traditional buildings were explored and defined. Historical database of these seven test-bed projects were then organized with standard classifications and numbering system. Finally, the historical database was analyzed based on the influencing variables in order to find patterns and compositions in applying new materials and methods for modernized Hanok. The findings of this study would provide a guide to selecting effective alternatives for new building types in terms of cost and performance.

Traditional housing, Information, Historical data, Evaluation framework

1 Introduction

1.1 Background and Objectives

There are active efforts to develop timber construction technologies around the world, such as large-scale and high-rise wood buildings. With this trend, researches in Korea are also being carried out to develop the technology of wooden buildings. One of them is to inherit the context of Korean traditional wooden building technology and modernize it [1].

In Korea, wood had been actively used in construction over the several centuries. Traditional architecture style of 'Hanok' had been widely used, and it was a typical housing type of Korea. However, due to the rapid industrialization, overseas technology such as masonry and concrete spreads rapidly, and the domestic wooden technology had relatively underdeveloped in Korea. As a result, 'Hanok' which was the traditional wooden structure of Korea now only exists as a traditional style, but it is hard to recognize it as a general urban building style [2].

Therefore, from 2010, Korean Ministry of Land, Infrastructure and Transport has conducted research on "Hanok Technology Development", which aims to develop Korean wooden technology by carrying on the legacy of Hanok. It has developed 'modernized Hanok' technology accommodating modern architecture technology [3]. 'Modernized Hanok' has been designed from the traditional Hanok to fit modern people's life, using modern methods and materials. This has resulted in improved durability and reduced construction costs. Currently, efforts are continuously being made to diffuse these technologies [4].

Moreover, using wood for high-rise and large-scale buildings is a world-wide trend. In line with this trend, researcher and practitioners are trying to develop large space and high rise [5] wooden buildings for modernized Korean traditional buildings.

The diversity of technology is largely divided into the user diversity and the technical diversity. The user diversity includes the requirements of the user such as the purpose of the facility, the size, etc., and the technical diversity includes the conditions applicable to the designer and the constructor such as the construction method and materials. Therefore, in the early stage of the project, it is required to technical diversity such as construction methods, materials and materials that can be applied to user diversity such as the use of buildings, size and budget. Especially, it is necessary to provide evaluation methods to solve this problem in boosting the architectural style of 'Hanok'.

Therefore, the purpose of this study is to propose an evaluation structure for examining various applicability of Korean wooden structure inheriting the traditional context of Hanok. For the purpose of developing the evaluation method, this study analysed seven test-bed projects those are actually constructed as part of this research. The evolving patterns of these seven test-bed projects are also analyzed in order to find implications

1.2 Hanok

Figure 1 Hanok - Ojukheon House
(Source: 'Korea Tourism Organization' Website)

Hanok is Korea's representative architectural style with more than 2000 years history. It is an eco-friendly building using wood as its main material and using natural materials such as stone and soil [7].

Traditional Hanok methods have only been connected by mortise and tenon joints [7]. This required considerable skill and effort, and it was disadvantageous for mass production. Further, it was difficult to have a large space due to the problems such as scarcity of large size wood materials. The inside space was formed by the column spacing of 2.4 ~ 2.6m [8], based on the unit space (칸, 間) consisting of four columns.

Traditional Hanok is a wooden building which has the advantages of eco-friendly and aseismicity, but it is difficult to reflect it in the modern age due to the structural limitations on durability and space enlargement.

Nevertheless, due to its traditional beauty, Hanok is still regarded as a type of housing that Koreans want to live in (As of 2008, 42% of Korean people want to live in Hanok) [9]. Today, although the appearance of the building seems to be a traditional Hanok style, its interior of the building is being developed using modern construction methods such as concrete. However, the discussion on how to define 'Hanok' in architectural style is controversial.

The purpose of this study is to provide a basis for the evaluation criteria of the applicability of modern construction methods to propose the continuous development direction of the Hanok applying various construction methods.

1.3 Hanok Scope of development

Before proceeding with research, 'Hanok' should be defined first. The reason is to propose a standard to judge to what extent Hanok can be defined as 'Hanok' when the Hanok evolved into various technologies.

"Hanok" in "Act on Value Enhancement of Hanok and Other Architectural Assets" is legally defined as follows. "the main structure of which consists of wooden columns, beams and Korean style roof frames and which reflects the traditional style of Korea, and any building annexed thereto [6]." According to the Seoul Metropolitan Government Ordinance of the Republic of Korea, "Hanok" is defined as follows. "The main structure is made of wood, and it means the buildings or their attached facilities that have traditional beauty among the buildings using Korean style tiles [7]". Table 1 summarized the definitions about Hanok in the literatures and the laws in Korea.

Table 1 Requirements of Hanok

Original Hanok[8]	・Main structure and all visible elements : traditional techniques, ・Indoor space: Modernized kitchens and bathrooms, applying modern technology for heating and air-conditioning equipment, electrical equipment, insulation, sanitary facilities
Traditional Hanok[9]	Hanok with traditional technology and space
Modern Hanok[8]	・Main structure: Wood ・Roof, Stylobate, Wall : traditional
Traditional Urban Hanok[10]	・Korean style tile, wooden column, ・Buildings that maintain the traditional style of the wooden structure
Hanok style House[11]	・Main structure: Wooden structure or Traditional hanok style using other materials, ・Korean style tile

As a result of examining related laws, ordinances and research literature defining Hanok, it could be summarized as follows.

1. The exposed main structural part should be wooden. (External columns must be exposed)
2. Korean style Tiles should be used on the roof.
3. Do not expose the metal connector to joints.
4. It should be finished with natural material.

According to these requirements, the material other than wood (e.g. steel, concrete) can be used for main structure of Hanok if it is finishing with wood.

In this way, it is very important to analyse quantitatively the process of the various materials and the construction method according to various demands in the historical and industrial aspects of Korean architecture.

It is also very valuable to set standards for analysing the changes in materials and construction methods and accumulating information.

2 Case Study

In the modernization of traditional Hanok, it is important to predict the range of applicable technology for various needs and apply the optimal combination through it. Therefore, this study aimed to classify the applicable technologies to Hanok through Hanok test-bed projects as a step to derive the optimal technology combination.

2.1 Analysis of the Hanok cases

'Modernized Hanok', which was constructed in the research process of modernizing traditional Hanok, was attempted as far as possible in the application of various modern new building methods and materials, without hindering the traditional aesthetic appearance. During the period of about 6 years, there were efforts of the research team to establish a total of seven different test-bed buildings. In addition, various as-built databases of test-bed projects such as construction cost, construction period, and productivity from the construction process were standardized and accumulated. Especially, intensive efforts to lower the high cost of construction, which was one of the characteristics of traditional Hanok, and to improve the quality had been concentrated.

The entire study was carried out in two stages. The first stage was residential facilities, and the second stage was extended from residential to public facilities for various applications of technology. In addition, the third stage of research is started in 2018, and the technology is being developed for large-scale Hanok.

In order to propose the evaluation structure, seven case studies were carried out except for the case of a village test-bed project. Case 1 used traditional Hanok construction methods for comparison purpose, Case 2 and Case 3 were built by using modernized methods for residential housing. Finally, Case 4, Case 5, Case 6 and Case 7 are modernized Hanok for public buildings.

Table 2 summarized the general outlines of the seven cases. Carpentry construction accounted for about 30% of the total construction cost. But the fact that proportion of construction cost is decreasing didn't mean the decreased use of wood materials. It was caused by increased cost of concrete in the foundation.

Though the total costs including carpentry, finishing, equipment, mechanical, and electrical works were analysed, this paper focuses on carpentry works cost per unit area, a large amount of construction cost was used without any major change in the absolute amount of

Carpentry is the main structural part of the Hanok and occupied a large portion in terms of total costs and quantities.

Table 2 Table 2 General outlines of 7 actual modernized Hanok cases

	Case 1	Case 2	Case 3	Case 4	Case 5	Case 6	Case 7
							
Total construction cost ($)	240,000	260,000	275,000	2,406,000	1,002,000	708,000	541,000
Total floor area (㎡)	70	130	140	950	450	260	250
Building area (㎡)	70	80	70	570	340	275	110
Characteristics	Traditional	Wet+Dry	Glulam	Curved Beam	Truss	Arch Frame	Steel Frame, Concrete Slab
Construction period (day)	-	-	154	337	237	167	199
Roof form	3	3	5	5	5	5	3
Carpentry Cost ($) per area	1,144	439	676	702	468	684	252
Carpentry ratio (%)	33%	21%	34%	28%	21%	25%	12%

2.2 Needs for Standard Classification for Hanok Construction

As mentioned above, the aim of this study is to develop an evaluation methods for selecting appropriate methods for different type of Hanok projects. The evaluation structure should reflect user diversity and their technical diversity. In order to explain this, it is necessary to classify the technical standard of the Hanok wooden structure and the following suggestions was drawn to define it.

First, the structure of Hanok should be based on wood columns and beams.

From the past, Hanok has emphasized the characteristics of each element of the building. Various terms were used depending on the details of the design used, the shape of the member, the size, and so on. It was also possible to estimate the era of Hanok construction through these characteristics. Therefore, a very complicated terminology has been used, and the problem has arisen that the standard classifications are not clear when modern architects try to describe modernized Hanok elements. However, this is one of the most representative features of Hanok. So it is difficult to apply modern classifications, while completely ignoring it. Therefore, in order to know the applicable technology range of the modernized Hanok, it is necessary to define the terms of the absence of the classification according to the element, and to organize the applicable techniques such as the construction methods and materials.

Second, in order to utilize the best combination of technologies for each span and scale at the time of building a Hanok, including large size and high-rise buildings, it is necessary to review the structural safety evaluation standards.

Third, it should be able to support the analysis of economic efficiency in the construction method and material selection in the state where the original design of the Hanok is fully reflected.

Fourth, it should be able to support the industrialization of materials. Industrialization of each member is essential for the spread of Modernized Hanok. Through the standard classification of Hanok technology, it is possible to derive efficient member dimensions for each technology according to the span and scale of the building, and these dimensions should be standardized to support establishment of industrialization base.

3 Standard Classifications for Hanok

Standard classifications for Hanok technique are defined as element classification, method classification, and material classification reflecting the characteristics of Hanok discussed above.

3.1 Element Classification

Element classification should be the first since Hanok has different characteristics and methods. The element classification was divided into five categories: roof, roof structural system, beam, column, and floor through previous studies [16]. Complex and various traditional terms were re-defined with simple descriptions.

Roof included timber used for roof parts such as rafters [*Seo-ka-re*] and wood board. Roof Structural system was located between the columns and the roof, and represent the overall structure of the roof and the building. This is one of the distinct characteristics of Hanok, and includes purlin [*Dori]*, etc. Beam in the highest floor was categorized as one of the roof structural systems. However, it was classified in order to perform detailed analysis for each applied method. When comparing quantities by element in this paper, they were combined and analysed together. The columns included inner columns [*Go-ju]* and outer columns [*Pyeong-ju]*. The slabs include joists [*Jang-sun*], floor boards [*Ma-ru*] and the like.

3.2 Method Classification

The classification criteria of methods based on literature reviews as well as domestic and foreign wooden building case studies (including 7 modernized Hanok test-beds) are summarized as follows. It was classified into one column system, one slab, four roof structural systems, four beams, and two roof systems. Table 3 below summarizes the applicable methods for each elements. The column method is divided into one vertical column, which supports vertical load, and the slab is divided into one, horizontal slab method. The roof structural system is divided into four types: Korean Traditional, truss, arch, and tension cable. Among them, the beam part which is one of the members of roof structural system is divided into four parts: straight beam, curved beam, truss beam, and Tension Supported Bending structure. The roof is divided into two types, wet type and dry type.

Of course, it is difficult to see the all applicable method for each element, but it was based on the possibility in the category of Hanok which is now recognized, and it can be added later

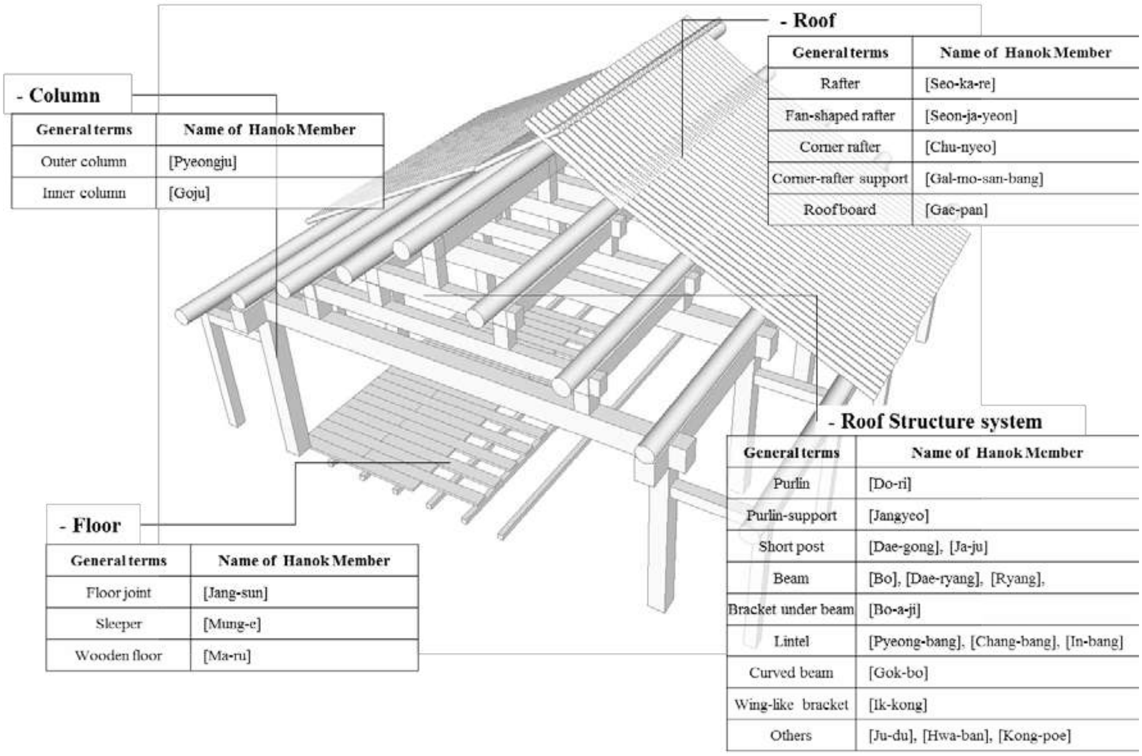

Figure 2 Element classification of Hanok (Preceding study) [16]

Table 3 Elements Classifications and Methods Classifications in each part

Elements		Methods	
C	Column	C01	Upright Column
S	Slab	S01	Floor Slab
F	Roof structure system	F01	Korean Traditional
		F02	Truss
		F03	Arch
		F04	Cable
B	Beam	B01	Straight Beam
		B02	Curved Beam
		B03	Truss Beam
		B04	Tension Supported Bending Structure
R	Roof	R01	Wet (Traditional Method)
		R02	Dry

3.3 Material Classification

Next, materials that can be used in each method should be selected. The classification of materials was summarized by using literature data and classified into five categories: wood, glulam, steel, reinforced concrete and composite. (Table 4)

Clearly Hanok architecture is a wooden building, so it is required to pay attention to use other materials other than the wood for the main structural parts. However, as the different requirements (size, use) of the main structural parts of the Hanok have been increased, other materials including steel and concrete have been applied to the standards so as able to be reflect the possibility of various applications.

Table 4 Classification of Materials

Materials	
W	Wood
G	Glulam
S	Steel
R	Reinforced Concrete
C	Composite

Among the standard classification of Hanok technology, the top three categories were summarized as elements, methods, and materials. When it has shown as matrix, the total range of its combinations was about 80,000 cases.

In future studies, the most unlikely combinations should be excluded through the quantitative evaluation to find a more optimal combination.

4 Utilization of SC Matrix

Hanok can be applied in various ways beyond the traditional style of the past by applying modern technology and it can be developed into a large scale and a high rise.

Therefore, in modernization of Hanok which has the potential of development, it is required to quantitatively analyze and systematize the variables.

4.1 Concept of Evaluation Framework

Hanok can be developed variously through application of modern technology.

Figure 3 shows the concept of the evaluation framework that draws the optimal combination of technologies according to the diversity of users by using the standard classification matrix of the Hanok technology. Variables according to user diversity, such as the size, use, and budget of the facility, are entered as input variables in the standard classification matrix of Hanok technology, and the matrix is used to evaluate the practical, productive, and economic combinations. In this way, optimized combinations of method and material are drew about each element, and optimal combinations of type1, type2, type3, etc. can be selected as output.

In conclusion, the purpose of the evaluation framework is to find out the optimal value required by the user more efficiently and to consider the correlation, quantity ratio, economical efficiency, productivity, etc. in the total number of possible cases of Hanok technology. In addition, it is to evaluate the combination of classification elements by analyzed quantitatively.

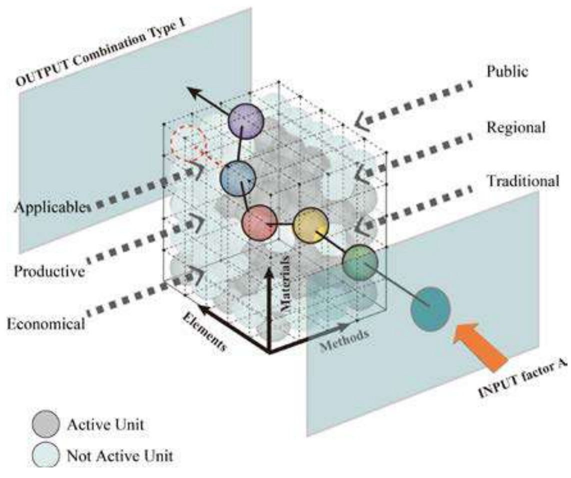

Figure 3 Evaluation Framework Structure using SC Matrix

The evaluation framework using the standard classification of Hanok technology can support to select the optimal technology combination, and it can be used in various ranges.

First, it can be used to estimate the appropriate construction cost. It is possible to analyze the correlation between each combination technique using the actual Hanok data and use it to predict each construction cost, and estimate it more accurately.

Second, it is possible to find the optimal combination according to various variables such as the size and the floor of the Hanok that users want to build. The combination of appropriate technologies based on span, number of floors, type of building, etc. is quantified and evaluate. And ultimately it makes it possible to select the optimum combination of high evaluation values.

Third, it is possible to consider the design which preserved the traditional Hanok. Proportion and harmony are important when designing considering the traditional Hanok. It can be evaluated in consideration of the dimensions and proportions of members, and it can be utilized in the design of traditional Hanok.

In the following chapters its utilization was explained with more specific examples.

4.2 Case-study using Evaluation Framework

In order to propose a combination of Hanok wood structure using the evaluation framework, it is necessary to draw elements through analysis of many accumulated actual cases.

Among the seven test-bed projects of the modernized Hanok introduced in the previous chapter, five cases were selected for this case-evaluation except case 1 and 3. Because case 1 and case 3 were too difficult for comparing with the others (Case 1 used traditional method and case 3 wasn't classified by the same classification).

Table 5 compared the main structures by case for technical classification of wooden structures. Case 1, Case 2, and Case 3 were residential buildings and had similar wooden structure characteristics. And these public buildings of cases 4, 5, 6 and 7 in which various requirements were changed from the residential were used for the analysis of the wooden structure.

As shown in Table 5, the evaluation framework could be effectively used to compare the wood structures by element, material and construction method. There were many cases where materials other than wood materials were used in the floor part when dividing the quantity of wood, so it was difficult to compare and it seems that it will become more serious in the modernization of Hanok.

Table 5 shows the share of wood per square meter. The wood quantity of the columns, the roof structural system part, and the roof part were examined by each case. When the wood quantities in the cases are compared (except for the quantities of wood flooring), the proportion of each part of total wood use is as follows. Case 2 showed 7% of columns, 44% of roof structural system, and 49% of roofs. Case 4 showed 12% of columns, 40% of roof structural system, and 48% of roofs. In Case 5, 11% of columns, 48% of roof structural system and 43% of roofs were used. In

C ㎥/㎡	**0.02**		**0.03**		**0.02**		**0.02**		**0.01**	
S ㎡/㎡	**2.30**		**0.49**		**2.56**		**0.62**		**0.00**	

Case 6, 7% of columns, 42% of roof structural system, 51% of roofs, 3% of cases 7, 44% of roof structural system and 53% of roofs were used.

By comparing the cases, the similar distributions of the wood quantity were found except for Case 7, where the first floor was constructed with a steel frame and then finished with wood. In this way, it can be inferred that the cross section and the number of columns are maintained at a constant ratio with the amount of wood in the roof structural system part and the roof part. In addition, other materials can be used through the ceiling finish, which can reduce construction costs by replacing traditional methods of exposing wood to roofs without ceiling finishes.

It can be seen that most wood structures use raw woods. This can be considered in relation to the emotional part of Koreans, and it means that the use of natural wood, which has been used from the past, has been recognized as a representative material of Hanok until now. However, the use of glulam is expected to increase in modern Korean Hanok, and it is expected that the use of this will become even higher due to safety reasons in the modernized Hanok, which is growing in size.

Most of the beams and roofs are similar, but the change of the partial construction method can be confirmed because of the increase of the space area or the installation of the attic room.

Although it is only the result of analyzing with few cases, it was possible to analyze the change of the structure of Hanok wood structure through the Hanok technique classification more accurately. It will analyze these more in detail in the future and incorporate it into the main component of the evaluation framework. In particular, it will be finally necessary to elucidate factors such as economic analysis, design proportion, regional characteristics, and structural safety of the evaluation structure proposed.

5 Conclusion

The purpose of this study is to suggest a framework for evaluating the application of various methods available in Hanok construction and for deriving optimal technology combinations.

For this purpose, this study defined a standard classification of Hanok wooden structure, which accounts for the highest construction cost in Hanok construction. Based on a literature review and seven test-bed projects, the concept of evaluation framework was proposed to develop a classification matrix.

Furthermore, a detailed and systematic evaluation will be developed in near future by building more test-bed projects.

Future study will include the relationship of wood quantities between the column and the roof structural system, the relationship between the area (or span length) of the space and the wood quantity, and the relationship between the sectional area of the member and building (or roof) area, and so on.

It is expected that this evaluation structure will be used as a research that would systematically suggests the combination of modernized Hanok technology that encompasses future large-scale Hanok and future Hanok.

Abstract –

Improvement of productivity in construction work is strongly required because a shortage of construction workers has become a major social issue in Japan. Marking work for installing building materials is indispensable. This work is currently carried out manually. If this work can be automated, construction workers can concentrate on installing the building materials. Therefore we intend to improve productivity by automating this work with a mobile marking robot system.

For the first step, we developed the marking robot system for a free access floor. To build this, grid-pattern lines should be drawn on the floor. Our system can automatically mark the intersections of the lines which are the positions for installing pedestal bases of the free access floor. Our system consists of a mobile marking robot and a laser positioning unit. The former is a mobile robot which has the marking device at its center. Cross marks are drawn on the floor by controlling the marking device. The laser unit accurately directs the point and line laser in the target direction and measures the distance to the object on which the laser spot is projected. The marking robot tracks the line laser and arrives at the target area. The deviation between the target position and the robot center is calculated, and the cross mark is drawn exactly on the target position.

This paper describes the mechanism of our system. It also shows the satisfactory tracking performance and marking accuracy in several experiments.

1 Introduction

A shortage of construction workers has become a major social issue in Japan. In 2015, the number of construction workers was about 73% of what it had been at its peak in 1997. In the construction process, marking work is indispensable. Construction workers need to draw marks and lines on the floors, walls, ceilings, and so on in the construction site in order to install building materials. In recent years, survey technology has progressed remarkably. Instruments such as laser scanners and total stations have been used in construction fields. Some 3D measuring and marking systems using a total station have been reported [1-3]. These systems are not aimed at automating marking work but at increasing the efficiency of manual marking work. By automating this work with mobile marking robots, construction workers will be able to concentrate on installing building materials and productivity will increase. There have been some studies on automated mobile marking robots. The system reported by Tanaka et al. draws specified figures on the ceiling board [4]. This robot needs to detect the edges of three existing pillars in the construction site by using a laser range finder (LRF). If the distance from the robot to pillar is far or the pillar is covered with fire resistant material, this system cannot mark with high accuracy. In the system reported by Zulkifli et al. [5], a camera needs to be installed on the ceiling and calibrated depending on the installation position, which is very laborious and costly work. Moreover, the area in which a robot can mark is limited by the visual field of the camera. Inoue et al. reported a system using a total station and LRF to measure the robot position [6,7]. In this system, the attitude angle of the mobile robot cannot be measured while moving. Therefore, in our viewpoint, it is difficult to stably navigate the mobile robot to the target position. The navigation method from a mark point to another mark point has not been reported in detail. "Laybot" developed by DPR construction [8] can mark lines on slabs for drywall layout. Since it draws lines while running, it is difficult to draw highly precise straight lines.

As a first step, we intended to automate the marking work for installing a free access floor. In order to build the free access floor correctly, grid-pattern lines should be drawn on the floor before they are installed. The intersections of the lines are the positions for installing the pedestal base of the free access floor. This paper deals with the development of the marking robot for automatically drawing cross marks on the floor which indicate the positions for installing the pedestal bases.

The marking robot is guided to the target position by the laser marker. The three dimensional measuring instrument measures the robot position accurately. Based on the actual robot position, the marking pen installed on the robot is controlled and draws the cross mark at the target position. After that, the robot moves to the next target position and continues this cycle. Since this process is fully automated, just giving all the target positions coordinates in advance to this system allows, all the cross marks corresponding to the positions for installing the pedestal bases to be drawn.

2 Outline of the marking robot system

Our system is composed of a laser positioning unit (LPU) and a marking robot (MR). The operation of the marking system is shown in Figure 1. In this figure, r is the distance from the LPU to the screen placed on the MR base and θ is the direction angle of the point laser. In our system, the marking flow is divided into the MR guidance phase and the cross-mark drawing phase.

In the MR guidance phase, the MR travels from the current position, A (r_a,θ), to the next target position B (r_{tgt},θ_{tgt}). At first, the LPU precisely directs the point laser parallel to the floor in the direction of the target position. Secondly the LPU turns the line laser toward the angle θ_{tgt}. The MR base includes cameras and screens. The cameras capture the screen image where the laser spot and line are projected. The MR tracks the moving laser line and travels on the circumference of a circle whose radius is r_a while keeping the screen perpendicular to the line laser. When the angle of the line laser reaches θ_{tgt}, the LPU stops turning the line laser and the MR stops. Subsequently the MR moves backward or forward on the straight line connecting the LPU and the position B so as to approach the target position B while keeping the screen perpendicular to the line laser. The MR stops when the difference between the distance r measured by the LPU and the target distance r_{tgt} become less than the threshold. However the arrival position of the MR does not exactly correspond to the target position. The actual center position of the MR is measured by the LPU and the camera.

In the cross-mark drawing phase, the MR draws a cross mark exactly on the target position. The MR has a marking device which can move a marking pen in the x, y, and vertical directions. The movement value of the marking pen is calculated by comparing the target position B and the actual center position of the MR. By controlling the marking device based on the calculated movement value, a cross mark whose center corresponds to the target position B is drawn on the floor.

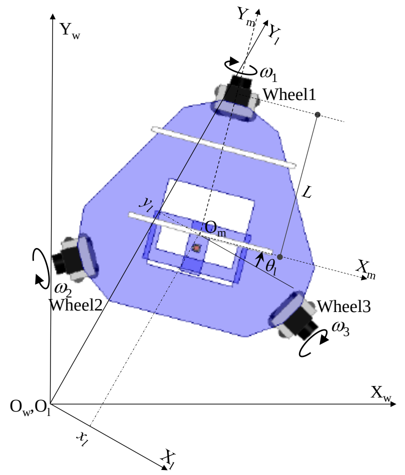

Figure 2. Kinematic model of ODV

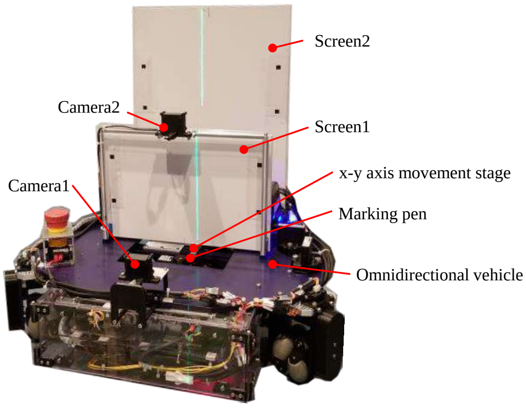

Figure 3. Photograph of marking robot

3 Composition of marking robot system

Our system consists of the MR and the LPU, each controlled by a computer. The two computers can communicate through the wireless network.

3.1 Marking robot (MR)

We use an omnidirectional vehicle (ODV) as the movement vehicle. It has three omnidirectional wheels mounted symmetrically, with 120 degrees between them. Each wheel is driven by a DC motor and is the same distance from the robot's center. Unlike the non-holonomic robots, this type of vehicle has a full mobility in the plane which means that at each instant it can move in any direction without any reorientation [9]. We can control the rotational speed of each wheel independently by sending commands to the motor driver. The kinematic model is shown in Figure 2. For the convenience of description, this paper defines three coordinate systems: Σ_w, the world coordinate system, Σ_R, the robot coordinate system, and Σ_L, the laser coordinate system, in which the coordinate Y_L axis corresponds to the direction of the line laser and the origin O_w and O_l are the same. Here ω_i (i=1,2,3) are the rotational velocities of the wheels (i represents the number of the wheel), R_w is the radius of the wheel, and L is the distance from the robot's center to the wheel. x_l, y_l, and θ_l are the positions and attitude angle in the Σ_L. The inverse-kinematic model in the Σ_L is represented in Equation (1) [10].

$$\begin{bmatrix}\omega_1\\ \omega_2\\ \omega_3\end{bmatrix} = \frac{1}{R_w}\begin{bmatrix}-\cos\theta_l & -\sin\theta_l & L\\ -\cos(\theta_l+2\pi/3) & -\sin(\theta_l+2\pi/3) & L\\ -\cos(\theta_l+4\pi/3) & -\sin(\theta_l+4\pi/3) & L\end{bmatrix}\begin{bmatrix}\dot{x}_l\\ \dot{y}_l\\ \dot{\theta}_l\end{bmatrix} \tag{1}$$

A photograph of the MR is shown in Figure 3. Two screens and cameras are placed on the ODV base. Screens 1 and 2 are parallel to each other and perpendicular to the floor. The distance between the screens is y_s. Cameras 1 and 2 face Screen 1 and 2 respectively and capture each screen image on which the laser spot and line are projected. The marking device is installed at the center of the robot. It consists of the x-y axis movement stage and the pen unit which can move the marking pen in the vertical direction. The pen unit can be moved on slider rails. By controlling the marking device, the cross mark is drawn on the floor.

3.2 Laser positioning unit (LPU)

This unit is composed of the guide laser unit (GLU) and the three dimensional measuring instrument (3D-MI: in our system, this is a Leica Geosystems 3D Disto. The accuracy of angle measurements is 5 seconds and the accuracy of the distance between two points about 10 m apart is approximately 1 mm). Like a total station, the horizontal and vertical axes of the 3D-MI can be motorized. This can direct the point laser accurately in the direction indicated in advance and measure the distance to the object on which the laser spot is projected. The GLU consists of a laser marker and a rotation stage. The laser marker can generate a vertical line laser. Construction workers often use this for drawing a reference line on the floor, wall and ceiling and so on. This is placed on the rotation stage. The vertical axis of the 3D-MI agrees with that of the rotation stage. It is also motorized and the rotational speed is controlled through the RS485 interface. A photograph of the LPU is shown in Figure4.

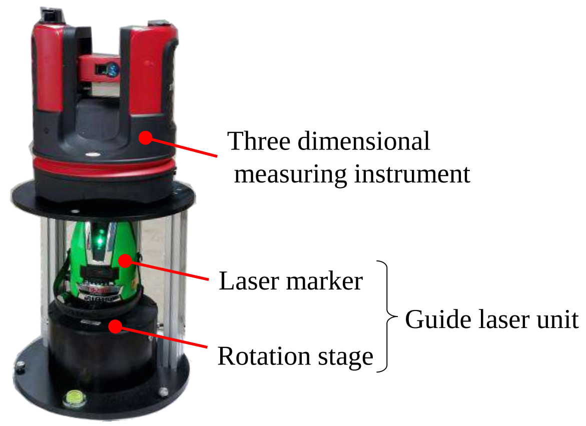

Figure 4. Photograph of laser positioning unit

Figure 5. Screen layout and laser projected on the screen

4 Control of MR and LPU

4.1 Mechanism for measuring MR position

As shown in Figure 5, the attitude angle θ_l in the Σ_l is calculated from Equation (2), where, d_1 and d_2 are the x-coordinates of the laser line projected on each screen in the Σ_R. In the drawing cross mark phase, a laser spot is projected on Screen 1. Δx_r and Δy_r, which are respectively the movement values of the pen unit in the x and y-axis directions in the Σ_R are calculated from

Equation (3) and (4) using the geometric relationship, where, d_{spot} is the x-coordinate of the laser spot in the Σ_R, r_{screen} is the distance from the LPU to Screen 1, and θ_s is the attitude angle of the MR with respect to the direction of the spot laser. The laser spot does not necessarily overlap the laser line exactly because of the rotation stage control error. Since θ_l is nearly equal to θ_s, we use θ_l instead of θ_s in Equations (3) and (4). By controlling the marking device, the cross mark is drawn on the target position exactly.

$$\tan\theta_l = \frac{d_2 - d_1}{y_s} \tag{2}$$

$$\Delta x_r = d_{spot} + (r_{screen} - r_{tgt})sin\theta_s \tag{3}$$

$$\Delta y_r = (r_{screen} - r_{tgt})cos\theta_s \tag{4}$$

4.2 Detection of laser line and laser spot

It is difficult to measure the laser position accurately from a captured image without image processing because the captured image has two types of distortions which we have to remove. First, the lens distortion is removed by using Zhang's method [11]. Figures 6a and 6b show the screen images before and after the distortion removal. Subsequently, the perspective distortion is removed by the homography transformation, based on the following formulae:

$$\begin{cases} u_i = \dfrac{a + bs_i + ct_i}{1 + gs_i + ht_i} \\ v_i = \dfrac{d + es_i + ft_i}{1 + gs_i + ht_i} \end{cases} \tag{5}$$

Where

u_i,v_i: camera coordinates after the transformation

s_i,t_i: camera coordinates before the transformation

Eight unknown parameters a, b, c, d, e, f, g, h are obtained by solving the Equation (5) substituting a combination of more than four known points (u_i, v_i) and (s_i, t_i). In our system, a calibration mark is drawn on the screen. Four black squares are arranged at the four corners of a rectangle whose width and height are W and H respectively. Figures 6b and 6c show the screen images before and after the homography transformation. The position of the laser line and the laser spot are measured from this image. First, the red, green, and blue channels are extracted. In each channel image, the average pixel intensity of each column is calculated as shown in Figures 7a, 7b, and 7c. Since the laser marker emits a green laser in our system, the difference pixel intensity is calculated by subtracting half of the red and blue channel components from the green channel component as shown in Figure 7d. $u_{max,j}$ (j is the screen number) is the horizontal camera coordinate with the largest pixel intensity. d_j which is the x-coordinate of the laser line in the Σ_R is calculated using Equation (6).

$$d_j = (\frac{u_{max,j}}{N_H} - 1/2)W \tag{6}$$

Where, N_H is the number of the horizontal pixel.

The laser spot with the 3D-MI is red. A binarized image is obtained from a red channel image utilizing a binarization threshold. The binarized image is smoothed by expansion and contraction processing. As shown in Figure 8c, the laser line and block noise are removed and only the laser spot remains after this process. From this image, the area centroid is calculated. After that, as shown in Figure 8d, the masked image is obtained by setting the pixel intensity except for the 50 x 50 pixels square region centered on the area centroid to zero in the red channel image. The horizontal camera coordinate of the laser spot, $u_{max,spot}$, is calculated as the brightness center of gravity in this masked image. d_{spot} , which is the x-coordinate of the laser spot in the Σ_R, is also obtained from Equation (6). This image processing is conducted by the computer installed on the MR. The calculation cycle depends on the computer performance. In our system, it is approximately 0.17 seconds.

4.3 Motion control

4.3.1 Control system

In our system, the MR tracks the line laser. The block diagram for tracking the line laser is shown in Figure 9. The meaning of each symbol is listed in Table 1. This PI (Proportional-Integral) control system feedback-controls the rotational speed based on the tracking error (e_x,e_θ) in Table 1. By converging the tracking error to zero, the MR tracks the laser line while keeping the screen perpendicular to the line laser. The actual center position and attitude angle is measured by the method detailed in the former section.

4.3.2 Traveling on the circular path

As explained in Section 2, as the line laser turns, the MR travels on circular path while keeping the screen perpendicular to the line laser. In the experimental setup shown in Figure 10, the tracking performance on the path was evaluated by changing the rotational speed of the rotation stage to 0.3, 0.6 and 0.9 degrees per second. The reference center position, attitude and translational velocity for the y axis direction in the Σ_l and the proportional and integral gains were set as listed in Table 2. Because $\dot{y}_{l,d}$ was set to zero, the MR tracked the moving line laser without approaching or moving away from the LPU. The proportional and integral gains were adjusted based on the values obtained in the simulation and preliminary experiment result. Figure 11 shows the relationship between x_l or θ_l and time. In the all rotational speed, the screen was nearly vertical to the

line laser. When the screen is vertical to the line laser, x_l indicates the deviation between the line laser position and the screen center. In our system, W is 270mm. Although the laser line remained on the screen with any rotational speed, the translational speed of the laser line projected onto the screen increases as the distance between the MR and the LPU increases. Therefore, our system is designed to change the rotational speed of the rotation stage based on the distance from the LPU to the MR to prevent the laser line from being off the screen. That is, the rotational speed is inversely proportional to the distance.

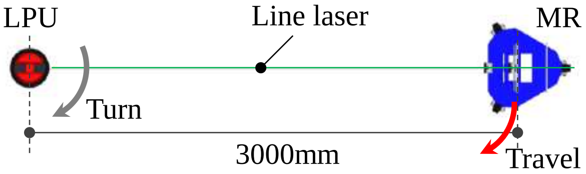

Figure 10. Experimental layout

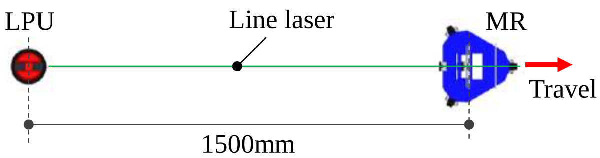

Figure 12. Experimental layout

4.3.3 Traveling on the straight line

When the line laser stops turning, the MR travels on the straight line connecting the LPU and the next target position while keeping the screen perpendicular to the line laser. In the experimental setup as shown in Figure 12, the tracking performance during travel on the straight line was evaluated. The setting parameters are listed in Table 3. Except for $\dot{y}_{l,d}$, they are the same as those for travel on a circular path. The MR travels at a speed of 50mm per second in the direction of the line. Figure 13 shows the relationship between x_l or θ_l and y_l. We confirmed that the MR stably traveled on the straight line until y_l was about 27 meters using this motion control method. The absolute values of x_l and θ_l were less than 25mm and 5 degrees respectively. Each standard deviation is 2.0mm and 0.5 degrees respectively. These values are very small.

5 Experiment

In order to evaluate the performance of the developed marking system, a basic test was executed. The experimental layout is shown in Figure 14. In the 4m x 10m test area, we set 50 target positions, which were grid intersections at intervals of 1m. The MR marked from Position A0 to Position J0 position in order. The total time spent marking was about 100 minutes. After marking all positions, the coordinates of the centers of every cross mark were measured using the 3D-MI.

Figure 15 shows the frequency distribution of x_l or θ_l, in the MR guidance phase. They are created from the measured x_l and θ_l every 0.17 seconds. They concentrate near zero. Each average value was 0.9mm and 0.03 degrees, and the standard deviation was 26.8mm and 1.2 degrees respectively. These results show that the MR stably tracked the line laser while controlling the attitude so that the laser line was in the screen center and vertical to the screen surface.

All of the deviations between the target positions and marked positions are summarized in Figure 16. Figure 16a shows the deviations at all marked positions. Figure 16b shows the deviations distribution. In this figure the radius of the red circle is 3mm. Figure 16c shows the frequency distribution of the deviation. The average deviation was 1.5mm, and the maximum value was 3.9mm. 94% of the measured values are within less than

3mm deviation. There is no strong correlation between the distance from the LPU to the MR and the deviation. Relatively large deviations are thought to be due to the local unevenness of the floor surface and detection error of the laser spot center from the screen image. By setting the target positions in advance, accurate and automatic marking was achieved in this system.

6 Conclusion and future research

We described the mechanism of our automated mobile marking system for free access floors in detail. In the experiment at the test site, the MR stably tracked the laser line generated by the LPU and then reached predetermined target positions. Furthermore, we confirmed the deviation between the mark drawn by the MR and the target coordinate was 1.5mm in average and 94% of the deviations are less than 3mm. This marking operation was fully automated. Therefore improved productivity in the construction work is expected.

However, some limitation can be identified. First, the time spent on marking is long. This work usually requires two workers using carpenter's ink pads or chalk line and measure. Experienced workers can mark with more than 10 times faster. Second, direct sunlight disturbs the detection of the line laser and the MR cannot track it. That is, the area where we can control the MR becomes smaller due to the influence of sunlight. Finally, some large deviations between the target positions and marked positions have been observed in the experiment. Some factors are considered. One is the local unevenness of the floor surface. The other is detection error of the laser spot center from the screen image. We have to solve these problems to improve performance of the MR in the future research.

Abstract -

The damaged area caused by disasters must be restored as soon as possible. So, remotely controlled construction machines are used to execute this dangerous work, safely.

In the remote construction, machine operators always watch images of the working field from pan-tilt monitoring cameras controlled by camera operators. Then, the automatic camera control system without camera operators is expected for machine operators.

Based on the above requirement, we are developing an automatic tracking camera control system for construction machine operators by using image processing. The most difficult point for this system is to realize a stable outdoor object detection by image processing. So, we proposed a new image processing method which is a combination of "Improved template matching" and "Moving object detection". From experimental results, we confirmed that the proposed method is improved about the robustness of outside construction machines tracking.

Unmanned construction; Camera tracking; Image processing

1 Introduction

A lot of disasters occur in Japan. So, the damaged area must be restored as soon as possible. However, the workers cannot approach the area because of dangerous. Therefore, the remotely controlled construction machines are used to restore there. In the remote construction, machine operators always watch images of the working field from pan-tilt monitoring cameras to control the construction machines. Therefore, the machine operators need to be helped by camera operators. Then, using an automatic camera control system without camera operators is expected for machine operators.

Based on the above requirement, we are developing an automatic tracking camera control system for construction machine operators. In order to track the construction machinery, it is necessary to detect the position of the heavy machine.

There are several methods to detect a construction machine and its position.

One is a method using UWB (Ultra Wide Band). In this method, an active electronic tag is mounted on the construction machine, and the receiving antenna is installed in the construction area. Based on the communication time between the tag and the antenna, the position of the construction machine is measured [1].

There is another method using BLE (Bluetooth Low Energy) technology [2]. In this method, a Bluetooth oscillator is installed in the construction area. The position of the device which has an antenna is measured based on the received radio wave intensity. The location of the installed antenna and the oscillator must be known accurately for this method. However, accurate installation of sensors at the desired positions in disaster areas is difficult.

The research of object tracking using a TOF (Time-of-Flight) camera is also conducted [3]. The TOF camera can get depth information of the acquired image, and track the desired object in the image based on this information. However, this method needs the TOF camera, and the effectiveness of this method is confirmed in the limited environment like on the belt conveyor. So, it is considered that the detection of the construction machine by this method is difficult in the actual disaster area.

In the actual disaster area, GPS is normally used to detect the position of the construction machine. However, unfortunately, some construction machines do not have GPS sensors. Usually, cameras are always used in unmanned construction. Then, we set our target to develop an automatic tracking monitor camera system for construction machines only using image processing.

Many methods have already been proposed for object tracking by image processing technology. However, camera tracking of construction machine based on image processing is difficult because of the following reasons.

- Generally, image processing is weak in outdoor environment. But, construction machines are used in outdoors, mainly. Depending on the weather and brightness change of the day, the color of the heavy machine recorded by the video camera changes.
- The construction machine changes its orientation during its works. So, its image recorded by the camera changes when the machine turns. Furthermore, since the heavy machine has a complicated shape and its appearance image changes drastically depending on its orientation.

As described above, camera tracking for construction machine in various environments by image processing is difficult. Therefore, we considered a solution, and proposed a new image processing method which is a combination of template matching and motion detection. Generally, template matching is weak to the change of the target shape. So, we added the detection of moving object process for our method to overcome the weaknesses of template matching. Our proposed method is explained in detail from the next chapter.

2 The Problem of Image Processing for Object Tracking and Its Resolution

2.1 The Problem of Image Processing for Object Tracking

Color based object tracking is one of the simplest method for image processing based tracking. The method is robust in changing of object's shape and turning of object. In addition, construction machines have conspicuous color, so this method seems effective for construction machines tracking. But, The problem of image processing for object tracking object detection by image processing and color based object tracking is difficult for outdoor objects because the object color data is affected by the sunlight. Furthermore, the recorded color data of construction machine and sand by video camera is sometimes very similar. Then, color based object tracking is not suitable for construction machine tracking.

Some tracking methods which are not color based tracking are provided by OpenCV libraries. These methods are MIL, TLD, MedianFlow, KCF, and Boosting [4]. We tried using these methods for construction machine tracking practically, and confirmed that these methods are not appropriate for it. Because, the speed of these image processing methods is slow, and the tracking by using these methods sometimes failed when the construction machine turns for changing its moving direction and input camera image drastically changes.

It is found that the accuracy of kernel based object detection is high in the construction site [5]. However, based on our trial, the processing time of KCF method which is one of the kernel-based methods was long, then we considered other simple methods.

As another object tracking method, there is a moving object detection using background subtraction method [6]. This method is robust for the above problems in the fixed camera image, but it cannot track the object when the camera is moving, because all camera image moves with camera's moving.

2.2 The Basic Idea to Resolve the Problem of Object Tracking by Image Possessing

Object tracking by image processing is achieved by the continuous detection of object in a camera image. This study proposes combination of two detection methods for robust object tracking. One of them is a template matching which is a simple and fast object tracking method. The other is a detection of moving object using background subtraction method. Generally, object tracking using template matching method prepares a template image for its target, beforehand, and tries to track it by searching the most similar area with the template image. Therefore, the template matching is weak in the appearance change of tracking object. In the construction machine tracking, the target machine moves and its appearance taken by the camera changes, so we considered that the combination method of template matching object tracking and moving object detection can track the construction machine, robustly.

First, we confirmed the ability of template matching based camera tracking method. This method can track construction machine in some cases, but it sometimes fails when the appearance of the construction machine changes drastically. This is a common issue of the image processing based object tracking methods. However, this method is effective for object tracking under camera moving situations.

Next, we confirmed the ability of construction machine detection based on the moving object detection by using background subtraction method. When the construction machine is moving in the captured image, this method certainly detects it. But, needless to say, this method cannot detect the construction machine when it is stopped, or camera moves.

The advantages and disadvantages of these two methods are confirmed, then we decided to combine these two detection methods for construction machine tracking. This combination method tracks the construction machine by using the result of moving object detection when the construction machine is moving, and the result of template matching based detection when the camera is moving. By combining these two methods, the system can track construction machine even if its appearance changes drastically.

Some people may think that the tracking camera moves continuously during its object tracking and moving object detection method cannot be used for construction machine tracking. However, it is no problem because the tracking camera does not move continuously in our target situation. There are two ways of construction machine tracking by the camera. One of them is a method for capturing the construction machine always at the center of camera screen by moving the camera continuously. The other is a method for capturing the construction machine not out of the camera screen by moving the camera with some intervals. In this case, the camera is stopped until the construction machine moves near the edge of the camera screen, and moved before the construction machine is out from the screen. In the actual construction site, the latter method is used for the remote control operation of the construction machine. If the former method is used, the machine operator cannot recognize the speed of the construction machine because of the camera's moving. Therefore, we adopted the latter method in our study, and we could use the moving object detection process based on the background subtraction method for the construction machine tracking.

3 The Trucking Method Combining Template Matching and Background Subtraction.

3.1 The Tracking Method Base on The Template Matching

Template matching is an object detection method in the camera image. It finds an object image part which matches the template image. In the construction machine detection, a template image of construction machine is prepared, and the construction machine image part is found from the image acquired by the camera. Even if the completely matched part with the template image is not found in the camera image, the most similar part is detected as the construction machine. Repeating this process in real time, we can track the target construction machine, continuously. However, object tracking by template matching is weak when the image of tracking object drastically changes. We made an experiment of construction machine tracking using template matching, and found that the tracking of the construction machine failed in several second after it start moving. Therefore, we improved the tracking method using template matching.

We updated template images in real time, so the tracking robustness has improved more than before. Generally, the template image is prepared in advance and the same template image is used during its process, but in this method, the template image is updated as the progress of the tracking process. The detailed process is explained as follows:

First, rectangular template image is selected in the camera image by dragging the mouse. The most similar part with the selected template image is detected from the next frame image acquired by the camera. A new template image is created from the detected image and this process is repeated for continuous tracking. By using this improved method, we could track the construction machine continuously. However, when the distance between the construction machine and the camera changes and the construction machine image size changes, or when the appearance of the construction machine drastically changes due to its turn, the similar matching part with template image disappears and the template matching method fails to track it. We also improved the processing speed of template matching based object tracking method. Matching process is executed only around the template image not for whole screen image because the construction machine moves gradually in the screen.

3.2 Object Detection by Background Subtraction

Template matching based object tracking cannot track the object when the construction machine moves hard. Therefore, we focused on the movement of the object and adopted the background subtraction method which is a typical motion detection method.

Background subtraction is a method which compare two images and extract the different parts. It can extract the changed part by comparing the current frame with the past frame of the camera image. So, it is possible to detect the moving objects and used for motion detection. However, in case when the camera moves or zooms and the whole screen changes, it is difficult to detect the moving objects. We tried to detect construction machines using background subtraction. The moving parts were extracted by comparing the images, but we could not detect the construction machine as one moving object. Figure 1 shows the result of moving construction machine detection using the background subtraction. The white points indicate the extracted parts which the frame image changes.

From background subtraction method, only the moving object edges are extracted in many cases as shown in Figure 1, so we improved this method. The background subtraction data obtained in the past several frames were overlapped and made an image like afterimage (Figure 2). After that, the expansion process is added to the overlapped image (Figure 3). As a result, moving parts can be extracted, clearly. However, moving parts are not yet recognized as one object at this point. Then, labeling is added to this image for recognizing the connected parts as one object. The rectangle in Figure 4 shows the recognized moving object by labeling process.

From the above results, we confirmed that it is possible to detect moving objects by using background subtraction method. Of course, when the camera moves and the whole screen image moves, or plural objects exists in the camera image, it is difficult or not able to detect the target construction machine, accurately by this method.

3.3 Proposed Combination Method of Template Matching and Background Subtraction

The improved template matching based object tracking method can track the construction machine, continuously. However, when the size or appearance of the construction machine image acquired by the camera changes, the

Figure 1. The results of object detection by background subtraction

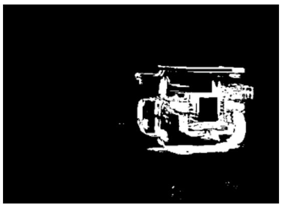

Figure 2. The result of past several frames overlapped image

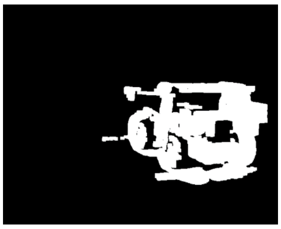

Figure 3. The result of expanded image

Figure 4. The result of moving object detection by background subtraction

matching part with template image includes some errors, and finally the template matching method fails to track it due to their accumulation. On the other hand, background subtraction method can detect and recognize the overall shape of the construction machine accurately when it is moving. But, the background subtraction method cannot detect the object when the camera is moving, or the target object is not moving.

Therefore, we considered to combine the template matching and background subtraction for the construction machine tracking. When the moving construction machine is detected by the moving object detection method, its result is compared with the result of improved template matching based method. If these two results are similar, the matching template is updated based on the result of moving object detection method.

The improved template matching method finds the most similar part with the template in the camera image, and draw a rectangle at the detected area. And, the moving object detection method finds the moving part, and draw a rectangle surrounding the moving object. When the results of rectangles from the moving object detection method and improved template matching method are similar, the template image is updated by replacing to the image of the result of moving object detection method surrounded by the rectangle. In other words, when the results of two methods are similar, the result of moving object detection is used preferentially as the updated template image. The degree of similarity of two results is determined using IoU (Intersection over Union) [7].

This method has the following three great advantages.

The first advantage of this method is that the object recognition ability is improved to the appearance change caused by the object turning. The main reason why the improved template matching lost tracking the construction machine is that the visible surface becomes invisible for its turning, that is, a big change of its appearance has occurred. Therefore, it this case, the construction machine can be tracked by the moving object detection method.

The second advantage is that the size of the template image becomes variable for the object recognition. In the template matching method, the template image size cannot be changed because of its algorithmic limitation. On the other hand, the image size of the construction machine detected by the moving object detection method changes. It changes gradually, because the construction machine approaches to or leaves from the camera gradually. So, the template image size acquired by the combination method also changes gradually. Here, the template image is generated from the result of moving object detection method based on the background subtraction similar to the result of template matching method.

The third advantage of this method is that this combination method prevents detection failure which is likely to occur in background subtraction method. In general, it is difficult to use background subtraction method when the camera moves. Also, if another moving object exists while the tracking object is stopping, the detection failure is caused in the background subtraction method. In the combination method, when the camera moves, the entire screen image acquired by the camera moves, and it is detected as one moving object. In this case, the result of moving object detection method is not similar to the result of improved template matching method, then the system recognizes that the detection failure occurs, and its result is ignored. The improved template matching method is less affected by the changes of the surroundings. So, even if the camera or another object is moving, it keeps tracking the target construction machine.

This combination method is better to be able to compensate for the each disadvantage of the combined two methods, and use their advantage points.

4 Evaluation Experiments

We conducted some experiments to confirm the effectiveness of the proposed method. In the experiments, we used a radio- controlled heavy construction machine model, and recorded its moving images by the fixed video camera. The experiments were conducted to evaluate whether our proposed combination method can track the heavy construction machine model in the video image or not. Tracking failure will occur in the moving object detection process of the combination method when the camera moves. In this case, the system will recognize it and the result of moving object detection will be ignored. Therefore, we also executed the experiment to confirm whether the proposed combination method can track the heavy machine model even the camera moves.

4.1 Robustness Confirmation of The Proposed Method

We prepared a video image of heavy construction machine model which includes large distance change between the object and the camera, and large orientation change by the turning of object, and made comparative tracking experiments using only improved template matching method and combination method. The experimental results are as shown from Figure 5 to Figure 12. The left figures of each row are the results of tracking only by the improved template matching, and the right figures are the results of tracking by the combination method. In these figures, the detection results are shown by the bold lined red rectangles, which are used as the updated template images in the next detection process. (The thin lined red rectangles show the image processing area around the template images for their speeding up.)

4.1.1 Results of Tracking Experiments Only Using Improved Template Matching Method

The initial template is set by the manual mouse operation on the beginning image of the movie. The heavy construction machine model is tracked by the improved template matching method at the beginning phase. It is shown in Figure 5.

However, when the heavy construction machine model approaches to the camera, the detection result does not cover the whole detected object because the improved template matching method cannot change the size of template shown in Figure 7. In other words, we confirmed that this method is not good for the distance change between the object and the camera. In addition, when the heavy construction machine model turns, the position of red template rectangle gradually deviates from the object, and finally it becomes impossible to detect the object. It is shown in FIgure 9 and 11.

4.1.2 Results of Tracking Experiments Using Combination Method

From the results of combination method, we can confirm that the tracking of heavy construction machine model is completely succeeded. After the object starts moving, the initial template image is updated and fitted to the external shape of the object shown in FIgure 6. Figure 8 shows the detection result by the combination method when the object approaches to the camera. This result shows that the moving object detection method can change the rectangular size. In other words, we confirmed that this method is good for the distance change of the object and the camera.

Figure 10 and 12 show that the continuous detection of the heavy construction machine model is succeeded even the object changes the moving direction by its turning. This result shows that the moving object detection method can update the template properly, and continuous tracking is achieved. In other words, we confirmed that the combination method is robust for the appearance change by the object turning. Comparing with the improved template matching based tracking and the tracking by the combination method, we confirmed that the ability of the proposed tracking method is greatly improved.

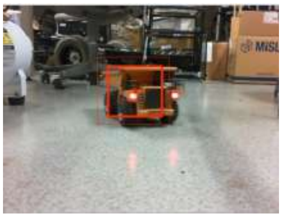

Figure 5. The result of improved template matching method at the beginning phase

Figure 6. The result of combination method at the beginning phase

Figure 7. The result of combination method when the object is approaching to the camera

Figure 8. "Combining method" at closing

4.2 Confirmation of The Influence of Camera's Moving

Tracking the heavy construction machine model only by moving object detection method is difficult when the camera moves or the object is stopping. Therefore, we made an experiment to evaluate the tracking ability of the proposed method by using the video image of these situations. Figure 13 shows the result of the experiment

Figure 9. The result of improved template matching method at the small turning

Figure 10. The result of combination method at the small turning

Figure 11. The result of improved template matching method at the big turning

Figure 12. The result of combination method at the big turning

when the camera and the object is stopping. In the right figure, white dots show the detected parts of the changing. As shown in Figure 13, some moving objects are detected (shown by small blue squares), but the heavy construction machine model is properly detected (shown by red square). This result shows that the combination method ignored the detected moving objects because they are not similar to the result of improved template matching method. Figure 14 shows the result of the experiment when the camera is moving. We can confirm that almost all area of the screen is white from the right figure, and the light blue rectangle surrounds the entire screen from the left figure. In other words, when the camera is moving, the whole screen is detected as one moving object. However, the heavy construction machine model is surrounded by the red rectangle and properly detected. This result also shows that the combination method ignored the detected moving objects including whole screen because they are not similar to the result of improved template matching method. And, we confirmed that the proposed method can track the object robustly in these situations.

4.3 Features of Proposed Combination Method

In this section, the features of the improved template matching based tracking and tracking by the combination method are summarized. Table 1 shows the comparison of

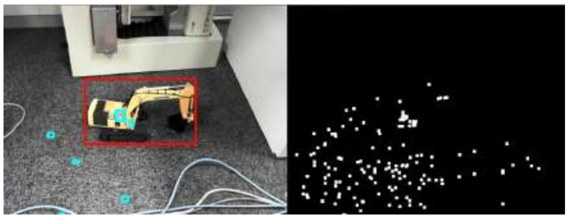

Figure 13. The result of moving object detection method when the camera is stopping

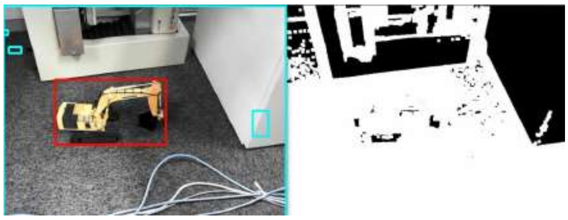

Figure 14. The result of moving object detection method when the camera is moving

the tracking ability in various assumed situations. Table 1 shows tracking accuracy in various situations.

About the tracking only by the improved template matching method, high tracking ability is achieved when the camera or the object moves on the plane parallel to the imaging surface of the camera (for example, move leftwards or rightwards, or move up or down in the camera image). This is because the appearance of the object on the camera image does not change significantly. On the other hand, high tracking ability is not achieved when the object is turning, or moving toward or from the camera, because the visible surface changes drastically. However, the proposed combination method is robust about the turning motion and the translational motion which changes the distance between the object and the camera.

Table 1. Features of Improved Template Matching Method and Proposed Combination Method

Situations	A	B
pan-tilt of camera	◎	◎
Zoom in-out of camera	△	△
Moving heavy machine right and left	○	◎
Moving heavy machine back and forth	△	◎
Turning heavy machine	△	○

A : Improved template matching method

B : Proposed combination method

◎: good ○: not bad △: not good × : bad

5 Conclusion

We proposed the robust camera tracking method for construction machines by image processing which is combining the improved template matching method and the moving object detection method. The proposed method compensates each weak point of both methods by adopting the reliable result according to the situation. By using this method, we succeeded to track the moving objects in outdoor environment where color-based tracking is difficult.

The monitoring of heavy construction machine is very important in unmanned construction site. This camera tracking system will be used instead of the camera operator. So, this system will contribute the improvement of unmanned construction technologies.

In near future, we will confirm the effectiveness of this method at the actual construction work site.

Abstract –

The usability of the Internet of Things (IOT) is accelerated by making intelligent and equipping different machines and devices with smart sensors. IOT is used in smart cities, transportation, construction cases. IOT has the capability to provide real-time information for drivers and citizens to design their routes to avoid traffic and reduce fuel consumption. However, there is a significant number of IOT barriers to IOT utilization such as the distrust of users and managers in sharing information, suspicion to privacy and the ease of using the relevant applications. Despite the importance of these factors, a model for predicting the use of this technology for specific disciplines has not yet been developed, especially for developing countries. Therefore, this research attempts to propose a model for prediction of application, taking into account the increased security of IOT in intelligent transportation. To this end, influential constructs on user trust were collected and tested by questionnaire from 62 experts. The data were analyzed using Smart PLS using confirmatory factor analysis. The results show that 11 hypotheses in the research have been confirmed. The results of this study are very important for technology specialists and urban managers to establish the IOT in the field of urban transport.

1 Introduction

Application of new technologies such as Internet of things (IOT) helps to increase the performance of smart cities The high number of intra-city trips is one of the reasons that cause traffic jam and air pollution, which can be reduced or monitored using IOT applications. However, managers in developing countries have encountered barriers to adopt IOT such as uncertainty and lack of trust. Whereas the amount of users' activity in the urban areas of developed countries is dependent on the IOT measured from the number of connected devices to the Internet at the end of 2015, was about 4.9 billion [1]. This growing trend reflects the increasing impact of IOT in life. Therefore, in close future without IOTs we are not able to control digital things in our life [2]. Therefore, the issues of security and confidentiality need to be considered to increase the IOT adoption rate. The purpose of this paper is to provide a model to increase the security of IOT in smart transportation in developing countries.

The paper seeks to answer how we can increase the security of IOT in urban transportation in developing countries. To answer this, based on the factors taken from theoretical foundations and reviewing the literature of research, twelve hypotheses are developed. Then, using the Smart PLS software, through expert analysis and expert interviews, hypotheses are examined and ultimately we tried to provide an effective model for increasing the security of IOT in smart transportation. This can increase the security of the smart city network.

In general, the structure of this paper is as follows: the first part, entitled literature review, according to the interdisciplinary nature of the research, requires some concepts examined and a common view of them. Therefore, there is a common chapter in the topics of the security domain, the IOTs, and smart transportation. In this section, the models and theories used in the analysis are identified and, in continue, the status of the constructs related to the security of the IOTs in these models is identified. In the second part, the method of confirmatory factor analysis is introduced as a research method to test the hypotheses of the proposed model for increasing the security of IOT in smart transport in smart city. In the third part, the results of factor analysis are presented and the conceptual model of increasing the security of IOTs in the urban transport sector is tested, corrected and finalized in order to realize the smart urban management. Finally, the results of the analysis are summarized in the final section.

2 Literature Review

One of the most controversial topic in the area of security is the emergence of a new paradigm for IOTs, which include a range of electronic devices that can connect to the Internet. The problem anticipated in IOTs is that things cannot be safely stacked and there is not enough memory to install and run security software on them. Therefore, the network should be protected to detect violations and prevent the entry of attacks [1]. Web-based technologies are moving at a fast pace and realizing the ideas of the smart city. Despite the speed of technologies that guarantee the security of users and their information, it is far behind the technology itself, and there are fewer studies in the research literature. The IOT has shown its most importance and application in the field of urban transportation [3-8].

The review of the literature in this field requires a lot of vigilance. However, what has been tried in this research is to investigate the IOT, network security and smart transportation. So, in the following, we try to identify shortcomings in each of these three areas in order to identify the effective factors in increasing the security of IOTs in smart transportation. Over the past decade, the IOT has entered silently and gradually in our lives, and we need to thank the availability of wireless communication systems, which are increasingly used as a technology motive for highly smart monitoring and application control [9]. The IOTs can be a collection of Web services, devices (RFIDs), infrared sensors, global positioning systems, barcode scanners, networking, and etc. by using the conventional protocol, the exchange of information and communication in order to achieve identification, tracking, monitoring and smart management of objects are used [10]. In other words, the IOT can be seen as a new form of network based on the Internet, which is much larger. A network is made up of advanced computers [11]. In the area of security of IOTs, it can also be said that traditional security interactions and privacy enforcement, due to their limited computing power, cannot be directly applied to the IOTs; in addition, the large number of connected devices causes scalability issues. Simultaneously, in order to gain full acceptance by users, it is necessary to define valid security models, privacy, and trust in the context of the IOT applications projects [12]. The purpose of security is to ensure that data anonymity, confidentiality, and integrity are guaranteed, as well as authentication and authorization mechanisms to prevent unauthorized users (i.e. humans and devices) to access this system. While privacy requirements are in place, data protection and the confidentiality of personal information of users must be guaranteed, as devices may handle sensitive information (for example, user habits). Finally, trust is an important issue because the IOT environment is characterized by a variety of devices that must process and manage the data in accordance with the needs and rights of the users.

Previous studies investigated sub topics of enabling technologies and middleware technologies in the IOT from the perspective of an application, analysis, and security and privacy issues with standardization, addressing, and the network is provided [13]. Security and privacy challenges were examined only from a legal perspective, with particular regard to the guidelines of the European Commission [14]; [15] in his paper discussed the Internet underwater objects, and only did a few notes present on the security issue; In another study [16], the advantages and disadvantages of centralized and dispersed architectures in terms of security and privacy on the IOTs, along with analysis of major attack patterns and threats, were examined. Yan et al. [17] focused solely on the issue of trust management in the IOTs.

Here are some brief references to some of the most important security issues on the IOTs. In relation to the issue of access control, various articles have addressed the subject from a variety of perspectives. For example, Ma et al. [18] is focused on the data literacy layer, which is responsible for the direct collection of information. An approach that addresses the outsourcing-data authentication problem can be found in [19, 20]. Sicari et al. [9] also suggests a semi-distributed approach. More precisely, in this research, a security framework and an access control model were proposed to secure the so-called DSMSs that extend the Borealis data flow engine to security requirements [21]. Finally, in [22], a UML conceptual model was defined for all objects and Internet architectures.

Review of resources about privacy on the IOT is also indicative of useful research. In the research [23], data labeling is proposed for managing the privacy of the IOTs; in [24], an access-controlled protocol by user is proposed; In [25], the continuous anesthetization of data flows was presented through the adaptive cluster; In [26], traditional privacy mechanisms are divided into two categories: optional access and limited access.

Another method, which uses a sign-on signing scheme to guarantee privacy on the Internet, is presented in the research [27]. [28] in their paper began to work on data mining privacy techniques, which aims to minimize the probability of disclosure of critical data and decomposing sensitive content.

In reviewing resources on the topic of trust of the IOTs are also briefly referred to several articles. [29] wrote about the evaluation of the trustworthiness of IOTs inputs. A similar methodology for evaluating reliability is provided by [30] on the so-called Internet of Social Things. This paradigm is due to the integration of the social networking concepts within the things of the Internet. The articles mentioned so far are merely to illustrate the large volume of studies on the dimensions of the IOTs. But this area of knowledge is less applicable to urban life applications and urban management.

The third area used in leading research to achieve the purpose of the research is smart transportation. The concept of smart city has been adapted from a variety of definitions that include the intelligent city, the information city, the knowledge city, the digital city, and the same concept as the smart city [31]. Cities play a prominent role in social and economic aspects all over the world [32]. The smart transportation system is a general term for the application of a combination of communication technologies, control and information processing for the transportation system. Using it will save lives, saving time, money, energy and environmental benefits.

An overview of the available resources shows that there are two theories of diffusion of innovation and technology acceptance model, which are rlated to technology acceptance dimensions. Having a special position in terms of both personal and psychological aspects, the technology acceptance model is one of the most widely-used models. This model addresses the causes of technology rejection from the psychological point of view for users. Other popularity that can be effective in achieving this goal is diffusion of innovation theory. This theory has redefined a set of constructs that can be used to study the adoption of individual technology.

The review of resources clearly refers to the extensive efforts of researchers in the field of the applicability of the IOTs. However, the lack of acceptance of this termination due to the lack of security in its application is one of the most important reasons that has not been tested in the field of smart transportation from the psychological point of view in developing countries. In the next section, with a closer focus on effective constructs in increasing the security of IOTs in the field of smart transportation, the paper is trying to provide an effective model in this regard.

3 Conceptual framework

In this part, the initial conceptual model to increase the security of IOTs in smart transportation is presented. Figure 3 illustrates the process of modeling the technology acceptance model by users in Iranian metropolitan areas in four main stages. In this research, in order to provide a proposed model for increasing the security of IOTs in smart transportation, the researcher is attempting to cover as broadly as possible a theoretical concept. For this purpose, both theories are used. Since the roots of the two models are common in some constructs, the two models can be considered together to provide the theoretical basis for their proposed model. In this paper, the implications of the proposed theory that affects the security of the IOTs in the field of smart transportation are introduced as construct, including the perceived usefulness, compatibility, or trial ability. In Figures 1 and 2, technology acceptance model and diffusion of innovation theory are introduced.

The investigating of the constructs of the models shows that the two constructs, the relative advantage and complexity, of the diffusion of innovation theory have the same concepts with the two constructs, perceived usefulness and perceived ease of use, respectively, of the technology acceptance model. As mentioned, the theoretical basis of the proposed research model was introduced in order to increase the security of IOTs in smart transportation as Fig. 4. Based on the theoretical foundations, eleven constructs are presented to provide the views and theories on which they are based. Table 1 lists the 12 final constructs used in the proposed model.

4 Research Method

In this research, eleven hypotheses have been developed based on the relations among fifteen constructs taken from the theoretical foundations to achieve its goal of increasing the security of the IOTs. The main purpose of this paper is to formulate hypothesis and develop the conceptual model rather than analyzing the data which require further investigation.

As shown in Fig. 1, a quantitative confirmatory factor analysis was used to test the model of increasing the security of IOTs in smart transportation. Factor analysis is performed using Smart PLS software. A questionnaire was used to collect the data to test the hypotheses. This means that for each hypothesis related to model constructs, questions have been raised and forwarded in the form of a questionnaire among experts. To determine the sample size, based on the method of structural equations, ten times more than the number of markers forming a construct is selected as the sample size. Namely, in the model, identifying the instruments that have the largest number of constituent markers, and this amount is 10 times that of the desired sample size [35]. Since in this research according to Fig. 4, in the attitude construct, there are 7 indicators, the sample size was determined to be 70. This sample size is used to collect data through questionnaires forwarded. These individuals have been selected by experts in the field of transportation, computer and information technology in organizations under the supervision of the municipality of Tehran. 62 questionnaires were returned to perform the analysis. Therefore, the return rate of the questionnaire is 88%. The validity of the proposed constructs for the model is validated using a confirmatory factor analysis method. The Smart PLS was used to test the model. This software is used to analyze multi-construct data. Smart PLS is based on the estimation of the least number of variables in order to optimize the explanation of variance in the constructs dependent on the structural equation models. The purpose of this is to maximize the variance of dependent variables defined by independent variables [35].

4.1 Hypotheses Formulation

In this section, research hypotheses that are presented on the basis of the relationships between the research constructs and the literature review are briefly presented. These relationships are shown in Figure 4.

- H1: Privacy has a negative relationship with observability in using IOTs in smart transportation.
- H2: Access Control has a negative relationship with observability in using IOTs in smart transportation.
- H3: Observability has a positive relationship with Attitude toward Use in using IOTs in smart transportation.
- H4: Trial ability has a positive relationship with Attitude toward Use in using IOTs in smart transportation.
- H5: Trust has a positive relationship with Compatibility in using IOTs in smart transportation.
- H6: Compatibility has a positive relationship with Attitude toward Use in using IOTs in smart transportation.
- H7: Mobile Security has a negative relationship with Perceived Ease of Use in using IOTs in smart transportation.
- H8: Secure Middleware has a negative relationship with Perceived Ease of Use in using IOTs in smart transportation.
- H9: Perceived Ease of Use has a negative relationship with Attitude toward Use in using IOTs in smart transportation.
- H10: Perceived Usefulness has a positive relationship with Attitude toward Use in using IOTs in smart transportation.
- H11: Policy Enforcement has a positive relationship with Attitude toward Use in using IOTs in smart transportation.

In continue, based on the analysis done on the hypotheses carried out using the data collected by the questionnaires, the hypotheses are either confirmed or rejected.

5 Data Analysis and Results

In order to evaluate the proposed model, the structural equation modeling is utilized using the Smart PLS 3.0 [36]. The paper also presents the results of two tests of the measurement model in terms of validity and reliability, the structure of the model in terms of the relationship among variables, and fitness of the model. If the model passes all three stages successfully, it shows the correctness of the selected constructs and their dependent terms. For testing the measurement models, we examined the ‘convergent validity’ and ‘discriminant validity’.

5.1 The Measurement Model

In this section, each of the proposed factors is referred to the construct and questions related to each construct. T-value is a test used to validate measurement models in statistics science. The t value for meaningful factor loads in the corresponding fields of each variable in the study indicates that the value greater than 2.66 is significant for the values of t obtained at the error levels of 0.01 [36]. Other indicators are categorized into two groups of convergent validity and discriminant validity for measuring the model of measurement. In the following, these two categories of tests are discussed.

5.1.1 Convergent Validity

Convergent validity is used to determine construct validity by defining factor loading, Cronbach's alpha, Average Variance Extracted (AVE), and Composite Reliability (CR) [40]. Table 1 shows the loading coefficients of the corresponding measures of each construct varying from 0.7 to 0.9. The load value of each item on the corresponding construct is well above the recommended value of 0.7 [39] indicating the proper and desirable load factor of each item on its related construct. Measures with the value of less than 0.7 can be omitted. Cronbach's alpha was applied to assess the validity of the measures. The CR coefficient distinguishes the correlation coefficient of measures in one dimension for fitting adequate measurement models [39]. The results validate the criteria as Cronbach's alpha is well above 0.7, and the AVE is also above 0.8, which surpasses the recommended threshold of 0.5 [39]. The CR is above 0.7 [38] for all constructs [39] excluding CT and PREL, which are very close to 0.7. The results validate that all criteria were satisfactory, since they are above the recommended values.

5.1.2 Discriminant validity

Divergence validity of the model was assessed through the comparison of the correlation coefficient of constructs with its indexes versus the correlation of that constructs with other constructs was presented. The results are shown in Table 2. According to [38], AVE the constructs located in main diameter of matrix are more than the correlation between them, which are arranged in the lower and left boxes of the main diameter. Therefore, it can be concluded that in the above model, the constructs interact more with their own indicators than with other constructs. This shows that the divergence validity of the model is appropriate.

5.2 Structural Model

To test the construct validity of factors in the model, a confirmatory factor analysis was conducted. To investigate the CFA using structural equation modeling, a model was first created based on the type of constructs such as observability and related measures of each construct such as OB1 to OB3. This analysis and model development were done in Smart PLS 3.0. The hypotheses were examined by assessing the parameters of the PLS structural model. The R^2 value for constructs vary from 0.16 to 0.92. The result of R^2 values shows the predictive power of the model including four dependent constructs is acceptable and indicates that the theoretical model explained a substantial amount of the variance in performance. The value of R^2 for observation, compatibility, perceived ease of use, and attitude toward use are 0.31, 0.3, 0.28, and 0.39, respectively. The standardized path coefficients also show the strength of the relationship between the independent constructs (e.g. PSY) and the four dependent constructs (e.g. OB). The multi-collinearity between the variables in our model was evaluated, and no cause was found for concern related to the variance inflation factor (VIF) criteria, as according to the Table 3 all of the values of VIF are below the proposed value of 5.00 [40]. In addition, the model's predictive relevance was assessed by using the blindfolding procedure [40]. The values of Q^2 which are greater than zero, indicate the sufficient predictive relevance of the model. If the model passes the determined tests in the confirmatory factor analysis method using smart PLS successfully, the proposed conceptual model and; in other words, the factors and the related questions (items) to each factor are verified. As the results are shown in Table 3, Access Control, Observability, Mobile Security, and Secure Middleware have not been able to explain more than 50% of the corresponding construct variance. The t-value was compared with the error level to assess the relationship between dependent constructs and independent constructs. Where the values are greater than of the minimum of 1.64 recommended by [40], all relationships were confirmed. At the error level of 0.01%, 0.05%, and 0.1. %, path coefficients with the minimum of 2.58, 1.96, and 1.64 in t-value are confirmed [40]. Table 3 shows that the value ranging from 0.03 to 30.79 and the hypotheses excluding H2, H7, and H9 are supported.

Table 2. Discriminant Validity

H11	PE → AU	4.31	0.89	4.84	Supported ($p<0.001$)	0.9		

5.3 Fit Model

The third step that needs to be considered in the proposed model is the overall model fit index. Model fit index is an acceptable criterion for confirming the developed theoretical model using the collected data [41]. The method for calculating the overall model Goodness of Fit (GoF) index [42] is as follows:

$$GOF = \sqrt{\overline{Communalities} \times \overline{R^2}}$$

The Communalities value is obtained of the average shared values of all constructs or, in other words, it is obtained of the average variance extracted presented in Table 1. The R^2 value is also obtained from the mean R square or explained variance of all model' constructs in Table 3. R^2 of determination is a number that indicates the percent of variances in the dependent variable. If R^2 be 1, it indicates that the regression line perfectly fits the data. The amount of GoF was checked at three levels: GoFsmall = 0.1, GoFmedium = 0.25, and GoFlarge = 0.36. The amount of GoF more than 0.36 represents a perfect fit conceptual model of research [42]. Therefore, the value of 0.67 for GoF of present research model is suitable fit and the proposed conceptual model is confirmed.

In general, due to the proper quality of the measurement models, the structural model, and also the appropriate model fitness, it can be concluded that according to the confirmatory factor analysis for this study, the items of the questionnaire can be used to explain the identified factors or suggested constructs.

6 Discussion

The purpose of this study is to propose a conceptual model, which can be used for increasing the security of IOTs in smart transportation in developing countries. For this purpose, firstly, the literature on the three areas of the IOTs, the security, and smart Transportation have been investigated. Then, based on theoretical foundations, the research hypotheses were presented. These hypotheses have been investigated by confirmatory factor analysis and Smart PLS software. Further confirmation or rejection of hypotheses has been discussed, but a large amount of data is required to exactly test the hypotheses and generalize them. The contribution of this paper is to propose a conceptual acceptance model.

Two factors should be considered to confirm or reject the research hypotheses. The first factor is the path coefficient. The positive path coefficient represents a direct relationship between constructs and the negative path coefficient represents an indirect relationship. This value in large measure represents the power of the relation that decreases with the establishment of indirect relations from the magnitude of a path coefficient. The second factor is t value. The t-value was compared with the error level to assess the relationship between dependent constructs and independent constructs. Where the values are greater than of the minimum of 1.64 recommended by (Hair Jr et al., 2016), all relationships are confirmed. At the error level of 0.01%, 0.05%, and 0.1. %, path coefficients with the minimum of 2.58, 1.96, and 1.64 in t-value are confirmed (Hair Jr et al., 2016). The results of the table 3 show that the t-statistic for hypotheses with an error level of 0.001 is greater than 2.58, except for H8, which is more than 0.05 with an error level of 1.96. Based on this index, three hypotheses H2, H7, and H9 are rejected based on t value. In the first section, the hypotheses that have been confirmed are discussed, and the following three rejected hypotheses are introduced.

Another importance point related to hypotheses is the power of them. In this way, the greater amount of the coefficient, the more powerful hypothesis whether this is negative or positive. Therefore, the hypotheses are further reviewed on the basis of their power. As shown in table 3, H5 has a lot of power and is very close to reality. The sharp difference between this hypothesis and other hypotheses can be attributed to the importance of questions related to this construct in the questionnaire for questioners. Accordingly, trust in the IOTS in the transportation system is important in connection with technology adaptation to increase the security of the IOTs in the transportation system. It was stated in the hypothesis that the confidence would be obtained when the system could be compatible with the existing values and psychological needs of the recipients and their experiences. Therefore, systems in the IOTs must be compatible with the values and psychological needs of its adopters. The path coefficient of H1 is in second place. In this hypothesis, privacy, when using IOTs in the transportation system, has a negative relationship with one's perception of being viewed by others. The almost strong significance of this hypothesis is that IOT users in urban transport are important in protecting their privacy when using this technology. This hypothesis has a third degree of importance for users. In H11, it has been argued that the policies enforcement by planners and supersonic devices, when using IOTs in the transport industry, have a positive relationship with the perception of the proportion of increasing the security of the IOTs in the transportation system. Thus, users tend to display government agencies and administrators their supervisory role to increase the security of the IOTs. So they will feel more secure. This hypothesis can also confirm the results of the previous hypothesis (H1). In H3, it is stated that observation by supermodels, when using IOTs in the transport industry, has a positive relationship with the individual's tendency to increase the security of the IOTs. Therefore, this category will be the second most important issue for IOT users in the transportation system. H8 also states that the interconnection between the large number of communication devices at different levels in the middleware at the time of using IOTs in the transportation has a negative relationship with the perception of the person's ease of use of the system. H10 discusses about having a positive relation between the usefulness of using IOTs in the transportation and a person's perception of the security of IOTs and his attitude toward its application. According to H6, compatibility of IOTs in the transportation system has a positive relationship with the perception of the individual about increasing the security of the IOTs. H4 also states that the ability of an individual to test the IOTs in the transport industry has a positive relationship with the perception of the individual about increasing the security of the IOTs.

As the results of table 3 show these three hypotheses are rejected. H7 is about the complexity of relationships in mobile devices when using IOTs in the transportation. According to this hypothesis, mobile security will have a negative impact on the perception of ease of use in using this type of technology. H2 anticipated that there is an inverse relationship between the access control of users to resources and data by government and supranational institutions, and the perception of one's being seen by others. This matter that this hypothesis is rejected indicates that there is not a positive relation between these variables. In other words, controlling the access of users during the use of IOTs in the transportation system is negatively related to the perception of the person than to be seen by others. In H9, it is stated that the perceived ease of using the IOTs in the transport industry has a negative relationship with the perception of the person about the security of IOTs and his attitude towards its application.

7 Conclusion

The purpose of this study is to achieve a model for increasing the security of IOTs in smart transportation. For this purpose, based on the review of the literature, the model was first proposed and the results of the 62 questionnaires collected by the experts were analyzed using a confirmatory factor analysis method based on the structural equation model. The validity of this model is confirmed by using a t-student test with an error rate of 0.001%. The results of Tables 1, 2, and 3 confirm the appropriateness of the reliability and convergence validity of the research model. In addition, according to the results of the appropriate quality of the measurement model, the structural model, as well as the fit model that was calculated in formula 1, the theoretical model confirmed by using the collected data confirms. Because of the confirmatory factor analysis for this research, the variables of the design questionnaires in the research can explain the identified factors or suggested constructs.

The results of the confirmatory factor analysis carried out on the hypotheses in the proposed model, examine the confirmation or rejection of the hypotheses based on the path coefficients in them comparing the t-value at the standard error level. According to Table 3, hypotheses 2, 7, and 9 are rejected. But the strength of the hypotheses can be determined based on their path coefficient. So the hypothesis 5, which has the highest path coefficient, has the strongest effect. It was stated in the hypothesis that the trust would be obtained when the system was compatible with the existing values and psychological needs of the recipients and their experiences. Therefore, existing systems in the IOTs should be compatible with the values and psychological needs of its users. Hypotheses 3 and 1 also are too strong. Finally, hypotheses 2, 7, and 9, which are rejected hypotheses, have a low path coefficient and are weak. The conceptual model presented in this paper is important for transportation, information technology, computer and urban managers and decision-making organizations for the provision and deployment of the IOTs in the field of urban transportation. However, the statistical results may very in larger samples and different contexts. The proposed model helps to provide a powerful tool for increasing the security of IOTs to increase the level of user's interest in this technology.

Abstract –

As construction projects become larger and more complicated, the importance of information sharing among various project participants throughout the entire life-cycle of a facility is ever-increasing. Establishment of standard classification system is the most fundamental task for systematic and efficient management of construction information. In recent years, technology advancement of smart manufacturing, which is for intelligent factories supported by ICT combined with existing manufacturing technology, is becoming a key issue.

However, due to the lack of information exchange (IE) standards for the management of smart manufacturing's construction and operation, it is very limited for various construction participants to generate and share information by using the standards. In addition, each standard classification should be used in a combined manner in order to improve information processing efficiency.

Standard classification requires a variety of facets such as facility, space, element, and work section. The purpose of this study is to propose a physical breakdown structure (PBS) that best reflects distinct characteristics of smart manufacturing. Firstly, the influencing factors for defining PBS were identified. A methodology for creating the facility classification suitable for smart manufacturing was then developed. Finally, cost breakdown structure (CBS) and work breakdown structure (WBS) were developed by combining the PBS and other standard classifications. This case-study of CBS and WBS formulation were used as a validation for the proposed methodology. The concept of "flexible WBS" by Jung and Woo [6] were utilized in this case study as well, in order to accommodate the managerial requirements of an owner organization from the display industry.

Keywords –

Standard classifications; Smart manufacturing; Facility management; Information exchange

1 Introduction

Recently, as part of the fourth industrial revolution, technology development and standardization of smart factories that can optimize relevant management by sharing and utilizing all production information and knowledge in real time based on ICT has become a key issue in the manufacturing industry. Planning, design, production, distribution, and sales could be conducted at lower cost and reduce time through the development of technology and standardization [9]. In addition, it is possible to build a next-generation factory that actively responds to new environments such as productivity improvement, energy saving, implementation of people-oriented working environment, and personalized manufacturing [9].

A lot of standards have been developed for standardized information exchange (IE) among the various components of the manufacturing process. However, due to the lack of information exchange standards for construction and operation management of smart factories, it is very limited for various construction participants to generate and share information by using the standards. Therefore, a great deal of effort is required to rework the data for the operation and maintenance (O&M) phase.

In an effort to develop standard classifications for airport projects, Jung et al. [2] pointed out that "the issues of information exchange could be discussed from various perspectives including level of detail (LOD), diversity of various facets, and business requirements".

The purpose of this study is to develop a physical breakdown structure (PBS) that best reflects distinct characteristics of smart manufacturing. Firstly, the influencing factors for defining PBS were identified. A methodology for creating the facility classification suitable for smart manufacturing was then developed. Finally, cost breakdown structure (CBS) and work breakdown structure (WBS) were developed by combining the PBS and other standard classifications.

This case-study of CBS and WBS formulation were used as a validation for the proposed methodology.

2 Needs for Standard Classifications in Smart Factory

There are two types of standards for smart manufacturing. One is directly related to manufacturing and the other one is indirectly related to manufacturing process [8]. Lee et al. [9] summarizes current ISO standard activities as listed in Table 1 based on KATS [7].

Table 1 International Organization for Standardization for smart manufacturing [7] [9]

IEC/SEG 7	- Smart manufacturing
IEC TC 65	- Industrial process measurement, control and automation
ISO TC 184/SC 4	- Industrial data
ISO TC 184/SC 5	- Interoperability, integration, and architecture for enterprise systems and automation applications
ISO/IEC JTC 1/WG 9	- Big data
ISO/IEC JTC 1/WG 10	- Internet of things
oneM2M	- Standards for M2M and the Internet of Things
IEEE P2413	- Standard for an Architectural Framework for the Internet of Things

These standards have been developed by ISO mainly in the fields of IoT, big data, cloud computing, security CPS, M2M, etc. For example, most of ISO TC 184/SC 4 is the series of representation and information exchange for product data (ISO 10303). IEC TC 65 mainly covers standards for industrial cable, wired and wireless network, and system integration [9].

However, due to the lack of information exchange (IE) standards for construction and operation of smart factories, it is very limited for various construction participants to generate and share information by using the standards. Therefore, the establishment of a standard classification for construction information exchange will contribute not only to realization of data-centric factory construction management but also to the improvement of managerial effectiveness.

From the owner's perspective, standard classifications enables to collect standardized information from many construction participants, like designers, engineers, contractors, operators, etc. This also allows new construction participants to share information automatically.

3 Standard Classification and Numbering System (SCNS)

Like the smart manufacturing, the construction industry has been using international standards for a long time. For example, MasterFormat [10], Uniclass [12], OmniClass [11], etc. In particular, information exchange through the standard classifications is a very important factor in terms of managerial effectiveness and information consistency, as there are many participants, including owners, designers, engineers, contractors and operators in factory construction projects.

In the early stage, this study attempted to use existing international standards for factory construction projects. However, existing international standards cannot adequately reflect the characteristics of the factory. Among the various classification facets, the facet that best reflects characteristics of factory is 'facility'. However, it is difficult to classify 'facility' according to existing construction standards, because the level of 'facility' classification is too high to present a special-purpose building to a factory. It is also difficult to define an equipment or a system as a part of a 'facility' classification in the existing construction standard classifications.

In order to solve this problem, a 'facility' classification of owner's perspective is developed, known as physical breakdown structure (PBS) in practice, which reflects characteristics of smart manufacturing for systematic and efficient management and utilization of construction information on factory.

As shown in Table 2, PBS is developed by the concept of standard for classification and numbering system (SCNS) [3]. SCNS consists of standard classifications (CLN) and project numbering system (PNS).

Establishment of CLN and PNS is the most fundamental task. It forms a framework for all related project management tasks, such as scope management, design management, process control, cost control, quality control [4].

There are many different facets in CLN that satisfies general requirements. ISO [1] recommended facility facet, space facet, element facet, work section facet, material facet, construction aids facet, management

Table 2 SCNS - Standard Classification and Numbering System [3]

L I	Level II	Level III	Remarks
Standard Classification and Numbering System (SCNS)	Standard Classifications (CLN) *	(CLF) Facility Facet	e.g. Building, Airport
		(CLS) Space Facet	e.g. Office, Bed room
		(CLE) Element Facet	e.g. Column, Beam
		(CLW) Work Section Facet	e.g. Steel structure
		(CLM) Construction Material/Assembly Facet	e.g. Re-bar, Concrete
		(CLA) Construction Aid Facet	e.g. Wood form, Crane
		(CLG) Management Facet	e.g. Cost, Contracting
		(CLP) Attribute and Property Facet	e.g. Heat transmission
	Project Numbering Systems (PNS)	(GBS) Geometry Breakdown Structure **	Multi-facet for 3D design
		(WBS) Work Breakdown Structure	Multi-facet for scheduling
		(CBS) Cost Breakdown Structure	Multi-facet for cost
		(EBS) Equipment Breakdown Structure	Multi-facet for procurement
		(OBS) Organization Breakdown Structure	Multi-facet for stakeholders
		(RBS) Risk Breakdown Structure	Multi-facet for risk
		(MBS) Measurement Breakdown Structure	Multi-facet for estimating
		(SBS) Specifications Breakdown Structure	Multi-facet for specs
		(DBS) Drawing Breakdown Structure	Multi-facet for drawings
		(PBS) Physical Breakdown Structure	Single facet
		(FBS) Functional Breakdown Structure	Single facet

* Eight facets defined by ISO [1], ** Patented by Myongji University [5]

facet, and attribute facet as the top level categories. In addition, combining these facets could be used as a PNS for specific purposes (e.g. cost, scheduling, etc.) [3]. Therefore, the continuous development of standard classifications for other facets in smart factory would be able to expand the influence for extensive application in practice.

As discussed previously, PNS has a structure that combines several different CLNs. As shown in Table 2, most of PNSs are 'multi-facet'. For example, CBS can be defined by combining CLF with CLW of CLN. However, PBS and FBS are 'single facet' and PBS can be defined as a 'facility' classification, which is CLF. Therefore, CBS also can be defined as a combination of PBS and FBS in this study.

4 Physical Breakdown Structure (PBS)

The proposed PBS of a factory construction project in the display industry has three-level structure as shown in Figure 1. The first level has eight categories. There are 'project general (000), panel equipment (100), module equipment (200), fab common facility (300), utility (400), electric power facility (500), architecture/civil (600), and trunkline (700)'.

The second level of 'project general (100)' has 'planning (010), site acquisition (020), licensing/permission (030), project/production management (050), and indirect cost/others (090)', which includes general items to perform the project. 'Panel equipment (100)' includes several panel-related production equipment, and 'module equipment (200)' includes module-related production equipment. 'Fab common facility (300)' includes several common items for fabrication buildings, and 'utility (400)' includes utility-related equipment. Items belonging to the second level of 'panel equipment (100) and module equipment (200)' are not open to the public at the display company's request.

'Fab common facility (300)' has 'CR (310) and FA (320)' as the second level, which are facilities that common includes 'panel equipment (100) and module equipment (200)'. 'Utility (400)' includes 'gas (410), chemical (420), water (430), vacuum (440), emission (450), waste (460), and air (470)', which are utility equipment. 'Electric power facility (500)' includes 'electrical facility (510), distribution facility (520), and generating facility (530)'. 'Architecture/civil (600)' has 'infrastructure (610), stock (620), storage (630), auxiliary building (640), and temporary facility (680)', which includes general buildings. Finally, the second level of 'trunkline' includes 'system wiring (710),

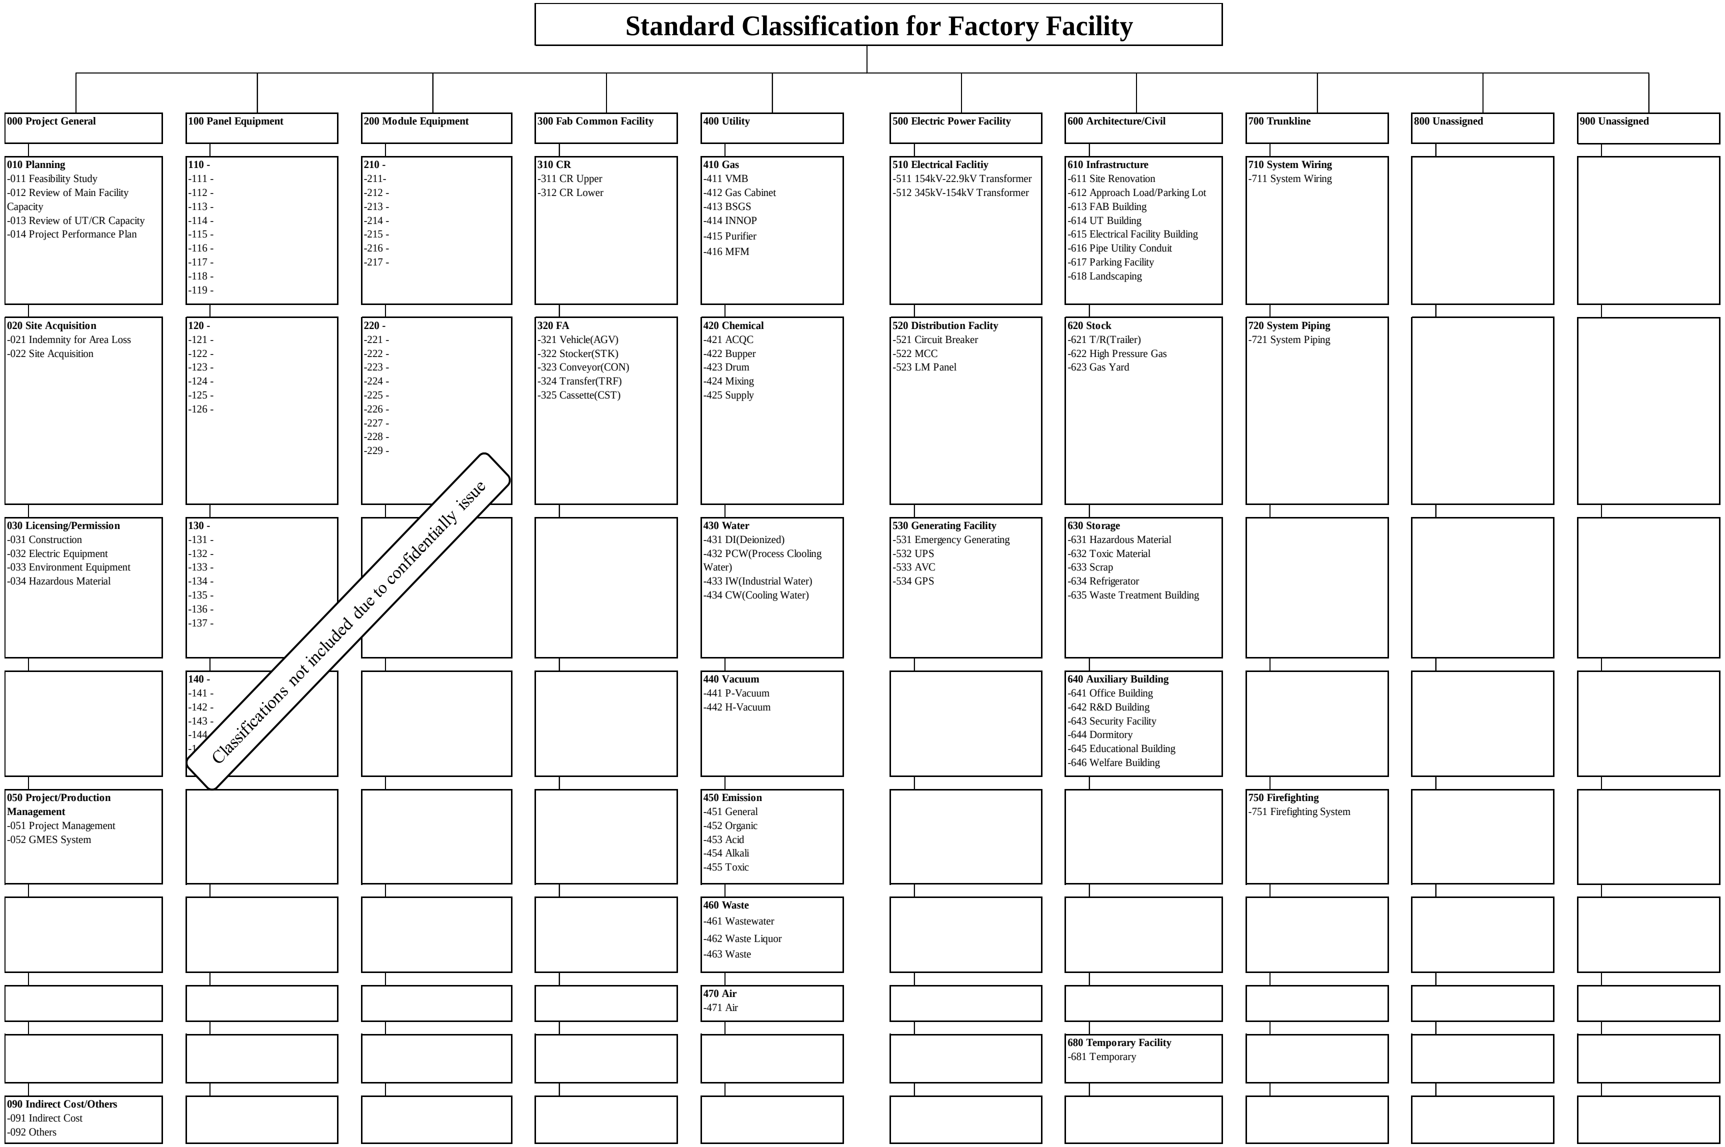

Figure 1. PBS Structure for Factory Facility

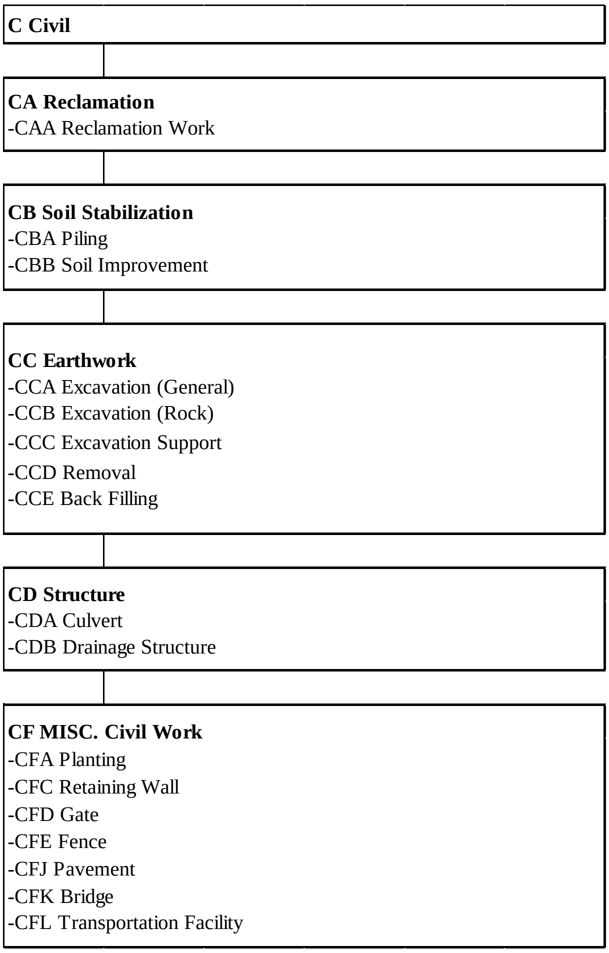

Figure 2. Part of PBS

system piping (720), and firefighting (750)'.

For example, Figure 2 shows the category of 'architecture/civil (600)'. 'Infrastructure (610)' includes 'site renovation (611), approach load/parking lot (612), fabrication building (613), utility building (614), electrical facility building (615), pipe utility conduit (616), parking facility (617), and landscaping (618)', which are infrastructures. 'Stock (620)' has 'trailer (621), high pressure gas (622), and gas yard (623)'. 'Storage (630)' includes 'hazardous material (631), toxic material (632), scrap (633), refrigerator (634), and waste treatment building (635)'. 'Auxiliary building (640)' includes 'office building (641), R&D building (642), security facility (643), dormitory (644), educational building (645), and welfare building (646)'. Finally, 'temporary facility (680)' includes 'temporary (681)'.

As a result, this category has five sub-categories in level 2 and twenty three items in level 3. In this way, PBS is defined that including a total of 8 categories in level 1, 31 sub-categories in level 2, and 125 items in level 3.

The proposed 'facility' classification in this study shows unique characteristics that cannot be found in existing construction codes. More specifically, 'project general (000)' are the general factors to perform a project. (700)' are defined with the factors for machines and 'Panel equipment (100), module equipment (200), utility (400), electric power facility (500), and trunkline systems rather than facilities. Because unlike general buildings, these factors are essential for supporting managerial tasks such as cost, scheduling, and operating in the factory construction project.

5 Case-Study

Due to the characteristics of factory construction, each standard classification of different technical fields should be used in a combined manner in order to improve information processing efficiency of construction participants according to share necessary information on entire related technical fields, such as civil, architecture, machinery, electricity, instrumentation, and communication.

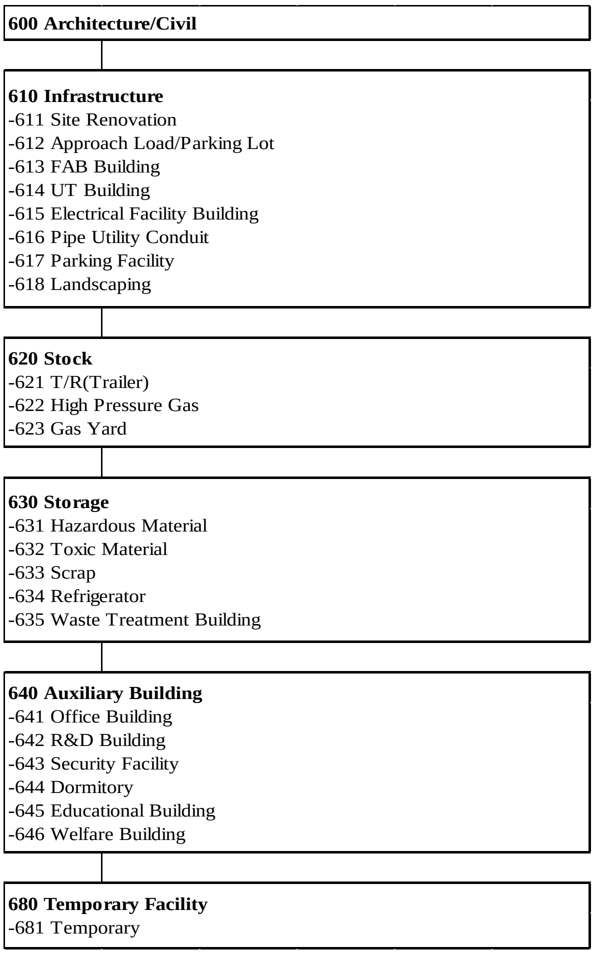

Figure 3. Part of FBS

		N	Automatic Control			●	700	Trunkline	D	Design	●		
		S	Commissioning			●			M	Mechanical Equipment	●		
									E	Electrical Equipment	●		

A case study of cost breakdown structure (CBS) structure is introduced by combining PBS and functional breakdown structure (FBS) at a display factory in this chapter.

Like PBS, FBS also has three-level structure. The first level has 12 categories. There are 'architecture (A), civil (C), design (D), electrical equipment (E), temporary (G), consulting (K), planning (L), mechanical equipment (M), automatic control (N), contract (P), commissioning (S), and ICT (T)'.

For example, Figure 3 shows the category of 'Civil Engineering (C)'. This category has 5 sub-categories. These include 'reclamation (CA), soil stabilization (CB), earthwork (CC), structure (CD), and MISC. civil work (CF). 'Reclamation (CA)' includes 'reclamation work (CAA)'. 'Soil stabilization (CB)' includes 'piling (CBA) and soil improvement (CBB)'. 'Earthwork' includes 'excavation (general) (CCA), excavation (rock) (CCB), excavation support (CCC), removal (CCD), and back filling (CCE)'. 'Structure' includes 'culvert (CDA) and drainage structure (CDB)'. Finally, 'MISC. civil work (CF)' includes 'planting (CFA), retaining wall (CFC), gate (CFD), fence (CFF), pavement (CFJ), bridge (CFK), and transportation facility (CFL)'.

As a result, this category has 5 sub-categories in level 2 and 17 items in level 3. In this way, FBS is defined that including a total of 12 categories in level 1, 45 sub-categories in level 2, and 130 items in level 3. If looking at the components of FBS, it also could define as a 'work section' classification.

In this case study, it has one specialty in CBS. When combining PBS and FBS, the FBS is combined at level 3, but PBS is combined at different level according to managerial objectives of owner. The criteria for combing PBS and FBS is shown in Table 3. In this table, level 1 is used as code '01', level 2 is code '02', and level 3 is code '03'.

Items of 'project general (000)' are combined PBS02 with the work items about 'planning (L) and consulting (K)'. Items of 'panel equipment (100) and module equipment (200)' are combined PBS01 with the work items about 'design (D)', and PBS03 with the work items about 'mechanical equipment (M), electrical equipment (E), and commissioning (S)'. Items of 'fab Common facility (300)' are combined PBS02 with the work items about 'design (D)', and PBS03 with the work items about 'architecture (A), mechanical equipment (M), electrical equipment (E), automatic control (N), and commissioning (S)'. Items of 'utility (400)' are combined PBS01 with the work items about 'design (D)', and PBS02 with the work items about 'mechanical equipment (M), electrical equipment (E), and commissioning (S)'.

Items of 'electric power facility (500) and trunkline (700)' are combined PBS01 with the work items about 'design (D) and electric equipment (E)'. In addition, items of 'trunkline (700)' are combined PBS01 with the work items about 'mechanical equipment (M)'. Finally,

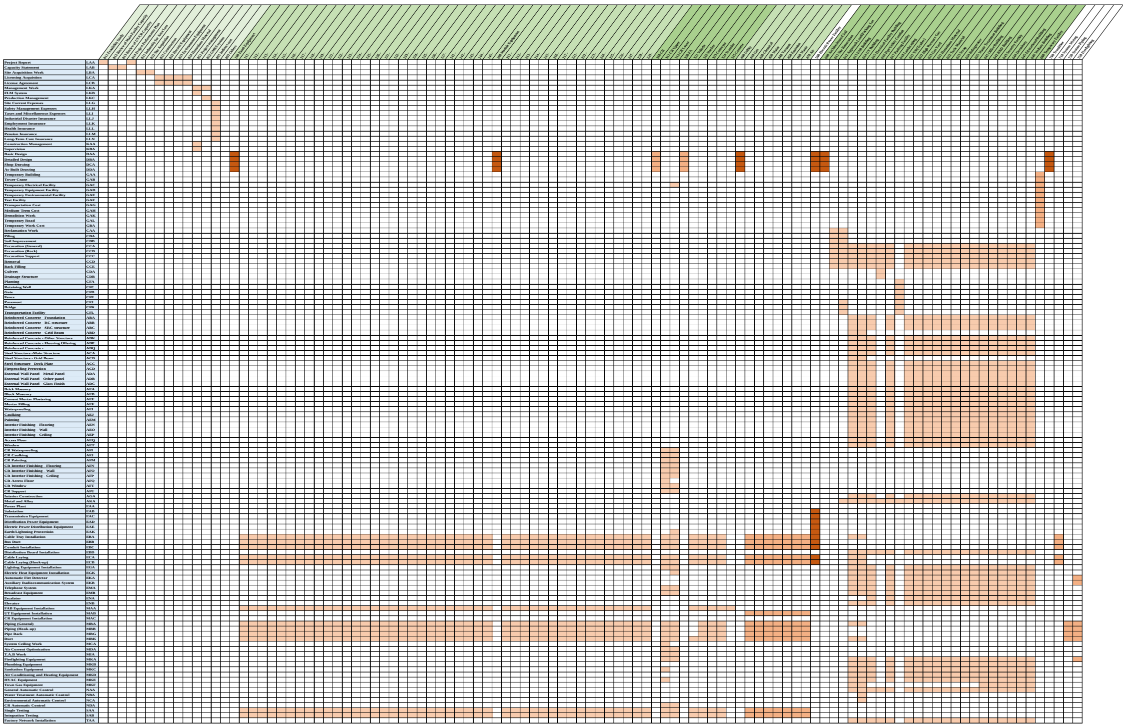

Figure 4. Matrix combining PBS and FBS

items of ‘architecture/civil (600)’ are combined PBS01 with the work items about ‘design (D)’, PBS02 with the work items about ‘temporary (G)’, and PBS03 with the work items about ‘civil (C), architecture (A), mechanical equipment (M), electrical equipment (E), automatic control (N) and ICT (T)’.

As shown in Figure 3, different CBS packages (cell) may have different levels in terms of combining a PBS with a FBS. The rationale behind having different levels is to accommodate the different importance of managerial requirement for a specific from the owner’s perspective. In other words, the concept of “flexible work breakdown structure (WBS)” is used in this research [6]. Due to the characteristics of the display factory in this case, ‘panel equipment (100) and module equipment (200)’ are very important parts. On the other hand, ‘electric power facility (500) and trunkline (700)’ are supporting function throughout the entire project.

In this way, a total of 1,709 Items for CBS are identified by combining PBS and FBS. It is represented by a matrix as shown in Figure 4. In this figure, a darkest cell is the combination of PBS01 and FBS03, dark cell is the combination of PBS02 and FBS03, and the lightest cell is the combination of PBS03 and FBS03.

The main objective of this case study is to develop criteria for managerial effectiveness of project cost on the owner’s perspective in the preliminary stage. In other words, it is to develop a standard CBS, which proposed in this study.

The case-study firstly defined FBS, which covers an entire life-cycle of smart factory construction based on the existing data of the display company. And each FBS was assigned standard code. CBS is developed by combining PBS and FBS with standard codes. This study used a relational data-base (RDB) system to create a list of CBS items through established relationship between each standard classification (Fig. 5). Therefore, historical data will be connected with the CBS items and it is possible to manage automatically and systematically. Standards codes can also be used to automatically information exchange (IE) among many different organizations [2].

6 Conclusions

Due to the lack of standard classifications for construction and operation management of smart factories, it is very limited for various construction participants to generate and share information by using the standards. This requires a great deal of effort to rework the data for the operational phase.

The purpose of this study is to develop a standard classification that could improve the effectiveness of information exchange among construction participants, and for systematic and efficient management and utilization of construction information for factory construction projects.

As firstly, PBS which is a standard classification for ‘facility’ facet that best reflects the characteristics of smart manufacturing has been proposed in this study.

Rev.00 As of 2018-01-31

Figure 5. Example of CBS Criteria Items List

The proposed PBS is verified through a case-study in the display industry. It could be seen that the CBS constructed through the combination of PBS and FBS best reflects the characteristics of the factory.

Although the smart manufacturing industry has been utilizing many well-established standards for a long time, standards for factory facilities have not been actively reviewed. In this context, the issues proposed in this study will contribute to the development of smart manufacturing industry.

Abstract –

This paper presents the integration of an *Internet of Things* wearable device as a personal interfacing node in an intelligent built-environment framework, which is informed by *Design-to-Robotic-Production and -Operation* principles developed at *Delft University of Technology*. The device enables the user to act as an active node in the built-environment's underlying *Wireless Sensor and Actuator Network*, thereby permitting a more immediate and intuitive relationship between the user and his/her environment, where this latter is integrated with physical / computational adaptive systems and services. Two main resulting advantages are identified and illustrated. On the one hand, the device's sensors provide personal (i.e., body temperature / humidity, physical activity) as well as immediate environmental (i.e., personal-space air-quality) data to the built-environment's embedded / ambulant systems. Moreover, rotaries on the device enable the user to override automatically established illumination and ventilation settings in order to accommodate user-preferences. On the other hand, the built-environment's systems provide notifications and feedback with respect to their status to the device, thereby raising user-awareness of the state of his/her surroundings and corresponding interior environmental conditions. In this manner, the user becomes a context-aware node in a *Cyber-Physical System*. The present work promotes a considered relationship between the architecture of the built-environment and the *Information and Communication Technologies* embedded and/or deployed therein in order to develop highly effective alternatives to existing *Ambient Intelligence* solutions.

1 Background and Introduction

The present work is situated at the intersection of the *Ambient Intelligence* (AmI) [1] and the *Adaptive Architecture* (AA) [2, 3] discourses. While AmI promotes a vision of future dwelling spaces integrated with sophisticated systems built on *Information and Communication Technologies* (ICTs), AA approaches the same endeavor via both high- and low-tech [4] architectural devices as well as physical transformations in order to instantiate active, reactive, and interactive built-environments. A common denominating objective of both AmI and AA is the promotion and prolongation of occupant well-being via built-environments capable of adapting to user-preferences as well as of encouraging healthy habits via non-invasive feedback loops (e.g., [5, 6]). At present, there are research groups and/or projects developing expressions of similar intelligent built-environments (e.g., [7–9]) via a variety of approaches. In this development, *Design-to-Robotic-Production & -Operation* (D2RP&O) [10] principles developed at *Delft University of Technology* (TUD) are used. D2RP&O extends beyond the AmI and AA discourses to conceive of built-environments imbued with high-resolution intelligence whose architectural and ICTs considerations mutually inform one another from the early stages of the design process. More specifically, D2RP promotes material and formal intelligence via geometry-optimization and heterogeneous material composition as well as *componentiality* and *hybridity* principles [11], while D2RO promotes the integration and deployment of sophisticated robotic as well as computational agents and mechanisms within the D2RP-informed architecture. In this manner, the sophistication of the physical built-environment as well as that of its ICTs mutually correspond to and complement one another, which results in more intuitive and effective solutions.

The present implementation builds on a D2RP&O-enabled system architecture previously developed by the authors [12]. The *Internet of Things* (IoT) wearable device (wearable, henceforth) described develops the

Wearables subsystem of said system architecture in order to render the user a *de facto* context-aware node in its *Wireless Sensor and Actuator Network* (WSAN), which underlies the *Cyber-Physical System* (CPS) that is the built-environment with its physical / computational mechanisms and services. Consequently, the built-environment is able to access user-specific physical / environmental data to consider in conjunction with data gathered by architecture-embedded sensors, which together enable the system's decision-making mechanism to yield highly informed actuations sensitive to the user. Similarly, the user is made aware of the status of his/her built-environment and of its interior environmental conditions, enabling direct or wireless intervention. This expression of intelligence in the built-environment supervenes on human and non-human collaboration.

2 Concept and Approach

The present implementation is divided into two main components developed in parallel, one corresponding to D2RP (see Section 3.1) and another to D2RO (see Section 3.2). Although the development focuses on a wearable belonging to D2RO systems, its proper operation requires the establishment of a WSAN that includes architecture-embedded nodes with which to exchange data and/or to instigate actuations. Such embedded nodes are integrated into architectural components specifically designed via D2RP to accommodate them in a seamless and considered manner. In this configuration, the very architecture of the built-environment is able to complement the technical sophistication of the wearable deployed within it. Without the architecture-embedded ICTs, the operability of the wearable would be limited to the services enabled by its own sensors, which would only provide information about the immediate surroundings of the user, leaving him/her unaware of the interior environmental conditions of the remaining surroundings. Moreover, without complementing architecture-embedded ICTs, the wearable would be unable to engage remotely with mechanism inherent in adaptive architectures.

In the present setup, real-scale architectural fragments composed of robotically fabricated components are developed via material subtraction in D2RP in order meet a variety of environmental, structural, and functional requirements as well as to host said embedded nodes (see Figure 1). That is to say, from the early stages of the design process, the envisioned technological services are taken into consideration along typical architectural considerations. In this manner, the resulting components are deliberately fabricated to sustain adaptive mechanisms in the form of computational services as well as in physical actuations in the built-environment.

With an established complementary infrastructure, four instances of the presented wearable—worn by four different users occupying the same built-environment—are developed and integrated into the WSAN via *Bluetooth Low Energy* (BLE). These wearables exchange sensor data and/or actuation commands with two coordinating nodes as well as with six router nodes, which in turn exchange data and/or actuation commands with one another via ZigBee, BLE, and/or WiFi (depending on distance, frequency, and/or latency requirements). This limited setup is intended to demonstrate seamless interoperability with respect to heterogenous microcontrollers / development platforms as well as to communication protocols within the WSAN.

Each wearable is equipped with eight attached sensors, regulators, and LED-bar displays, viz.: (1) an *MQ-4 Air-Quality* sensor to gauge air-quality within the user's personal space; (2) a *DHT-22 Temperature and Humidity* sensor to ascertain the user's thermal comfort; (3) an illumination override rotary as well as (4) a ventilation override rotary to enable the user to deviate from prescribed standards according to preference; (5) a notification confirmation button to acknowledge sent notifications by other WSAN nodes; (6) a notification buzzer to enable other WSAN nodes to provide audible prompts; (7) a LED-bar indicator of human presence or environmental events (e.g., gas-leaks, etc.) in any of six presently defined regions within the built-environment to notify the user; and (8) a LED-bar indicator of the immediate air-quality to warn the user of personal-space air-contamination levels. Additionally, the *Microcontroller Unit* (MCU) on which the wearable is based is integrated with a *BOSCH BMA250E triaxial accelerometer*, which may be used for gathering spatial displacement data for latter *Human Activity Recognition* (HAR) (see Figure 2 and Section 3.2). The functional advantage of these attached and integrated mechanisms is discussed in Section 3and demonstrated in Section 4.

Finally, the values and states of each mechanism of every wearable-instance are relayed to any of the architecture-embedded nodes for real-time streaming to Plotly© [13] for remote visualization and/or subsequent analysis of gathered datasets (within cloud-service storage limits) (see Figure 3).

3 Methodology and Implementation

3.1 Design-to-Robotic-Production: Intelligent Architectural Components

The developed D2RP components are considered from three different perspectives, each pertaining to a different set of functional requirements and scale—i.e., *Macro*, *Meso*, and *Micro*—in order to yield geometries with deliberate densities and porosities (see Figure 1).

Figure 1. Robotically fabricated components via material subtraction in D2RP. Left-to-Right: Single-layer physical prototype, (1) front-view and (2) side-view; Virtual 3D model, (3) single-layer side-view and (4) double-layer (inner and outer) side-view. Concept by Chong Du, Jihong Duan, and Floris van Buren [14].

The components are fabricated from Styrofoam blocks via material subtraction with a 6-axis KUKA robot [15]. From the *Macro* perspective, human movement is mapped unto an initial geometry with data from human body-posture analysis. The resulting form is optimized via structural analysis, consideration of environmental conditions and loads (e.g., wind direction and loads, etc.), and solar radiation with respect to a specified geographical location. Throughout this process, *componential* principles inform the design, which ensures that differentiated components are deliberately fabricated to conform seamlessly with one another to yield a unified whole. Furthermore, *hybridity* principles enable material heterogeneity within specific components as required by functional considerations. For example, structural analysis identifies areas across the geometry that are subjected to tension, compression, shear, bending, and torsion forces. The components within which these areas are located require deliberate material heterogeneity in order to properly account for said forces while preserving componential principles

From the *Meso* perspective, each component is designed to consist of two irregular yet mutually complementary layers—one external and one internal (see Figure 1, item 4)—while conforming a middle cavity as a continuous air-channel. Moreover, other cavities across both layers are designed to integrate mechanized cooling, heating, ventilation, and illumination systems, where their operation is controlled by architecture-embedded nodes in the built-environment's WSAN.

From the *Micro* perspective, variation of densities and porosities at the material level are considered with respect to functional requirements related to natural illumination and ventilation as well as to the potential for particular views.

3.2 Design-to-Robotic-Operation: Bluetooth Low Energy Wearable node

The developed D2RO wearable is built with a battery-powered PunchThrough© LightBlue Bean+™ (LBB+) MCU, a corresponding *Groove Expander*, and the eight previously listed mechanisms (see Figure 2, *WSAN/BAN: BLE Wearable Node*). The four instances of this wearable exchange data (via BLE) with two Raspberry Pi© 3 Model B™ (RPi3) *Single-Board Computer* (SBC) coordinating nodes as well as with six router nodes—i.e., three Asus© TinkerBoard™ SBCs and three Intel© Joule™ system on modules (see Figure 2, *WSAN: Arch. Embedded Nodes*)—which exchange data via ZigBee, BLE, and WiFi. These six nodes correspond to the six defined regions in the built-environment of this setup. As mentioned earlier, this heterogeneity in systems and communication protocols serves to highlight the effective interoperability between diverse ICTs within the WSAN. Nevertheless, these specific ICTs are deliberately included in the WSAN for their individual capabilities.

For example, all of the presently mentioned coordinating and router nodes may be dynamically clustered together *ad hoc* for Machine Learning activities as described and implemented by the authors elsewhere [12].

In the inherited and presupposed system architecture, a variety of environmental sensors monitor the *Interior Environmental Quality* (IEQ) [16] of the inhabited space. Whenever sensed-data deviates from prescribed illumination, ventilation, cooling, and heating standards, mechanical systems are activated in order to restore and sustain values within optimal thresholds. The wearable adds another dimension of sensing and aids the built-environment's decision-making mechanisms in accurately gauging the environmental conditions of the inhabited space, while simultaneously raising awareness in the user via its notification / feedback mechanisms.

In order to describe how this wearable does this, the implementation and functionality of each one of its attached and embedded mechanisms is described as follows:

1. *MQ-4 Air-Quality sensor*: This sensor has a methane-gas detection range of 300-10,000 *parts-per million* (ppm) [17]. Its purpose on the wearable is to detect the immediate air-quality surrounding the user. Should the built-environment's embedded-sensors fail to perceive contamination, the wearable's air-quality sensor instigates localized ventilation mechanisms nearest to the user to activate. In order to reduce unnecessary energy-consumption, the sensor is programed to take a reading every ten minutes. However, if sudden deterioration of air-quality is detected, the frequency increases to five minutes.

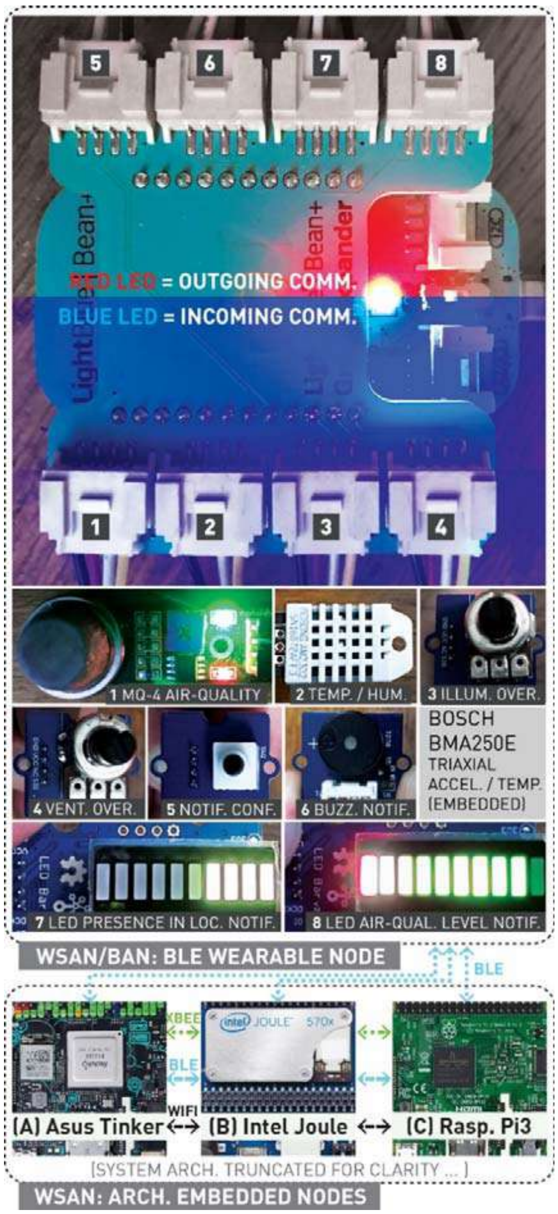

Figure 2. BLE Wearable Node as WSAN / BAN, Features.

2. *DHT-22 Temperature and Humidity sensor*: This sensor detects the temperature and humidity within the user's personal space. Like the previous sensor, if it detects deviations from optimal thresholds (in conjunction with or independently of architecture-embedded counterparts), localized cooling or heating mechanisms activate to sustain user comfort. Since the probabilities of a sudden drop in temperature and humidity within an enclosed environment are low, the sensor is configured to take readings every half hour.
3. *Rotary Illumination override*: This rotary mechanism enables the user to override illumination settings automatically determined by the built-environment's decision-making mechanism, should personal preferences deviate from optimal standards. Unlike the previous two sensors, this mechanism does not have a predetermined activation interval, as its activation requires the user's manual rotation.
4. *Rotary Ventilation override*: This rotary mechanism performs as the previous one only with respect to ventilation. The IEQ-sustaining mechanisms in the built-environment are configured to maintain conditions within *Comité Europeen de Normalisation* (CEN) Standard EN15251-2007 [18] thresholds, but precedence is assigned to human prerogative. Contingency measures limiting this override prevent sustained over-heating or over-cooling detrimental to human well-being.
5. *Notification Acknowledgement button*: There may be instances when the built-environment attempts to notify the user of urgent environmental events and/or conditions in particular regions (see item 7). This button serves to acknowledge such notifications.
6. *Notification Buzzer*: Two kinds of notification are implemented for this paper, one using visual cues (see items 7 and 8) and the other using sound. This buzzer is used only for urgent notifications, where a range of tones correspond to varying degrees of urgency. This mechanism works in conjunction with items 7 and 5.
7. *LED-bar "Presence / Event in Location" notification*: This LED-bar represents a visual cue that notifies the user of either human presence in a given regions of the built-environment or environmental events and/or conditions in those regions. For example, with respect to its *notification of human presence* function, the user may be notified of the presence of other users in any of the six hypothetical regions defined in this setup. It may be observed in Figure 2 that this LED-bar indicates that four regions are occupied by other users. With respect to its *notification of environmental events and/or conditions* function, it may be that a given region has detected a gas-leak, and in this case the LED corresponding to that region would turn red and the buzzer (i.e., item 6) would require acknowledgement via the notification button (i.e., item 5). The architecture-embedded ventilation mechanisms themselves would automatically intervene in such a scenario, but the user is notified to raise awareness of his/her surroundings.

8. *LED-bar "Air-Quality in personal space" notification*: This LED-bar works in conjunction with item 1 and serves to inform the user of the air-quality of his immediate surroundings. In order to prevent unnecessary energy-consumption, this visual cue only activates when the user raises his/her arm in a specific gesture—a mechanism adapted from Fitbit© Activity Trackers such as the *Charge HR*™, which also belongs to the *Wearable* subsystem of the inherited WSAN.

Finally, the embedded *BOSCH triaxial accelerometer* is used for HAR as a secondary data-source, if a primary accelerometer-enabled smart-device is absent from the ecosystem. This is due to the energy-consumption of continuous streaming of accelerometer data. In the inherited system architecture, HAR via smartphones [19] is preferred.

4 Results and Discussion

As mentioned in earlier sections, in the present setup four instances of the wearable are developed and used in a built-environment containing six defined regions, each one monitored via real-time streaming of the data generated / gathered by its attached and embedded mechanisms to Plotly in different frequencies—for example, accelerometer data frequency, for purposes of HAR, must be higher than that of the Temperature and Humidity sensor. Since the wearables only work with BLE, their generated / gathered data is streamed to any of the architecture-embedded nodes, where each may write directly to data streams pertaining to the attached and embedded mechanisms of any of the wearables. All the data emitted by the wearables include a device identifier which is used to ascertain that each of their corresponding data is fed to the correct Plotly stream. In this section, the Plotly charts corresponding only to one wearable— shown in Figure 3—are discussed (from top to bottom).

The first chart in Figure 3 shows that in that particular instance of the test-run, the air-quality surrounding the user is consistent, which is expected from a built-environment integrated with self-regulating ventilation devices. The values of the *y-axis* range from 1 to 0, where 1 attains optimal standards.

In the test-run interval corresponding to the *temperature* component of the second chart (i.e., chart 2a), the user first manually overrides automatic settings to increase ventilation, resulting in a deviation from the optimal temperature of 22.5° C.—an average of the accepted human-comfort range of 21° C. – 24° C. [20]. That is, it may be observed that between the 7,180th and 7,190th reading the actual sensed temperature dropped to ~55% of 22.5° C.

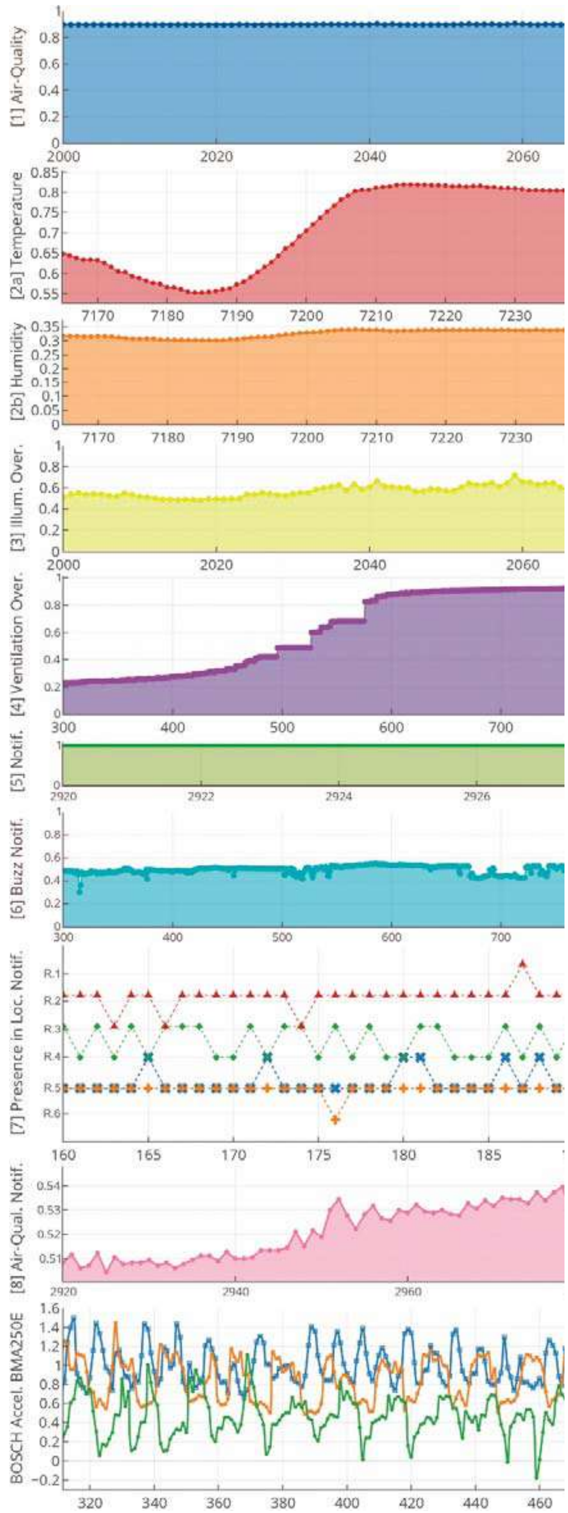

Figure 3. Gathered data plotted in real-time in Plotly©.

After this interval, and with no further human override, the temperature climbed steadily to more comfortable temperatures. The *humidity* component of this chart (i.e., chart 2b) indicates a slight decrease in humidity when ventilation systems were manually engaged, which is an expected result of higher air-flow.

The third chart indicates how much of the automatically determined values of illumination intensity is actually permitted to shine. That is to say, the illumination overriding mechanism works as a function of the built-environment determined output. For example, it may be observed in this chart that throughout this test-run interval, the actual illumination was kept between only ~50% to almost ~80% of the prescribed intensity-levels.

In the fourth chart, automatically determined temperature levels were decreased to ~21% of the actual values and gradually increased to ~90%.

The fifth and simplest chart records no instance of notification acknowledgements. The visualization of *pressed* vs. *unpressed* is inverted, where instances of the former are shown as 0 and of the latter as 1. Accordingly, no instance of notification acknowledgement is registered throughout the test-run, which corresponds to no undesirable environmental events being detected in any of the regions of the built-environment.

Urgent notifications result from a function over environmental readings. For example, it is not the case that any air-contamination triggers an urgent prompt, as healthy environments invariably contain degrees of air-contaminants, only within negligible levels. Accordingly, an urgent phenomenon is gauged based on the concentration and duration of undesired contaminants—in the present case, of methane gas, which has a *Threshold Limit Value* (TLV) of 1,000 ppm during an 8-hour period [21]. It is observed from the fifth chart that no notification acknowledgement instances are registered in the test-run's interval, which suggests an absence of urgent environmental events. This, however, does not suggest that the environmental conditions of any of the six regions are optimal. At most, it suggests that no air-contamination levels exceed accepted limits. This may be observed in the sixth chart—corresponding to the *buzzer* notification—where methane levels are detected at ~50% of a the prescribed TLV. Note that there are no instances below ~30%, since the sensor's lower-bound limit is 300 ppm.

The seventh chart maps the presence of the four users (each with a wearable, represented in red, green, blue, and orange) with respect to the six predetermined regions in the built-environment. The present set of charts correspond to the user in red. Unlike the other charts, this one in particular is common to all wearable users, which enables everyone in within the same built-environment to know one another's location.

The eighth chart, which corresponds to the LED-bar Air-Quality notification or indicator, indicates up to which LED is turned on in accordance with the air-quality ascertained (see the first chart). The *y-axis* ranges from 0 – 1, where 0 corresponds to no LEDs being turn on, 0.5 to five being on, and 1 to all being on. In this chart, it is observed that ~5 LEDs in the LED-bar were on during the corresponding test-run interval. As with the sixth chart and corresponding mechanism, the LED-bar corresponding to air-quality is driven by a function over air-quality readings, which explains the high-precision of logged values in this chart. Although at first glance it may appear simpler to define eleven possible states (i.e., 0-10) to correspond to the air-quality range of zero to ten, where high precision air-quality values with several decimals are simply rounded to the nearest single digit decimal. But this is redundant, as the eighth chart demonstrates that the present mechanism is capable of turning five LED bars on whenever the value ranges anywhere within 0.5, regardless of trailing decimal places.

Finally, the last chart—corresponding to the MCU-embedded triaxial accelerometer—demonstrates that three-dimensional displacement data is accurately logged and plotted by the present setup. As mentioned at the end of Section 3, it is preferred that accelerometer data-gathering be relegated to another smart-device (e.g., smartphone) due to the energy-consumption involved in high-frequency data transmission. However, if no such alternative is present, the wearable's accelerometer fulfills this task.

5 Conclusions

The present paper detailed the development of a wearable device to complement and to be complemented by ICTs embedded in intelligent and robotically fabricated architectural components via material subtraction in D2RP. In conjunction, said wearable and architecture-embedded systems provide higher precision and fidelity in the continuous promotion of user well-being in the built-environment, which the authors argue is a necessary feature for effective alternatives to existing AmI solutions. In the limited setup and corresponding test-run, the wearable performed as expected of a prototype, although aspects for latter optimization were indeed identified. A more efficient approach to energy consumption is to be developed in order to render the device a viable system in built-environments subsuming *high-resolution intelligence*.

Moreover, the majority of attached mechanisms will be embedded in the device in subsequent developments, which would require a custom-designed MCU. This will reduce the size of the wearable as well as moderately increase its battery-life.

Furthermore, the LED-bar indicating the position of users across regions in the built-environment will be reconsidered, as the present hardware limits the number of regions monitored to ten (i.e., ten LED bars in the module). Present work is being undertaken to replace the LED-bars with a low-energy *electrophoretic display*—i.e., Plastic Logic©'s 1.1" Lectum® display [22].

Finally, ZigBee communication capabilities are also presently being added unto the device in order to extend its longer-range data exchange capabilities.

Acknowledgement

This paper has profited from the contribution of TUD Robotic Building researchers, tutors, and students. In particular, the authors acknowledge students Chong Du, Jihong Duan, and Floris van Buren for the conceptual development of a student housing unit as well as its corresponding real-scale fragment.

Abstract

Environmentalists express concerns about the health of the planet and the vital role of wetlands on Earth. Sufficient knowledge of wetland changes is becoming more crucial as loss of wetland area increases. However, an ability to efficiently map and monitor the wetland topographies requires technology advancement. Producing high resolution and high quality digital elevation models (DEMs) requires substantial investments in personnel time, hardware, and software while increasing accessibility of three-dimensional imaging methods, such as digital photogrammetry. Further refinements have highly improved the method while preserving its convenience. This study investigates the use of unmanned aerial system (UAS) coupled with structure-from-motion (SfM) technology as a new methodology for monitoring vegetation and topographical changes in the southeast Texas Wetlands. This study aimed at maximizing the efficiency and accuracy of the data collection process for mapping the wetlands and other related applications. This paper serves as a summary and evaluation of various photogrammetric and data extraction techniques.

Keywords –

Unmanned Aerial System (UAS), Unmanned Aerial Vehicle (UAV); Structure-from-Motion (SfM); Wetland Mapping; Digital Photogrammetry

1 Introduction

It has been estimated that wetlands occupy approximately 4-6% of the world's land, Southeast Texas included [1]. Wetland is a generic term used for the wet habitats impaling land that is either temporary or permanently wet. No matter to what extent human race contributes to wetland processes, wetlands are greatly beneficial for global ecology, and therefore, are valuable [1]. The study area is located on the Gulf coastal plain of the United States in Southeast Texas. Southeast Texas is located along the coast of the Gulf of Mexico and includes most of the Texas portion of the Intracoastal Waterway; it is crossed by numerous rivers and streams. The land is low, extremely flat, and often marshy - the perfect set of conditions to sustain wetlands. Along with freshwater wetlands, the area also includes salt marshes and coastal mangrove swamps that create a unique ecological system in the area. However, industrial development, human factor, and global warming tendencies contribute to freshwater losses of wetlands. Not only social well-being but also political development and economics are associated with the availability and distribution abilities of freshwater resources [2]. Furthermore, groundwater and surface water resources are essential for livelihoods [3]. This study introduces a new methodology in mapping and monitoring wetlands in Southeast Texas. Unmanned aerial system (UAS) combined with structure-from-motion (SfM) technology is able to create a new remote sensing market and open the doors to the future, where a UAS system is a necessity, not a luxury.

Today, a degraded wetland is not able to perform its functions fully, therefore, it's crucial to assess the status and quality of the wetlands frequently [4]. In order to monitor and map the wetland area, it is necessary to meet society's expectations considering the cost of analyzing method and potential benefits of sustainable wetlands. Unmanned aerial systems (UAS) coupled with structure-from-motion (SfM) photogrammetric process have a potential to revolutionize wetland mapping processes. The proposed method is gaining significant recognition from scientists, engineers, foresters, farmers, private practitioners, resource managers, and policy makers [5, 6]. Degradation of air quality, destruction of fresh water wetlands, the minimal federal standard of the environment regulation: all these factors have led to an environmental crisis in the Southeast Texas area. Some environmental problems are anthropogenic rather than natural. The loss of fresh water wetlands is caused by the urban sprawl: expansion of the industrial sector, forestry, and agriculture; tidal wetlands and beachfront are used for residential and commercial purposes [7]. Urban heat island effect significantly contributed to the current state of natural ecosystems, such as wetlands, and put habitat fragmentation at the top of the list of environmental concerns [8]. Therefore, the matter of environmental and social implications should be discussed in a specific context before it can be generalized [9].

1.1 Wetland Function and Classification

The interdependence between wetlands and aquatic ecosystems cannot be stressed enough; wetlands in southeast Texas maintain water quality and exceptional biodiversity [10, 11]. Wetlands are important components of the landscape: the holding capacity helps maintain flood control or act as a barrier to recharge, and reduce low flows [12]. Wetlands also act as recharge areas for groundwater. Groundwater supplies 25% of industrial water needs and serves as an important source of drinking water for more than half of the nation [13].

Substantial scientific evidence supports the claim that the wetland terrain type influences the hydrological cycle, colloquially known as the water cycle, the process in which water evaporates, condenses, and precipitates [12]. However, Dugan (1990) states that there are more than 50 definitions of “wetlands” in current use [14]. Defining whether it is a terrestrial ecosystem or a deep water aquatic habitat is exceptionally challenging due to their highly dynamic character and some limitations in evaluating wetlands conditions and their borders. Therefore, not all functions are present in the different types of wetlands, and many are unique due to particular floras and faunas. Wetlands include a complex range of ecosystems – for instance, nurseries for various species including shellfish and seasonally migrating birds.

Regardless of its effect on the area, the wetlands strongly influence the hydrological cycle. Successful water management proposes further research on which wetlands perform different hydrological functions [12].

1.2 Value of Wetlands

In the light of climate change, the impact of global warming on wetlands is not yet generalized or sufficiently investigated [15]. Without integrative environmental research and dialogue, solutions to environmental challenges will be unsuccessful and new problems will be kept on arising [16]. Economic methods, specifically cost efficiency and cost-benefit analysis, are a part of environmental policy evaluation and regulatory planning since 1983 in the United States [17]. The tools used for implementing a new environmental policy should adjust or limit economic activity [18, 19]. The purpose of an effective appraisal work of wetland’s potential benefits to society and environment is to efficiently reduce the cost of existing wetland monitoring methods, introduce new methods and reevaluate the importance. For instance, the World Wildlife Fund reported that coastal wetlands reduced the severity of impacts from hurricanes in the United States and provided storm protection services with an estimated value of $23.2 billion per year [20]. By providing protection against the impact of hurricanes, the wetlands significantly reduce the cost of damage repairs.

For a specific region, the value of wetlands can be measured both qualitatively and quantitatively. The value of wetlands should not only be measured by how much they contribute to the quality of life but also by how much money is associated with their functions. Despite some beliefs, assessing the value of wetlands is a complex procedure, involving a complex network of factors [2]. First, wetlands perform several processes in parallel. Optimizing for one process generally, happens at the expense of another creating the need to assign a unique value to each process. Second, based off of the economic principle of scarcity, the size of the wetland area contributes to its value. For example, the practice of wetland abundance it is often viewed as a social necessity to convert the wetlands for other needs.

The value of wetlands is evaluated by how many goods it yields, its hydro geomorphic position, and its position relative to human settlements. The ability to accurately gauge the value of wetlands allows regional, national, and international government officials to make the right decisions regarding conservation and utilization.

The importance of the wetlands and their contribution to the environment and the society is clear. However, the method through which they should be mapped and monitored is open for discussion. The difficulty of monitoring wetland is finding a spatial measurement technique that encompasses numerous desirable properties, such as reliability, accuracy, low cost, and ease of installation [21]. Many methods have been implemented throughout the years that purport some of these advantages, but this study will focus on the use of photogrammetry that can be relatively inexpensive to map and monitor the wetlands [22, 23, 24]. In the decision-making process, especially regarding technology advancement, it is necessary to take into account possible impacts evaluated by other disciplines [25]. For example, Building Information Modeling (BIM) can be used not only to analyze site conditions but also wetlands and protected habitats [26].

2 Introducing photogrammetry

The use of UAS has increased over the past years to monitor environmental changes. However, wetlands are difficult to map from the ground due to their fast-changing boundaries and the diversity of species. Adaption of innovation in any industry is a complicated and extensive process – academic researchers and educators have to pay special attention to new ways to communicate new ideas to construction industry practitioners, for example [27].

The idea of photogrammetry has been in development since 1480, and as digital technologies advance, its concepts have been used to further develop its derivative technologies such as Structure-from-Motion (SfM). "Topographic structure from motion: a new development in photogrammetric measurement" discusses the production of topographic datasets via the structure from motion photogrammetric approach. [28] produced high-resolution digital elevation models of the Pedernales River in Texas from photographs acquired by a handheld helikite using an online SfM program. The paper compares the SfM approach to the traditional photogrammetric approach. While the SfM approach uses a series of still images, the key difference between classical digital photogrammetry and SfM is the execution of image matching algorithms which calls for less strict requirements during the image acquisition phase. Substantiated by thorough comparisons and evaluations, the principal conclusion of the paper is that, compared to classical digital photogrammetry, the image matching algorithms of the SfM approach provide a higher level of automation and greater ease of use. Furthermore, the authors offer additional suggestions for future SfM implementation. The SfM approach is considered for the application discussed in this paper.

Regardless of the method of photo acquisition, many components contribute to the overall quality (i.e. accuracy and precision) of the data, and therefore, the method must be evaluated by several considerations. First and foremost, the method must be optimized for what is being observed. For example, if the goal is to estimate and monitor the vegetation that inhabits a wetland, then the incorporation of photointerpretation will be necessary to improve the quality of the data [29]. In the flow and erosion rates measurements algorithmic techniques and matrix conditioning can be applied in the data processing phase to reduce errors in the final model [30]. Other factors that strongly influence the integrity of the model include the quality of the metric camera(s), photographs scale, scanner efficiency, resolution at the ground, view angles and limitations such as surface morphology, vegetation, shadows, and atmospheric conditions [31]. Finally, the most significant and fundamental consideration is effectiveness; if the method is inadequate for the needs, then it can be dismissed. Pertinent to the scope of this paper, research has determined that digital photogrammetry can yield suitably accurate results and has a significant impact in terms of monitoring and planning for changes [32, 33, 34]. The method evaluation is complete when every factor of optimization has been considered.

This provides sufficient evidence that reinforces the necessity to map, monitor the wetlands and create a structured process for developing a method to do so. The studies explore emerging and revolutionizing technologies that are low-cost, high-quality and innovative. The use of UAS in agriculture sector alone is an emerging industry that is set to expand the next few years and become a U.S. $13.6 billion industry in the United States [35]. The research findings delivered by this review serve as a foundation for the method proposed in this paper.

2.1 Current practice of wetland mapping

The practice of monitoring the wetland changes over time is crucial to port cities, coastal communities, and wildlife habitats all over the world. Monitoring the changes in the environment can allow experts to study these changes and determine the causes of many environmental shifts. They can also use the knowledge about the changes to help slow the deterioration of the wetlands which is home to many species of animals and insects. Working with the local cities, officials across the world have several options to conduct this surveying in order to secure their environment's safety and to track the changes for the scientific study of the wetlands.

In Beaumont, Texas, the city officials are concerned with the deterioration of the wetlands caused by flooding, ship traffic, strong winds, and hurricane damage. These factors play an important role in shaping the Neches and Sabine Rivers and the wildlife that call these regions home. Currently, Beaumont opts for a geolocation technique in which videos are taken of specific points along the water front from an aerial position. These videos are taken as a panoramic view of the waterfront and the GPS coordinates where the video was taken is then documented. Once the videos are uploaded from the camera, they are linked to a map of the area. This interactive map takes the coordinates of the video taken and pins the video to the map for viewing. After several videos are taken at numerous points along the water front areas the map will represent a comprehensive string of videos that document the entire river's environment for that year. In order to take the videos, researchers must fly in a helicopter each year and hover in a specific location specified by the coordinates for each video to be taken.

This process in expensive due to the cost of renting the helicopter and the fuel cost for flying (Figure 1). The videos are generally shot over the course of two days each year. These videos are uploaded to the geolocation database where the interactive map for each year shows the change in the environment over time. These maps are very useful to the city and local industries as well as the environmental agencies tasked with the protection of the wildlife and recourses of the area. Although it is difficult to fly at the precise coordinates each year that was used the previous years, the team of surveyors does attempt to take data from the same vantage point each time they generate a geolocation map. The accuracy of the coordinates is estimated to be a 30-yard radius from the previous year's location. More accuracy could improve the quality of area mapping and vegetation observation. Helicopter-based GPS videography increases a risk of error, bias, and pseudo accuracy assessment. The conventional method of image acquisition using planes, helicopters or satellites can collect data for large land but can cost large amounts of money depending on the region of interest [5]. Nevertheless, it could be difficult to use these methods for a specific date due to weather conditions and flight regulations.

2.2 Proposed method

Considering an increased awareness of wetland losses and threats to water quality, scientists recognize the importance of wetland mapping using the most advanced technology [36]. Researchers are in constant search for a more efficient, cost-effective way to monitor wetlands. Technological advances in mapping technology have opened up new avenues for innovative methods. The methodology can be greatly improved and made much more efficient through the use of UAVs (Unmanned Aerial Vehicle), aerial photogrammetry, and model overlapping analysis. Comparing to ground-based methods and any other conventional aerial technology, UAVs are cost-efficient and smaller, providing a high-resolution aerial image at low altitude [37].

The current method of the city of Beaumont does not take advantage of some of newest technology that is readily available. Instead of operating a helicopter each year to obtain videos of the area's wetlands, UAVs can be used to make the process much more cost effective and simpler. The use of a drone also makes it easier to take the video more than once a year, as it is cheaper and simplistic in comparison to helicopter usage practice. UAVs also allow for the video to be taken at a much closer distance giving a much more detailed look at the wetlands (Figure 2).

Once a video is recorded, it can be processed using a 2D or 3D aerial photogrammetry software. The two-dimensional model will be more advantageous, if erosion and the changing of the coastline location are the main areas of study, while the three-dimensional model examines the vegetation and elevation changes (Figure 3).

Figure 2. Video screenshot using UAV (Jefferson County, Texas, March 2017)

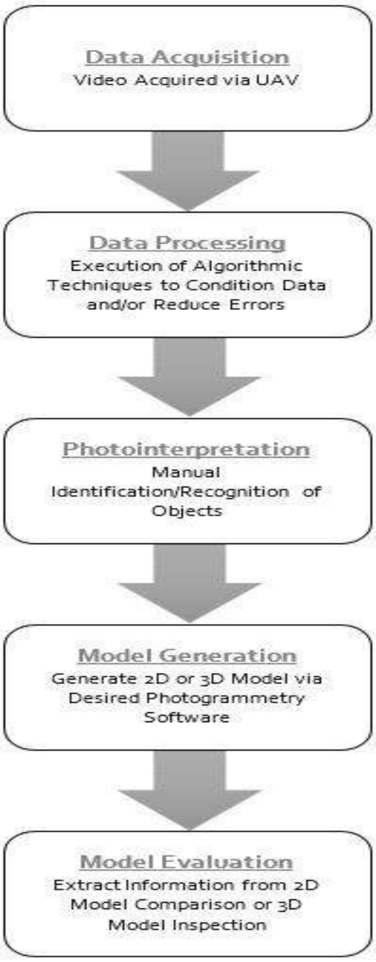

Figure 3. Current practice of monitoring vegetation and topographical changes

The two-dimensional software produces a map of the area videoed. This map can then be used to compare the same area of the wetlands to what it looked like in the past or how it looks in the future. For example, if the city of Beaumont used a UAV (a drone) to capture video of the same area every six months, the video could be turned into a map each time. These maps could be stored and used to compare the changes over a period of time using a method called layering in a program such as AutoCAD. Overlaying each map on one another would easily illustrate the changes in that particular area over time and also measure the exact change. It would simplify monitoring erosion and also help to alert trends of erosion happening at a more rapid pace.

The three-dimensional model helps monitor vegetation and sea level changes in the wetlands. The main advantage of a 3D multi-view model is the ability to examine a closely particular portion of the area at any convenience with a centimeter-level accuracy [38]. Complete control and navigation of the three-dimensional model is possible by using programs like AutoCAD. Figure 4 shows an example of created 3D model using PhotoModeler software to generate a point cloud dataset representing vegetation structure and wetland geovisualization. There are several programs that are able to convert images into useful three-dimensional data. For instance, PhotoModeler PC program is a platform that can generate the dense surface three-dimensional model, get accurate measurements and scans. PhotoModeler is able to quickly capture a large scene and to model accurate volume of stockpile using the PhotoModeler Scanner. One of the most important additions to modern UAVs (unmanned aerial vehicle) is global positioning system (GPS) – now, a UAV can determine its own location in three-dimensional space and apply this to its image data. Mapping can be a costly venture – budget is usually strictly limited or may not be sufficient enough to cover suitable mapping. With the help of all these features, a complex measurement task can be greatly simplified, done quickly, and at a low cost. Ground-based, helicopter and satellite observations do not contribute to wetland research as much as UAV practice could.

Figure 4. Sample of the created 3D model using PhotoModeler (Jefferson County, Texas, March 2017)

The process of creating two-dimensional or three-dimensional models is completely automated. Once uploaded, the software uses algorithms to detect particular features, match and mark the images, sense orientation layout, and then, produce the model using the data collected. The produced model will be a collection of point collates from the uploaded images or videos. In most cases, the model will not be entirely complete. It will be necessary to fill in the missing parts of the model, which in most cases is very minimal. This can either be done in the software where the model was created if possible, or using a program such as Adobe Photoshop.

In this study, we used a multi-rotor (DJI Phantom 3 Advanced Quadcopter Drone with 2.7K HD Video) to acquire high-resolution images and videos from a high angle. Throughout each flight, the drone sends GPS coordinates to a mobile device. The three-axis gimbal stabilizes the camera even with sudden movements or wind.

3 Discussion

Extreme summer temperatures put Texas in a position when Lone Star state faces severe, multi-year drought (Figure 5). Research shows that annual economic losses from not meeting the Texas's water needs could result in $12 billion annually and over one million jobs lost. This shows the importance and need for mapping and documenting the state of the Southeast Texas surface water for making effective decisions [39].

This section will compare the current practice and the proposed method from the previous two sections based off of the following attributes: quality of the final model, method efficiency, personnel time and effort, and cost. A comparison of the two methods will provide a sufficient foundation for method evaluation.

The current practice of mapping and documenting the state of the Southeast Texas wetlands only involves videos taken from an aerial perspective. The method proposed in this paper is an extension of the current practice; it integrates the application of photogrammetric techniques into the existing method. By doing so, this method allows for a more intensive inspection of the wetland areas through the generation of three-dimensional modeling. Furthermore, the photogrammetric techniques in the proposed method can also be coupled with photointerpretation to yield greater degrees of accuracy in estimations. While the proposed method is not designed to improve the video quality, it delivers a model that can be more thoroughly examined, and therefore, produces a final model higher in quality than the current method.

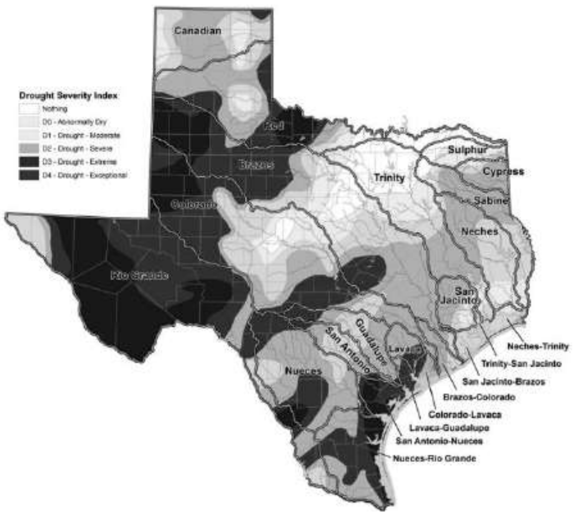

Figure 5. Drought impact on Texas surface water reported by TCEQ

The proposed method also accommodates for a more efficient process through which changes in the wetlands can be monitored. Unlike the current method, the proposed method has the ability to generate two-dimensional maps that model a specific wetland characteristic, i.e., vegetation, elevation, etc., which can then be overlaid and compared simultaneously. By overlaying two-dimensional models acquired for different dates, a more concrete comparison of the wetlands can be obtained more quickly and with less work.

Improved efficiency of the proposed method would reduce personnel time and effort, but that is without considering the learning curves associated with photogrammetry techniques, equipment, and software. Regardless, once the aforementioned learning curves have been surpassed and the method becomes a routine, the personnel time and effort will be greatly diminished.

The long-term costs required by the current method undoubtedly and significantly exceed the costs required by the proposed method. Initially, high-end photogrammetry software, equipment, and expertise must be attained with major expenses. However, the costs associated with the implementation of a UAV will be notably less than the costs associated with helicopter rentals and fuel. The reduced costs of using a UAV will also allow officials to map the wetlands more frequently, resulting in a more detailed and accurate depiction of how the wetlands change over the course of a year. Therefore, the proposed method offers long-term economic benefits which, in turn, allows officials to obtain more knowledge about the wetlands.

3.1 Limitations and optimization of the proposed method

As expected, the method proposed in this paper has several limitations. However, the number of limitations of the proposed method is less than those of the current practice. The limitations of this method affect videos that are acquired and the quality of the final product; this includes instantaneous atmospheric conditions, wetland morphology, and vegetation.

The following parameters can be considered for optimization: equipment, when videos are acquired (i.e., environmental conditions, season, etc.), how videos are acquired (i.e., camera angles, distance from objects, etc.), and photogrammetry software and algorithms. These four parameters are variable; method optimization should be contingent upon what is being mapped, measured, or estimated.

4 Conclusion

Using UAS to bridge the gap between aerial mapping and ground-based measurements can highly benefit wetland research and improve the economic situation in the area. Wetlands serve many purposes that are beneficial, and more often than not, crucial to humans. Therefore, the ability to accurately and efficiently monitor them is of high importance. Photogrammetry techniques provide a moderately inexpensive and efficient way through which accurate models and comparisons of the wetlands throughout time can be obtained. This allows officials to be more informed and make the appropriate and better decisions when planning for wetland utilization. The method proposed in this paper produces models that can be examined more thoroughly, is more efficient, does not require an unreasonable amount of personnel time, and is more cost efficient in the long-term. Although this method is designed to improve the practices used by officials in the Southeast Texas area, it is widely expandable and can be used to map and monitor most characteristics of any wetland area.

Abstract -

Automated progress monitoring becomes more and more common in the construction industry. Recent approaches often use new methods like Unmanned aerial vehicles (UAVs) for a capturing large construction sites. However, the used methods often lack accuracy due to occluded elements and/or reconstruction inaccuracies from using photogrammetric methods. This paper presents a novel approach for further improvement of element detection rates. 4D BIM semantic information is used, to generate precise "as-planned" geometric models. These models are used to render a building from all points of view during the monitoring phase. Based on this information, a more accurate and reliable estimation of all detected elements can be achieved.

Keywords -

Progress monitoring; photogrammetry; BIM; UAV;

1 Introduction

Large construction projects require a variety of different manufacturing companies of several trades on site (e.g. masonry, concrete and metal works, HVAC). An important goal for the main contractor is to keep track of accomplished tasks by subcontractors in order to maintain the general time schedule. In construction, process supervision and monitoring is still a mostly analogue and manual task. To prove that the work has been completed as defined per contract, all performed tasks have to be monitored and documented. The demand for a complete and detailed monitoring technique rises for large construction sites where the complete construction area becomes too large to monitor by hand and the amount of subcontractors rises. Main contractors that control their subcontractors' work, need to keep an overview of the current construction state. Regulatory issues add up on the requirement to keep track of the current status on site.

The ongoing digitization and the establishment of building information modeling (BIM) technologies in the planning of construction projects can facilitate the use of digital methods in the built environment. In an ideal implementation of the BIM concept, all semantic data on materials, construction methods and even the process schedule are connected. Therefor it is possible to make statements about cost and the estimated project finalization. Possible deviations from the schedule can be detected and following tasks rearranged accordingly.

This technological advancement allows new methods in construction monitoring. As described in [3] the authors propose a system for automated progress monitoring using photogrammetric point clouds. The main idea is to use common camera equipment on construction sites to capture the current construction state by taking pictures of all building elements. When enough images from different points of view are available, a 3D point cloud can be reconstructed with the help of photogrammetric methods. This point cloud represents one particular time-stamp of the construction progress (as-built) and is then compared to the geometry of the BIM (as-planned).

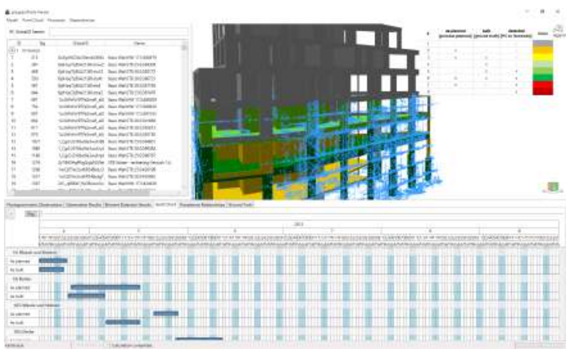

Figure 1. progressTrack: 4D BIM viewer incorporating detection states, process information and point clouds from observations

Figure 1 shows the C#-based WPF software tool, developed in the scope of this research. The tool visualizes a building information model and all corresponding semantic data. Additionally, the observation results can be selected and are supported by the possible overlay of the corresponding point clouds.

2 Related work

Several methods for BIM-based progress monitoring have been developed in recent years [15]. Basic methods make use of rather minor technical advancements like email and tablet computers into the monitoring process. These methods still require manual work, but already contribute to the shift towards a digital process. More advanced methods try to track individual building components by means of radio-frequency identification (RFID) tags or similar methods (e.g. QR codes).

Current state-of-the-art procedures apply vision-based methods for more reliable element identification. These methods either make direct use of photographs or videos taken on site as input for image recognition techniques, or apply laser scanners or photogrammetric methods to create point clouds that hold point-based 3D information and additionally color information.

In [2] and [1], a system for as-built as-planned comparisons based on laser scanning data is presented. The generated point clouds are co-registered with the model using an adapted Iterative-Closest-Point-Algorithm (ICP). Within this system, the as-planned model is converted into a point cloud by simulating the points using the known positions of the laser scanner. For verification, they use the percentage of simulated points, which can be verified by the real laser scan. [20] and [19] use and extend this system for progress tracking using schedule information for estimating the progress in terms of earned value and for detecting secondary objects. [13] detect specific component types using a supervised classification based on Lalonde features derived from the as-built point cloud. An object is regarded as detected if the type matches the type in the model. As above, this method requires that the model is sampled into a point representation. [21] introduce a measure for deciding four cases (object not in place, point cloud represents a full object or a partially completed object or a different object) based on the relationship of points within the boundaries of the object and the boundaries of the shrunk object. The authors test their approach in a very simplified artificial environment, which is significantly less challenging than the processing of data acquired on real construction sites.

In comparison with laser scanning, the use of photo or video cameras as acquisition devices has the disadvantage that geometric accuracy is not as good. However, cameras have the advantage that they can be used in a more flexible manner and their costs are much lower. This leads to the need for other processing strategies when image data is used. [16] give an overview and comparison of image-based approaches for monitoring construction progress. [11] use a single camera approach and compare images taken during a certain period of time and rasterize them. The change between two time-frames is detected using a spatial-temporal derivative filter. This approach is not directly bound to the geometry of a BIM and therefore cannot identify additional construction elements on site. [12] use a fixed camera and image processing techniques for the detection of new construction elements and the update of the construction schedule. Since many fixed cameras would be necessary to cover a whole construction site, more approaches rely on images from hand-held cameras covering the whole construction site.

For finding the correct scale of the point cloud, stereo-camera systems can be used, as done in [18, 5, 6]. [17] propose using a coloured cube of known size as a target, which can be automatically measured to determine the scale. In [7] image-based approaches are compared with laser-scanning results. The artificial test data is strongly simplified and the real data experiments are limited to a very small part of a construction site. Only relative accuracy measures are given since no scale was introduced to the photogrammetry measurements. [9] and [8] use unstructured images of a construction site to create a point cloud. The orientation of the images is computed using a Structure-from-Motion process (SFM). Subsequently, dense point clouds are calculated. For the comparison of as-planned and as-built geometry, the scene is discretized into a voxel grid. The construction progress is determined in a probabilistic approach, in which the parameters for threshold for detection are determined by supervised learning. This framework makes it possible to take occlusions into account. This approach relies on the discretization of space as a voxel grid to the size of a few centimeters. In contrast, the approach presented in this chapter is based on calculating the deviation between a point cloud and the building model directly and introduces a scoring function for the verification process.

3 Problem statement

Monitoring of construction sites with photogrammetric methods has become a working solution in many research areas. Currently a number of companies (e.g. Pix4D, DroneDeploy) already provide commercial all-in-one solutions for end users that allows to generate 3D meshes and point clouds from UAV-based site observations. All these methods give good solutions for finished construction sites or clearly visible elements of interest.

However, the authors noticed that monitoring of construction sites poses several problems. Photogrammetric methods are sensitive to low structured surfaces or windows. Because of the used method, each element needs to be visible from multiple (at least two) different points of view. Thus, elements inside of a building cannot be reconstructed as they aren't visible from an UAV flying outside of the building. Monitoring inside of a building is currently still under heavy research [14] and not available in an automated manner as orientation and observation in such mutable areas like construction sites is hard to tackle. These problems lead to holes or misaligned points in the final point cloud, that hinder correct and precise detection of building elements.

Figure 2. Occluded construction elements in generated point cloud caused by scaffolding, formworks, existing elements and missing information during the reconstruction process

As can be seen in Figure 2, another problem are elements that are occluded by temporary construction elements. Especially scaffoldings and formwork occlude the view on walls or slabs, making it harder for algorithms to clearly detect the current state of construction progress.

Since many construction elements that are correctly built and in place are occluded by other elements and hence out of view for a monitoring system outside of the building, the overall detection rates severely drop, despite the fact that most visible elements were detected correctly. Current methods do not take these problems into account and make only limited use of BIM related information such as type of construction or the general structure of a building.

As proposed in [4], the element detection based on point clouds is possible by calculating the distances between the generated point cloud and the surfaces of all building elements, derived from the BIM. After applying various optimization algorithms such as color filtering and octree based region filtering, still not all elements can be detected due to the before mentioned occlusions. Thus, the authors propose a method that includes process-based rendering of all visible elements at time of observation. In order to achieve this, all elements are rendered from all points of observation for each individual observation. After applying computer vision methods, it is possible to determine, which elements are visible at an observation. This helps to evaluate the as-built vs. as-planned comparison in regard to its efficiency and in the end results in more realistic detection rates, that take only visible elements into account.

4 Detecting visible elements

For the detection of all visible elements, the building information model needs to be rendered from all points of observation for every single observation.

4.1 Camera positions

As proposed, the point cloud is produced using photogrammetric methods. In this process, pictures are taken for example by UAVs (Unmanned aerial vehicles) from different points of view. These pictures can then be used to generate a 3D point cloud if all elements are visible from a sufficient amount of viewpoints. During the reconstruction process, the camera positions around the construction site are estimated. This is illustrated in Fig. 3. This estimation is refined during the dense reconstruction and can get more accurate by using geodetic reference points on site.

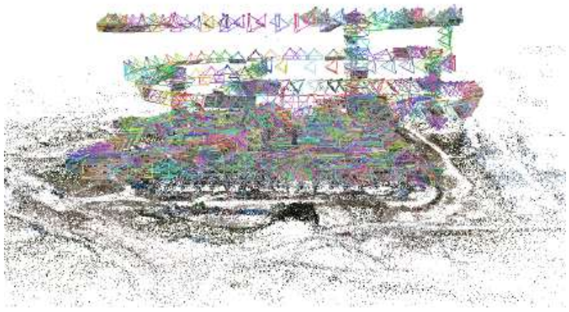

Figure 3. Estimated camera positions during point cloud generation using VisualSFM

These camera positions are required for the proposed method, as the detection accuracy will be refined by detecting all elements that are visible from these positions.

4.2 4D process data

Building information modelling can be used to combine geometry of construction elements with semantic data such as material information but also process schedules. In the scope of this research, the corresponding process schedule is connected to all elements. This allows to identify all elements that are expected to be built at each observation time stamp.

As visible in Fig. 4, the software tool used in this research is capable of integrating the building model, as well as process data and construction elements such as scaffoldings and formwork.

This data is required to define the sets of elements that are used for the visibility analysis described in this paper. Since the process schedule may change during construction, it is crucial to update the schedule permanently based on the gathered observation data.

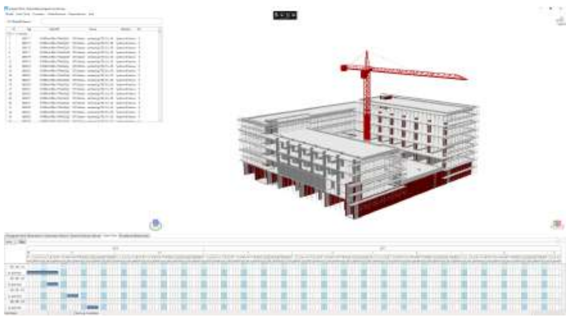

Figure 4. 4D building information model including all additional construction materials like scaffoldings and formwork

4.3 Re-projection

Based on the gathered information, it is possible to do a visibility detection using the camera positions as point of view and the process information to define the set of construction elements that are meant to be built.

To achieve this, the building model coordinate system needs to be transformed into the camera coordinate system or vice versa. Several parameters are needed for this transformation.

On the one hand, the intrinsic camera matrix for the distorted images that projects 3D points in the camera coordinate frame to 2D pixel coordinates using the focal lengths (F_x, F_y) and the principal point (x_0, y_0) is required. It can be described by the matrix K as defined in equation 1.

$$K = \begin{bmatrix} F_x & s_k & x_0 \\ 0 & F_y & y_0 \\ 0 & 0 & 1 \end{bmatrix} \quad (1)$$

Additionally, the rotation matrix for each image as defined in equation 2 is needed.

$$R = \begin{bmatrix} r_1 1 & r_1 2 & r_1 3 \\ r_2 1 & r_2 2 & r_2 3 \\ r_3 1 & r_3 2 & r_3 3 \end{bmatrix} \quad (2)$$

Using the model coordinates of all triangulated construction elements, it is possible to calculate the re-projection of each element into the camera coordinate system and therefore overlay the model projection and the corresponding picture taken from the point of observation with equation 3.

$$t = K * R * point; \quad (3)$$

The resulting 2D coordinates that are rendered into the picture are calculated by using the vector t and getting the x and y coordinates by calculating $x = t[0]/t[2]$ and $y = t[1]/t[2]$. This is done for each point belonging to the triangulated geometry representation of all construction elements.

As visible in Fig. 5 for an explanatory column, the re-projection works as expected and helps to identify the respective construction element in the recorded picture. The mentioned calculations need to include an optional transformation and rotation if the model is geo-referenced and thus the two coordinate systems differ largely.

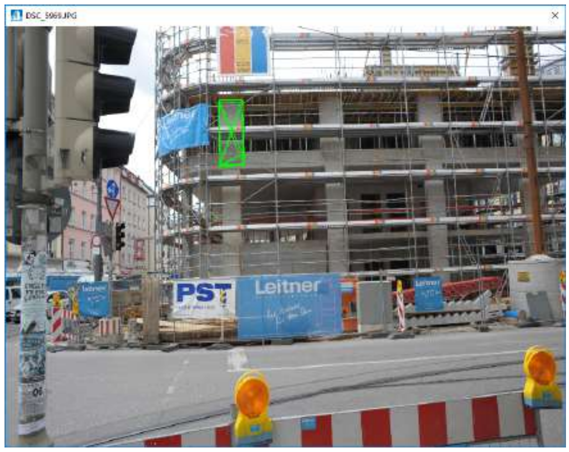

Figure 5. Reprojected triangulated column into a corresponding picture

4.4 Render model based on camera position

The algorithm introduced in section 4.3 enables the element-wise rendering of all construction elements in the respective coordinate system. In order to get a rendered image of all visible construction elements, the following steps are carried out:

1. Iterate over all pictures in observation
2. Iterate over all construction elements
3. Iterate over all points, representing the construction element
4. Get new, reprojected coordinates for all points, including distances to camera. Assign an identifier (e.g. unique RGB color) to each element
5. Iterate over all pixels/coordinates of picture and order points according to their distance to the camera

Whilst all geometric information is available, three problems need to be solved for an accurate rendering of all construction elements:

1. For triangulated elements, only the boundaries are known, however, the complete surface needs to be rendered correctly.
2. The rendered surface needs to be connected to the corresponding element since this information is crucial for a proper visibility analysis

3. Elements may blend over from the viewpoint in some circumstances. This needs to be addressed to get a correct rendering.

The first issue is solved by using basic inside/outside tests for points inside a bounding box around each individual triangle. This is combined with min/max tests to verify that all points are inside the given coordinate system of the current picture. The second issue is addressed by assigning an individual color in the RGB color range to every construction element. This allows to identify each element after the rendering is finished.

The third issue is solved by applying the Painter's algorithm [10] to each pixel in the given picture. In the given challenge, the distance to the point of view is stored for the current construction element and the color information is replaced in case an element has a smaller distance to the point of view and is also visible in the same pixel of the picture.

The applied algorithms result in a rendering as seen in Fig. 6.

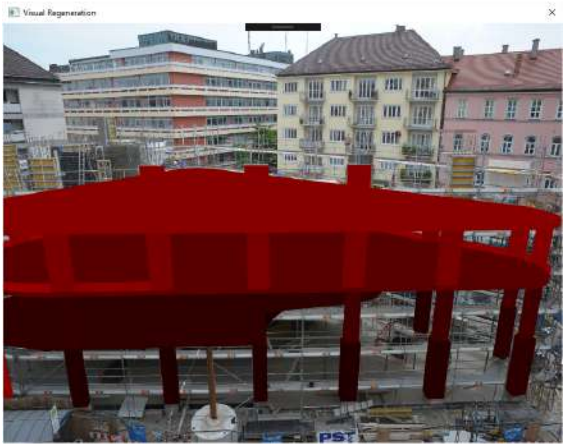

Figure 6. Using re-projection methodology for model rendering based on the Painter's Algorithm and 4D semantic information

After applying this technique to all observations and all camera positions, a distinct list of all visible construction elements can be generated by iterating over all pixels of each rendered image. The color of each pixel is assigned to an construction element and since the painters' algorithm is applied, only the element is visible, that has the lowest distance to the point of observation. Therefore, all visible, non-occluded elements can be determined with this method. This method allows for an automated construction element detection with more realistic detection rates.

5 Case study

The developed methodology has been applied to several construction sites.

As depicted in Fig. 2, most observations lack details at some point and have largely occluded areas due to the observation methods. In very disadvantageous observations the detection rate can drop down to 50% of the overall built construction elements. With the help of the presented methods, these rates can be explained since most of the undetected elements were not visible from the observation points. To quantify the efficiency of an algorithm for as-planned vs. as-built detection, it is very important to have a valid ground truth to allow a reasonable evaluation of the used methods. This approach helps to correctly quantify the used methods.

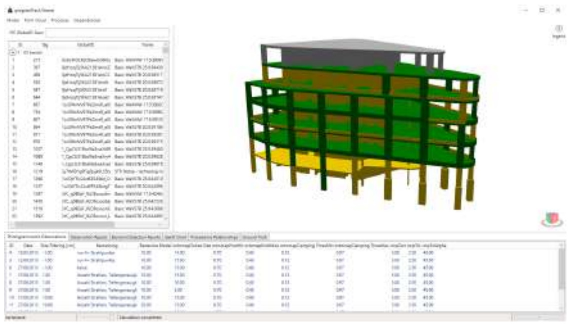

Figure 7. Detected construction elements from one observation. Green elements were successfully detected, yellow elements were not detected but are built.

This is clearly visible in Fig. 7. The green elements were detected correctly. The yellow elements, however, are actually built but were not detected. This is due to the fact that the inner walls were not visible from a sufficient number of viewpoints. Thus there was not enough points in the corresponding point cloud that allowed to validate the existence of the elements. However, these elements were identified as not visible by means of the method introduced in this paper. This helped to get a more realistic impression of the efficiency of the used detection methods.

6 Summary and Outlook

To obtain more realistic detection rates for photogrammetric monitoring methods, the paper addressed the question of visibility of individual building components. To this end the paper introduced a vision-based method which is based on rendering the building information model from all points of view of the photogrammetric capturing campaign. Since the finished building information model with installed facade elements would provide wrong information regarding element visibility during construction, only elements are rendered, that are supposed to be present at time of observation. This is achieved by using semantic and process information from the 4D building information model. The procedure's output is a list of all visible elements of a given point in time. This set of elements helps to further refine detection results based on photogrammetric methods.

Since the introduced methods do not help to identify all temporary construction elements, further research in this field is necessary. The authors are proposing to use the re-projected element positions and the relating pictures and apply machine learning methods to these parts of the picture. This could help to identify further elements such as scaffoldings or formwork, that might not be modeled in current design processes.

Acknowledgments

This work is supported by the German Research Foundation (DFG) under grants STI 545/6-1 and BO 3575/4-1. We like to thank Leitner GmbH & Co Bauunternehmung KG and Kuehn Malvezzi Architects, Staatliches Bauamt München, Baugesellschaft Brunner + Co and BKL (Baukran Logistik GmbH), Geiger Gruppe as well as Baureferat H5, Landeshauptstadt München, Baugesellschaft Mickan mbH & Co KG, h4a Architekten, Wenzel + Wenzel and Stadtvermessungsamt München for their support during the case studies.

We thank the Leibniz Supercomputing Centre (LRZ) of the Bavarian Academy of Sciences and Humanities (BAdW) for the support and provisioning of computing infrastructure essential to this publication.

Infrastructure Asset Management For Strategic Planning

Jeff G. Jurgens, Sean Casey, Jeffrey Clements, Jeong Woo, PhD

Abstract

The inventory of deteriorating infrastructure is increasing, and government resources are contracting inversely. The added expenditures of "emergency" repairs caused by asset mismanagement is too expensive and untenable. In response to the funding shortfall for transportation projects throughout Wisconsin, the Wisconsin Department of Transportation (WisDOT) needs to develop a strategic level asset management analysis tool for strategic planning. Infrastructure Asset Management (IAM) is a cohesive process that integrates data storage, software systems and analytical methods for strategic planning. The purpose of this paper is to analyze how the WisDOT currently manages their infrastructure assets and demonstrate how IAM technologies could improve efficiency and cost savings. Interviews were conducted with WisDOT staff on multiple occasions to ascertain current methods of asset management and project planning. Case study research and comparisons of successful asset management by other progressive state agencies were utilized to formulate the results. It was determined that the only instrument that can effectively realize long term performance, dependability in financial assessment, and prevent an unanticipated inflow of repair work is an Infrastructure Asset Management (IAM) system.

Keywords

Infrastructure; Asset; Management; Information; Technology;

1 Introduction

The costs associated with America's deteriorating infrastructure is well documented, along with a chronic shortage of funding available for maintenance, repairs or replacement. Additionally, much of America's infrastructure is nearing the end of its design life and will need to be replaced over the next decade. The American Society of Civil Engineers estimates that $3.3 trillion dollars is needed over the next 10 years just to maintain our aging public transportation network [1]. Meanwhile, government agencies are encountering increasing difficulties because of the aging and decline of infrastructure assets, insufficient budgets, escalating repair costs, swelling demand, and new environmental requirements to comply with.

Unfortunately, it has become obvious how dilapidated the state of Wisconsin's transportation infrastructure has become. The American Society of Civil Engineers 2017 Infrastructure Report Card estimates that, 1) of the 14,230 vehicular and pedestrian bridges in the state of Wisconsin, 1,232 (8.7%) are classified as structurally deficient, and 2) of the 115,372 miles of Public Roads, 27% are in poor condition [2]. Several years before the $1.7 billion Zoo Interchange reconstruction project began in Milwaukee, one of the existing bridges had a catastrophic failure and needed an emergency, temporary replacement. More recently, there was a WisDOT project where a bridge was overlaid with new asphalt as part of a larger project, and shortly thereafter it was determined that the bridge was failing and needed a fast track replacement. With the list of aging assets growing and government budgets shrinking in comparison, the additional costs of "emergency" repairs due to asset mismanagement is unaffordable and unsustainable. Or as Curry puts it, "Putting aside the complete chaos that any major failure of our infrastructure would cause to the economy, it's just flat out unsafe" [1].

Infrastructure Asset Management (IAM) is a fundamentally cohesive process that requires the integration of an array of information, methods and IT/software systems [3]. New asset management technology can greatly reduce the need for emergency repairs and replacements, as well as "to store and manage information and to support tactical and strategic decisions regarding the operation, maintenance, rehabilitation, and replacement of their infrastructure. Implementation of efficient and cost-effective management strategies largely depends on the ability of these systems to share and exchange asset life cycle information" [4]. IAM is "helping to control costs and program maintenance by combining its various infrastructure inventories into a single platform, resulting in an integrated pavement, bridge and utility management tool. It will overlay sewer, water line, pavement and bridge conditions to facilitate programming of maintenance and capital projects by city management, as well as assist in determining optimal allocation of the city's funds" [5]. Mahmoud Halfawy also points out that many of WisDOT's software tools were not developed to exchange data with other systems. The unforeseen result is information "silos" causing issues with "data consistency, accuracy, and accessibility" [3].

The intention of this paper is to illustrate how escalating construction and preservation costs along with amplified traffic loads have momentously increased the need for an effective Infrastructure Asset Management (IAM) software at WisDOT. This paper will also investigate the use of the IAM to supplement or replace existing management tools for strategic planning at WisDOT by exploring data flows, return on investment, I.T support requirements, staff requirements, and data analysis outcomes.

2 Measuring Infrastructure Deterioration

Currently, WisDOT is using legacy systems such as META manager. These systems have several shortcomings. They:

- Do not all connect to Geographic Information Systems (GIS).
- Do not connect to Building Information Modeling (BIM).
- Are not stored in the cloud.
- Do not communicate with each other, creating information silos.
- May only have printed copies for output.
- Are up to thirty years old.

2.1 Current Measuring Techniques

Due to the excessive costs of replacing infrastructure there has been an increased focus on maintaining existing infrastructure to extend its useful lifespan as much as possible. This strategy is also used to maximize the usefulness of the limited funds available by spending it where it is most needed and preventing larger replacement costs in the future. Bridges can suffer structural deterioration due to aging, misuse or lack of proper maintenance. It is crucial to inspect the bridge periodically and to assess its condition and evaluate any possible damage.

Visual inspection, complemented with Non-destructive Testing and Evaluation (NDT/NDE) has long been used to determine the structural health of bridges. The Wisconsin DOT relies almost exclusively on manual inspections to determine the status of their infrastructure. These inspections are recorded either on paper copies in the field and then manually entered in to a data base or tablets that can input the inspections directly from the field. These inspections follow the National Bridge Inspection Standards (NBIS) and the requirements are explained in detail in the WisDOT Structure Inspection Manual. Table 1 below contains an overview of inspection types and recommended intervals.

Table 1. WisDOT Structure Inspection Manual Requirements

Structure Type	Inspection Type*	Max. Inspection Interval
Public Roadway Bridges	Initial/Inventory Update	After Const. & Major Rehab. or 48 months
	Routine Visual	24 months
	Damage	As needed
	Interim	As needed
	Load Posted	12 months
	In-Depth	72 months
	In-Depth with NDT	72 months
	Fracture Critical	24 months
	Fracture Critical with NDT	72 months
	Paint Assessment	As needed
	Movable	12 months
	Underwater Survey	24 months
	Underwater Diving	60 months
	Underwater Probe/Visual	24 months
Traffic Operations Support Structures	In-Depth	48 months
	NDT	As needed
Roadway Lighting Structures	Routine	48/96 months
	NDT	As needed
Earth Retention Structures	Routine	48 months
Noise Barriers	Routine	60 months
Culverts and Tunnels	Routine	24/48 months
Impact Protection Systems	Routine	60 months
Other Structures over Roadways	Routine	24 months
Pedestrian Bridge	Routine Visual	24 months
Ferries and Ferry Terminals	Routine	24 months
	Underwater	60 months
Truck Weigh Scales	Inspection and Maintenance	48 months
	Calibration	12 months

The key inspection points are as follows:

- All bridges with spans over 20 feet must be regularly inspected.
- There are several types of inspections that are classified based on their level of thoroughness. The normal inspection frequency is 2 years, but this can be extended to 4 years when an in-depth inspection has not reveled any major deficiencies.
- Both WisDOT and the NBIS have stringent qualification requirements to becoming certified to perform bride inspections. The inspector has five general responsibilities:
    1. To ensure public safety and confidence.
    2. To protect the public's investment.
    3. Identify and assess structure needs.
    4. Provide accurate structure records.
    5. Fulfill legal responsibilities.

- The best approach at present is to obtain a baseline evaluation of all bridges and note any damage. 2-3 inspection cycles will yield excellent prognostic data on bridge deterioration. Those structures found with deterioration not yet requiring repair should be monitored closely, at shorter time intervals.
- The WisDOT Structure Inspection Manual discusses testing methods in detail, ranging from visual and audible inspections to ultrasonic and impact echo testing.
- The WisDOT Structure Inspection Manual provides all the forms required for carrying out an official bridge inspection.

These inspections show how the bridge is deteriorating with time, and provide inspectors and engineers with information about how long before repairs are necessary.

2.2 Current Data Management

In theory, this system is simple, effective, and easy to track. However, Wisconsin Department of Transportation is responsible for approximately 13,400 fixed roadway bridges, 50 moveable bridge, and 100 pedestrian bridges over highways [6]. This makes it extremely difficult to efficiently prioritize maintenance needs. Often preventive maintenance actions should occur when a structure appears to be in a “state of good repair” to nonprofessionals, which compounds the challenge of demonstrating and communicating the value of the right sequence of actions over a facility’s life cycle [7]. In times of significantly constrained resources, delaying preservation activities is often attractive in the short term to fund other programs even though the long-term costs and consequences of such a strategy can be significant. There is currently no “golden measure” that is likely to resolve all the difficulties in properly evaluating and communicating preservation needs. Every transportation agency is different. Each face unique challenges in measuring performance and preserving their transportation system.

The next challenge is to be able to analyze data from all the bridges in the state and rank them to determine which have the greatest need for repair or maintenance to prevent higher repair costs in the future. Over the past ten years, a significant amount of research has focused on performance measures, data requirements, analytic tools and approaches for integrating measures into a performance management process that supports performance-based decision making at both the state and regional levels. With recent advances in computer technologies, developing intelligent bridge monitoring systems is becoming a more viable option. Data sensing is become more common.

A data sensing system will typically consist of six common components:

- Sensors and data acquisition networks;
- Communication of data;
- Data processing;
- Storage of processed data;
- Diagnostic and prognostic analysis (i.e. damage detection and modeling algorithms, event identification and interpretation)
- Retrieval of information as required.

3 Literature Review

When transportation departments are considering whether to make the investment into IAM, it can appear expensive. There can be costs associated with gathering new data and modernizing existing data. Fortunately, WisDOT has done an admirable job of inspecting their assets. The costs would be in integrating and managing asset data. To positively influence data management, Brous et al. [8] proposes four fundamental facets to data governance. These facets are; Coordination mechanisms, data quality requirements, monitoring data quality, and creating shared data commons. Naturally, because IAM is a data driven discipline, its effectiveness is dependent on the data being of superior quality as well.

Governing bodies at every level acknowledge the need for asset management as reflected by regulations such as ISO-55000 and the Moving Ahead for Progress in the 21st Century Act [9]. These are devised to swing management approaches away from funding reactive repairs, and toward embracing strategies to proactively finance a more enduring infrastructure. “The most efficient way to satisfy these requirements, secure funding and ensure a process that proactively detects needed repairs and safely prolongs the life of equipment is by investing in asset management and the technologies that provide the needed visibility and predictive maintenance.” [1]

Because of IAM’s dynamic nature, integrating sustainability practices is straightforward [10]. When making sustainability decisions, each phase needs to consider the triple bottom line (TBL) of sustainability to create greater value [10]. The TBL framework considers the potential social, environmental, and financial impacts. The US Environmental Protection Agency (EPA) has provided direction [10] to facilitate agencies to establish targets and execute methods that feature TBL considerations. Adding sustainability to IAM can compensate for shifting environmental changes and fluctuation in transportation demands.

Finally, as agencies consider and evaluate the implementation of asset management, a cohesive management team who share a common vision for system objectives is critical to success. [9]

4 Asset Management Software

As an example, Deighton is an asset management software used by several transportation departments. It is designed specifically to prevent data fragmentation and incorporate pavement, bridges, subsurface utilities, signs, safety, and traffic data using cross-asset analysis capabilities [5]. Regulations such as ISO-55000 and the Moving Ahead for Progress in the 21st Century Act are devised to swing the approach away from using funding to go after reactive repairs, and rather implement a strategy to proactively finance a more enduring infrastructure [1]. "The most efficient way to satisfy these requirements, secure funding and ensure a process that proactively detects needed repairs and safety prolongs the life of equipment is by investing in asset management and the technologies that provide the needed visibility and predictive maintenance. Government agencies that can administer public infrastructure are finding that new asset-centric software helps them prioritize projects based on risk and criticality, and invest their capital improvements funds in ways that will have the greatest impact [1].

4.1 Pricing

There are several (IAM) software packages available to Departments of Transportation, such as Deighton's Total Infrastructure Management System (dTIMS), Bentley AssetWise, or Decision Lens. For simplicity, this paper will use pricing information for Deighton software. The dTIMS software appears to contain an initial cost for the license and an annual fee dedicated towards maintenance and updates for the software. A comparison between various infrastructure asset management (IAM) software conducted by an individual at Saitama University in Japan found the initial cost of the license to be in the range of $60,000 to $80,000 and the annual fee to be around $4,000 per license. Considering these costs, they estimated that the typical cost to implement the dTIMS CT software at around $225,000 [8].

4.2 Price Comparison

Several department of transportation (DOT) budgets were examined to determine the costs of a single license. The City of Des Moines (Iowa) paid an initial cost of $64,125 for a single license in 2016, with the annual fee at $12,000 [9]. The South Dakota DOT conducted a year-long research project into the life-cycle sustainability for various rehabilitation structures and paid $65,000 for a single license. An annual maintenance cost did not appear in the budget for the project due to the project taking less than one year [10]. Research conducted by the University of Wisconsin-Madison into the Wisconsin DOT budget yielded a cost of $60,000 for license, and an annual maintenance and support fee of $7,000 [11]. An investigation by Caltrans into the Colorado DOT's use of the dTIMS software estimated that the total cost to implement the software at $225,000. This supports the claim that was made earlier from Saitama University; however, this includes the cost of approximately 2000 working hours dedicated to the investigation [12]. Even assuming a high hourly wage (such as $80/hour), the labor cost comes out to $160,000, leaving $65,000 for the initial purchase of the software. Table 2 contains a summary of the various costs researched:

Table 2. Summary of dTIMS CT

Source	Single License Cost	Annual Fee
City of Des Moines	$64,125	$12,000
South Dakota DOT	$65,000	-
Wisconsin DOT	$60,000	$7,000
Saitama University	$60,000 to $80,000	$4,000

4.3 Return on Investment

Purchasing IAM software and incorporating it can pay for itself by preventing only one of the two instances of resource mismanagement at WisDOT. Earlier in the paper, a project was mentioned that included a bridge that was overlaid and then needed emergency reconstruction. This is a perfect example of why an IAM system is needed to prevent further occurrences, and it is also an optimal demonstration of the Return on Investment (ROI) potential. The initial project was three miles long, or 15,840 linear feet. The cost of the initial project was $1.5 million. The cost of the initial project divided by the length of the initial project results in a cost of $94 per linear foot of overlaid roadway. On a similar project with a road overlay that included a bridge reconstruction, the length of the bridge reconstruction "footprint" was 0.5 miles, or 2,640 linear feet. It is assumed that the initial projects bridge reconstruction "footprint" will also be close to 2,640 lineal feet, multiplied by the overlay cost of $94 per lineal foot, the lost funds spent on the overlay are $248,160. This one occurrence cost WisDOT is $23,000 more than the projected price of implementing dTIMS CT, for $225,000.

4.4 Workflow

Investigating two state DOTs can provide useful insight into the workflow for the implementation and use of the dTIMS CT software. Two are examined: Pennsylvania and Colorado.

The Pennsylvania DOT (PennDOT) uses dTIMS as a pavement asset management system for its interstates, US highways, and state roadways. There are two types of primary inputs into the analysis: inventory, current conditions, and financial records, along with decision criteria and performance. The inventory, current conditions and financial records come from diverse types of monitoring and control software, such as PennDOT's Engineering and Construction Management System (ECMS) or Multi-modal project management system interactive query (MPMS) [13]. Data from the two types of main inputs are then inputted into the dTIMS CT software. The analysis from the software then outputs strategies, recommendations and strategic reports. This is then given to other field and office staff. Field personal end up submitting maintenance records to the dTIMS analysis, while office staff provide feedback in what PennDOT calls the district feedback program. Figure 2 demonstrates an overview of the dTIMS workflow.

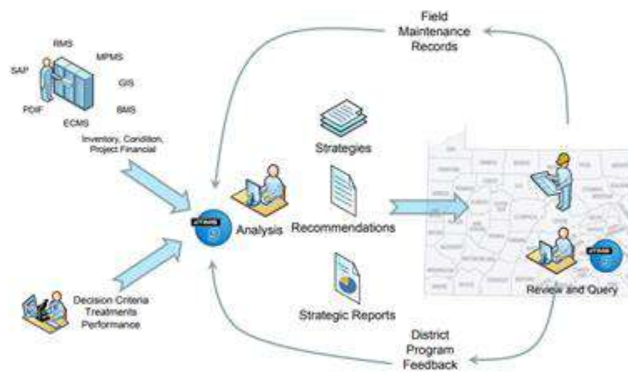

Figure 2. PennDOT Workflow for dTIMS CT (PennDOT, n.d.)

The Utah DOT (UDOT) provides a simpler outline for their implementation of dTIMS CT. They are applying it on a larger scale compared to PennDOT, using it not only for pavement, but bridges, safety, mobility and maintenance features. This appears to be part of a cross-optimization model, which will be discussed later. UDOT's two inputs are infrastructure data, and analysis parameters [14]. Presumably, like PennDOT, they have their own ways of collecting and gathering infrastructure data. These, along with the required analyze parameters, are analyzed by dTIMS. Outputs are provided in terms of long-term impacts and construction schedules [14]. The workflow process for dTIMS CT is illustrated in Figure 3.

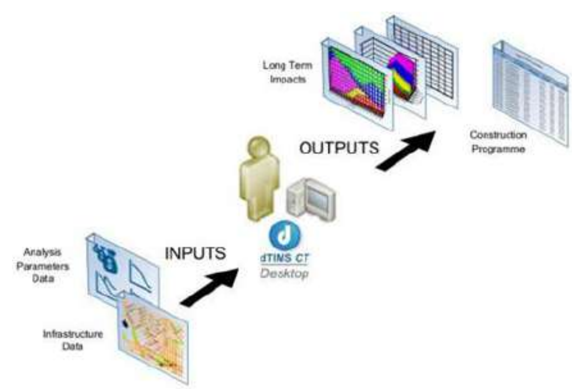

Figure 3: UDOT Workflow for dTIMS CT [14].

The Colorado DOT and others utilize a Cross Optimization Model. Cross optimization IAM systems take in multiple types of asset data, such as pavement data, structure data and safety data, runs it through the dTIMS software, which provides analyses in the distinct types of assets, suggests strategies based on the various assets analyzed, and finally culminates in a cross-asset analysis report [15]. Figure 4 shows an illustration.

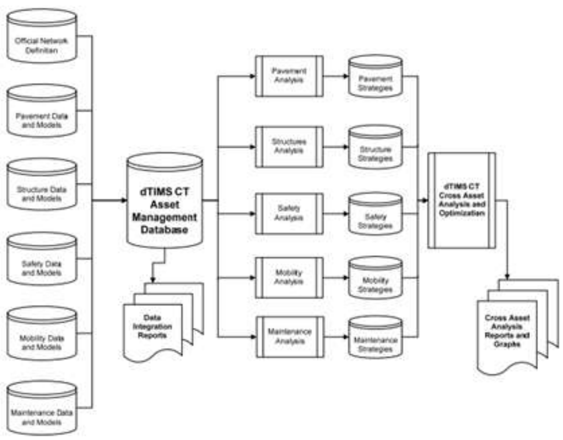

Figure 4. Typical Workflow for Cross Optimization Model Analysis [15].

The Wisconsin DOT is plagued by information silos as seen in Table 5. Because there isn't the opportunity for communication between systems, cross-optimization cannot occur. Which results in departments taking a reactionary, tactical approach instead of a proactive, strategic one towards asset management.

Table 5. Typical WisDOT Workflow demonstrating the creation of information silos.

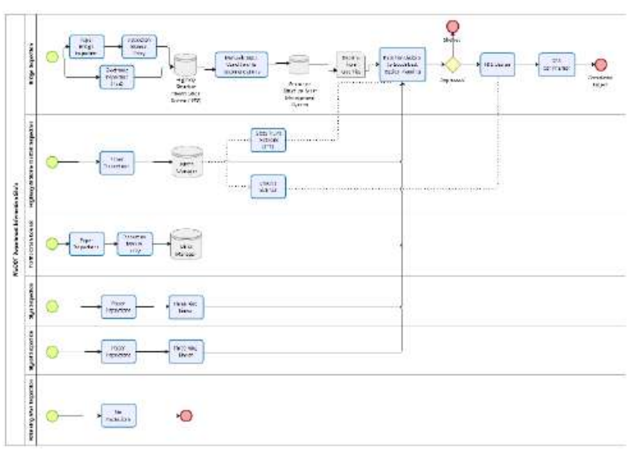

Figure 5 contains a proposed WisDOT dTIMS CT workflow. It attempts to streamline the workflow from Table 5, as well as a cross-asset optimization model hybrid as seen in Figure 4.

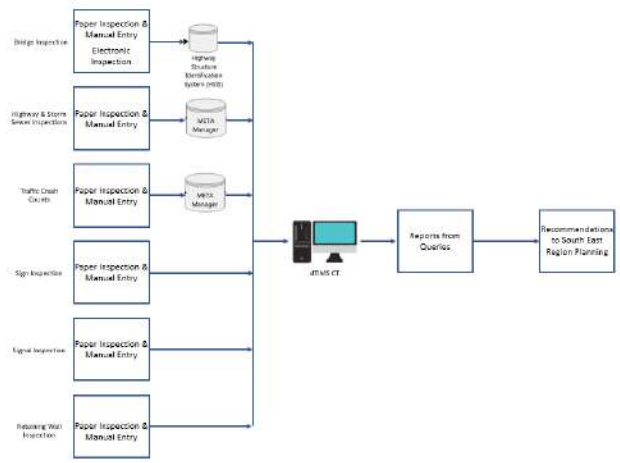

Figure 5. Proposed WisDOT dTIMS Workflow to achieve streamlined integrated outcomes

5 Conclusion

Exact long-term planning of maintenance and management is critical to safeguarding the 115,145 miles of Wisconsin's public roads [16] and ensuring their performance is in appropriate condition for today and in the future. Often, road controlling authorities are using decision-making tools that work on a snapshot of the condition of roads. To achieve for any given time, an appropriate analysis approach needs to be selected for the best possible results. For short term planning, field decisions and project prioritization may be appropriate to deal with various maintenance situations, while longer terms require more specialized and accurate planning. Deterministic models can often provide a reliable measure of the condition of the assets for medium-term planning, and anything longer requires more full-picture type techniques, such as stochastic models. There is a fine balance between attending to the urgent short-term maintenance needs of a road network, and at the same time plan well-ahead into the future to avoid an unexpected influx of maintenance work. It is not only important to know what the next treatment should be for a site, but it is also beneficial to identify the follow-on treatments based on today's decisions and planning. Currently the only tool that can successfully achieve these objectives is an Infrastructure Asset Management (IAM) system.

E-mail: simon.vilgertshofer@tum.de, andre.borrmann@tum.de

Abstract –

Sophisticated geometric and semantic models are the basis for many applications in the field of Building Information Modeling. While the requirements in terms of detail, flexibility and conformity on those models and thus on the corresponding modeling tools increase, especially in the case of parametric and procedural modeling, open questions remain regarding the support of the user during the modeling process and the loss of modeling knowledge after finishing a modeling task. Graph Theory can be used when addressing these questions. It can be employed to represent parametric models in a vendor-neutral way and to capture modeling operations by formalizing them in graph rewrite rules. This paper describes the further development and generalization of graph-based model creation for the support of feature-based parametric modeling. We show how such procedural 3D models that are based on two-dimensional sketches can be represented by graphs and how modeling steps can be formalized by using rule-based graph rewriting. This approach enables a user to semi automatically reuse previously formalized modeling tasks, thereby supports and accelerates the modeling process and, additionally, allows the formal definition of expert engineering knowledge for later use and reapplication.

Keywords –

Graph rewriting; Parametric modeling; Modeling support

1 Introduction

Realizing the design and engineering of construction projects successfully is a challenging process for all the parties involved.

While even small and straightforward projects may evoke complex issues, this is typically the case for large projects in which various boundary conditions and constraints as well as a vast number of participants from different areas of expertise are involved.

The technological advancements developed alongside the ongoing introduction of Building information modeling have addressed those challenges and support designers and engineers in their daily work and their interdisciplinary communication. However, the availability of sophisticated models containing geometry as well as semantics are a major requirement for many applications and workflows. Use scenarios such as automated construction progress monitoring [1], automated code compliance checking [2], automated cost analysis or BIM-based generation of construction schedules [3] would not be possible without underlying BIM-models comprising various kinds of information.

The task of creating models is therefore an indispensable prerequisite for the use cases mentioned above as well as a large variety of additional scenarios. The modeling of shield-tunnels, for example, can benefit from geometric models comprising different Levels of Detail (LoD) as introduced by Borrmann et al. [4]. To avoid inconsistencies among the different LoDs, it is necessary to apply parametric modeling techniques, which allow the automatic preservation of the model's consistency across the different LoDs in case of alterations. The research by Borrmann et al. has revealed that the manual creation of consistency preserving parametric product models is a very complex, time consuming and error-prone task. An approach by Vilgertshofer and Borrmann [5,6] introduces the possibilities of using graphs and graph transformation to support the necessary modeling process by formalizing parametric 2D sketching operations and subsequent procedural operations, which semi-automatically create 3D models for linear parts of shield-tunnel facility models. In this context, "linear" denotes the part of the model that rely solely on the course of the alignment, the most important basis for infrastructure facilities ranging over longer distances. Parts of the model which are positioned at specific points on the alignment (crosscuts, fire exit shafts, etc.) are called "non-linear".

An overview of the concept of this existing approach is shown in Figure 1, which conceptually illustrates how a model is represented by a graph and how this graph is

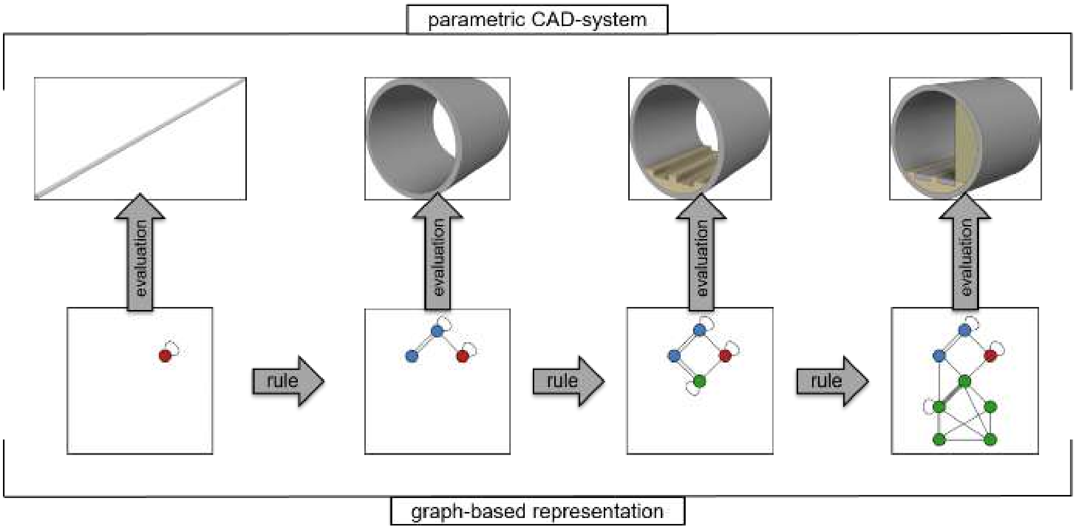

Figure 1: Conceptual illustration of using graph rewrite rules that formalize detailing steps of the graph-based representation of a shield-tunnel model. Each instance of the graph can be evaluated to create an actual model in a parametric CAD-system.

transformed by applying predefined rewrite rules. An arrow "rule" indicates the application of a rewrite rule. At each stage of this process, a parametric CAD system can interpret and process the graph in order to create an editable parametric model. This model is further called the evaluated model. An arrow labeled "evaluation" marks the generation of the evaluated model out of the graph. Note, that the graphs in Fig. 1 do not actually represent the respective geometry. They merely illustrate the presented concept.

In this paper, we will show how this approach can be refined and developed further in order to enable the representation and formal generation of more complex models. In the case of shield-tunnel models we extend the method towards the additional support of nonlinear (meaning "not based solely on the alignment") geometry parts, such as fire exit shafts or crosscuts. Furthermore, we will introduce a possibility to use the graph-based method for the semi-automatic parametric model generation in the scope of high-rise construction, namely steel connections (Figure 2). To achieve this, we will show how we can refine our graph rewrite system to allow the representation of procedural models comprising assemblies and constraints on assembly level.

Figure 2: Detailing of a steel connection.

The paper is structured as follows: Subsequent to the introduction, Section 2 will give an overview of previous and related research as well as the theoretic background of parametric modeling and graph rewriting. Section 3 will introduce our method of graph-based description of parametric modeling and show how this method is further refined. Additionally, it will summarize our implementation work and possible use cases of our extended method. The paper concludes with a summary.

2 Background and related work

The benefits of the computer-aided or (semi-)automated creation of designs and models have been addressed by researchers before. This section puts the presented approach in context of a short overview of existing approaches. It further presents the theoretical background of the proposed methodology in terms of parametric and procedural modeling and graph rewriting.

2.1 Modeling support

Computers successfully support the process of generating technical drawings or product models and parametric CAD software is widely used and enormously valuable in the building sector [7]. However, the main purpose of such software is to assist an engineer in his creative design work, which is one of the most complex human tasks, as it depends on the consideration of various constraints to obtain satisfactory solutions [8]. Therefore, a further step is the development of methods and tools, which actively support a designer by automatically generating whole sets of design variants or by the automation of repetitive and trivial tasks in the design process. As the concept presented in this paper contributes to this field of research, major approaches, which also utilize graph representations, are summarized here.

In the field of Computational Design Synthesis (CDS), Helms [9] uses a graph grammar for the computational synthesis of product architectures. Design knowledge is captured in a port-based metamodel and the procedural design rules of the grammar. Hoisl [10] presents an approach for creating a general spatial grammar system that introduces interactive definition and application of grammar rules in the scope of CDS. It aims at actively supporting a designer in the modeling process using mechanical CAD systems. The approach by Kniemeyer [11] in the domain of biology makes use of a graph grammar to design and implement a language to support the functional-structural modeling of plants.

Furthermore, Lee et al. [12] fundamentally describe how parametric building object behavior can be specified for building information modeling systems. Their approach shows how a common method to “describe the design intent in order to share and reuse the user-defined parametric objects” between collaborating experts can be realized. This approach, however, is not intended to automate the encoding of parametric object behavior definitions.

2.2 Parametric modeling

The concept of parametric, procedural and feature-based modeling was developed in the 1990s [13] and is by now well established and used in many commercial and open source CAD applications such as Autodesk Inventor, Siemens NX and FreeCAD.

While a pure geometric model stores only the coordinates of the geometric elements, the concept of parametric feature-based modeling is to store the sequence of sketching and subsequent 3D modeling operations: The construction history of the model. Generally, a construction history has the following structure: Parametric geometric 2D models (sketches) are composed of geometric objects and parametrical constraints. During the creation of a sketch in a parametric CAD application, a system of constraints and objects is defined and forms a constraint problem. A geometric constraint solver (GCS) [14] can solve such a problem. Schultz et al. [15] define the set of parametric constraints that is implemented by all major constraint solvers as the standard geometric constraint language. It comprises the dimensional constraints for distances and angles as well as the following geometric constraints: *coincident, collinear, tangential, horizontal, vertical, parallel, perpendicular and fixed*.

A parametric sketch created in this manner can then be used as the basis for an extrusion, sweep, loft or rotation to create a 3D object, a so-called *feature*. By applying Boolean operations, several of these features are then combined to models that are more complicated and result in parts. The combination of various parts lead to the creation of an *assembly*. On assembly level, different parts are arranged by *mating conditions*, which are basically complex parametric constraints applied to points, lines or surfaces of parts.

The main advantage of a 3D model created in this manner is, that it allows changes of any operation in the construction history without losing the consecutive modeling operations. Therefore, alterations are easier, and errors can be fixed without the necessity of a complete remodeling. This modeling technique, however, relies on a deep understanding of its basics and therefore requires extensive training of possible users, as a multitude of constraints and parts lead to very complicated models that can get almost unmanaged without knowing the originator’s intentions Lee et al. [12]. Our approach therefor aims at introducing automation mechanisms into parametric feature-based modeling.

2.3 Graph rewriting

The presented approach for automating the detailing process in this paper is based on graph theory and also uses graph rewriting methodology as comprehensively described by Rozenberg et al. [16]. We employ graphs and graph rewriting mechanisms to enable the representation and the modification of procedural parametric models. An application of graph rewriting to semi-automatically create and alter parametric sketches has been presented in Vilgertshofer and Borrmann [5] and was further developed [6].

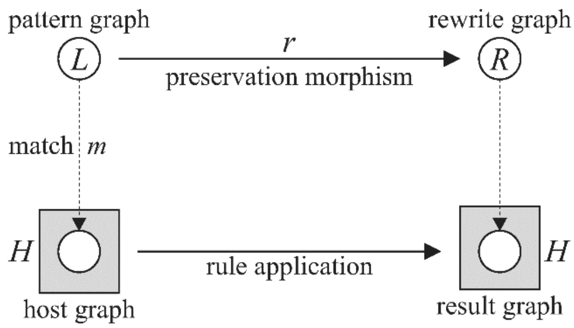

Figure 2: Graph rewriting via the SPO (inspired by Blomer et al. [19]).

Graph rewriting operations are used to create a new graph out of an existing graph by altering, deleting or replacing parts (subgraphs) of the existing graph. The changes are formalized through graph rewrite rules written as $L \rightarrow R$. A graph rewrite rule is defined by a pattern graph L and a replacement graph R. When a rule is applied to a graph (called the host graph), this graph is searched to find a subgraph that matches the graph pattern defined by L. A successful matching leads to the replacement of L with R under the consideration of a preservation morphism r. This preservation morphism controls how R substitutes or alters an instance of L in the host graph. The outcome of this rule application is called the result graph H' as illustrated in Fig. 2.

There are several different approaches to graph rewriting. Two main examples are the Single-Pushout Approach (SPO) and the Double-Pushout Approach (DPO) [17].

3 Conceptual approach

This section will give an overview of the basic concept of our existing approach and show how it was extended

3.1 Graph-based description of parametric models

In the following section, we will first give a short comparison of our work so far and discuss its limits. Thereafter, we describe how we revise and extend it to generate a wider range of parametric models.

3.1.1 Overview

Parametric modeling CAD-systems use geometric elements such as points, lines or circles as primitive planar entities. The parametric constraints as described in Section 2.2 define the topology of these entities and result in parametric sketches. Those are the basis for further procedural modeling operations, which create 3D features. To represent a procedural parametric model by means of a graph, it is necessary to define, which types of geometric elements, parametric constraints and procedural modeling operations are employed. In the scope of our research so far, we generally considered the following types:

- geometric elements: *point, line, spline circle, arc*
- parametric constraints:
  - geometric constraints: *coincident, collinear, equal, concentric, horizontal, vertical, parallel, perpendicular, fixed*
  - dimensional constraints: *dimensions of one geometric element, distances between two geometric elements*
- procedural modeling operations: *workplane, extrusion, sweep*

This listing roughly reflects the standard geometric constraint language defined in Schultz et al. [15] summarizing the most common operations provided by any parametric CAD system (see Section 2.2).

3.1.2 Formalization

For formal representation of these items, a graph metamodel describes the necessary attributed types of graph nodes and edges are. They can then be instantiated during the generation of a graph. The metamodel also forms the basis for the definition of graph rewrite rules, which formally describe modeling steps. An end user can apply those instead of manually executing the underlying procedural or parametric modeling operations. Fig. 1 in Section 1 conceptually illustrates how a graph represents a model and how the application of predefined rewrite rules transforms this graph.

The graph representing a procedural geometry model is a directed multigraph with loops $G = (V, E, T^v, T^e, s, t, lb, ty^v, ty^e, att)$. It is defined as follows:

- $V = V_P \vee V_S$ is a nonempty finite set of vertices. Elements of V_P are vertices that represent procedural modeling operations, while elements of V_S represent geometric objects in a sketch.
- $E = E_P \vee E_S$ is a nonempty finite set of edges. Elements of E_P are used to represent general relations or dependencies between the procedural operations and allocate geometric elements to a specific sketch. Elements of E_S represent parametric constraints of a geometric element or between two geometric elements.
- $V_P \wedge V_S = \varnothing$ and $E_P \wedge E_S = \varnothing$.
- $s : E \rightarrow V$ is a mapping that indicates the source node of all edges.
- $t : E \rightarrow V$ is a mapping that indicates the target node of all edges.
- Σ is an alphabet of labels of vertices and edges.
- $lb : E \vee V \rightarrow \Sigma$ is a labeling function.
- $T^v = T_P^v \vee T_S^v$ is a set of types for the vertices in V. T_P^v and T_S^v are sets of types for nodes in V_P and V_S respectively.
- $T^e = T_P^e \vee T_S^e$ is a set of types for the edges. T_P^e and T_S^e are sets of types for nodes in E_P and E_S respectively.
- $ty^v : V \rightarrow T^v$ is a typing function for the vertices, such that $ty^v(V_P) \wedge ty^v(V_S) = \varnothing$.
- $ty^e : E \rightarrow T^e$ is a typing function for the edges, such that $ty^e(E_P) \wedge ty^e(E_S) = \varnothing$.
- At is a set of attributes of vertices and edges.
- $att : E \vee V \rightarrow At$ is an attributing function.

The metamodel describes the possible set of types T^v and T^e of the graph entities V and E. They can then be instantiated to execute a rewrite rule to create or alter the graph. Additionally, the metamodel defines the attributes of a certain type as well as conditions that control which nodes and edges may be incident or which node types can be adjacent. As the type of a graph entity clearly determines which attributes that entity has, an attributing function is not given.

Instead of using separate graphs to represent sketches and subsequent procedural operations we concluded that combing all information needed for the representation of a particular model should be embedded in a single graph. This is realized by integrating graphs that represent a sketch into the procedural graph. The benefits of this method are presented in [6] in detail. We still conceptually separate the subgraphs representing sketches and the procedural operations that subsequently create 3D features and therefore use the terms *sketch graph* and *procedural graph*.

3.1.3 Limits

While the presented method enables the automated generation of basic shield tunnel models, based on the alignment, limitations occur. This is especially the case, when we approach the question of non-linear geometry or use cases in other domains. Creating and placing various features in a model proves quite difficult when there is no possibility to arrange them without altering the position of the sketches. In the parametric feature-based modeling theory, so-called assemblies remedy this problem. One or more features are combined into one part, whereas an assembly consists of multiple parts. While each part has its own local coordinate system to position one or more features (each sketch has its own local coordinate system, too), the assembly itself defines yet one more coordinate system in which the different

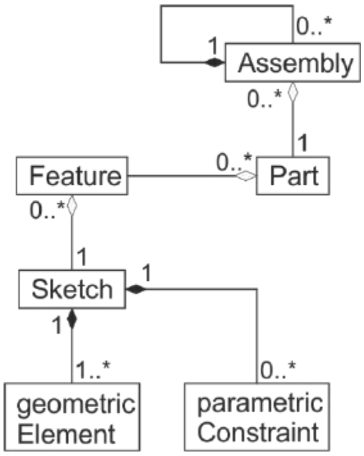

Figure 4: Structure of a model consisting of sketches, features, parts and assemblies.

parts are positioned. This placement is achieved by using either fixed coordinates (which is usually the case for the first part to be positioned) or by placing one part relatively to another one. The relative positioning works quite similar to the parametric constraints, which define the topology of the geometric elements in a sketch. In this context, however, the term mating conditions is used. Basic mating conditions define points, lines or faces of a part to be constrained to those of another part in terms of being coincident (points), collinear (lines) or on the same plane (faces).

In this regard, we also encountered the problem of referencing geometric entities that are the result of a

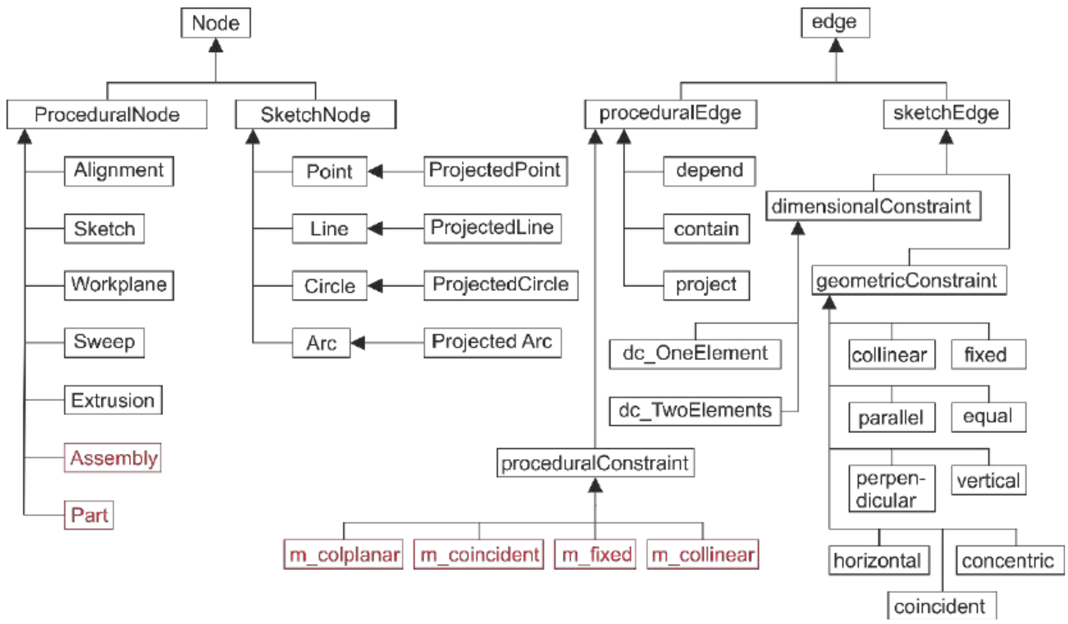

Figure 5: Extended version of the graph metamodel.

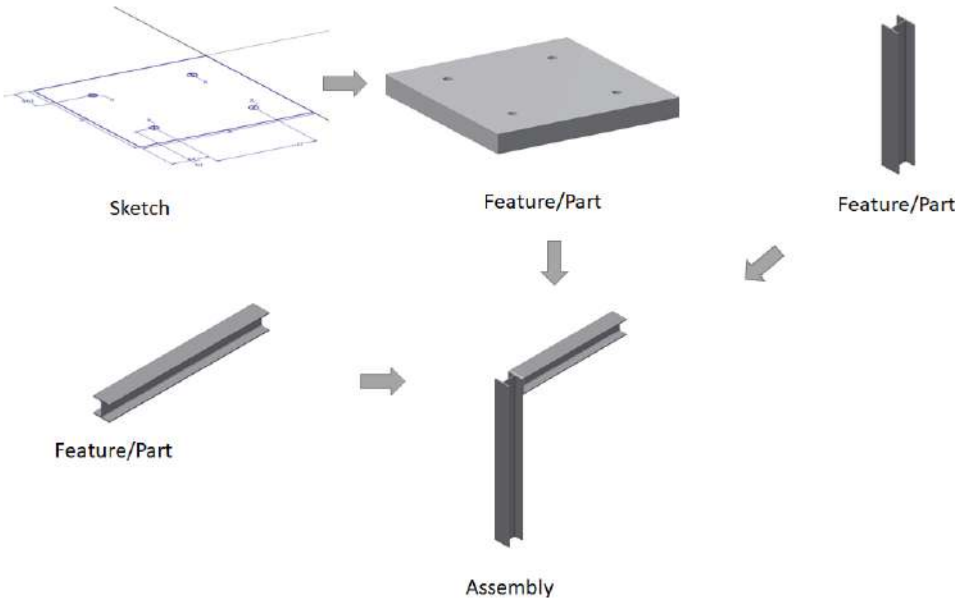

Figure 6: Modeling of a steel connection with the use of features/parts as an assembly.

procedural operation in the graph. The extrusion of a rectangle, for example, forms a cuboid. Here, the four points and four lines that the sketch describing the rectangle contains, are represented in the graph. Another eight lines, however, bound the resulting cuboid. Additionally, four new points connect those lines and the cuboid itself comprises six faces. However, the graph does not represent these 18 new entities and it is therefore not possible to reference them in subsequent graph transformation operations. Therefore, we need to refine the rules creating subgraphs that represent feature objects to comprise such geometric entities, if they objects need to be referenced by consecutive rewriting operations.

The necessary extensions to our graph metamodel in order to include assemblies and mating conditions are described in the following subsection.

3.2 Extension of the approach

As the graph metamodel is the formal description of types of graph nodes and edges that can be instantiated, it has to be extended in order to cover the representation of the described modeling operations on an assembly level. Figure 5 depicts the previous version of the metamodel in black color, while the necessary extensions are drawn in red color.

Most important extensions are the new node types *part* and *assembly*. They are used in a similar manner as sketch nodes are used to group the geometric elements of a sketch: Part nodes group one or more features created from sketches, whereas assembly nodes group one or more parts. Furthermore, constraints in the procedural context are added, to define the relative positioning of the parts in an assembly.

While this refinement is not extensive in terms of new node and edge types, it allows us to model more complex geometry than in the previously presented approach. We are now able to construct a model consisting of more than one part and to position these parts relative to one another. This decomposition of the model allows us to generate subgraphs representing model parts that are either completely independent from one another or only related by mating constraints.

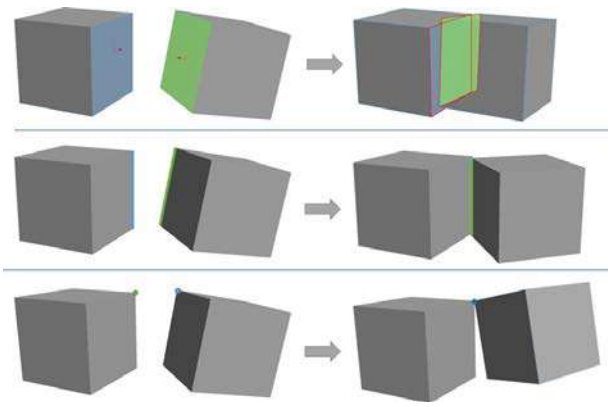

Figure 7: A model before and after applying three different types of mating constraints: coplanar, collinear and coincident.

These mating constraints are much better suited to the relative positioning of three-dimensional objects to one another than parametric constraints, as we do not have to consider the positioning of workplanes or the projection

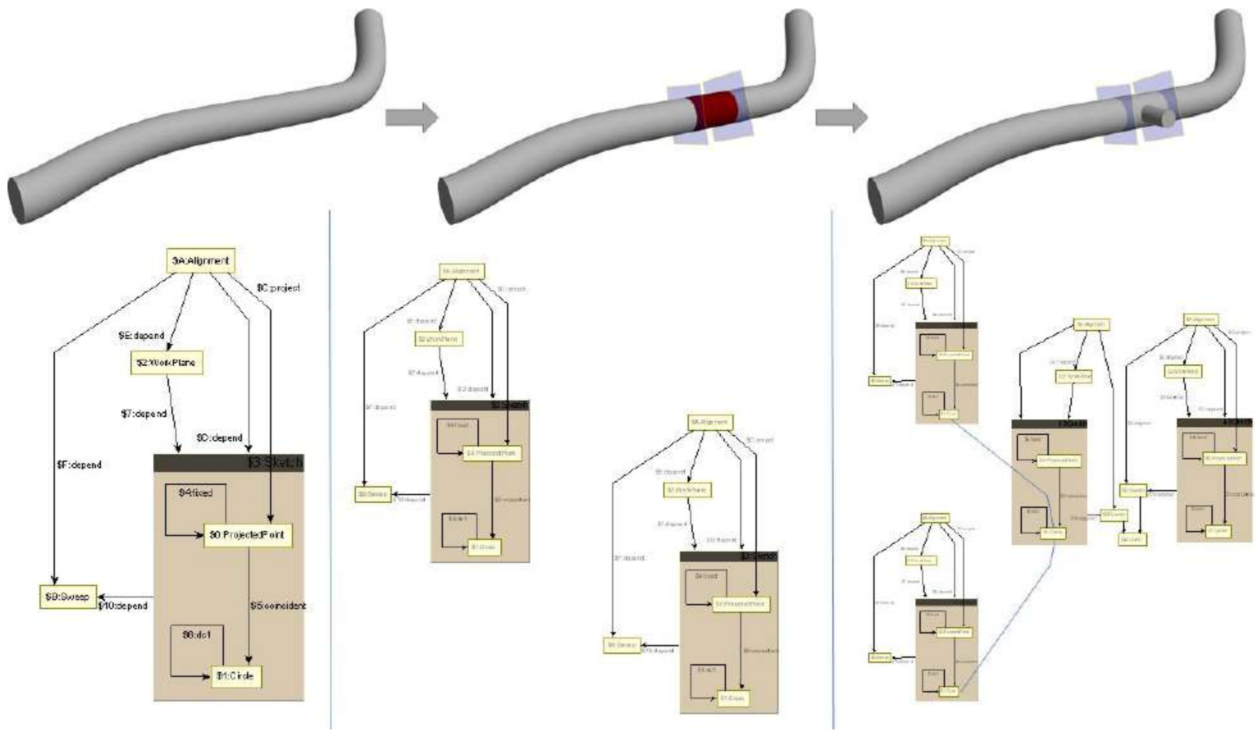

Figure 8: Process of adding a crosscut to a tunnel model. Bottom: States of the graph representing the model. Top: Geometric result of the graph transformation process.

of existing geometry between sketches. During the modeling of parts those operations are still necessary and helpful, though. When positioning parts in an assembly they can also be rotated via the application of mating conditions. As this is not the case with features combined in a part without using a procedural operation, this also gives us more freedom in the positioning process. The graph is in its definition now much more conform to the general concept of parametric feature based modeling.

As described before, the entities that mating constraints link to one another have to be present in the graph in order to apply those constraints. We concentrated on two possible solutions for this problem: We can either define a rewrite rule in a way that all new entities (points, lines and faces) are also created within the representing graph and can be referenced by further rewrite rules. Another possibility is to only create those entities that are necessary for later rewriting operations. This, of course, is only reasonable if we know at that point, which entities this will be. We are still considering which of these solutions is more constructive or if they should both be implemented simultaneously.

3.3 Use cases and implementation

For the definition and extension of the graph rewrite system consisting of a metamodel and appropriate graph rewrite rules, the graph rewrite generator GrGen.NET [18] has been used while the generation of the evaluated sketch is performed with the commercial parametric CAD application Autodesk Inventor. Inventor contains a geometrical constraint solver, which interprets the constraint problem defined by the graph. A software prototype was developed to utilize both the functionalities of GrGen.NET and of Autodesk Inventor to apply rewrite rules and perform the consecutive creation of the evaluated model.

In order to verify the improvements made to the graph rewrite system we examined two test scenarios. First, we employed the graph system to model the connection of two steel beams (Figure 6). Here, the connecting plate is designed from extruding a sketch to create a 3D feature. A part consisting only of this feature is then combined with two other predefined parts (the beams) in an assembly. To position those three parts in accordance with each other, several planes of the respective parts were constrained by mating conditions.

In the scope of modeling non-linear geometry of shield-tunnels, a crosscut was added to an existing model of a tunnel. We also realized this by using the introduced assembly nodes. While the tunnel model without the crosscut would be modeled as only one part, we now cut the alignment at both sides of the future position of the crosscut. As we now have three alignment sections, we use them as basis for three different parts. The two outer parts are created by reapplying the existing rules that rewrite the graph to create the linear 3D geometry. The inner part however is represented by a new subgraph. This subgraph is created by executing a corresponding rewrite rule that creates the representation of a tunnel section comprising the opening for the crosscut. This process is graphically illustrated in Figure 8. Thereby we create three rather independent subgraphs representing the three model parts shown in the figure. Mating constraints are then used to combine them to a consistent model. In the graph representation the subpgraphs are therefore connected by edges representing those mating constraints. For example, they are used to mate the faces of two tunnel parts that have to align in order to keep those parts in position respective to each other.

4 Summary

The presented research introduces and extends a concept for the graph-based representation of product models and their automatic generation and detailing by performing graph rewrite operations based on formal rules defined in a graph rewriting system.

It has already been successfully applied to the product models of shield-tunnels and the automatic creation of consistency preserving multi-scale versions of such models. The main contribution is the further elaboration of the underlying graph rewriting system that enables the generation of more complex graphs covering the representing of a larger variety of parametric representations. To prove the feasibility of our approach, the graph rewriting system has been implemented in the graph rewriting tool GRGEN.NET.

Further research will focus on creating a larger set of rewrite rules, which enables end users to create more diversified models in different contexts.

Abstract –

Crack detection has vital importance for structural health monitoring and inspection of buildings. The task is challenging for computer vision methods as cracks have only low-level features for detection which are easily confused with background texture, foreign objects and/or irregularities in construction. In addition, difficulties such as inhomogeneous illumination and irregularities in construction present an obstacle for fully autonomous crack detection in the course of building inspection and monitoring. Convolutional neural networks (CNN's) are promising frameworks for crack detection with high accuracy and precision. Furthermore, being able to adapt pretrained networks to custom tasks by means of transfer learning enables users to utilize CNN's without the requirement of deep understanding and knowledge of algorithms. Yet, acknowledging the limitations and points to consider in the course of employing CNN's have great importance especially in fields which the results have vital importance such as crack detection in buildings. Within the scope of this study, a multidimensional performance analysis of highly acknowledged pretrained networks with respect to the size of training dataset, depth of networks, number of epochs for training and expandability to other material types utilized in buildings is conducted. By this means, it is aimed to develop an insight for new researchers and highlight the points to consider while applying CNN's for crack detection task.

Crack Detection in Buildings, Convolutional Neural Networks, Transfer Learning

1 Introduction

Architectural artefacts and civil infrastructures are exposed to loss of structural performance due to both deterioration of materials in time and structural challenges such as natural disasters. Structural monitoring and assessment of buildings have utmost importance for both sustaining the lifespan of structures and predict possible failures.

Visual crack inspection and detection is a widely used method for gaining insight into the condition of the architectural artefacts and structures. While the majority of the inspection is conducted by means of manual observations, several disadvantages of manual observation process are documented in literature such as being time-consuming and subjectivity of the evaluation. [1,2]

Advancements in robotics and image capturing hardware make autonomous data capturing possible while machine learning methods and deep learning algorithms in image processing show promise in the fully autonomous inspection of structures. Utilization of deep learning in these tasks not only provides reduction of computational time but also enables precise measurement of features to be inspected without human error.

On the other hand, autonomous conduction of visual crack detection is a challenging task for all image processing methods due to three major practical reasons caused by nature of the subject matter as:

1. discriminative crack features are low-level which is easily confused with noise in the background texture or foreign objects (such as hair or vegetation)
2. inhomogeneous illumination of the surface endangering the conservation of crack continuity [3]
3. irregularities in the application such as exposure of jointing

These practical challenges mentioned above are illustrated in Figure 1.

Resolving the practical challenges of images based crack detection in the course of autonomous inspection is an active field of study.

Convolutional neural networks (CNN's) are adequate frameworks with their high accuracy predictions in image classification and recognition tasks. There are several studies on crack detection on buildings and civil infrastructures with the use of CNN's. Within the scope of this study, it is aimed to investigate the relationship between the performance of CNN's and the affecting parameters.

2 Background

Visual crack detection task can be evaluated as a classification problem of crack presence in essence. Two types of methodological approaches are observed in the course of autonomous visual crack detection. The first type of studies is based on the sequential operation of feature extraction and classification by means of machine learning classifiers [4, 5]. In such studies, adaptive filters, transformations and/or morphological operations are utilized for extraction of features which are to be used for discriminating crack images from non-crack images. These features are then fed to machine learning classifiers to conduct classification. Studies of Adhikari *et al.* on pavement cracks [2] and Wu *et al.* and Sinha *et al.* on pipe defects [4,5] can be given as exemplary studies of this group. The second type of methodological approach is observed in studies utilizing deep learning (e.g. convolutional neural networks) which the feature extraction stage is conducted within the black box algorithm. In such a workflow, the input data is provided as raw images without the specification of features to search for, and algorithm finds patterns among the image data to conduct the desired task. As the features to be used for the classification of crack presence are determined by the system, human bias/error is avoided but replaced with the error of the system. In this sense, the workflow has a data-driven approach rather than knowledge-driven approach. Even though the adaptability and extensibility of the framework are more promising than sequential workflow, the errors and the factors affecting should be understood to further progress the potentials of deep learning based implementations.

Following studies are exemplary studies employing CNN's. It should be noted that it is not aimed to make a complete list but rather provide a baseline for the present study. The studies are compared in terms of number of convolutional layers utilized, number of images used for training and reported accuracy for crack detection. On the other hand, the classification accuracies of the inspected studies are highly dependent on the training and test datasets and not directly comparable.

Studies of Zhang *et al.* [6] and ASINVOS developed by Eisenbach *et al.* [7] can be given as example studies regarding the application of convolutional neural networks on crack detection on roads. Zhang, *et al.* uses a CNN with 6 convolution layers to conduct binary crack detection task on roads. Authors used 600K images for training and 200K for testing and got 0,8965 F_1 scores. The framework utilized in Eisenbach *et al.*'s study 11 convolution layers. Authors used 4,9 M image patches and tested the network with 1,2M images. ASINVOS is reported to score slightly better than the network developed by Zhang, *et al.* by scoring 0,7246 F_1 score compared to 0,6707 Zhang, *et al.*'s network on the dataset provided by Eisenbach *et al.* Similarly, Wang *et al.* [3] utilizes CNN with 5 convolutional layers for classification of asphalt pavement cracks but differently from the studies mentioned above, Wang *et al.* utilizes 3D data input including depth with 1mm resolution. Authors used 640K training image cells, 128K test image cells and scored 0,9429 accuracy. Pauly, *et al.* [8] also focus on crack detection on pavements and investigate the relation between the number of layers in CNN (deepness of network) by comparing performances of 6 layered and 7 layered networks. Authors also worked on two different subsets with the first subset contains 200K training images versus 40K test images, and the second subset contains 40K training images versus 60K testing images which are collected from different locations compared to training images. Study scored 0,913 accuracy with CNN containing 7 convolutional layers on the first subset. As the studies mentioned above are trained from scratch, they require a considerable amount of images for training which can be a limiting factor in terms of layers utilized in the network.

The study conducted by Cha, et al. [9] uses deep learning for crack damage detection for structural health monitoring. In that sense, the study is significant as it is implemented on building scale which the illumination conditions and forces which the material is subjected to show more variations compared to pavement and road inspections. Authors used a framework with 4 convolutional layers for concrete crack detection. The network is trained with several datasets with varying sizes from 2K to 40K images and testing is done with 54 full resolution images. Based on validation accuracies it is advised to use more than 10K images for training a network from scratch. For test results, mean accuracy of 0,9683 scored.

Availability of the pretrained networks eases the applicability of CNN's in new tasks without the requirement of high computational cost and deep knowledge on how CNN's operate. AlexNet developed by Krizhevsky, et al. [10], VGG networks developed by Oxford Visual Geometry Group [11], GoogleNets [12], and ResNet networks developed by Microsoft [13] can be given as examples for highly acknowledged pretrained networks which are used as the basis for application to new tasks. Study of Gopalakrishnan *et al.* [14] can be given as an example which uses transfer learning to utilize a pretrained network for pavement distress detection and employs the VGG16 network trained on ImageNet data. The study compares different classifiers in conjunction with VGG16 network. Authors used 760 images for training and 212 images for testing purposes and achieved the highest accuracy of 0,90 with the single-layered neural network classifier. When compared to studies which CNN's are trained from scratch, a similar accuracy is obtained with considerably fewer data with the use of transfer learning which is promising in terms of fast and easy implementation to new tasks.

All of these studies are concluded with accuracies above 90% for detecting cracks in images. On the other hand, performance of the mentioned studies based on several factors such as selection of data, number, and type of layers utilized other than convolutional layers, choice of filter sizes. Hence, these studies don't provide any indication of how deepness of networks and size of image datasets affect the performance of these frameworks.

Within the scope of this study, a comprehensive analysis on the applicability of CNN's on crack detection in building-oriented applications is conducted by means of transfer learning. In this regard, the influence of training dataset size, number of epochs used for training, number of convolution layers and learnable parameters on the performance of CNN's are inspected. In addition, transferability to new material types are investigated.

3 Data Preparation

In the present study, datasets utilized are explained in three categories as training, validation and test sets. The base dataset is obtained by extracting 40K image patches with the dimensions of 224 to 224 pixels, from 500 full resolution (4032 pixels to 3024 pixels) images taken from walls and floors of several concrete buildings in METU Campus. These images are taken approximately 1m away from the surfaces with the camera facing directly to the target. Even though the concrete surfaces have variation in terms of surface finishes (exposed, plastering and paint), the images are captured on the same day with similar illumination conditions. No data augmentation in terms of random rotation or flipping is applied. Image samples for training and test cases are shown in Figure 2. The base dataset is publicly shared [15].

The preparation of these datasets are explained as below:

Training dataset: As a convention, %70 of randomly selected images from the base dataset is used for training while %15 is used for validation throughout the training and %15 is used for testing. As a result, the biggest training dataset consists 28K images. The size of training dataset is then randomly reduced from 28K to 21K, 14K, 7K, 3,5K, 1,75K, 0,7K and 0,35K to imitate grid search for investigation of the relation between performance and size of the training dataset. All of the datasets are balanced in terms of classes, containing an equal number of positive and negative images.

Validation dataset: Validation dataset is used throughout the training to monitor the learning curve of the networks. The number of images used for validation is chosen with regard to the size of the respective training dataset size. The %70-%15 ratio between the training set and validation set is conserved for all training cases

Figure 2. Training and test image samples. Positive training samples (top left), Negative training samples (top center), Possible false-positive training samples (top right), Concrete test samples (bottom left), Pavement test samples (bottom center), Brickwork test samples (bottom right)

Test datasets: Four distinct cases are chosen for testing purposes. The first case uses 6K images which are randomly chosen from the 40K base dataset. This partition corresponds to the %15 of the 40K dataset which is not utilized in either training or validation. All networks which are trained with varying sizes of training datasets are subjected to the same test dataset in order to observe the effect of training dataset size and performance in predicting visually similar images.

The second, third and fourth cases focus on the performance of the trained networks to investigate the transferability of learned features to new cases in terms of both physical conditions, such as illumination or camera angle, and material variations. The cases are respectively crack detection in pavements with concrete material, in buildings components with concrete material, and in buildings with brickwork material. 50 full resolution images are used for obtaining 500 test images per test case. All images are taken from different buildings and locations compared to the ones used training and validation at different times of the day.

The number of images used for training, validation, and tests is shown in Table 1 and Table 2.

Table 1. Number of images in datasets used for training, validation

	Training		Validation	
	Positive	Negative	Positive	Negative
28K	14000	14000	3000	3000
21K	10500	10500	2250	2250
14K	7000	7000	1500	1500
7K	3500	3500	750	750
3,5K	1750	1750	375	375
1,75K	875	875	188	188
0,7K	350	350	75	75
0,35K	175	175	38	38

Table 2. Number of images in datasets used for testing

Cases	Testing	
	Positive	Negative
15% randomly selected from base dataset (Test1)	3000	3000
Concrete Pavements (Test2)	250	250
Concrete Buildings (Test3)	250	250
Brickwork Buildings(Test4)	250	250

4 Performance Comparison

Within the scope of this study, the performance of seven highly acknowledged pretrained networks; namely, AlexNet [6], VGG16, VGG19 [7], GoogleNet [8] and ResNet50, ResNet101, and ResNet152 [9] on crack detection of concrete surfaces are inspected in relation with the size of training dataset size and number of epochs to obtain best results. In addition, the effect of complexity and depth of CNN's are investigated. The number of convolutional layers and number of learnable parameters which gives an insight into the number of filters used by networks is shared in Table 3.

Table 3. Pretrained networks, number of convolution layers and learnable parameters

	# of Convolution Layers	# of Learnable Parameters
AlexNet	8	60M
VGG16	16	138M
VGG19	19	144M
GoogleNet	22	7M
ResNet50	50	25.6M
ResNet101	101	44.5M
ResNet152	152	60.2M

The networks utilized in the scope of the study are pretrained on ImageNet data and obtained from MatConvNet website [16]. All tests are conducted using MatConvNet and Matlab on a desktop workstation with 2 Intel Xeon E5-2697 v2 @2,7 GHz CPU cores, 64GB RAM and NVIDIA Quadro K6000 GPU. While batch size is bounded with the GPU memory, other hyperparameters are determined as provided by MatConvNet website. On the other hand, the approach followed for the comparison is extendable to any pretrained network on any dataset with varying hyperparameter values.

Each of the pretrained network mentioned above is trained with training datasets shown in Table 1 for 10 epochs. It is observed that 10 epochs are sufficient for convergence of all network and after 10 epochs performance of networks fluctuate. Training on 7 pretrained networks on 8 different sizes of training datasets for 10 epochs yields 560 trained networks corresponding to all combinations of parameters taken into account in the comparison. After obtaining trained networks, the performance of these networks is evaluated with four cases resulting in 2240 scores which can be represented as 7x8x10x4 (network, dataset, epoch, test case respectively) matrix. For performance evaluation metrics, accuracy and F-scoring are used.

It is observed that the accuracy and F-scores of best-performing networks are compatible with each other. Even though the discussion regarding the performance of networks is advanced mentioning accuracy scores, the same remarks can be made for F-score results. For the sake of simplicity, the maximum accuracy and F-score results obtained per network are shown in Table 4 together with training dataset and epoch information. The results per row are discussed below.

Table 4. Maximum validation and test accuracies of pretrained networks

	AlexNet		VGG16		VGG19		GoogleNet		ResNet50		ResNet101		ResNet152	
	Mean Acc.	F-Score	Mean Acc.	F-Score	Mean Acc.	F-Score	Mean Acc.	F-Score	Mean Acc.	F-Score	Mean Acc.	F-Score	Mean Acc.	F-Score
Test1 Epoch1 0,35K	0.896	0.890	0.996	0.996	0.991	0.990	0.900	0.899	0.810	0.794	0.860	0.853	0.610	0.715
Test1 Epoch1	0.999 28K	0.998 28K	0.999 21K	0.999 21K	0.999 28K	0.999 28K	0.998 21K	0.997 21K	0.999 14K	0.997 14K	0.999 21K	0.992 21K	0.995 14K	0.998 14K

E: Epoch

4.1 Test Results

AlexNet, VGG16, VGG19 and GoogleNet networks converge quickly by scoring over 0,90 accuracy at the first epoch with 350 training samples while ResNet family achieved poorer scores at first iteration with the smallest training dataset. At second epoch all networks scored over 0,9. However, it is observed that higher test scores are obtained from higher epochs and larger datasets.

All networks benefitted from larger datasets achieving the best test score with more than 14K training samples. While ResNet50 and ResNet152 achieved best scores with 14K training set, VGG16, GoogleNet, and ResNet101 obtained best scores with 21K training dataset. Yet, the accuracy differences between results obtained with 14K, 21K, and 28K are barely noticeable and it is not possible to make an inference regarding the performance comparison of networks by solely inspecting maximum scores for test 1 which is based on the images similar to training dataset. Following test cases, which shows diversity in terms of illumination, camera orientation and distance with respect to the surface and material, are conducted to examine whether the networks overfit or prominent to learn generic crack features for further cases.

As can be seen from Figure 2, crack images on pavements are visually more discernable due to homogeneous illumination conditions and high contrast between cracks and background textures with respect to building application. As a result, all networks except AlexNet scored higher or similar scores with respect to third and fourth test cases. Low scores of ResNet101 and ResNet152 networks show that these networks are subjected to overfitting even with 350 training images. While both networks scored 0,99 accuracy in test 1 case, the maximum score obtained for test case 2 is below 0,8. The mismatch between the networks showing best performance for accuracy and F-score metrics also indicate that the networks are not stable.

Also, ResNet50 achieved the highest score with smallest training size and first epoch showing tendency to overfit. This tendency is evaluated as a mismatch between ResNet’s high capability of classifying objects with high-level features and cracks’ low-level features.

GoogleNet and VGG19 networks achieve over 0.95 accuracies with relatively limited training data. For VGG16, even though the obtained highest score is with the 21K dataset, it achieved 0.96 accuracy with 0,35K dataset at first and second epochs which are also comparable with successful counterparts.

Similar to the pavement case study, VGG networks, and GoogleNet were able to transfer learned features to building case scoring over 0,92 accuracy with at most 3,5K training dataset. While VGG networks are barely affected by the variations in illumination, background texture and camera orientation with respect to the surface, GoogleNet is subjected to 0,06 performance loss. On the other hand, ResNet networks show overfitting with decreasing scores regardless of the size of training data and number of epochs.

Brickwork images are relatively the most challenging case among the four test cases as brickwork jointing and background textures are challenging noises. Among the tested cases, VGG16 and GoogleNet achieved more than 0,90 accuracy. Especially 0,96 accuracy performance of VGG16 is promising in terms of achieving a generic crack detection framework regardless of material with limited dataset size.

4.2 Discussions

Regardless of the test case and utilized network, the performance of training datasets with fewer samples are comparable to counterparts with a high number of samples. While obtaining test 1 accuracy with the highest number of training samples, training datasets with 3,5K were sufficient for obtaining the best scores for other test cases. One exception can be given as the ResNet family performance for Test 2, Test 3, and Test 4 where the performance scores significantly drop indicating overfitting. In the case of the training data and test data being similar, size of training dataset positively influences accuracy. On the other hand, when the networks are used for varying cases in terms of illumination or spatial relations between camera and surface, then the increasing the size of dataset pose a risk of overfitting. This analysis is also valid for training epochs. As the number of epoch for training increase, accuracy for test data with similar conditions increases while for diverse test cases, the networks have a tendency to overfit or have a bias towards the training dataset with the increased number of epochs. For future studies, it is advised to start with few hundreds of images per class for training and gradually increase the number of training samples until overfitting is observed. It is also noted that the level of variance in the dataset is more important than the number of samples. Yet, variance among the training dataset is highly case specific and should be evaluated with respect to representation level of real-life cases.

Regarding the influence of network complexity in terms of the number of convolution networks and learnable parameters, it is observed that the influence of the number of convolution layers is more dominant than the number of learnable parameters. Best performing pretrained networks have 16-22 convolution layers (VGG16, VGG19, and GoogleNet). While AlexNet with 8 convolutional layers has difficulties in transferring learned features to new cases, ResNet networks with more than 50 convolutional layers have a tendency to overfit the training data. It should be noted that the layer configuration (GoogleNet having inception module and

ResNet being based on residual units) is disregarded within the scope of this study. In order to examine the influence of different layer configuration ResNet family networks are required to be truncated to obtain the same number of convolution layers. On the other hand, similar layer configuration of AlexNet, VGG16, and VGG19 shows that increased number of convolution layers contributes to the performance of networks in crack detection task for VGG16 and VGG19 compared to AlexNet. Another deduction can be made considering the number of fully connected layers. Simple CNN's having hierarchical layer connections (AlexNet and VGG networks) have shown resilience in varying test cases while DAG networks (GoogleNet and ResNet networks) have difficulty in transferring learned features to new cases. Even though the number of fully connected layers is not the only reason for the performance drop, hierarchical networks have proven themselves to adapt to new cases.

The number of learnable parameters, on the other hand, does not have a direct relationship with the performance but plays a significant role in computation time. GoogleNet, having almost five percent of VGG parameters scored a similar score. This can be linked to the low number of features defining cracks.

The computational time required to train 28K dataset per epoch for all networks are shared in Table 4.

Table 4. Computational time for training 28K dataset per epoch

28K dataset | per Epoch	Training Time (s)
AlexNet	133
VGG16	2827
VGG19	2943
GoogleNet	1227
ResNet50	1666
ResNet101	2447
ResNet152	3789

It should be noted that the majority of the learnable parameters are used by the fully connected layers of VGG networks. Hence, the trade-off between computational time and performance emerges as a trade-off between the number of fully connected layers and training time. On the other hand, it is possible to limit the number of filters to reduce the number of learnable parameters, thus the computational time while conserving the number of convolution layers for developers constructing the network from scratch.

5 Conclusion

Within the scope of the study, the performance of highly acknowledged pretrained networks on crack detection task is evaluated for buildings. The relations between training dataset size, number of epochs for training, number of CNN layers and learnable parameters are thoroughly investigated. It is shown that the pretrained networks can be fine-tuned for crack classification task with a limited number of training samples when the variance among data is provided or the test case constitutes images similar to the training samples. In the absence of variance among training images, increasing number of image samples not only contributes to the computational time without enhancing performance but also increases the risk of overfitting as the number of images with similar features analyzed per epoch increases. In the case of test case being visually incompatible with respect to training samples, it is advised to train the network with a limited number of samples and observe the tendency to overfit with the increasing number of training dataset size.

Regarding the effect of the number of convolutional layers to accuracy, even though the study does not involve a grid search for an optimum number of layers for the task, networks with 16 to 22 convolutional layers scored highest compared to both AlexNet with 8 convolutional layers and ResNet networks with more than 50 layers. In addition, networks with hierarchical layer connections and multi fully connected layers are observed to perform better in varying conditions and show promise in the course of achieving a generic crack detection framework regardless of material.

In conclusion, the pretrained networks have high applicability on crack detection even if they are trained on completely different datasets due to the low-level features shared with cracks and any objects with more abstract features. It is observed that the features learned in the course of training are transferable to other materials with high accuracy. In addition, the required number of less training samples and fast convergence networks make pretrained networks a favorable option for implementing CNN's for crack detection task.

Abstract –

Construction management courses are currently mostly based on frontal lectures, homework and exams – where the exams comprise of questions similar to the ones that the professor showed in the lectures & later the student is asked to solve at home. In practice, construction engineers are required to be able to quickly resolve unstructured complex problems, under conditions of uncertainty, by finding, collecting and integrating information from different sources and providing creative solutions. We propose that a learning-centered approach to the education of the construction management student, in which s/he is confronted with the need to find solutions for such complex problems, and to identify the relevant data, will better prepare the future engineer for the profession. Moreover, the students have to be exposed to the fact that there is more than one correct solution and none of the solutions is perfect. Ethical dilemmas in particular may require construction managers to resolve problems for which they cannot rely on simple formulas. An elective course in construction management, which has been developed over the past four years, in which these principles have been incorporated, will be described.

Construction management; Education; Learning-centered approach; Problem solving; Ethics.

1 Introduction

Most of today's students will still be professionally active in the 2060-70s (!). Hence, the curriculum and teaching methods of the previous century, which still prevails, will not be sufficient to provide the engineers of the future with the appropriate skills. Very early in their career they will find their education irrelevant. In fact, we already hear from young engineers and their employers that this is the situation.

With this in mind, we believe that the main objective of academic studies is not merely to provide technological and engineering knowledge. Instead, they should focus on EDUCATING students and developing their CREATIVE THINKING and their analytical skills. However, Construction Engineering & Management (CEM) studies currently focus mostly on a very particular type of quantitative analysis, which does not prepare the student well enough for the actual challenges of the profession.

The framework within which CEM students are educated has changed very little over the past decades. CEM courses are still mostly based on the use of frontal lectures, homework and exams. Moreover, in most of those courses the data required to solve assignments is given to the students in advance. Not only that, but the assignment normally has ONE "correct solution". As a result, many of those courses seem similar to students, and their content becomes merely a series of technical assignments. Such assignments are generally solved through well-structured procedures, as described in generic terms in Figure 1. This paradigm does not encourage creative thinking at all. In fact, it often even inhibits thinking altogether. With such an approach it is no wonder that many construction engineers and their employers ask questions, such as the ones quoted above.

The need to engage students and encourage learning and creative thinking has been recognized by some when it comes to engineering design courses, including civil engineering (e.g. Stouffer et al. [7]). We argue that the need for such an approach is just as clear when it comes to educating CEM students, as it is for gearing Civil Engineering students toward a career as design professionals who will concentrate on the engineering design work.

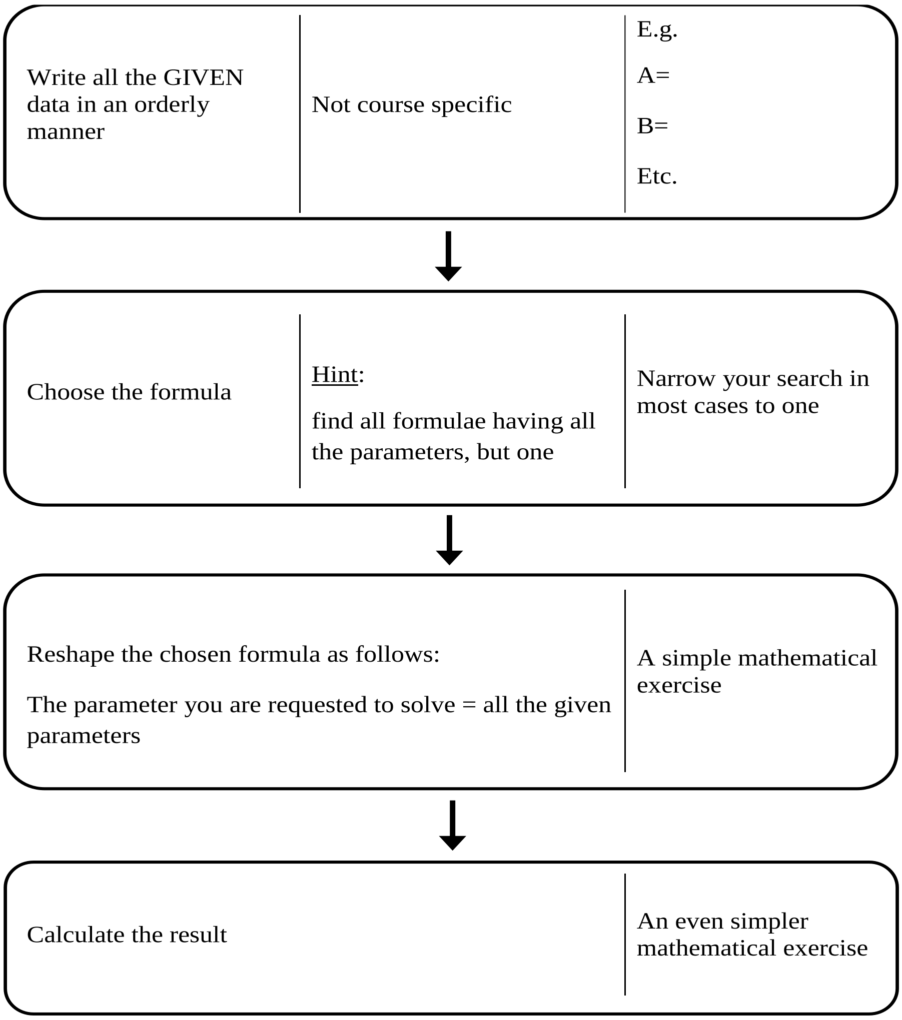

Figure 1. A typical procedure to solve assignments and exams in CEM

Construction engineers will concentrate in their professional career on project management aspects such as construction procedures, methods, and people management, which may appear to some to be more technical than creative design processes. In practice, however, construction engineers are required to be able to quickly resolve complex unstructured problems, under conditions of uncertainty and in “no time”, by collecting and integrating information from different sources and providing creative solutions.

A clear example of a situation in which construction managers have to resolve a complex problem for which no simple formula exists, is when they face ethical dilemmas. Such dilemmas may occur when an engineer needs to quickly solve a complex problem while adhering to the project schedule– the customary solution for which may conflict with engineering ethics. The complexity is amplified because such dilemmas not only do not have easy solution, but in many cases, if not the majority of them, they are not even RECOGNIZED by the engineer. This is possibly why construction engineers focus more on the technical issues, and in turn, the civil engineering schools align with current practices of the industry instead of serving as the beacon, indicating what the practice SHOULD be.

Many of the colossal accidents in Israel, if not all, were caused because of such a situation. Areas in construction management in which such a situation may occur range from accounting practices to onsite worker safety, as well as others. A limiting paradigm, which can address only specific technical problems, will obviously not prepare the student to deal with such issues.

We, therefore, propose that a learning centered approach to the EDUCATION of the CEM student, in which they are confronted with the need to find not only solutions for such complex problems, but also to select the data from databases containing partial, excess and often conflicting data, will better prepare them for their profession.

Consequently, the objective of this paper is to discuss the prevailing paradigm in CEM education, and to present an alternative model, which seeks to engage the students and encourage them to think creatively in order to provide solutions to the types of problems that they are likely to encounter in their professional careers. This model was implemented in a course that has been developed by the first author over the past four years.

2 Enabling Student Learning

A number of educational methods that stimulate student learning have previously been proposed. These include: interdisciplinary focus, collaborative learning and active experiential learning, and more [6].

Kolb and Fry [3] have argued in this context that experiential learning entails a cyclic process containing four different steps:

1. Concrete experience.
2. Reflective observation.
3. Abstract conceptualization.
4. Active experimentation.

This integrated process begins with here-and-now experience (1), followed by the collection of data about that experience (2). The data regarding the immediate concrete experience is then analyzed in order to form abstract concepts and generalizations concerning the experience that is studied (3). Finally, the implications of these concepts are tested in new situations through active experimentation (4), leading to a modification of behavior and choice of new experiences when returning to the first step of the cycle. Immediate concrete experience is thus the basis for observation and reflection that lead to a theory from which new implications for actions can be deduced.

Two common strategies that have been used to engage students and encourage learning and creative thinking are problem-based learning and group learning.

<u>Problem-based learning</u> uses real-world problems to encourage critical thinking and problem-solving skills (e.g. [1,5]). The main difference between problem-based learning and other types of active, student-centered learning processes is in that it introduces concepts to students by challenging them with problems related to their future profession. It thus reverses the conventional model, by using problems before the content has been introduced, in order to initiate learning. Problem-based learning also focuses on problems that are open-ended, unstructured and do not have only one “correct” answer.

<u>Group learning</u> is a term used for exercises in which students learn to work together in small groups on a task, which usually mimics a real-life project [4]. Students carry out realistic tasks, without direct supervision, in order to acquire through experience knowledge and skills. The aim of these exercises is to give students a chance to experience group dynamics, to learn project and time management, prioritizing and to enhance their inter-personal skills. It is clear that construction engineering graduates will need high levels of such teaming and communication skills to be successful in their work places.

3 A Practical Implementation

An elective course in CEM has been developed by the first author over the past four years, in which the above mentioned principles and methods of a learning centered approach have been incorporated. The objectives were to create a course in which the students are actively engaged, and are required to think creatively in order to tackle real-world problems. These objectives were determined for the course despite the fact that its domain was construction management, rather than structural engineering design in which such an approach has more often been implemented.

The course involved the four steps of experiential learning that were defined by Kolb and Fry [3]. These are reflective observation, abstract conceptualization, active experimentation and concrete experience:

1. <u>Reflective observation</u> was attained by holding class discussions based on topics that were presented in lectures. Students were expected to reflect upon those topics, and to take an active part in the discussions. The outcome of those discussions was usually not a single authoritative conclusion regarding the topic discussed. Instead, students were encouraged to form their own individual opinion, even if it differed from that of the lecturer.
2. <u>Abstract conceptualization</u> was attained by assigning the students an academic paper to read, to interview an industry expert on the same topic, and finally to compare the findings obtained from both sources. This required the students to confront differing opinions, from an academic and from a professional point of view, on a single topic. Despite these differences, the students were expected to form concepts and generalizations of their own concerning the topic investigated. The students presented their findings in a short presentation (a very important by-product on its own).
3. <u>Active experimentation</u> was carried out by iteratively preparing a bid for a tender, based on data that they collected themselves from different sources (e.g. the statistical analysis of data, interviews with industry experts, an analysis of plans, etc.). The students were required to follow the entire process of preparing a tender

for the execution of a real-life BOT project, based on a real call that had been issued at the time. The process started with an analysis of the existing planning conditions, proposing alternative programmatic solutions, carrying out feasibility studies, and investigating financial and contractual aspects. A key to this process was the fact that it had to be carried out through a number of iterations, as previous decisions were revisited based on additional information that was gathered.

4. Concrete experiences were gained through the simulation of team work and multi-team exercises. The students were required to carry out all the exercises in teams in the classroom, in a studio environment. The preparation of the tenders was competitive, with only one team eventually winning the bid. In some exercises, a multi-team experiment was conducted, in which different teams were required to negotiate with each other and to reach a consensus.

The attitude of the students often changed considerably during the course. Bernold [2] has observed that in practice, most people are not equally proficient in all four of the abilities that are part of Kolb and Fry's framework [3]. Similar to the findings in Bernold [2], it was clear from informal exchanges with the students participating in the course, that they were initially not all equally comfortable with the different components of the course. In particular, all students found it challenging to deal iteratively with an open, ill-structured problem. This was for them the first time they experienced dealing with such a problem in their studies, having previously had to solve mostly well-defined assignments, as described in Figure 1, for which all the information required to solve the assignments was given to the students in advance. Many expressed concerns on this when given the assignments. However, whereas Bernold [2] reports findings according to which most Civil Engineering students do not consider active learning as being effective, the overall opinion of the students, once they had participated in the course, was very positive.

Anonymous on-line survey was conducted, the results of which showed a general satisfaction with the course. When asked to rate on a 5-point Likert scale whether they had acquired new knowledge, tools and an understanding of the subject that provided them with new analytical abilities, the average response was 4.6, with a standard deviation of 0.6 (where 1 indicated "very little" and 5 "very much"). When asked whether they had felt that they needed to invest a significant effort in the course, the average response was 4.3, with a standard deviation of 0.8. But when asked whether they had encountered difficulties completing the course the average response was 2.8, with a standard deviation of 1.2.

4 Conclusions

Whereas the experience in this particular course was positive, it does raise the question of how the proposed approach can be expanded to other courses, or even to the entire curriculum. In particular, this course was an elective course, in which relatively small groups of students (on average 15-30 students) participated, in the fourth year of their studies. It could therefore be a challenge to apply a similar learning-centered approach in courses with larger groups of students, and at an earlier stage of their studies. Nevertheless, we believe that this is vital in order to make CEM studies an experience that will be more valuable and relevant for students.

One possible solution for working with a larger number of students, which has already been partly explored in the existing course, is to use multiple-team exercises, in which multiple teams of students work on a single project, with each team responsible for a specific part of the project. Such exercises simulate the more complex real-life work environment, in which large engineering projects are often executed by multiple teams. Such projects require not only the coordination of the work of individual team members, but also some form of organizational structure that ensures the coordination of the work of different teams. Multiple-team exercises are therefore also an opportunity to allow students to become familiar with different project management structures and roles.

Another possible solution in order to engage students more actively in courses at earlier stages of their studies is the use of IT solutions. Technologies such as online learning platforms can be used during lectures, even in introductory courses, in order to ask the students to answer questions during the lecture, display their answers to the class immediately afterwards, and promote discussions. The introduction of such innovations in the classroom can be an inherent part of the effort to bring about a paradigm change in CEM education.

The second author is currently leading the development and establishment of a new Civil Engineering Department in ORT Braude College of Engineering. The proposed departmental curriculum, submitted to the Council for Higher Education, is based on principles such as the one described above. We will be reporting the progress in this area in the next paper.

Lately we conducted a very limited pilot study, in which the students had to do two things:

1. IDENTIFY a dilemma in given scenario which we described to them.
2. Evaluate the optional solutions in a structured manner.

This pilot study will be described and demonstrated in the presentation.

Abstract

Fall from heights (FFH) has been a major contributor towards both minor and major work-related injuries in the construction industry of many countries. In order to facilitate knowledge reuse/sharing and the development of knowledge-based systems for working at height, this paper aims to develop a lightweight ontology of control measures for fall from height (FFH) in the construction industry. The FFH-Onto is developed based on a generic ontological framework which consists of nine concepts: actor, task, building element, hazard, construction method, constraint, safety resource, hazard control measure, and residual risk. These nine concepts are categorized into three main parts: problem, context, and solution. The FFH-Onto can be used to facilitate knowledge re-use and sharing among the end-users (e.g., designer, engineer, safety professional, supervisor, and site manager. It also forms an important basis for developing knowledge-based systems for automated and intelligent fall protection engineering and management in the construction industry. Future efforts can be made to upgrade the proposed lightweight ontology to a heavyweight one which includes axioms and constraints. In addition, ontologies of other key hazards (e.g., struck by objects) are to be developed.

Construction safety; Fall from height; Ontology; Knowledge engineering

1 Introduction

While the overall safety performance in the construction industry has improved over the past decades, fall accidents and injuries in some countries have increased [1]. Fall from heights (FFH) has been a major contributor towards both minor and major work-related injuries in the construction industry of many countries and regions, such as Singapore [2,3], UK [4], US [5], Hong Kong [6]. For example, FFH accounted for over 20% of the major injuries in Singapore workplaces over the past five years.

To prevent or control the effect of a fall, a combination of control measures is often adopted. Based on the hierarchy of control [7], the control measures usually include elimination, substitution, engineering controls, administrative controls, and personal protection equipment (PPE). A large number of work-at-height (WaH) standards, best-practice, and guidelines were developed to help key stakeholders manage fall hazards on sites. However, similar fall injuries constantly occur [8, 9]. This is in part attributed to the fact that control measures for fall hazards are often not well designed and implemented and the information/knowledge is not communicated to workers. Due to the highly fragmented construction environment, lack of safety knowledge sharing and reuse is another critical reason for high fall accident rates [10].

Last two decades have seen a rapid growth in the use of Building Information Modeling (BIM) to facilitate communication, collaboration, and cooperation between key stakeholders of a construction project. Different information is integrated into BIM models for better cost management, scheduling, and facility management. However, the integration of safety information (e.g., fall hazard and control measures) into BIM models has been rather limited. Current safety practices are largely manual, paper-based, and therefore time-consuming and highly inefficient.

The integration of safety into BIM requires a formal knowledge base of construction safety domain. Developing an ontology is often considered an important starting point to construct the knowledge base [11]. The concept of "ontology" comes from philosophy, which is concerned with the nature of being and existence [7]. Gruber provided a popular definition of ontology: an ontology is an 'explicit specification of a conceptualization' [12] (p. 908). A "conceptualization" refers to an abstract model of a domain of interest based on relevant concepts, relations, and axioms within the domain. Ontology is an important means for knowledge representation, interoperation, and integration. It often plays key roles in the development of knowledge base and intelligent systems. Previous effort was made to develop an ontology for the design of active fall protection system (AFPS) [7]. Note that AFPS is only a part of control measures for fall hazards. There is no common ontology describing the knowledge of the domain of FFH in the construction industry and therefore more effort is needed to develop a more comprehensive ontology for fall from height by incorporating other fall control measures.

Thus, this paper aims to develop a lightweight ontology of control measures for fall from height in the construction industry. According to [13], lightweight ontologies only include concepts, concept taxonomies, relationships between concepts, and properties that describe concepts. An ontology must formally represent the domain knowledge that can serve for its purposes. In this study, a main purpose of the FFH-Onto is to facilitate selection, implementation, and maintenance of fall hazard controls. It also aims to facilitate the modeling and visualization of fall hazard controls in building information models and thus improve safety engineering and planning.

2 Literature review

Fall from height has received significant attention from researchers in the construction industry. For example, Hinze [14] investigated the root causes of fall accidents based on the data from OSHA. A number of contributing factors were identified, including lack of safety training, human error, and inappropriate use of controls. Similarly, Chan [15] identified twelve common contributing factors by analyzing twenty-two fatal fall injuries in Hong Kong. They suggested five strategies to reduce fall accidents, including (1) provide and maintain a safe system of work, (2) provide a suitable working platform, (3) provide safety information, training, instruction, and supervision, (4) provide suitable fall arresting system/anchorage; and (5) maintain safe workplace. Wong [16] adopted the Human Factor Analysis Classification System (HFACS) to identify and classify the root causes of fatal fall accidents. Goh and Binte Sa'adon [17] investigated the unsafe behavior of scaffolders based on the theory of planned behavior. They suggested that subjective norm was a key variable influencing a worker's decision-making.

In order to facilitate safety knowledge sharing/reuse and intelligent safety management, a number of safety-related ontologies were developed. For example, in order to improve safety knowledge sharing and reuse, Le et al. [18] developed a social network system using semantic wiki web and an ontology approach. Three main components (i.e., safety information module, safety knowledge module, and safety dissemination module) were constructed to represent construction safety knowledge based on safety semantic wiki template. In the meantime, efforts are made to develop ontology-based framework for job hazard analysis. For example, Wang and Boukamp [19] developed an ontological framework which represents knowledge about activities, job steps, and hazards. The framework can be used to conduct job hazard analysis based on ontological reasoning and document evaluation mechanism. This pioneering work has demonstrated the utility and importance of ontology in intelligent safety management. They suggested that the ontological framework be integrated into BIM tools to enable more automated site safety management. In addition, in order to reduce the level of human effort in job hazard analysis, Chi et al. [20] applied ontology-based text classification to identify hazard controls for specific unsafe scenarios. The ontology developed by them is based on three main text resources: CPWR construction solution database, the NIOSH FACE reports, and the OSHA standard. The ontological framework consists of nine concepts: task, activity, hazard, CPWR unsafe scenario, NIOSH fatality case report, safe approach, OHSA standards for construction industry, subpart, and standard. However, the ontological framework, as well as the ontology, may not be suitable for modeling and visualizing hazard controls in BIM tools, as it appears that there is no obvious links with BIM data model (e.g., Industry Foundation Classes (IFC) data format).

Information technologies have been used to help reduce fall accidents and injuries. For example, Navon and Kolton [21] developed an automated model that can identify dangerous work-at-height activities and areas. The schedule is integrated into the model which enables it to produce both textual and graphical reports that correspond to the schedule. The automated model was implemented in a prototype written in Visual Basic (VB), AutoCAD, and MS Project. Zhang et al. [22] explored the automation in modeling and planning fall hazard controls based on BIM models. The tool they developed can detect unprotected slab edges and holes and install guardrail system automatically. A limitation of this study is that the fall hazard controls modelled in BIM are not comprehensive (limited to scaffold and guardrail systems). Other important fall hazard controls such as active fall protection systems are not included. More recently, Qi [23] developed a PTD (prevention through design) software tool to help designers implement best practices to prevent fall accidents. Using the PTD tool, automatic safety checking can be performed by using BIM technology and a knowledge base that was designed based on best practices. These efforts were aimed at reducing fall accidents by improving building design and optimizing production planning. Supported by these advancements, a part of fall hazards could be either eliminated, substituted, or managed by engineering and administrative controls. However, personal protection equipment, including AFPS, is still required as a last line of defense to protect workers in many situations [24].

More recently, Zhang et al. [25] developed a construction safety ontology to facilitate automated safety planning by formalizing job hazard analysis (JHA) knowledge. The ontology consists of three ontological models: construction product model, construction process model, and construction safety model. The ontology is in part based on IFC data schema and the link between the ontology and BIM is bridged. However, the ontology is aimed at job hazard analysis and does not capture high levels of detail for selection, design, and implementation of hazard control measures.

In order to better facilitate safety engineering and hazard control design in the construction industry, Guo and Goh [7] developed a generic ontological framework which can be used as a harmonization framework for developing sub-domain ontologies. Based on the ontological framework, they developed an ontology for the design of active fall protection system (AFPS). The ontology (i.e., AFPS-Onto) provides a formal and shared knowledge base for the design of AFPS and forms an important part of the domain knowledge of FFH. Using the AFPS-Onto, Goh and Guo [26] designed a online knowledge-based system, *FPSWizard* to support the design and selection of AFPS.

3 Method

A number of methodologies for ontology building have been developed by researchers since the early 1990s, including the Grüninger and Fox [27] approach, the Uschold and Gruninger [28] approach, CO4 [29], METHONTOLOGY [30], and SKEM [31]. This study adopted the METHONTOLOGY to build the FFH-Onto. The METHONTOLOGY consists of seven main steps: specification, knowledge acquisition, conceptualization, integration, implementation, evaluation, and documentation (see Fig. 1).

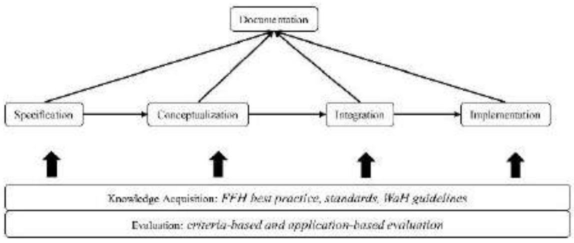

Fig. 1 Development process of FFH-Onto

Specification focuses on determining the purpose, scope, level of formality, intended uses, and end-users of the FFH-Onto. A set of competency questions were established in this step (see Table 1). These questions include, but are not limited to, “What are the purposes of the ontology?”, “Who are its end-users?”, “What information should be captured in the ontology?”, and “What design criteria should be followed?”. By answering all competency questions, this step produced an “Ontology requirements specification”, which severed as guidelines for the whole ontology building process.

Table 1 Key ontology requirements

Competency questions	Answer
What are the purposes of the ontology?	• Represent knowledge of fall protection in the construction industry • facilitate safety engineering and hazard control design in the construction industry • facilitate modelling and visualization of fall protection in BIM tools
What is the scope	All control measures for fall from height in the construction industry
Who are its end-users?	Designer, engineers, safety professional, supervisors, site managers
What information should be captured in the ontology?	Information that is important for the selection, implementation, engineering, and maintenance of fall hazard controls
What design criteria should be followed?	Clarity, extendibility, completeness, coverage

In order to acquire knowledge for the ontology development, a number of knowledge sources were collected and studied to elicit the domain knowledge, including industry standards, WaH best practice guidelines, fall accidents, CPWR construction solution database, and NIOSH FACE reports (see Table 2). These knowledge sources capture structured expert knowledge and industry norms of fall protection in the construction industry.

Table 2 Knowledge sources

Corpus	Title
Industry standards	AS/NZS 1576 series Scaffolding
	AS/NZS 1577 Scaffold decking components
	AS/NZS 1892 Portable ladders
	AS/NZS 4389 Safety mesh
	AS/NZS 4576 Guidelines for scaffolding
	AS/NZS 4994 Temporary roof edge protection for housing and residential buildings
	AS/NZS 5532 Manufacturing requirements for single-point anchor device used for harness-based work at height
	AS/NZS selection, use and maintenance for fall arrest equipment
Best practice guidelines	Preventing falls in housing construction [32]
	Safe use of safety nets
	Best practice guidelines for working

	at height in New Zealand
	Best practice guidelines for working on roofs
	Managing the risk of falls at workplaces
	Scaffolding in New Zealand
Fall accidents	OSHA accident database
Other knowledge base	CPWR construction solution database
	NIOSH FACE Reports

A comprehensive list of fall protection systems and tools were collected and categorized according to their hazard control mechanism. Key attributes of each system were extracted from industry standards and guidelines. A main purpose of using multiple databases is to reduce or eliminate conceptual and terminological confusion and reach a shared understanding of the domain of interest.

4 FFH-Ontology

The FFH-Ontology is developed based on the generic ontological model designed by [7] (see Figure 2). The ontological model consists of three main parts: problem (i.e. specific hazards that need to be managed), context (i.e. the situation in which the problem exists), and solution (i.e. hazard controls).

The problem includes five concepts: hazard, actor, task, IFC building element, and construction method. These five concepts and their relations and attributes describe a safety problem or an unsafe scenario. Context is composed of two concepts: constraint and safety resource, which are aimed at providing information about the context in which safety problems exist and solutions are designed. Solution is composed of two concepts: hazard control measure and residual risk.

From a global perspective, the three parts are interconnected: a problem is solved by solutions which, in turn, are constrained by the context in which the problem occurs.

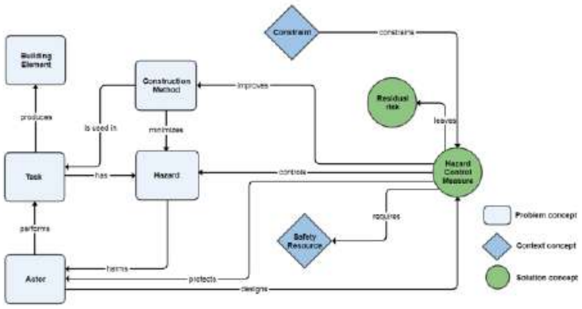

Fig. 2 The generic ontological model

The components (i.e., concepts and relations) of the FFH-Onto is presented as follows.

4.1 Concepts

4.1.1 Task

Task is used to represent the hierarchy of construction process. Being consistent to the AFPS-Onto [7], the FFH-Onto adopted types of task defined by the Industry Foundation Classes (IFC), which consist of 12 main tasks: attendance, construction, demolition, dismantle, disposal, installation, logistic, maintenance, move, operation, removal, and renovation. Different sub-tasks (e.g., floor laying, wall framing, and installing prefabricated roof trusses) can be grouped into the 12 main tasks according to their nature. Note that this is not the only way to model task. Other ways can be referred to [19].

4.1.2 Actor

Actor defines all actors or human agents involved in hazard management. Compared to the AFPS-Onto which only defines workers and professional engineers, the FFH-Onto expands the concept by defining other key actors, including “a person conducting a business or undertaking (PCBU)”, “officer”, “manufacturer”, “supplier”, and “installer”. By doing so, the FFH-Onto is able to formalize richer information and knowledge such as legal duties and manufacture information.

4.1.3 IFC building element

IFC building element comprises all elements that are primarily part of the construction of a building [33]. Considering that the FFH-Onto is in part aimed at facilitating modelling and visualization of fall hazard control in BIM models, it adopts the structure of IfcBuildingElement from IFC schema. The class *Ifc Building element* include the following subclasses: IfcBeam, IfcBuildingElementProxy, IfcChimney, IfcColumn, IfcCovering, IfcCurtainWall, IfcDoor, IfcFooting, IfcMember, IfcPile, IfcPlate, IfcRailing, IfcRamp, IfcRampFlight, IfcRoof, IfcShadingDevice, IfcSlab, IfcStair, IfcStairFlight, IfcWall, and IfcWindow. By adopting the IFC building elements, the FFH-Onto is linked with BIM models and can exchange information with BIM models and other programs as an application programing interface (API).

4.1.4 Construction method

Construction method represents methods, techniques, and technologies that are used to construct a building. More often than not, a combination of safety work methods are required to perform safely a sub-task such as floor laying. Thus, safety knowledge of WaH can be meaningfully defined and formalized based on tasks, which facilitates the visualization of fall hazard controls in 4D schedule BIM models. When a robust knowledge base of WaH is developed, the FFH-Onto is potentially able to assist designers and engineers with integrating the concept of "design for safety" in building design. Examples of alternative construction methods include: (1) prefabricating wall frames horizontally before standing them up, (2) using precast tilt-up concrete construction instead of concrete walls constructed in situ, and (3) pre-painting fixtures/roofs before installation.

4.1.5 Hazard

A *hazard* is anything in the workplace that has potential to harm people. The FFH-Onto focuses only on fall hazard.

4.1.6 Constraint

The FFH-Onto adopts the taxonomy of constraint defined in the AFPS-Onto. The taxonomy consists of four main constraints: project constraint, design standard, regulatory constraint, and environmental constraint. Details of each constraint can be referred to [7].

4.1.7 Safety resource

Safety resource represents resources that are consumed and used in designing and implementing control measures for FFH. It is composed of financial resource (e.g., money), human resource (workers, safety professionals, and project managers), physical resource (e.g., existing fall prevention and fall arrest devices and equipment), safety knowledge, and safety item (fall protection plan, best practices, and rescue plan and procedure). This component covers important information and knowledge that can justify the selection of control measures for FFH.

4.1.8 Hazard control measure

Control measures for fall hazards are categorized into nine main groups, including: (1) guardrail, (2) temporary work platform, (3) harness system, (4) safety mesh, (5) mechanical access plant, (6) safety net, (7) soft landing system, (8) access/egress, and (9) administrative control (see Figure 3).

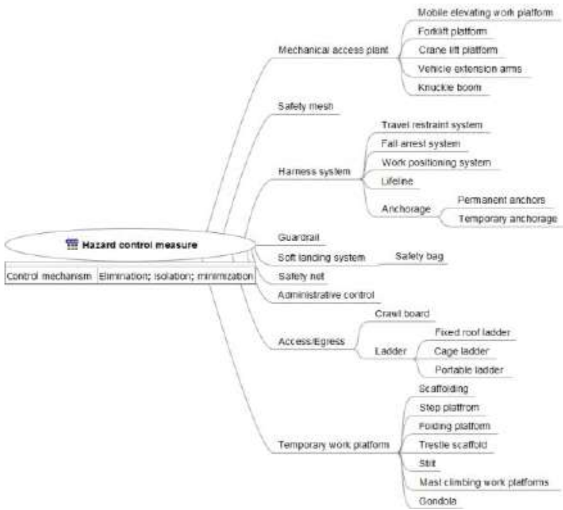

Fig. 3 Main control measures for fall hazards

According to [32], control measures for FFH can also be categorized into a 5-level hierarchy.

Level 1 controls aim to eliminate the risk of a fall by either carrying out tasks on the ground or platforms (e.g., flat roof) with edge protection (e.g., parapet).

Level 2 controls represent fall prevention devices and equipment, such as temporary work platforms (e.g., scaffold, elevating work platforms, step platforms, mast climbing work platforms, and ladders), guardrails, and safety mesh.

Level 3 controls include any work positioning systems that can restrain workers within safe areas.

Level 4 controls are used to arrest a fall when it is not reasonably practicable to prevent a fall. For examples, catch platforms, and active fall arrest systems are common measures to arrest a fall. Safety net should be used when it is not practicable to provide scaffolds or temporary guard railing.

Level 5 captures all administrative controls such as safety training.

4.1.9 Residual risk

Residual risk refers to hazards and risks remaining after the inherent risks have been reduced by hazard controls. Any implementation of a specific hazard controls may bring about new risks or leave some risks unaddressed. For example, the design of active fall arrest system may leave some residual risk such as poor installation, inadequate training and supervision.

4.2 Semantic relations

Semantic relations are defined as "meaningful associations between two or more concepts, entities or sets of entities" [34]. Semantics refers to the meaning of the concepts within an ontology. Semantics play important roles in information modelling and knowledge representation. There are five main semantic relations:

(1) Hyperonym-hyponym relations: they refer to the relations between a broader and narrower concept.
(2) Meronym-Holonym relations: they refer to the relations between a concept and its constituent parts.
(3) Concept-object relations: they refer to a class and its instances.
(4) Cause-effect relations: they refer to cause-effect relations between concepts using causative verbs.
(5) Locative/spatial relations: they are used to specify how a concept is located in space in relation to other concepts.

Examples of semantic relations are provided in Table 3.

Table 3 Semantic relations

Type	Relation	Example
Hyperonym-hyponym relations	"is_equivalent_to" "is_disjoint"	Horizontal Lifeline System <is_disjoint> with a Vertical Lifeline System
Meronym-Holonym relations	"is_subsystem_of" "is_part_of"	Longitudinal Wire <is_part_of> Safety Mesh
Concept-object relations	"is-instance-of"	Installing prefabricated roof trusses <is_instance_of> Construction
Cause-effect relations	"performs", "produces" "harms" "minimizes" "designs"	Hazard <harms> Worker
Locative/spatial relations	works_on	Worker <works_on> Roof

4.3 Attributes

According to El-Gohary and El-Diraby [35], an "attribute" is defined as "*a characteristic that describes a thing*". Modelling and visualizing fall hazard controls without information about attributes is less meaningful and useful. Attributes should cover information that is important to end-users of an ontology. For example, it is not enough to model and visualize a safety net without any information about its size, material, class, energy absorption capacity. The information is significant for selection and implementation of safety net on site. Note that attributes of the concepts of active fall protection system are not presented here. Details can be referred to [7].

"Hazard control mechanism" is an attribute of hazard control measure and it is inherited by all sub-classes of hazard control measure. The attribute has three values: elimination, isolation, and minimization, which are consistent with the traditional hazard control hierarchy.

Key attributes of other main concepts are presented in Table 4.

Table 4 Key attributes of main concepts

Concepts	Key attributes
Fall hazard	• fall scenario; • fall height; • severity; • likelihood
Safety net	• material; • maximum fall distance; • minimum clearance below the working area; • class; • energy absorption capacity; • mesh configuration; • mesh size; • manufacturer; • data of manufacture; • net's unique identify or serial number (ID); inspection status
Scaffold	• intended use; • dimension; • duty loading; • weight; • height; • bay length; • lift height; • base-to-height ratio; • load-bearing capacity of the supporting foundation; • inspection status;
Safety mesh	• dimension; • the supplier and country of manufacture; • diameter of safety mesh wires; minimum • tensile strengths of safety mesh wires; • dimensions of the mesh aperture; • width of the mesh; • nominal weight of the mesh; • UV stabilization rating; • initial sag;
Guardrail	• span; • material; • rail height; • portability; • collapsibility; • free-standing-ability; • inspection status
Roof	• slope; • length in the direction of its slope; • material; • strength;

Values of attributes take different data types, including Integer, Float, String, and Boolean. These attributes in the ontology are grouped as slots attached to specific concepts. These attributes carry importance information for selection, implementation, and maintenance of fall hazard controls.

4.4 Coding

The FFH-Onto was coded using Protégé 5.2.0, as shown in Figure 4. Protégé is a free, open-source ontology editor and framework for building intelligent systems [36]. In protégé, “Classes”, “Object properties”, and “Data properties” are used to model concept, relations, and attributes, respectively. Some plug-ins (e.g., OntoGraf) can be used to present key classes and their relationships (see Fig. 5).

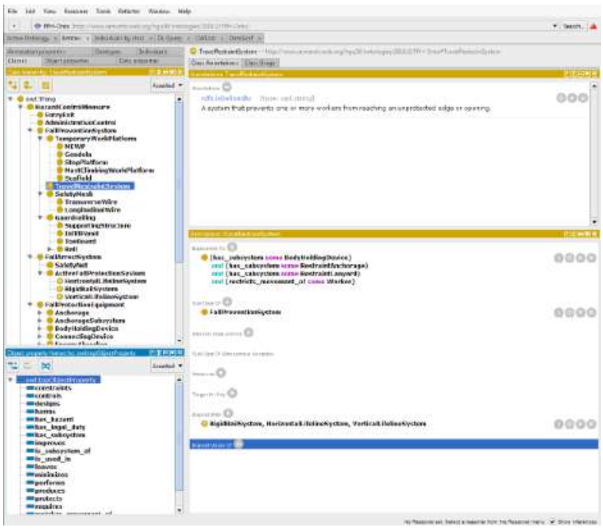

Fig. 4 Screenshot of the ontology editor Protégé.

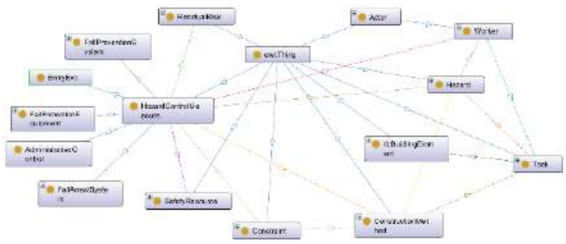

Fig. 5 Key classes and their relationships

5 Ontology evaluation

Ontology evaluation is essential for the development of ontologies. It represents a “*judgement of the ontology content with respect to a particular frame of reference*”. [35]. The paper only aims to develop a lightweight FFH-Onto which does not include axioms and constraints. As a result, it is not possible to conduct automated consistency checking using logic reasoner such as Pellet. FFH-Onto is initially evaluated using a criteria-based evaluation approach.

5.1 Criteria-based evaluation

Four key criteria which match the objectives of FFH-Onto were adopted from past studies [12, 37, 38], including clarity, extendibility, completeness, and coverage.

Clarity refers to whether an ontology effectively communicates the intended meaning of defined concepts, relations, and attributes without ambiguity [37]. To ensure the clarity of the FFH-Onto, all concepts and their definitions were extracted directly from the knowledge sources presented in Table 2. The knowledge sources were developed by groups of safety experts and are deemed to capture unambiguous concepts with clear definitions. Standards developed in different countries may use different concepts with similar meaning. For example, “Professional engineer” used in SS 607 [39] is a synonym of the “Qualified engineer” used in Z259.16-15. To clarify, synonyms of a given concept were listed in the Protégé through the use of <rdfs:comment>, an instance of <rdf:property> that may be used to provide a human-readable description of a resource.

Extendibility refers to an ontology’s ability to expand itself to “*describe specific application domains in a way that does not change the current definitions within the ontology*” [37]. The authors made effort to capture the majority of concepts and their attributes underlying the generic ontological framework. The FFH-Onto is scalable so that new relevant concepts and attributes can be integrated without changing the current structure of the ontology.

Completeness means whether definitions of concepts are complete. Although the completeness cannot be proven, the incompleteness of the ontology was detected by considering its reference to the real world itself, as suggested by Yu et al.[37]. For example, “ladder” is not only a subclass of temporary work platform, but also can be a kind of entry and exit.

Coverage refers to the coverage of the concepts over the domain of fall from height in the construction industry. In order to improve the coverage of FFH-Onto, a combination of knowledge sources were collected (see Table 2) and core concepts and attributes were manually extracted from these industry standards, best practice guidelines, etc.

Despite these efforts, it is acknowledged that more efforts should be made to further evaluate the FFH-Onto when it is upgraded to a heavyweight ontology which includes concepts, concept taxonomies, relationships between concepts, properties, axioms, and constraints.

6 Discussion, conclusions and future study

This paper developed a lightweight ontology for the domain of fall from height in the construction industry. It represents an effort to develop the global ontology for construction safety hazard management (CSHM-Onto), as suggested by [7].

The FFH-Onto builds itself on the generic ontological framework designed in [7]. A major consideration is that a hierarchy of hazard control measure ontologies (FFH-Onto, AFPS-Onto, and struck-by-objects ontology) can be built and combined based on the harmonization framework. The lightweight ontology captures the vocabulary (i.e., concepts, attributes of and relations between the concepts) in the domain of fall from height in the construction industry. In particular, nine groups of fall hazard controls were categorized, including (1) guardrail, (2) temporary work platform, (3) harness system, (4) safety mesh, (5) mechanical access plant, (6) safety net, (7) soft landing system, (8) access/egress, and (9) administrative control.

Compared to previous safety-ontologies developed for job hazard analysis, the FFH-Onto is more comprehensive, powerful, and flexible. It servers purposes beyond conducting job hazard analysis. By unifying multiple databases in the FFH domain, it can be used to (1) promote knowledge reuse and sharing, (2) facilitate the development of knowledge-based systems, and (3) improve the modeling and visualization of fall hazard controls in BIM tools.

The ontology can be used to facilitate knowledge re-use and sharing among the end-users (e.g., designer, engineer, safety professional, supervisor, and site manager. As a foundation of knowledge engineering, ontologies represent effort to engineer domain knowledge into a high level of human expertise [40].

The FFH-Onto formalizes empirical experience, standards, best practices in the domain of fall from height in the construction industry. Specific fall protection systems and devices are explicitly defined and thus it promotes modeling and visualization of fall protection in BIM models. Engineers and safety practitioners can demonstrate the design and installation of hazard controls (e.g., active fall protection system and guardrail systems) in BIM models and therefore improve communication and safety planning.

Recent years have seen a growing interest in developing knowledge-based systems for construction safety engineering and management. Building these intelligent systems poses special requirements for interoperability. Thus, establishing agreements about domain knowledge becomes critical. The FFH-Onto captures consensual the domain knowledge in a generic way and as such facilitates interoperability of formal knowledge across computer programs. By organizing objects (e.g., workers and scaffold) into categories, semantic networks, rules, and logic can be designed and integrated into computer programs for certain tasks. For example, by capturing a working at height scenario using concepts like actor, task, building element and their relations and attributes, it is possible to write rules that enable automatic hazard recognition and classification based on additional information extracted from BIM models. Intelligent hazard control recommendation systems could also be designed based on the temporal-spatial relationships between building objects, materials, tools, process, practices, and workers.

The ontology developed in this paper has the following limitations. First, the proposed lightweight ontology needs to be further developed by including axioms and constraints. Second, FFH-Onto is by no means a "perfect and only" ontology to represent the knowledge of FFH domain. Other representation strategies are possible. Future efforts should be made to develop ontologies for other key hazards such as struck by objects. Once local ontologies are developed, they can be mapped and integrated into a global ontology of construction safety hazard management. The success of these efforts would significantly promote automation in construction safety engineering and management.

Abstract –

Upward high load works such as the installation of ceiling boards are severe work. We have developed an upper limb support system (ULSS) for the works. The purpose of this study is to develop compound movement support algorithm for the ULSS, and to confirm the effectiveness of the ULSS with the algorithm. The installation of the ceiling boards is compound movement. The workers move a tool vertically with one arm while holding the heavy board with another arm. The ULSS is a powered exoskeleton and has enough range of motion (ROM) for the works. The developed algorithm controls each arm part of the ULSS separately and achieves the compound movement support based on a bioelectrical signal (BES). The BES is detected on the surface of the human skin covering the muscle when the human is going to move their muscle. Volunteers perform the compound movement simulating the actual work in the evaluation experiments. As a result, the ULSS with the algorithm had a positive effect on the support. The average number of the compound movement with the ULSS increased 2.0 times compared to the average number without the ULSS.

Keywords –

Compound movement; Upward high load works; Powered exoskeleton; Bioelectrical signal

1 Introduction

At demolition or construction sites, workers have to perform upward high load works. Examples are installation of ceiling boards, cutting of metal pipes, and chipping of cement [1]. The workers hold heavy loads overhead, and move heavy loads vertically. It is difficult to sustain such the upward high load works, and working environment will be severe. For this reason, actual working time of whole working time decreases, and work efficiency will be reduced. In addition, the severe working environment causes decrease of the workers in the construction industry [2]. Therefore, It is necessary to improve the working environment, and movement support for upper limbs is required.

A wearable system with a sufficient degree of freedom (DOF) and support power will be effective to sustain these upward high load works for a long time. Many wearable systems for the movement support have been researched and developed [3]-[9]. However, these studies focus on the high power support for the works performed under the wearer's head, or light power support for the works performed on the wearer's head. In this study, we focus on the upward high load works, and have developed an upper limb support system (ULSS) [10]. The ULSS is a powered exoskeleton and follows complex movements of the wearers by redundant DOF. In the actual work sites, it is necessary for the ULSS to perform voluntary movement support by following motor intention of the wearers. Estimation of the motor intention is important for the voluntary movement support. In this study, we adopt a bioelectrical signal (BES) as the method for estimating the motor intention [11]-[16]. The BES contains nerve command signals and myoelectrical signals. The BES is detected on the surface of the human skin covering the muscle when the human is going to move their muscle. The BES is effective for voluntary movement support because this electrical signal reflects muscle activity and the motor intention directly. A movement support algorithm for the ULSS based on the BES is required to achieve voluntary movement support.

In previous research, we have developed a static movement support algorithm for the holding movement such as the cement chipping work, and dynamic movement support algorithm for the vertical movement such as the pipe cutting work [17][18]. These algorithm supports simple static or dynamic movement. In the simple work such as the chipping work or cutting work, the workers treat tools and materials by their both hand. However, the workers perform compound movement of the static holding movement and dynamic vertical movement in the actual work sites. The installation of ceiling boards is compound movement. This work is one of the most demanding types of the work in terms of the weight of the tools and materials. The workers move a nailing machine vertically with one arm while holding the heavy ceiling board with another arm. During this work, required support power changes according to the movement of each arm. Thus, it is necessary to develop a new compound movement support algorithm for the upward high load works such as the installation of ceiling boards.

The purpose of this study is to develop a new compound movement support algorithm for the ULSS based on a BES to achieve continuous upward high load works. In addition, we confirm the effectiveness of the ULSS with the algorithm through evaluation experiments. In the evaluation experiments, we assess the voluntariness of the ULSS, and the effectiveness of the ULSS for the compound movement.

2 Material and Method

2.1 Upper Limb Support System (ULSS)

Figure. 1 shows an overview of the ULSS. The ULSS is a powered exoskeleton. Basic points of the movement of the arms are shoulder joints. When the workers raise their arms, the clavicles and the scapulas of the wearers which hold the humeruses tilt to upward [19]. In addition, the spine moves three-dimensionally. Consequently, the positions of the shoulder joints move significantly. The ULSS has the middle joins, and this joint is redundant with respect to the structure of the wearer in the sagittal plane. The wearers of the ULSS can move smoothly through the middle joints. Moreover, Japanese adult males, who have dimensions of the human body between 5%tile to 95%tile, can wear the ULSS by the shoulder width adjusting mechanism.

A total of six power units are installed on the arms of the ULSS. The ULSS supports the wearer's upper limb movement by moving independently on the left side power units and the right side power units. The shoulder joints and middle joints are connected by the parallel link mechanism to reduce the required support force [20]. The ULSS is attached to the wearer by belts. There are cuffs that transmit support forces to the wearer. Each joint has a mechanical angle limiter. The lumber load support unit transmits the reaction force of the support force to the iliac horns of the wearer. The total weight of the ULSS is 8.3 kg. The minimum safety factor for the breaking strength is over 2.0 in a state of maximum load. In order to ensure safety, the wearers only handle tools and materials that they can handle without the support of the ULSS. In addition, the wearers have enough training and explanation before the evaluation experiments.

Figure. 2 shows a system configuration of the ULSS and the method for measurement of the BES. Power units in each joint have angle sensors and actuators. There is a control unit in the back part of the ULSS that consists of a main-computer, BES sensing unit, A/D converters, absolute angle sensor, and motor drivers. The reset switch is within reach of the jaw of the wearer. There is a battery unit in the lumbar load support unit, and the battery unit supplies electricity to the power units and each unit circuit. The BES sensing unit

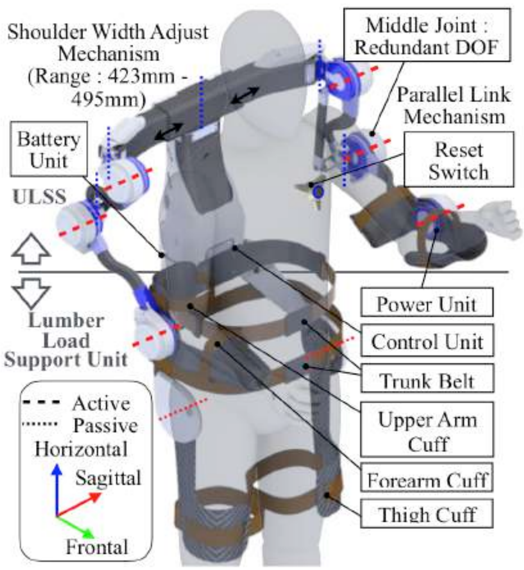

Figure 1. Overview of the ULSS. The ULSS is a powered exoskeleton and has redundant DOF for smooth movement of the wearer.

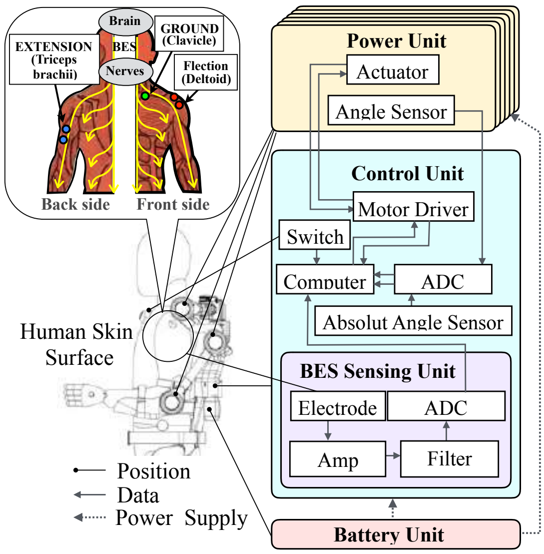

Figure 2. System configuration of the ULSS and the method for measurement of the BES.

measures the BES for the estimation of the motor intention by the wet type electrodes. The BES contains nerve command signals and myoelectrical signals and reflects muscle activity and the motor intention directly. The BES is detected on the surface of the human skin covering the muscle when the human is going to move their muscle [11]-[16]. The electrodes are attached on the deltoid, the triceps brachia, and the roots of the clavicle. The ULSS performs calibration process of the BES before the movement support.

2.2 Compound Movement Support

During the upward high load works, required support power changes according to the movement of each arm of the wearer. The ULSS supports the wearer by the compensation of gravity and viscosity according to the control phase. The developed algorithm achieves the compound movement support by shifting control phases. The support torque in each drive joint is

$$\tau = MgL + \tau_S + \tau_W + \tau_V \tag{1}$$

The M is the assumed weight which is held by the wearer in wearer's hand. We treat M as the known value because the weight of tools and materials will not change particularly in one upward high load work. It is considered that the method can support the actual works by inputting the weight value of the tools and materials. The ULSS achieves the compound movement support by changing the M according to the control phase. The g is the acceleration of gravity. The L is a moment arm of the position of M and each drive joint. The τ_S is the self-weight compensation torque around each joint, and the τ_W is the wearer's arm weight compensation torque around each joint, The τ_V is the viscosity compensation torque around each joint. It's possible to reduce the required gravity compensation torque around the shoulder joint by the parallel linkage [20].

The algorithm is compatible with the compound movement such as the installation of the ceiling boards. The workers move a tool vertically with one arm while holding the heavy material with another arm in such the work. The algorithm distinguishes between whether the movement of the wearer is the holding movement or the vertical movement based on the BES.

Figure. 3 shows a state transition diagram of the control phase. The control phase decides support power. This diagram illustrates the control phase of a single arm of the ULSS. The symbols in parentheses are equivalent to the M of the equation (1). The MH simulates the weight handled in holding movement, and the MV simulates the weight handled in vertical movement. In most cases, the MH is heavy than the MV in the compound movement such as the installation of ceiling boards. After the calibration, the control phase shifts to the NO-LOAD phase. When the reset switch was pressed, the control phase shifts to the WAIT phase. After that, the control phase shifts voluntarily based on the BES. The flection side BES is the fl, and the extension side BES is the ex. The control phase does not shift, when the co-innervation of the flexor muscle and extensor muscle occurs. The decision condition is

$$THR_{CO} < | fl - ex | \tag{2}$$

The THR_{CO} is the threshold value of the decision condition.

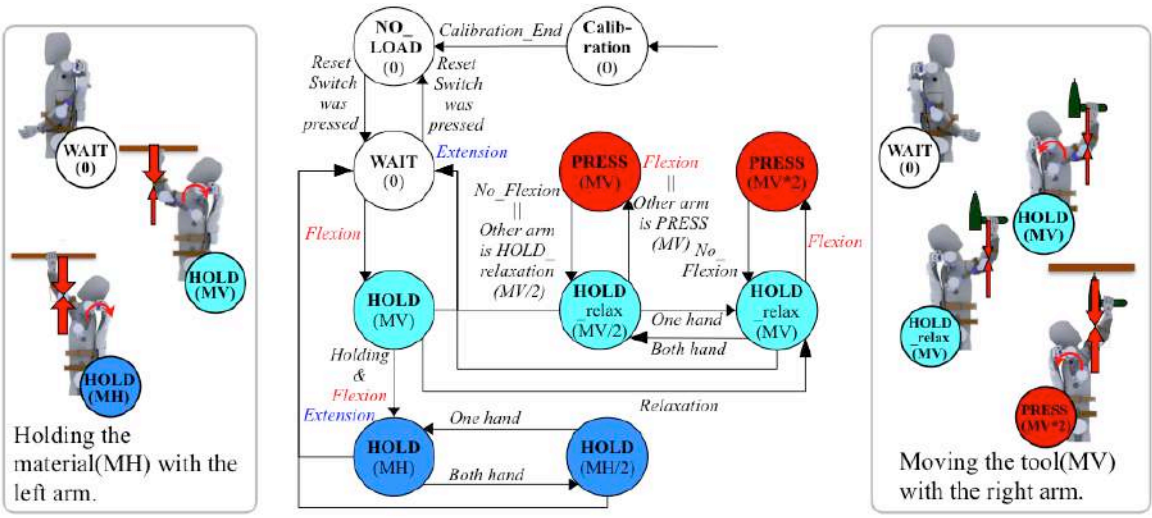

Figure 3. State transition diagram of the control phase for one arm part of the ULSS. When the reset switch was pressed, the control phase shifts to the WAIT phase.

The shift of the control phase in the vertical movement is shown below. The Flection indicates that the fl exceeds the threshold value THR_{FH}. The Extension indicates that the ex exceeds the threshold value THR_{RE}, and fl goes below the threshold value THR_{FL}. The THR_{FH} is larger than THR_{FL}. When the wearer holds the MV with his one arm, the state of the BES changes to the Flection. In addition, the WAIT phase shifts to the HOLD(MV) phase. At this time, the arm of the wearer can relax by the support of the ULSS. The decision condition of the relaxation is

$$(fl < (fl_{max} - THR_{FR})) \,\&\, (fl - THR_{FL}) \tag{3}$$

The fl_{max} is the maximum value of the fl, and the THR_{FR} is a threshold value of the relaxation. After the relaxation, the control phase shifts to the HOLD_relaxation(MV). When the wearer presses the MV upward, the state of the BES shifts to the Flextion, and the control phase shifts to the PRESS(MV*2). When the state of the BES shifts to the No_Flextion, the control phase shifts to the HOLD(MV). The No_Flextion indicates that the fl goes below the threshold value THR_{FL}. When the wearer pulls down his arm, the state of the BES shifts to the Extension, and the HOLD phase shifts to the WAIT phase.

The shift of the control phase in the holding movement is shown below. When the wearer holds the MH with one arm, the state of the BES changes to the Flection, and the WAIT phase shifts to the HOLD(MV) phase. At this time, the gravity compensation for the weight in the wearer's hand is less than the support required for the MH. Thus, the BES keeps the Flection. At this time, the joint angular velocity shifts the Holding state and goes below the threshold value. For this reason, the control phase shifts to the HOLD(MH). When the control phases of both arms are the HOLD(MH) or the HOLD_relaxation(MV), the ULSS estimates that the wearer handles the heavy load by both arms. In this case, the control phases of both arms synchronize, and the assumed weight of the single arm becomes a half. Thus, the compound movement algorithm can support the holding movement and vertical movement voluntarily.

3 Experiment

3.1 Outline

Evaluation experiments were conducted to confirm the effectiveness of the system with the developed algorithm. The experiments were a random instruction experiment and a movement support experiment conforming to the installation of ceiling boards. Figure. 4 shows the pattern diagram of the experiments. A weight of 15 kg simulated the ceiling board, and a weight of 5kg simulated the nailing machine. Another weight of 5 kg simulated the reaction force, and this heavy load was passively moved vertically. The volunteers were five healthy adult Japanese males who had heights below the 95%tile value. The volunteers moved the two heavy loads of 5kg vertically with the dominant hand while holding the heavy load of 15kg with the non-dominant hand in synchronization with an instruction. The instruction was performed by a beep sound. The volunteers wore protectors.

3.2 Random Instruction Experiment

The random instruction experiment was conducted in order to confirm that the control phase changes by following the motor intention. The volunteers wore the ULSS and moved the heavy loads vertically. At first, the volunteers waited 5 s. Next, the volunteers gripped both of the below head height heavy loads at random intervals of 1 - 4 s. Next, the volunteers moved the upper heavy load vertically 3 times with dominant hand while holding the heavy load with the non-dominant hand. At this time, the rise of the two heavy loads of 5kg was performed for random intervals of 1 - 4 s, the descent of the heavy loads was performed for 1 s, and each vertical movement was performed after random intervals of 1 - 4 s. Next, the volunteers put the heavy loads on the pedestal after random intervals of 1 - 4 s, and pressed the heavy loads down. Finally, the volunteers waited 5 s. We measured the timing of the instructions, the movement of the wearers, and the shifts of the control phases.

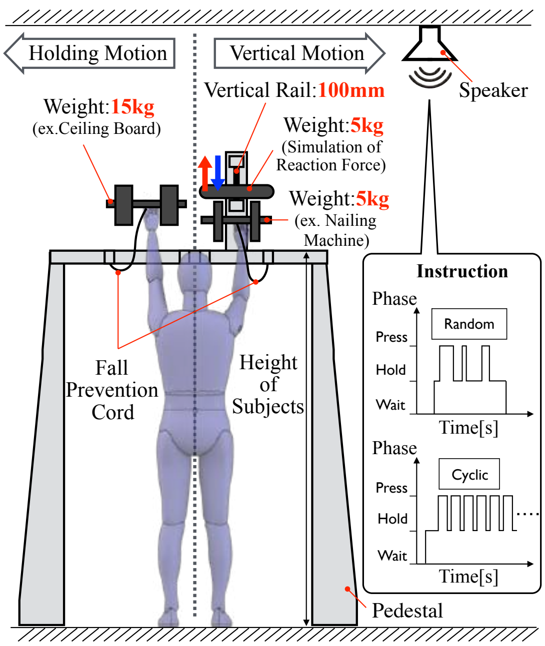

Figure 4. Pattern diagram of the experiments.

3.3 Movement Support Experiment

The movement support experiment was conducted in order to confirm that the ULSS with the developed algorithm had a supportive effect for the compound movement. The volunteers performed the compound movement in synchronization with cyclic instructions. The volunteers continued the movement to the limit of the physical strength without and with the ULSS. At first, the volunteers waited 5 s. Next, the volunteers gripped both of the below head height heavy loads for 5 s. Next, the volunteers moved the upper heavy load vertically with the dominant hand while holding the heavy load with the non-dominant hand. At this time, the rise of the two heavy loads of 5kg was performed for 4 s, and the descent of the heavy loads was performed for 1 s. When the volunteer could not continue this compound movement, they put the heavy loads on the pedestal and pressed the heavy loads down. Finally, the volunteers waited 5 s. We measured the number of the compound movements. Moreover, we conducted a dependent t-test to compare the number of compound movements without and with the ULSS, and the level of significance was 5 %. The volunteers took a rest between both of experiments to recover.

4 Result

Figure. 5 shows results of the holding movement in the random instruction experiment. The control phase of all volunteers followed the instruction with a delay. In addition, the control phase shifted in the order of the WAIT(0kg), the HOLD(5kg), and the HOLD(15kg).

Figure. 6 shows the results of the vertical movement in the random instruction experiment. The control phase of the volunteer A, B, and E followed the instruction with a delay. As for the volunteer C, the HOLD(5kg) shifted to the PRESS(10kg) 2.25 s faster than the instruction. As for the volunteer E, the number of phase shift is smaller than the number of vertical movement instruction. In addition, when the instruction phase shifted from the PRESS(10kg) to the HOLD(5kg), the control phase didn't shift from the PRESS(10kg) to the HOLD(5kg) once in a while. As for the control phase of all volunteers, the control phase shifted in the order of the WAIT(0kg), the HOLD(5kg), and the HOLD(10kg).

Figure. 8 shows the state of the movement support experiment. Figure. 9 shows the results of the movement support experiments. In the experiment without the ULSS, the average number of the compound movement repetitions was 9.4 sets, and the 95%CI was 11.7 - 7.1 sets. In the experiment with the ULSS, the average number is was 19.0 set, and the 95%CI was 23.4 - 14.6 sets. The number of all the volunteers increased with the ULSS. The average number of the compound movement repetitions with the ULSS was 2.0 times higher than without the ULSS. The result of the t-test was that the number of compound movement repetitions with the ULSS was significantly large higher.

5 Discussion

The volunteers performed holding movement and the vertical movement in the random instruction experiment. The results of the holding movement showed that the control phase of all volunteers followed the instruction with a delay. From this result, the volunteers performed the holding movement as per the instruction, and the developed algorithm voluntarily shifted the control phases by following motor intention of the wearers who perform the holding movement. In addition, the control phase shifted in the order of the WAIT(0kg), the HOLD(5kg), and the HOLD(15kg).

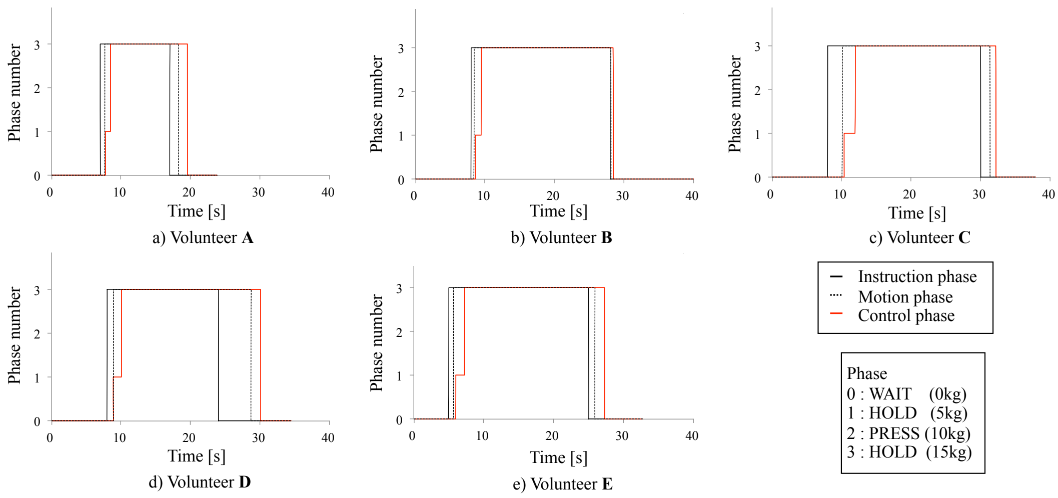

Figure 5. Results of the random instruction experiment (holing movement).

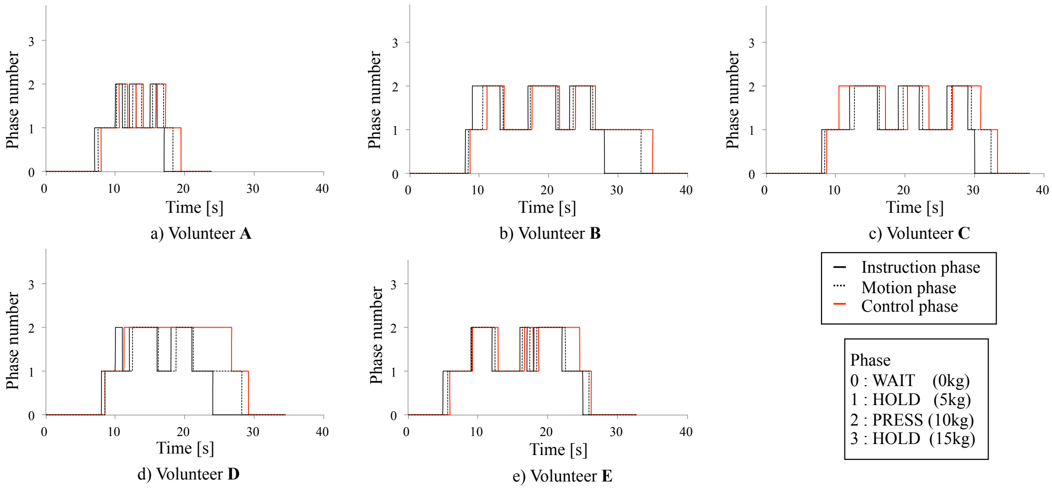

Figure 6. Results of the random instruction experiment (vertical movement).

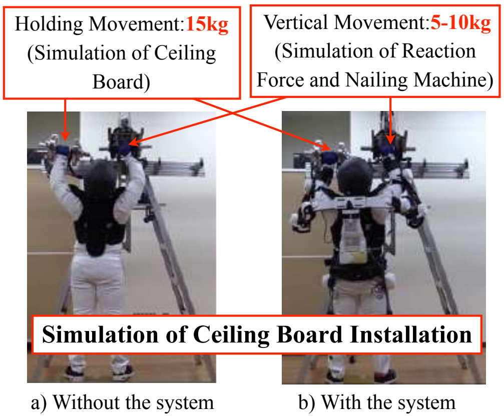

Figure 7. State of the compound movement experiment.

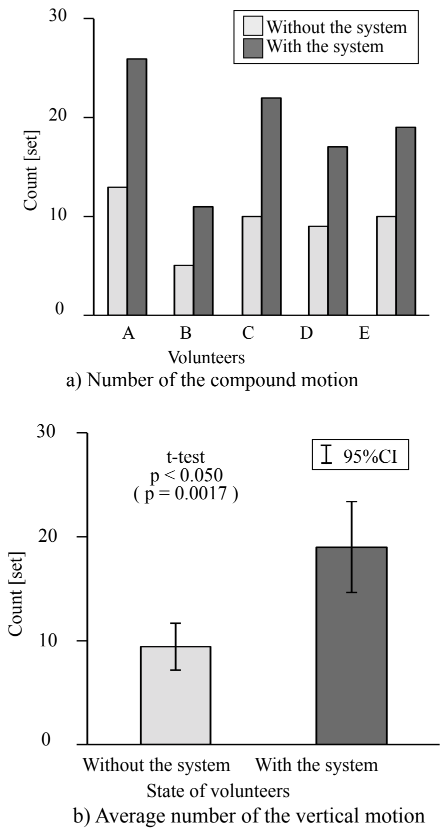

Figure 8. Results of the movement support experiments. The number of compound movement repetitions with the ULSS is significantly greater.

Thus, the developed algorithm detected the lack of the support power based on the BES, and switched the control phase adequately.

The results of the vertical movement showed that the control phase of the volunteer A, B, and E followed the instruction with a delay. From the result of the vertical movement, the volunteers A, B, and E performed the movement as per the instruction. As for the volunteer C, the HOLD(5kg) shifted to the PRESS(10kg) 2.25 s faster than the instruction. When the control phase of the vertical movement side shifted to the PRESS(10kg) from the HOLD(5kg) for the first time, the control phase of the holding movement shifted to the HOLD(5kg) from the WAIT. For this reason, we could assume that he moved both of his arms as per the instruction for his one arm.

As for the volunteer E, the number of phase shift is one smaller than the number of vertical movement instruction. We could assume that he couldn't react to the first instruction for the PRESS(10kg) because the instruction was performed for a short time. In addition, when the instruction phase shifted from the

PRESS(10kg) to the HOLD(5kg), the control phase didn't shift from the PRESS(10kg) to the HOLD(5kg) once in a while. We could assume that the volunteer E supported the heavy loads while performing the descent of the heavy loads. For these reasons, the developed algorithm voluntarily shifted the control phases by following motor intention of the wearers who perform the vertical movement having a large personal deviation. Thus, the control phase changes by following motor intention of the wearers who perform the compound movement.

The volunteers performed cyclic compound movement in the movement support experiment. The number of the compound movement repetitions of all the volunteers increased with the ULSS. The average number of the compound movement repetitions with the ULSS was 2.0 times significantly-higher than without the ULSS. From the result, the ULSS with the developed algorithm had a supportive effect for the compound movement consist of the static holding movement and the active vertical movement. We could assume that the support torque of the ULSS reduced the joint torque of the volunteers for the compound movement. For this reason, the volunteer could perform the more continuous compound movement.

The developed algorithm changed the control phases by following the motor intention of the wearers, and the ULSS had the effect of support for basic compound movement. Because of that, the ULSS with the algorithm was effective for the continuation of compound movement. When the control phase shifted by following the wearer's movement, the delays of the phase shift were large in the random instruction experiment. The volunteers performed the movement without a problem and had the effect of the support, but there is room for improvement for the delay of the phase shift. It is necessary for the algorithm to develop a function adjusting the threshold values automatically. In the evaluation experiment, the basic compound movement conforming to the installation of ceiling boards was performed. This movement is the one of the most demanding types task in terms of the weight of tools for heavy overhead task. For this reason, we can apply the ULSS with the developed algorithm to other construction sites using lighter tools and materials.

6 Conclusion

In this study, we developed a novel compound movement support algorithm for the ULSS based on the BES to achieve the continuous upward high load works. The developed algorithm achieves the compound movement support by voluntary shifting of the control phase in response to a change of the BES. In the random instruction experiment, the algorithm voluntarily shifted the control phases of the ULSS by following the motor intention of the wearer. In addition, the algorithm had the effect of the support for the basic compound movements, conforming to the actual work. Therefore, we could confirm that the ULSS with the algorithm had effectiveness for the compound movement. In our future work, we will improve the delay of the phase shift. We can expect that the ULSS with the algorithm increases the work efficiency, and improves environment of the actual work sites.

Abstract –

In this paper, we report a method that a mobile robot operates automatic inspection of embankment. The mobile robot KENAGE, which has been developed by Japan Aerospace Exploration Agency, tows a truck with an inspection instrument and is basically controlled by Robot Operating System. From the result of way point navigation experiment, it is confirmed that the mobile robot is able to go through several way points and to inspect the embankment automatically.

1 Introduction

Construction demand is keeping high not only in modern times but also expected to grow in the future because of reconstruction of buildings and maintenance management of the infrastructures such as bridges and tunnels. However, decrease of the working population in the construction industry is becoming a severe problem especially in America and Japan. For example, in Japan, the population in construction was 3.4 million in 2014 which is estimated to become 2.2 million in 2025. Despite of the population problem, the construction demand is predicted to rise. Therefore, shortages of workers are exceedingly concerned, so young workers on construction are desired.

For the problem about shortages of workers, it is necessary to take measures not only to employ young workers but also to create more efficient construction methods. It is considered that one of the methods is bu introduction of construction robots. The robots which work autonomously or support human workers lead to more efficient constructing. Many researches and developments on the construction robot are in progress. Menendez et al. developed tunnel structural inspection and assessment robot which detects defects of tunnel by using computer vision system and ultrasonic sensor[1]. Cebollada et al. are on research of a robot which sprays foam insulation in underfloor[2]. SAM (Semi-Automated Mason) produced by Construction Robotics company in America which lays bricks faster than human[3]. BIM (Building Information Modeling) will also become one of support technology for automatic constructing robots.

In this paper, we propose the automatic embankment inspection robot system for manpower saving in construction site.

2 Inspection Procedure of Constructed Embankment by using Radio Isotope

Quality of constructed embankment is checked by an instrument using radio isotope in Japan. For developed embankment, density and moisture content is measured at several points by the placing the instrument. A selection method of the measuring points is ruled by MLIT (Ministry of Land, Infrastructure, Transport and Tourism) Japan. The rules are as follows. [4]

1. Embankment is divided into several units. It is necessary that quality is checked and recorded at each unit.
2. It is ruled that unit size is one layer of embankment area constructed for one day. Standard unit size is 1500m2. If embankment area size is over 2000m2 a day, the area is necessary to be divided into 2 units.
3. Each unit is inspected at 15 points in principle and an average of them is calculated and recorded. If embankment area size is smaller than 500m2, At

least 5 points inspection is required.
4. The inspection is executed on the constructed day in principle.
5. If several layers of embankments are constructed in a day, an unit area doesn't cover the layers.
6. When the nature of soil used for filling changes, the area in where the corresponding soil is used becomes another inspection unit.

Fig. 1 Embankment inspection instrument ANDES[5]

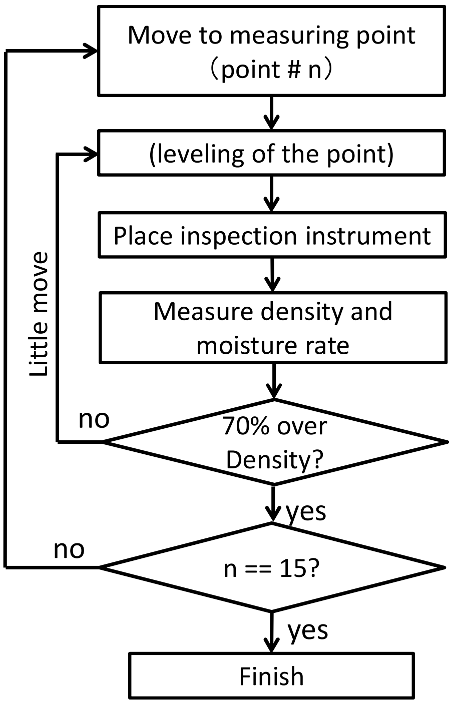

Fig. 2 Embankment inspection procedure

Fig. 1 and Fig. 2 show the instrument of inspection and inspection procedure respectively. The weight of the instrument is 10.5kgw. Additionally, 2kgw steel stick with radiation source is attached. Although the inspection procedure includes calibration before measurement strictly, explanation of the calibration is omitted because of low importance in this paper. Detail of inspection procedure is as follows: density and moisture content are measured 1 time per second at each point and averages of them are recorded. For avoiding defective measurement, the recorded data that shows smaller than 70% density is removed. With changes of measurement points, this procedure is operated 15 times in principle.

3 Hardware of inspection system

3.1 Multi-crawler type Mobile Robot

In this research, we used a multi-crawler type mobile robot which was developed at JAXA (Japan Aerospace Exploration Agency) and called KENAGE[6][7]. Fig. 3 shows overall view of the robot and electric equipment. Specification is shown in Table 1. The robot has four crawlers and eight passive links structure. By utilizing this structure, the robot is able to climb over an about 450mm wall and a slope of 45 degrees. Because of the ability, we considered that the mobile robot is useful in construction site.

Additionally, the mobile robot equips with 2 dimensional LIDAR, GNSS module and IMU (inertial measurement unit) as sensors for self-localization.

3.2 Towing truck with inspection instrument

For accomplishing unmanned inspection, the mobile robot equipped with embankment inspection instrument goes around the measuring points and inspects at each point automatically. To carry the instrument, a towing truck is developed.

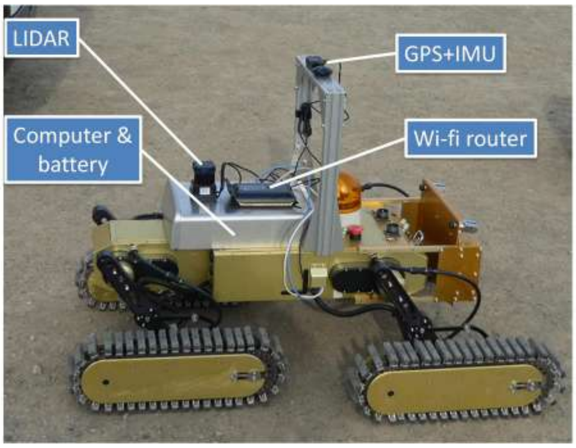

Fig. 3 Multi-crawler type mobile robot KENAGE

Table 1 specification of the mobile robot

External dimensions	1115L x 780W x 250H
weight	45kg
equipment	4 crawlers
Power source	Li-ion battery(54V/6Ah)
sensors	GNSS, IMU and LIDAR

Fig. 5 Mobile robot and developed towing truck

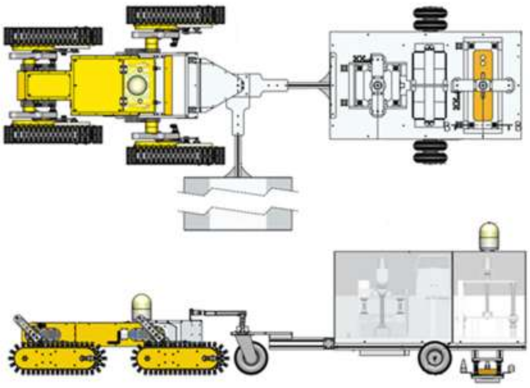

Fig. 4 Top and Side view of towing truck

Fig. 4 shows top and side view of robot and towing truck CAD images. Fig. 5 shows overall system picture which captured on construction site. The inspection instruction is equipped in the truck. A micro-controller is also placed. By sending signal from the micro-controller, the instrument goes up and down. When measuring density and moisture content of embankment, the instrument goes down and is placed on the ground. After finishing the measurement, the instrument goes up and the robot moves to next point. Furthermore the battery for the truck and the mobile robot is equipped inside the truck. The towing truck is connected by link joint, so the truck follows the robot same as a trailer.

4 Autonomous mobile system

The mobile robot is necessary to move automatically for the unmanned inspection. To achieve it, the autonomous mobile system is required, which consists of self-localization, path planning and obstacle avoidance. For applying the developed system on the construction site in a short period, we used ROS (Robot Operating System) for robot control in this research[8].

4.1 Control program structure

Program packages for robot control are provided by ROS. Combination of several packages leads rapid prototyping of robot control system. In this research, we used mainly two packages called robot localization package and navigation stack. Connections and data flow of each function are shown in Fig. 6.

Datum from GPS and IMU modules are inputted to robot localization package and self-localization is calculated by using them. The obtained self-localization data is lead to local planner which is a part of navigation stack. The role of navigation stack is path planning and trajectory generation. Global planner and local planner generate rough trajectory to an inputted goal and short term trajectory to be on the rough one respectively.

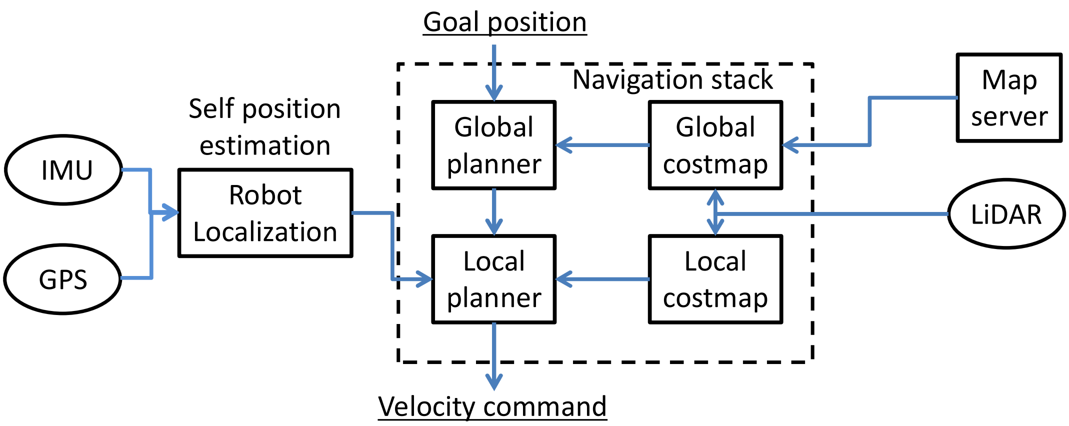

Fig. 6 Connections and data flow of each function

Inputs of global planner are the goal point data and costmap data. In local planner, difference between predict position in only navigation stack and estimated self-localization data from localization package is calculated and local trajectory is corrected.

On the other hand, LIDAR data and static map information which is set in advance make global costmap. Although the static map is usually used for showing floor plan of buildings, it is used for assigning entry permitted area in this research. It depicts in right side of Fig. 4. In contrast, local costmap only uses LIDAR data. When an obstacle appears on the planned trajectory, costmap is updated and obstacle avoiding trajectory is generated. Finally, navigation stack outputs velocity command of the robot and the command is sent to motor drivers hardware.

In this research, the goal information as input data to navigation stack corresponds measuring point, so after arriving the goal the mobile robot starts to measure density and moisture content of terrain. As mentioned before, there are 15 measuring points, so the robot begins to move next point after finishing the each measurement.

4.2 Evaluation of automatic driving of robot

For evaluating the developed system, we tested how accurate the robot moved on planned path to consist of several way points. The way points are supposed to be the measuring points in the construction site. The evaluation procedure is as follows.

7. Assign several points by mouse clicking on Google map.
8. Input the assigned points to the computer of the mobile robot
9. Start the robot to move to first way point
10. After arriving first way point, set the second way point as a next goal and the robot aims there
11. Repeat #4 several times

As supplemental information, the ROS program judges arrival at the goal when the robot completes travelling in a circle of goes into a 2 meter in diameter with the center as the way point. An Experimental field is selected to be outdoor environment for receiving GNSS signal. The size of the experimental field is about 50m by 50m square. The 7 way points are set in the field so as to form hexagonal shape based on the above procedure. For checking whether or not the robot goes out of entry permitted area, only one way point is set outside of the experimental area. Fig. 7 shows trimmed captured screen image when way points are setting.

4.3 Experimental result

Fig.8 shows the result of automatic moving experiment. Star marks represent assigned way points and continuous line shows connected GNSS signals.

As a rough analysis, the mobile robot went through assigned way points. However there is an error of several meters. It is considered that the reason of the error caused by the accuracy of the GNSS signal and judging requirement of arriving which is to go into the 2m diameter circle.

Concerning about the evaluation that the robot didn't go out of permitted area, the robot canceled corresponding point and aimed to next way point.

Fig. 7 Captured screen image when setting way points

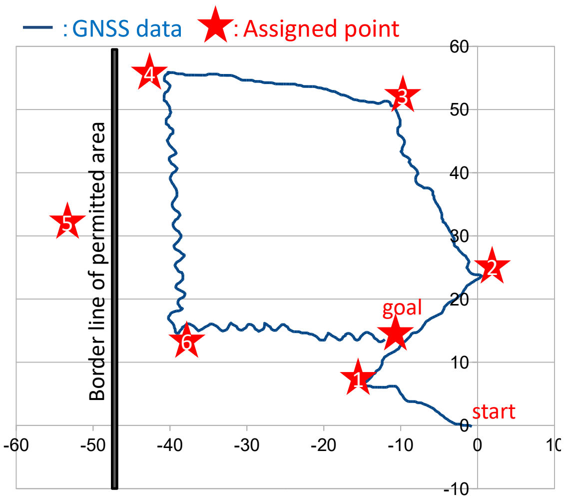

Fig. 8 Obtained self-localization data

Therefore the global planner functions performed correctly. A part of the continuous line is seen to have wave form. Posture measurement of IMU sensor seems to have an error on the way of moving, so it is required to prepare a more accurate posture sensor.

4.4 Evaluation of automatic inspection of embankment

Based on the inspection procedure mentioned in section 2, we evaluated automatic inspection of embankment. A procedure of inspection by using autonomous mobile robot is as follows.

1. GNSS coordinates data of 15 measuring points are acquired in advance
2. Input the coordinates data to the mobile robot
3. The mobile robot tows truck and aims to the measuring point
4. After arrival, the mobile robot takes down the instrument, places on the ground and starts to measure
5. After finishing measurement, the instrument is lifted up and the mobile robot start to move to the next point
6. Back to iv and repeat procedure

According to the above procedure, the automatic inspection was evaluated. The size of the experimental field was about 30 meter by 200 meter. The 15 measuring points were assigned at an interval of 10 meter. Same as experiment at section 4, the mobile robot judged arrival to the goal when the robot traveled into a 2 meter diameter circle of which center was the measuring point. Just after placing the instruments, the robot waited 1 minute for measurement.

Fig. 9 shows a picture of the experiment. X mark in Fig. 9 represents the measuring point. Furthermore the inspection instrument is seen to be taken down from bottom of the towing truck and placed on the ground. Table 2 shows the density and moisture content derived from the experiment. The data represents the average of 15 times measurement and includes standard existing method and automatic inspection method which is proposed in this paper. The results are much the same and 2% difference of measured value which is less than measurement error. This result proves that the proposed automatic inspection is feasible.

5 Conclusion

In this paper, we propose the automatic inspection of embankment system which consists of the crawler-type mobile robot and towing truck. The mobile robot goes through several way point as measuring point. The evaluation experiment indicates that the robot accurately goes on the planned trajectory. Furthermore through the other experiment, we show automatic placing of the instrument and measurement work fine for the reason that the measured value is within the measurement error. As a future work, we will make the system practicable.

Fig. 9 Field test of inspection

Table 2 comparison of density and moisture content

Inspection method	Automatic	Existing standard	Difference
Density(g/cm^3)	2.192	2.242	0.05
Moisture content (%)	7.0	6.9	-0.1

Abstract –

Earthwork productivity varies depending on a unique geologic condition, types of earthwork equipment, and an equipment allocation plan. For this reason, it is difficult to accurately estimate the productivity of an earthwork. To address this issue, this paper develops an imaging-to-simulation method in which a real jobsite data is automatically collected and used for analyzing the earthwork productivity. Object existence and its location in image data are identified by convolutional networks, and they are used to infer the earthwork context. The context information is transformed into the simulation input by the context reasoning processes. A productivity report is produced by using the WebCYCLONE simulation. The developed method was tested in a tunnel construction site, providing a new equipment allocation plan, which minimize the cost and time compared with the original plan.

1 Introduction

Since earthwork in construction involves various types of construction equipment, establishing the optimal equipment allocation plan is a primary concern of site managers. Construction process simulation can be used to generate a productivity report to a given earthwork plan, thereby enabling comparison among different earthwork plans [1,2]. However, even with the simulation results, the optimal plan is not easily established due to a unique geologic characteristic and dynamic working conditions in jobsite. These issues cause the simulation input to deviate from the real jobsite working status. As a result, the reliability of the productivity report is degraded, because a small deviation of the simulation input significantly affects the simulation results. Previous studies proposed vision-based productivity analysis methods, which provides the cycle time of earthmoving [3-5] or concrete pouring operations [6]. Ham, et al. [7] presented an imaging-to-simulation framework to detect hazards related to strong winds. However, integration of construction simulation and vision-based monitoring for productivity analysis has not yet been proposed.

To address these issues, this study proposes an imaging and simulation integrated method to analyze an earthmoving process productivity, as shown in Figure 1. This method automates the process of jobsite data collection for productivity analysis, thereby improving the reliability of the simulation results. An earthmoving process in a tunnel construction site was selected for validating the proposed method. The initial idea of this study was presented in [8].

2 Vision-based context reasoning

A tunnel site, construction under the new Austrian tunneling method (NATM), was selected to apply the proposed method. In the tunnel construction site, the amount of muck produced daily was 680 m^3, and a closed-circuit television (CCTV) was installed at an elevated position to monitor muck-loading tasks by a single excavator and seven dump trucks. The maximum amount of muck that can be stored in the temporary

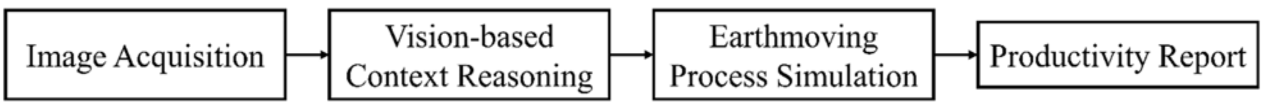

Figure 1. Overview of the proposed method

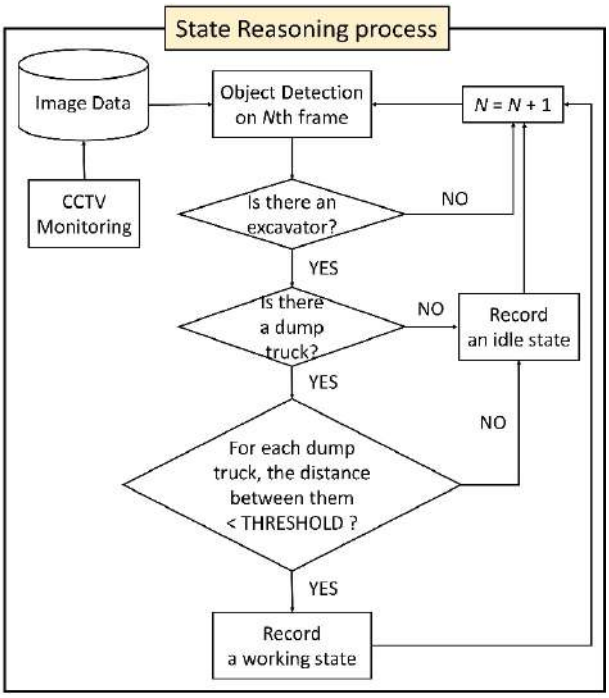

Figure 2. State reasoning process

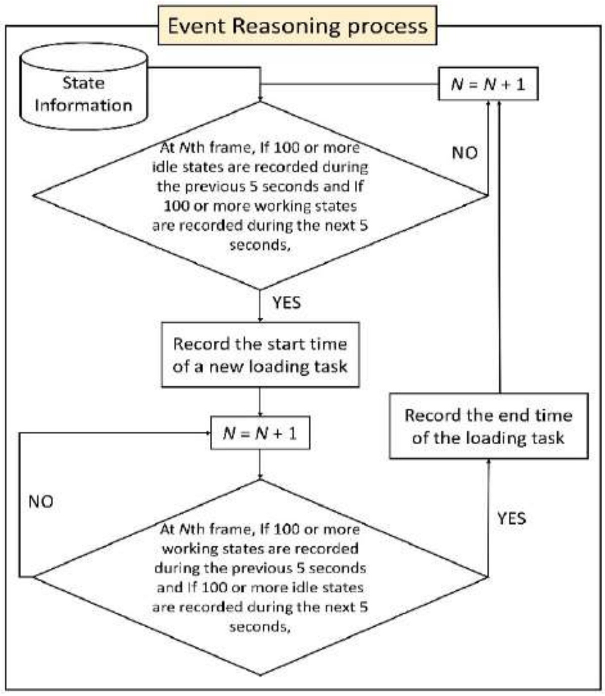

Figure 3. Event reasoning process

disposal area was 1,500 m^3. To detect the target objects in tunnel CCTV image data, a region-based fully convolutional networks (R-FCN) proposed by Dai, et al. [9] is utilized. Using R-FCN, construction equipment such excavators and dump trucks can be detected with the high accuracy at a short processing time [10]. R-FCN comprises three main modules for object detection, which are the feature extraction layers, region proposal network, and the position-sensitive score maps for determining the object class and location in image data. Refer to Dai, et al. [9]'s work for details.

For producing the simulation input, object class and location information from image data can be converted into the context information [3-6]. The context information includes the state and event information. The state information denotes a working or idle state of an excavator and dump trucks in regard to loading or hauling tasks. Figure 2 illustrates the state reasoning process. The event information denotes the time to complete a single loading or hauling task. It records the start and end time of a loading task, following the process illustrated in Figure 3. The start and end time of a hauling task is recorded by the site access information of a dump truck.

2.1 Earthmoving Process Simulation using WebCYCLONE

For the construction process simulation using the WebCYCLONE [11], the earthmoving process should be modelled as a form of discrete event elements used in WebCYCLONE such as NORMAL, COMBI, Q NODE, and ARROW. The target earthmoving process includes eight elements, which are "Loading", "Excavator Idle", "Hauling", "Loaded Truck Queue", "Dump", "Dump Spotter Idle", "Return", and "Dump Queue". The elements constitute the earthmoving process structure, representing loading and hauling cycles of an excavator and dump trucks.

3 Experiments and Results

The proposed method was performed on the Intel i7-6700 CPU and the GTX1080 8GB GPU with the Ubuntu 16.04 operating system. The R-FCN model [9] pretrained with the ImageNet data was re-trained using the AIMdataset [10] and the tunnel image data. The length of the tunnel video for the test was 8 h 11 m. The video resolution was 720 × 480. To evaluate R-FCN for object detection, the evaluation criterion of the PASCAL VOC [12] was used. The experimental results of object detection and vision-based context reasoning are shown in Table 1. R-FCN trained with the AIMdataset and the tunnel image data recorded the mean average precision (mAP) of 99.09% for detecting an excavator and dump trucks. The samples of the detection results are shown in Figure 4. The errors of the context reasoning processes were 0%, 1.6%, and 0.12% for estimating the number of task cycles, average duration of loading tasks, and average duration of hauling tasks, respectively.

Figure 2. Samples of the detection results

Table 1 Performance of equipment detection and vision-based context reasoning

Detection performance (mAP)		99.09%
Error rates of context reasoning	Number of task cycles	0%
	duration average of loading tasks	1.60%
	duration average of hauling tasks	0.12%

Table 2 Productivity report

Daily muck output	680m^3
Capacity of disposal storage area	1500m^3
Current resource allocation	1 excavator, 7 dump trucks
Current productivity	100.88 m^3/hour
Current unit cost	5.59 $/m3
Optimal resource allocation	1 excavator, 10 dump trucks
Optimal productivity	141.78 m^3/hour
Optimal unit cost	5.45 $/m^3
Cost savings (for 600 days)	$310,858

To validate the simulation model, the simulation result was compared to the actual earthmoving process. The deviation of the total working time between the actual earthmoving process and the simulation result was only 2.23% for the 44 task cycles, confirming that the simulation model was correctly modelled as the actual earthmoving process. The productivity report indicates that the current earthmoving process can be improved by changing the number of dump trucks to 10 from 7, as shown in Table 2. The equipment operation costs are $523.33 and $566.94 for each dump truck and excavator, respectively. The payload of a dump truck was 17m^3. With the new equipment allocation plan, the idle time of the excavator can be reduced to 21.12% from 43.97%. Moreover, the total earthmoving cost can be saved by $310,858 (12.25%) for 384 working days of earthmoving in the NATM process of 600 days.

4 Conclusion

This study presents an imaging and simulation integrated method for analyzing the earthwork productivity based on the actual jobsite data. Image data was process by R-FCN to identify the location and class of a target object. The context information was automatically interpreted by the context reasoning processes. By using the actual construction site data, the reliability of the construction process simulation results was enhanced. Integration of imaging and simulation enables rapid generation of a productivity report under changing geologic conditions. This capability allows site managers to optimize the resource allocation for the current geologic condition. Currently, the proposed model is suitable for analyzing a single earthmoving process. The developed model should be further improved to analyze a complex interaction among various jobsite work processes as well as the earthmoving process.

Abstract –

Constructing soil and water conservation (SWC) facilities is crucial to protect soil and water resources, maintain natural ecology and landscape, and prevent erosion, landslide, debris flow, and other disasters. Due to the existence of mountainous terrain in Taiwan and the frequent prevalence of extreme climate changes, thousands of SWC construction projects are built or renovated all over the island in each year. The responsible central governmental entity (home bureau) in Taiwan continuously seek for solutions to improve their current database management system which collects only numbers, texts, and two-dimensional photos to monitor the construction progresses of these projects. This study applies the building information model (BIM), augmented reality (AR) and virtual reality (VR) to develop a new construction management system that can visualize each construction project on a three-dimensional model and access the project information promptly in a cloud environment to support both home bureau and local bureau (the actual project owner). The proposed system is applied to a case project to demonstrate its benefits in supporting construction quality management. The application results suggest that the governmental bureau should provide sufficient incentives to encourage those middle- or small-size designers and contractors to apply the proposed system to the SWC construction projects.

Soil and water conservation construction projects; building information model; augmented reality; virtual reality; construction quality management

1 Introduction

Soil and water conservation (SWC) facilities are used to protect soil and water resources, maintain natural ecology and landscape, and prevent erosion, landslide, debris flow, and other disasters [1]. Due to the existence of mountainous terrain in Taiwan and the frequent prevalence of extreme climate changes, thousands of SWC construction projects are continuously built all over the island in each year.

From the government's viewpoint, the management of each SWC construction project can be classified into two parts, including the one from the branch bureau and the other from the home bureau (that is, the Soil and Water Conservation Bureau, Council of Agriculture, Taiwan). While the branch bureau is the project client in managing the construction project, the home bureau is responsible for monitoring the progresses of all construction projects in an integrated manner.

Currently, both branch and home bureau uses a database management system to collect project data that are in a form of texts, numbers, and a few jobsite photos (and even without drawings) to describe the construction progress and site conditions of each project. That is, the current system has a weakness in helping engineers to visualize a project. Consequently, the governmental engineers must frequently visit the jobsites (with eyes) to get familiar with the projects so that they can manage them accurately on quality, safety and schedule control. Without in-depth understanding about those projects, the bureau engineers would have little sense of the project conditions (in terms of construction quality and safety, for example) and may pay wrong attention to the projects with high vulnerability to an in-coming disaster (e.g., typhoon).

Moreover, these SWC construction projects are often located in mountains or at the places where transportation is not convenient. Hence, engineers would need to carry heavy hardcopies of design drawings and specifications to find project data to support their quality and safety inspections in the construction jobsite.

Enhancing the visualization ability on the SWC construction projects and improving the efficiency in retrieving project data have been identified by both home- and local-bureau engineers as a solution to reduce extensive engineer's laborious work and improve the management of these construction projects. This study proposes to apply the building information model (BIM), augmented reality (AR) and virtual reality (VR) to develop a new construction management system that can visualize each construction project on a three-dimensional (3D) model and access the project information promptly in a cloud environment.

2 Literature review

2.1 Soil and water conservation construction projects

A soil and water conservation (SWC) construction project is related to civil engineering, hydraulic engineering, agronomic/planting engineering; and, it usually exists in slope areas. Additionally, the treatment work of torrent, river, and landslide is the main work scope of SWC construction project [2].

According to the SWC design handbook [3], the major SWC facilities include: sediment storage dam (check dam), slit dam (comb dam), groundsill works, and revetment. Their usages are described as follows:

1. Sediment storage dam (check dam): A check dam helps reduce channel velocity, prevent erosion, and trap small amounts of sediment by intercepting flow along a channel. See Figure 1 for example.
2. Slit dam (comb dam): Depending partly on the spacing of the posts, the slit dam can keep larger clasts (cobbles and boulders) behind the dam, thus preventing damage downstream [4]. See Figure 2 for example.
3. Groundsill works: A groundsill work is constructed across the waterway to prevent riverbed degradation. See Figure 3 for example.
4. Revetment: Revetment are sloping structures placed on the banks of a river in such a way as to absorb the energy of incoming water. See Figure 4 for example.

Figure 1. Concrete gravity dam

Figure 2. Slit dam

Figure 3. Groundsill works

Figure 4. Revetment

2.2 BIM applications in Civil Engineering

BIM has been mostly used in building projects. Only very few BIM applications are in Civil Engineering. For example, considering that BIM remains a relatively underutilized tool in horizontal construction, Fanning, et al. [5] implemented BIM on bridge construction projects. In their study, BIM may have provided approximately 5–9% cost savings during construction by contributing to reduced change orders and rework. Additional and potentially significantly greater benefits may be realized through future BIM-enabled operation and maintenance of such infrastructure.

2.3 Augmented reality (AR) and BIM

Augmented reality (AR) and Virtual reality (VR) and are two categories of visualization techniques. AR preserves the user's awareness of the real environment by integrating the real world and the virtual contents in a mixed 3D space, while VR replaces the user's physical world with a totally synthetic environment and isolates the user's sensory receptors from the real physical world [6].

There are two types of simple augmented reality: marker-based which uses cameras and visual cues, and marker less which use positional data such as a mobile's GPS and compass [7].

Wang et al. [8] provided examples how BIM and AR can be integrated and used on site. In general, AR can visualize as-planned BIM facility information right in real-world jobsite to enable project participants to review the as-built progress against as-planned.

2.4 Virtual reality (VR) and BIM

Visualization can improve a user's cognition and help communication in discussing an abstract concept or physical object to real-world situations. Virtual reality (VR) is an immersive multimedia technology that uses VR headsets to create realistic images, sounds and other sensations to simulate a user's physical presence in a virtual environment and interact with digital objects in real time.

As indicated by Du et al. [9], most VR applications in design and construction problems must start with an established design deliverable in a form of CAD or BIM. Considering that there is a lack of automated data transfer approach between BIM and VR, Du et al. [9] proposed a BIM-VR real-time synchronization system to update BIM model changes in VR headsets automatically and simultaneously.

3 Proposed system

The proposed system aims to integrate BIM, AR and VR to provide 3D visualization and information accessibility to facilitate the branch- and home-bureau engineers in managing SWC construction projects. Additionally, the proposed system is operated in a mobile device and cloud environment.

Figure 5 presents the framework of the proposed system which consists of four parts: (1) developing SWC facility BIM model and terrain BIM model, (2) integrating BIM and AR, (3) integrating BIM and VR, and (4) developing construction management modules (including quality and safety management modules).

3.1 Developing SWC facility BIM model and terrain BIM model

Executing a SWC construction project consists of the construction of main SWC facilities (such as check dams, slit dams and ground sills) and other appurtenant construction work (such as drainage facilities) which are all located in the jobsite. Thus, a complete BIM model for SWC construction project preferably integrates both SWC facility BIM model and terrain BIM model. This study applies the Autodesk Revit software package to build the BIM model for the SWC facilities (such as slit dams and ground sills). The level of development (LOD) of this BIM model is LOD 300 [10]. That is, each BIM model element (such as slit dam, groundsill work, and revetment) of SWC facility is graphically represented in terms of quantity, size, shape, location, and orientation. Additionally, non-graphic information (such as specifications and unit prices) can be also attached to each element.

In developing a terrain BIM model is comparatively complex. This study uses the digital surface model (DSM) (representing the earth's surface in which the construction project is located) to build a terrain BIM model. To do so, this study write a series of matlab equations to support the transfer of the DSM data (representing the coordinates and elevation for each location point) which are in ASCII format to the data which are in comma separated values (CSV) format. Such a CSV format file can then be read by Revit for producing a terrain BIM model [11].

3.2 Integrating BIM and AR

This study uses a AR model to interconnect to corresponding segmented BIM model and associated information (e.g., design dimensions, quality specifications, etc) of each part (e.g., could be the part of comb dam, groundsill work, etc) of the SWC construction project. Then, the jobsite engineers can scan the AR makers (related to particular AR models) by mobile devices to visualize the 3D design objects and retrieve required information.

The above integration is carried out by the following three steps: Step 1 transfers the BIM model in .fbx format so that Autodesk 3Ds Max software can read and render. Step 2 builds the AR model by Unity 3D software and developing the relationships between the AR makers the corresponding segmented BIM model. Step 3 uses Unity 3D to attach information to the AR model and save in .apk file format so that a mobile device can read the AR model.

For reading AR model from mobile device, the camera lenses of the mobile device will catch the AR markers' 2D image, and then interpret the marker detection to create the AR model.

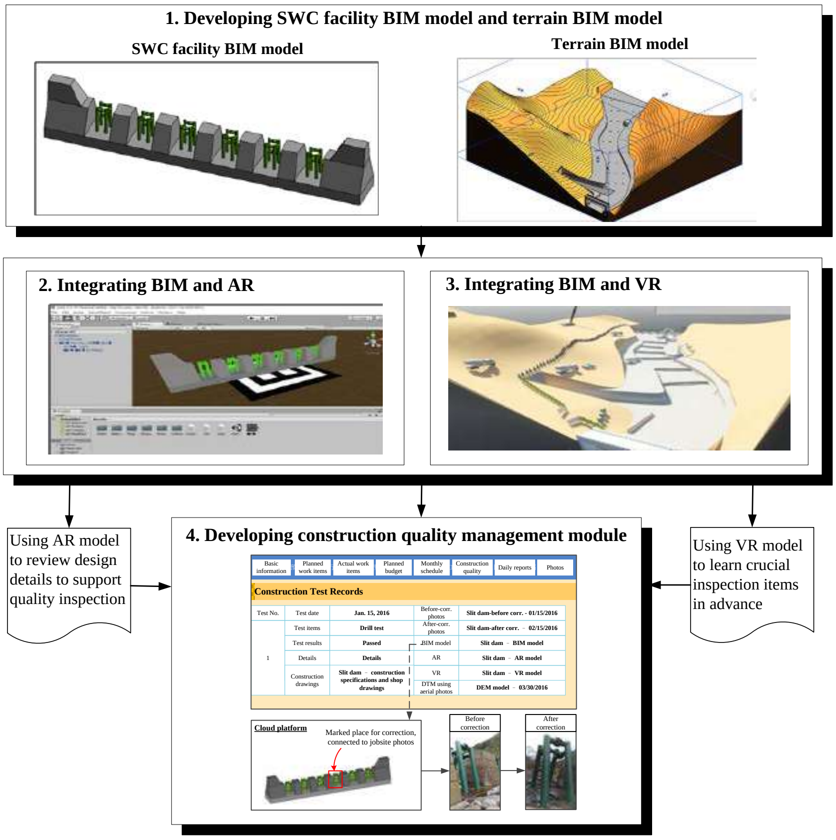

Figure 5. Framework of the proposed system

3.3 Integrating BIM and VR

The proposed system applies a 3D rendering engine called "Enscape" which can be plugged in Revit. Integrating BIM and VR is conducted by the following three steps: Step 1 is to open Revit which has possessed the Enscape functions. Step 2 activates Revit's Enscape function to transfer the BIM model into VR model. Step 3 is to view the VR model from computer screen or VR glasses.

3.4 Quality management module

The current system collects the quality management data of the "sampling inspection records" (including data of inspection date, sampling items, and results) and "quality audit records" (including data of audit date, performance score, A/E defects, and contractor defects). All these data are numbers and texts.

By integrating the current database system with the AR, VR and BIM, the proposed quality management module provides the following five functions (Q1~Q5) in supporting construction quality management: (1) using BIM model to review the quality correction results, (2) accessing information readily, (3) using AR to review design details to support quality inspection, and (4) using VR to learn crucial inspection items in advance.

4 Case study

The proposed system is applied to a case project located in Northern Taiwan. This project consists of the following main SWC facilities: a set of steel-pipe-type slit dam, six sets of arc-shape drop structure, 1,100 meter of revetments, and 1,385 square meters of masonry boulders. The contractual duration and price of the project are 300 calendar days and around US $1,248,000 US dollars (37,450,000 NT dollars), respectively. Figure 6 displays the bird view of the jobsite and Fig. 7 shows the steel-pipe-type slit dam of this project.

Notably, this case study is the after-the-fact analysis to demonstrate the feasibility of the proposed model.

Figure 6. Bird's view of case project

Figure 7. Steel-pipe-type slit dam of the case project

4.1 Developing SWC facility BIM model and terrain BIM model

4.1.1 Developing SWC facility BIM model

A complete BIM model integrates two BIM models of SWC facilities the terrain. Four steps are conducted to develop the SWC facilities BIM model. The following uses the steel-pipe-type slit dam for example.

1. Step 1: developing slit dam (or comb dam) templates. Drawing a plane section to be a template for representing the cross section of slit dam, as shown in the left of Fig. 8.
2. Step 2: defining parameters to describe slit dam. In the template, parameters, such as the height, the width on the top, the width on the bottom, the width of anti-sliding tenon, and so on (as displayed in the right of Fig. 8), and used to depict the slit dam. Thus, a user can develop a BIM object of slit dam by simply specifying the scale numbers of those parameters and the length of the slit dam.
3. Step 3: developing BIM objects of the steel pipes. That is, repeating Step 1 and 2 can build the steel-pipe templates and define parameters to depict the steel pipe.
4. Step 4: integrating the slit dam BIM objects and steel pipe BIM objects to generate the steel-pipe-type slit dam, as shown in Fig. 9.

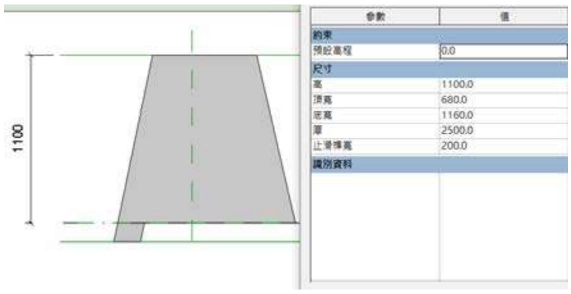

Figure 8. Using parameters to define the slit dams

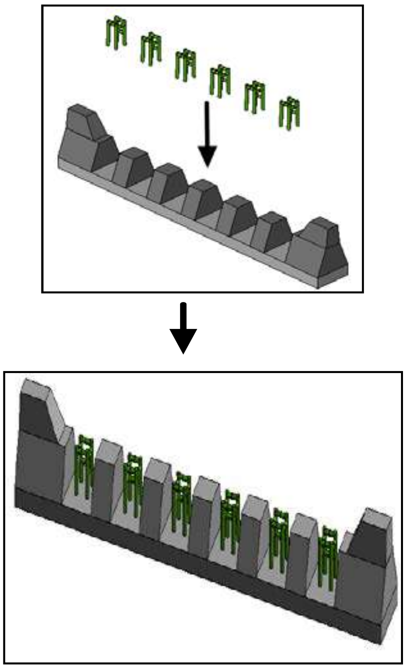

Figure 9. BIM objects of the steel-pipe-type slit dam

4.1.2 Developing terrain BIM model

Then, according to the steps described in Section 3.1, the proposed system generates a BIM model of the terrain in which the case project is located. Figure 10 presents the complete BIM model integrated with SWC facilities and terrain for the case project.

Notably, while each the SWC facility (such as slit dam and ground sill) can contain its geological information or data (such as design dimensions and construction specifications), the terrain can also carry with relevant information or data (such as the governmental regulations of the terrain, and the information of ecological sensitive areas)

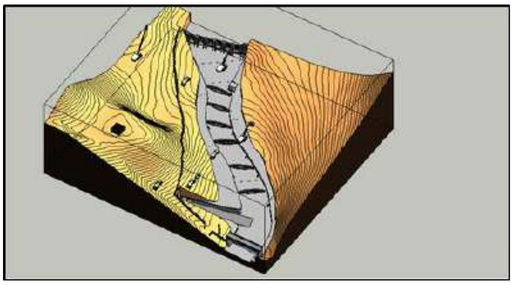

Figure 10. Complete BIM model integrated with SWC facilities and terrain for the case project

4.2 Integrating BIM and AR

After the proposed system develops the BIM model of both SWC facilities and terrain, the system follows the steps described in Section 3.2 to integrate the BIM model and AR for the case project. Figure 11 shows the BIM model that is read by Autodesk 3Ds Max software (Step 1 in Section 3.2). Figure 12 presents the screenshot of the AR model for the jobsite overview of case project.

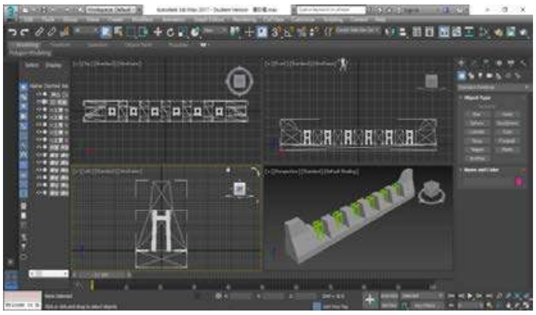

Figure 11. BIM model imported into 3Ds Max

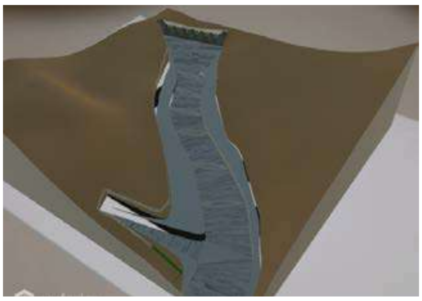

Figure 12. AR screenshot of the jobsite overview

4.3 Integrating BIM and VR

The proposed system applies a 3D rendering engine called "Enscape" which can plug in Revit. That is, the system uses Enscape to transfer the established BIM model to VR model. Figure 13 presents the VR screenshots of the jobsite overview, construction fence, and falsework of the case project, respectively.

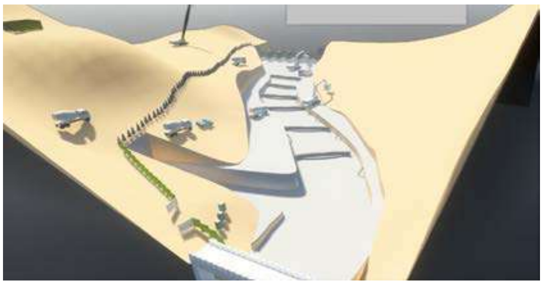

Figure 13. VR screenshot of the jobsite overview

4.4 Construction quality management module

Based on the integrated BIM model, AR model, and VR model, the construction quality management modules can support the following quality control activities:

1. Using the BIM model to support review the quality correction results. This can be carried out by evaluating the quality-correction photos, specifications, quality inspection/testing records which are retrieved from to the BIM model. See Figure 14 for example.
2. Accessing quality information readily. An engineer can visualize the 3D model and view/download project documents in the cloud device or in mobile devices for supporting communications.
3. Using AR model to review design details to support quality inspection: An AR model provide both 3D visualization and design information by scanning an AR maker for comparing the planned and actual conditions for a particular construction object in the jobsite. See Figure 15 for example. An AR model can be applied especially in the suburbs where a SWC construction project is usually located and internet is not available. This is because an AR maker represents a particular AR model which corresponds to a specified portion of BIM model and associated information (see Section 3.2). Hence, a mobile device can activate each AR model by scanning the AR marker without the need of internet.

Using VR model to learn crucial inspection items in advance: Before conducting field quality inspections, a VR model with 3D and information can be walked through freely in the office to get acquainted with the construction project and learn the crucial inspection items in advance. Such a walk though with marked notes can also be recorded in a file for educating young engineers. A recorded VR file can be viewed from a mobile device in the jobsite. Figure 16 displays the snapshot using VR for the case project.

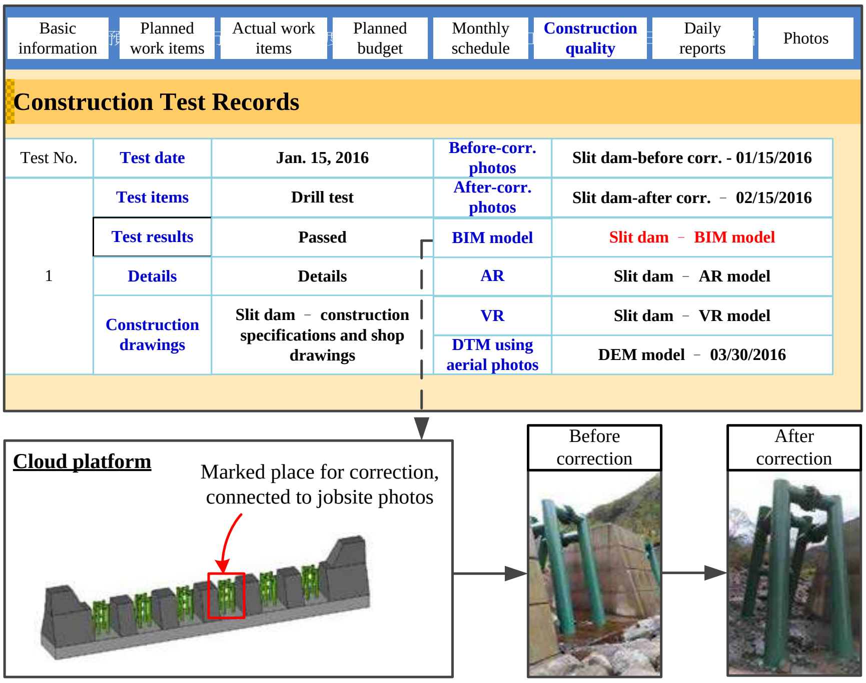

Figure 14. Using BIM model to support review the quality correction results

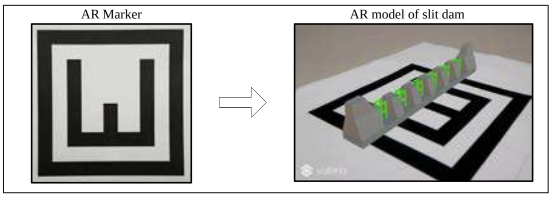

Figure 15. Using AR to review design details to support quality inspection in the field

5 Discussions

During the course of this study, several governmental engineers are appreciated of the proposed system's benefits in providing 3D visualization and easy information accessibility to support construction quality and safety management of the SWC construction projects. However, several difficulties of future implementation of the system are also raised. Their feedback can be summarized as follows:

First of all, insufficient budget available to perform new technologies for each contractor and designer is an obstacle to implement the proposed system. According to 839 SWC projects performed during 2014 and 2016 in Taiwan, the average contractual cost of each project is only about US$200,000, which is relatively small comparing with building projects. Assuming that 0.5% of averaged construction costs is budgeted for adopting these new technologies mentioned here, only US$1,000 (=200,000x0.5%) is available, which is mission impossible. Hence, additional budgets must be provided to support contractors and designers.

Secondly, insufficient capability to conduct new technologies is another obstacle herein. As can be found, most designers and contractors involving in these small-scale projects are often from small- or middle-size firms and are unacquainted with BIM, AR and VR. Thus, training those designers and contractors for using these new technologies is needed. Listing the capabilities of using these new technologies as one pre-qualification for bidding could be a solution for overcome the obstacle here.

6 Conclusion

This study applies BIM, AR and VR to develop a new construction management system to support the government bureaus in managing numerous SWC construction projects. The proposed system built in a cloud environment provides 3D visualization model and access project information from mobile devices.

The case-study results are appealing. However, additional budgets and training must be provided to encourage those middle- or small-size designers and contractors for adopting the proposed model.

Besides the future research directions discussed in Section 5, additional future research may include applying the proposed system to the maintenance/ operation project phase. Although this study focuses on the applications of construction phase, the proposed model should have greater benefits in the maintenance/ operation project phase. For instance, Moreover, the graphic and non-graphic information provided by the proposed model (integrating BIM, AR, and VR) may be useful for government officers in evaluating the conditions of SWC facilities after the occurrence of natural disasters (such as earthquakes or floods).

Embodied Energy Assessment of Building Structural Systems Using Building Information Modeling

H. Zhou[a] and E. Rezazadeh Azar[a]

[a] Department of Civil Engineering, Lakehead University, Canada
E-mail: hzhou2@lakeheadu.ca, eazar@lakeheadu.ca

Abstract

Buildings contribute to socio-economic development of the human societies, but they are also among the main consumers of energy and contributors to the greenhouse gas emissions during their lifecycles. The construction phase of building projects is typically recognized for substantial use of natural resources and energy consumption. Steel, reinforced concrete, and engineered wood are the most common structural materials used in the Canadian construction industry. The environmental impact of the structural material is typically overlooked mainly because the industry lacks a documented assessment framework. There were some research efforts that studied energy consumption of the construction phase of building projects, but they mostly used a large number of complex calculations to estimate the consumed energy and emission. This paper introduces an innovative framework for the environmental assessment of the construction of building structural systems. This method uses a building information modelling platform to automate data extraction and then links them to certain databases to calculate embodied energy and emissions. This framework considers production, transportation, wastage, and installation/construction processes to calculate the impacts. An experimental study was carried out on two residential buildings, with a similar layout but different structural systems, to evaluate the practical use of this framework. It demonstrated a straightforward method to estimate embodied energy and emission of the structural system using the BIM model of the design. Similar to other studies, the manufacturing phase has the greatest impact on the embodied energy and emission of a building structure.

Keywords –

Embodied energy; Embodied carbon; Building information modelling; Structural system

1 Introduction

Buildings use energy either directly in the construction, operation, maintenance, renovation, and final demolition, or indirectly in the initial production of the construction materials, consumables, and other embodied energies [1]. Operational energy (OE) and embodied energy (EE) are the two types of energy consumption in buildings, where the embodied energy includes the energy used in extraction, manufacturing, transportation, and construction of building elements, and the operational energy covers with range of energy types used for operation of a building (e.g. lighting, and heating and cooling). It is estimated that the direct energy used in buildings is about 30%-40% of all primary energy, which results in 40%-50% of total GHG emissions [2].

Although operational energy constitutes 80%-90% of the total energy consumption of a building in its lifecycle [3], the embodied energy of the construction phase still can have a considerable environmental impact. Structural system is estimated to have the largest portion (more than 50%) of the total embodied impact of a building [4-5]. Several selection criteria, such as cost, speed of construction, mechanical performance, and availability of the material are usually considered to choose a certain structural system; however, the environmental impact is usually ignored [6].

A number of studies investigated the embodied energy and embodied carbon while using different structural materials and systems. The scopes and viewpoints of these studies, however, were different. A research stream assessed the impact of different structural materials and systems through the entire lifecycle of buildings using lifecycle assessment (LCA) framework. They commonly reported that the energy use in the operation phase has the greatest portion [7-8]. Another group of research efforts focused on the embodied impacts of different structural systems in the construction stage. The embodied carbon (EC) of the structure can vary by up to 18% in different subclasses of steel- and concrete-framed structures with different number of floors [6]. The finding of case studies in Italy

[9] and Iran [10] revealed that the embodied energy of the steel-framed buildings is usually greater than the reinforced-framed structures. Application of high-strength concrete instead of regular concrete could also reduce energy consumption and CO_2 emission in the construction phase [11]. There was, however, a research study that showed similar embodied carbon levels in three steel and concrete-framed buildings (about 200kg CO_2/m²), and it was argued that the embodied carbon of the medium rise buildings with regular geometry and no basement is around this value. There are, however, opportunities to reduce the embodied impact through careful modifications [4]. Moreover, embodied energy of particular structural elements such as slabs [12] and beams [13] were investigated.

Although most of these studies reported a lower total embodied energy for concrete-framed buildings compared to the steel structures, on-site construction of cast-in-place concrete requires greater on-site equipment and labor efforts, which in turn results in larger amount of on-site energy consumption and emission [14-15].

Cost, speed of construction, stakeholder requirement, and availability of the material and skilled labor are typically considered during the selection process of a structural system for a building project. Embodied energy and carbon of the alternatives, however, is not usually ignored. Lack of an easy-to-use and documented assessment framework is a reason for this, because the research efforts on this subject used a large number of manual calculations for different processes to obtain the results. Building information model (BIM) of a project contains variety of information for different building components, which can be used to develop an automated embodied energy assessment system for different structural systems. Certain attributes of structural elements, such as material type, and geometrical and spatial data, could be extracted and used to estimate the embodied energy of the building components. There are a number of BIM-based systems for lifecycle assessment and modelling of the operational energy usage of buildings [16-17]; but only a few research efforts exclusively employed BIM for embodied energy estimation of the construction phase. For example, automated quantity take-offs (QTO) from a BIM model were mapped to embodied energy [18-19] and CO_2 databases [18] to estimate the embodied energy and carbon of building projects. The scopes of these methods, however, are limited to the manufacturing processes and they do not estimate the impact of transportation and on-site construction processes.

This paper presents an innovative BIM-based framework to estimate the embodied energy and carbon of the construction stage of different structural systems. The scope of this framework covers the construction phase, which includes the manufacturing of the structural material, transportation, and onsite installation/construction. This system extracts structural elements and their properties from a BIM model, and then estimates manufacturing, transportation, and onsite construction energies using a created model, defined databases, and user inputs.

2 Methodology

The architecture of the proposed system is presented in Figure 1. The first module of the system extracts the required data from a BIM model. Then the calculation model sorts elements' attributes and maps them to the corresponding energy and CO_2 inventories to estimate the impacts of production/manufacturing, transportation, and construction phases of the potential structural systems.

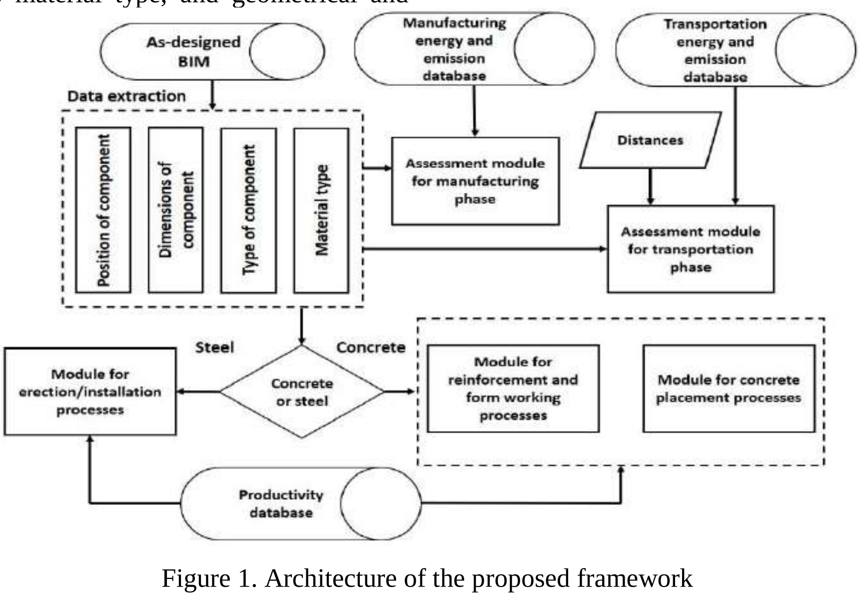

Figure 1. Architecture of the proposed framework

2.1 Data Extraction from BIM

Accurate quantity estimation from the design is essential in the construction industry [20], and this data are also necessary for environmental impact assessment. Completeness and accuracy are the most important factors in QTO and getting reliable estimates requires detailed model of a building project. Most BIM platforms have an automated QTO tool which calculates work quantities by extracting properties of building elements, such as material type, size, volume, space area, location, and weight, from the BIM model and reports them to the user-defined tables [21]. It is also possible to extract attributes of the elements' directly from an Industry Foundation Classes (IFC) file [21]. This module uses a script to extract all the main structural elements (i.e. columns, beams, bracing, floor slabs, and shear walls) and some of their main properties, including material type, and geometrical and spatial data.

2.2 Assessment Model for the Manufacturing Phase

Calculation of energy consumption during the manufacturing phase is mainly based on the embodied energy of the structural materials. The database of Inventory of Carbon and Energy (ICE) was used for the manufacturing embodied energy and carbon [22]. Table 1 shows the embodied energy and carbon coefficients of the main structural material.

Table 1. Embodied energy and carbon coefficients [22]

Materials	Embodied Energy(EE) (MJ/kg)	Embodied Carbon(EC) (kg CO_2e/kg)
Steel	20.1	1.46
Glulam	12	0.42
Concrete	0.88	0.132
Rebar	17.4	1.4
Plywood	15	0.45

The overall manufacturing embodied energy and embodied carbon of the structural system are calculated using Equations 1 and 2, respectively.

$$EE_m = \sum m_i EE_i \tag{1}$$

$$EC_m = \sum m_i EC_i \tag{2}$$

where EE_m = overall energy used in material manufacturing process; m_i = mass of elements i needed in the building; EE_i = embodied energy coefficient of material i; EC_m = overall embodied carbon during manufacturing phase; and EC_i = embodied carbon coefficient of material i.

It is common to have some level of material waste in the building construction process for various reasons, including the need to extract uniquely shaped building elements from standard-sized manufactured items, defects in products, poor handling, and damage to material during delivery. The wastage should be considered in the estimation of embodied energy and is commonly calculated as a percentage of the required amount of material. The waste factor depends on the type of building materials and the waste factors for the main material were considered as: 0.05 for steel and 0.025 for concrete and timber [23].

2.3 Assessment for the Transportation Stage

The differences in the embodied energy of material transportation are attributed to size, type, distance, and the quantity being transported [11]. The type of vehicles can also affect energy consumption in the transportation stage, which can complicate the estimation process. Some of the previous LCA studies ignored transportation or simplified the problem by assuming direct travel from the manufacturing plant to the jobsite. However, it is common for the manufactured structural materials, such as steel and timber elements, to go through several distribution centers before arriving at the construction site. Loading and unloading processes in each distribution center consume energy, which are considered in this study.

Energy consumption and CO_2 emission factors reported by Hong et al. [24] were used for the material transportation vehicles. To simplify the estimation process, GHG emission factors were converted to carbon dioxide equivalent (CO_2e), based on the global warming potential (GWP) of each form of greenhouse gas, where the GWP for carbon dioxide is 1, for Methane is 25, and for Nitrous oxide is 298 [25].

Both haul and return trips between the manufacturing plant/distribution center and construction site were considered by this system. It was estimated that the energy consumption and emissions in empty return trips is about 66% of the value of full-load trips [26]. Moreover, the energy consumed for loading/unloading in distribution centers were considered in transportation of steel, rebar, and forms, which were calculated similar to the lifting process of the erection stage (described in the next section). Energy usage and GHG emissions of transportation stage were calculated using equations 3 to 6.

For concrete:

$$E_t = 1.66 \sum m_i EE_i^t . D_i \tag{3}$$

$$GHG_t = 1.66 \sum m_i EC_i^t . D_i \quad (4)$$

For steel and Plywood (forms) products:

$$E_t = 1.66 \sum m_i EE_i^t . D_i + n. E_{LP} \quad (5)$$

$$GHG_t = 1.66 \sum m_i EC_i^t . D_i + n. EC_{LP} \quad (6)$$

where E_t = energy consumption during transportation; GHG_t = CO_2 equivalent emissions during transportation; m_i = weight of material i (including waste); EE^t_i = Energy consumption per kilometer per ton of material i; EC^t_i = CO_2 equivalent emissions per kilometer per ton of material i; D_i = Distance traveled between the origin and destination of material i; n = number of distribution centers; E_{LP} = Energy consumed for material handling process in a distribution center; EC_{LP} = Emission of material handling process in a distribution center.

2.4 Assessment Model for the Onsite Construction Stage

There are specific construction equipment and methods for onsite construction of different structural systems. Energy consumption during onsite construction, e.g. erection and installation, is represented by the energy used by various pieces of construction equipment. Mobile cranes are commonly used for material delivery in steel- and wood-framed buildings, and a concrete pump or a crane is employed for concrete pouring in low- to mid-rise concrete buildings. Mobile cranes are also used for delivering rebars and forms to the installation location in the concrete-framed structures.

Equipment working hours were the basis to estimate energy consumption and emission of the onsite construction operations. The energy consumption of the equipment is calculated using equation 7.

$$E_{equipment} = \sum E_i = \sum T_i \times ECF_i \quad (7)$$

where E_i = Energy usage of equipment i; T_i = Working hours of equipment i; ECF_i = Energy consumption factor of the equipment i (MJ/h).

The first step is to calculate the energy consumption factor of the envisioned equipment. A calculation model (see Equation 8) was adopted from Food and Agriculture Organization [27] to estimate the rate of fuel consumption per machine-hour for each equipment type.

$$LMPH = \frac{K \times GHP \times LF}{KPL} \quad (8)$$

Where LMPH presents liters used per machine hour; K is the rate of fuel consumed per hp/hour in kg; GHP is the gross engine horsepower; LF is the load factor in percent; KPL is the fuel density in kg/liter.

Given gross engine horsepower (GHP) of the selected equipment and the related values in Table 2 [27], fuel consumption of the machines (LMPH) were estimated. Then, the energy and emission conversion factors of diesel and gasoline [25] were used to estimate energy consumption and emissions (see Equations 9 and 10).

Table 2. Weight, fuel consumption rates, and load factors for diesel and gasoline engines

Engine	Weight (KPL)	Fuel Consumption(K)	Load Factor(LF)		
	kg/liter	kg/brake hp-hour	Low	Med	High
Gasoline	0.72	0.21	0.38	0.54	0.7
Diesel	0.84	0.17	0.38	0.54	0.7

$$ECF = LMPH \times Energy\ coversion\ factor \quad (9)$$

$$EF = LMPH \times Emission\ conversion\ factor \quad (10)$$

Where ECF is the energy consumption factor and EF is the emission factor.

2.4.1 Equipment Working Time

Mobile crane operations include two processes: (1) Lifting process; (2) Installation process.

There are five motion types in a lifting process: hoist down for the element, hoist up with the load, slew with the load, hoist down the load, and slew without load. One piece of structural element is carried in each cycle. The lifting time (T_{LP}) is the total duration of the five operations. Duration of each motion was calculated based on the slewing and hoisting speeds of the selected mobile crane, the lifting height, and the angle between the component loading area and the installation position (please see [28] for details). The spatial data of each structural element were used to obtain the last two pieces of information, which were extracted from the BIM model (See Figure 2).

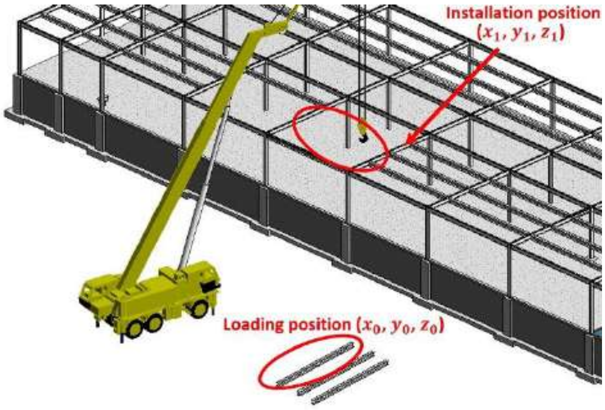

Figure 2. Sample 3D view of the spatial data for lifting of each element

Given the lifting process duration, the energy consumed in the lifting process (E_{LP}) was estimated as: $E_{LP} = T_{LP} \times ECF_{Crane}$.

In addition to the lifting time, the crane has to keep the component in its installation position until the crew initially fix it. The system calculates the installation time (T_{IP}) based on the productivity of the crew, which were obtained from RSMeans construction cost data. Given the installation process time, the energy consumed in the process (E_{IP}) was estimated as: $E_{IP} = T_{IP} \times ECF_{Crane}$.

Additional processes are required in the construction of concrete-framed structures (e.g. form working and rebars). If the reinforcement details exist in the BIM model, the system is able to extract them. Availability of such data, however, depends on the required level of details (LoD) and some BIM models might not include them. This system calculates formwork materials using the geometrical data of the structural component extracted from the BIM model. A mobile crane is considered for delivery of formworks and rebars, which has two types of processes: lifting and installation operations. The lifting efforts were estimated similar to the lifting of steel elements and the installation times were calculated using RSMeans.

A mobile concrete pump was selected for concrete placement in this model. The working time of the concrete pump (T_P) for each component was estimated by dividing the concrete volume of the element by the crew productivity (using RSMeans database). Given the concrete placement time, the energy consumed in this process (E_P) was estimated as: $E_P = T_P \times ECF_{Pump}$.

3 Case Study

A reinforced concrete and a steel-framed residential building with rather similar layouts were used to assess the developed system. Both of the buildings include three stories and ground level, where the total gross floor area of the concrete- and steel-framed buildings were 5,490.7 m^2 and 4,934.6 m^2, respectively. Concrete building had a one-way slab flooring system and the steel-framed structure had composite steel decks.

3.1 Quantity Take-off

Both designs were modelled in the Revit environment. The required element attributes, including length, width, volume, location, reinforcement volume, and customized shared parameters, namely formwork area, were extracted from the models.

3.1.1 Implementation of the Manufacturing Phase Model

Embodied energy and emission values for the manufacturing phase are calculated by multiplying the quantities of materials, including wastage, and corresponding embodied energy and carbon coefficients (see Equation (1) and Equation (2)). Figure 3 illustrates the embodied energy and emission values of the different materials used in the two studied structures. It is evident that the manufacturing embodied energy of the steel structure is larger than the concrete structure. The embodied carbon of the concrete structure, however, was larger than the steel-framed one. This is mainly due to the much greater ratio of the embodied carbon to embodied energy of concrete compared to steel (See Table 1). Because, large amounts of CO_2 are released during production of cement due to high temperature of clinker production as well as the CO_2 release in chemical reactions.

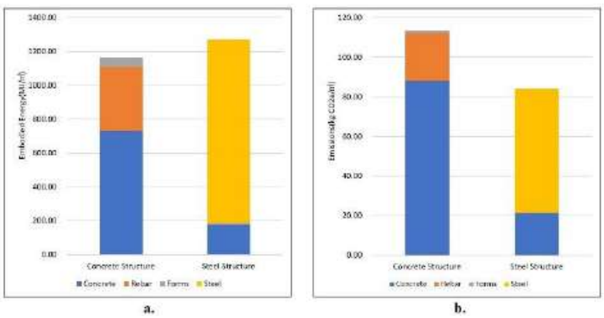

Figure 3. Results of the assessment of manufacturing phase of the studied buildings for: a) embodied energy; b) embodied carbon

3.1.2 Implementation of the Transportation Phase Model

This case study assumed 1000 km, 2000 km, and 3000 km distances for transportation of steel and rebar products, with the number of distribution centers varying from zero to three. For the concrete components, 25km transportation distance was assumed, because fresh concrete is a locally-sourced material. These numbers can be altered by the user.

Energy consumption and GHG emissions in the transportation stage were calculated by applying energy consumption and GHG emission factors of the selected vehicles and the quantity of materials in equations (3), (4), (5), and (6). Figure 4 shows the variation of the embodied energy and emissions values in the transportation stage with changes in transportation distance and the number of distribution centers. These figures show that the growth rates of embodied energy and emissions of the concrete structure are both higher than that of the steel structure, which means that the impact of the number of distribution centers for rebars and formworks on the concrete structure is greater than it is on the steel structure.

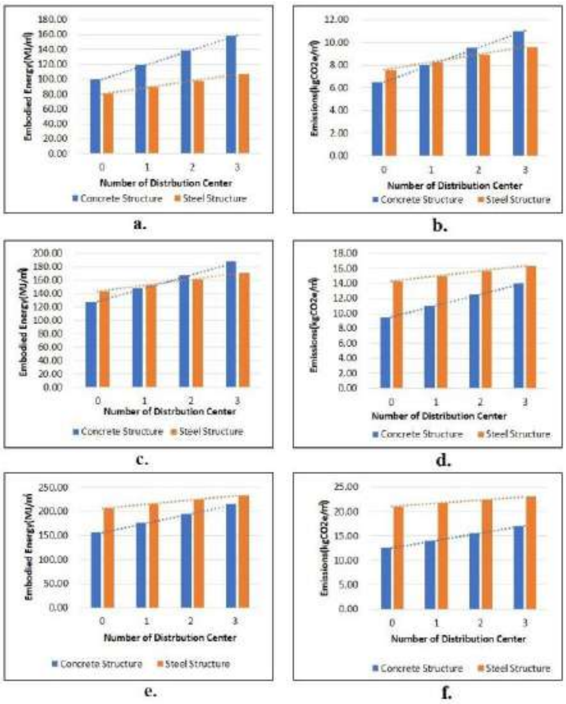

Figure 4. Embodied energy and carbon in the building structures during transportation stage: a) EE in 1000 km; b) EC in 1000 km; c) EE in 2000 km; d) EC in 2000 km; e) EE in 3000 km; f) EC in 3000 km

3.1.3 Implementation of the Onsite Construction Model

This module of the system estimates the onsite energy consumption by multiplying equipment working hours and energy consumption factor. A 30 t mobile crane with engine power of 164hp, maximum hoist speed of 136 m/min, and maximum slewing speed of 2 RPM was considered for lifting processes in this case study. A truck-mounted boom pump with a 395hp engine was selected for concrete pouring operations. The hoisting and slewing speeds were assumed between 40% and 60% of the maximum speeds. The swing angles (between loading area and installation position) of 90° to 105° were assumed for component delivery. Figure 5 shows the results of this phase, in which the concrete structure sample resulted in greater energy consumption and emissions than the steel-framed building (See Figure 5).

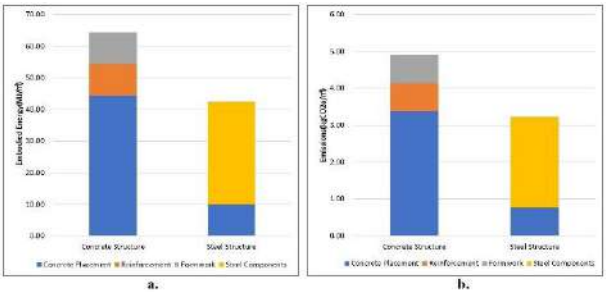

Figure 5. Results of the assessment of erection/construction phase of the studied buildings for: a) EE; b) EC

4 Discussion

The findings of this the study showed that application of different structural systems in a building project could result in different embodied energy and emissions. The manufacturing phase has the highest portion of the total embodied energy in both structural types (81%-91%). The results of this research were close to the ranges that were reported by other studies [6 and 29], but there are some differences (see Table 3). For example, the embodied energies differ from the results reported in [10]. One main reason was the difference between the energy inventories, in which their database included larger values for material and transportation. This is an important consideration, because production technologies and methods vary in different countries and should be adjusted in assessments.

Table 3. The estimated EE and EC of the concrete and steel structures studied previously

Research	Embodied energy and embodied carbon during construction			
	Embodied Energy (MJ/ m^2)		Embodied Carbon (kg CO_2-e/ m^2)	
	Concrete Structure	Steel Structure	Concrete Structure	Steel Structure
[29]	328-678	1419-2976	-	-
[6]	-	-	153-168	153-163
[10]	1720-3580	2540-4180	-	-
This study	1400-1520	1463-1624	163-175	125-142

In addition, the results were compared against the results of manual assessment by two groups of senior Civil Engineering students. The results for the manufacturing and transportation phases had the lowest difference, which were 3.8% and 4.5% for steel and concrete structures, respectively. But the estimation of the embodied energy for the erection/installation phase had larger differences, which were 7.2% and 10.7% for steel and concrete structures, respectively. These larger differences were due to large number of parameters and assumptions needed for the erection/installation process, whereas the values in manufacturing and transportation phases mainly depend on QTO and delivery distances that have less uncertainties.

This system, however, has some limitations. First, the LoD of model (e.g. reinforcement details) could have a significant impact on the accuracy of the results. Second, data inventories for material production and transportation are different in different locations, because employed technologies and methods vary in locations and they should be modified accordingly. Third, transportation data, such as the distances and the number of distribution centers might not be easily obtained in some practical cases.

5 Conclusion

A BIM-based framework was developed to estimate the embodied energy and carbon dioxide equivalent emissions of building structural systems. Different energy and emission calculation models were developed and data inventories were used for different construction phases of structural systems. This system automatically extracts required data from a BIM model and links the calculation model to the databases. A case study on a concrete and a steel-framed building showed that the type of structural system could result in a significant difference in the embodied energy and the emission of a building. It was also found that the energy consumption of the manufacturing phase has the greatest impact on the overall embodied energy of a structural system. In the transportation stage, the energy consumption is affected by the material transportation distance and the number of distribution centers. Finally, concrete-framed building consumed more energy than the steel structure in the onsite construction phase.

The future research will investigate the impacts on other building components, such as architectural, mechanical, and electrical elements.

Abstract –

Despite the rapid development of reality capture technologies and progress in data processing techniques, current visual strategies for defect surveying are time consuming manual procedures. These methods often deliver subjective and inaccurate outcomes, leading to inconsistent conclusions for defect classification and ultimately repair needs. In this paper, a strategy for monitoring the evolution of ashlar masonry walls of historic buildings through reality capture, data processing (including machine learning), and (H)BIM models is presented. The proposed method has been tested, at different levels of granularity, in the main façade of the Chapel Royal in Stirling Castle (Scotland), demonstrating its potential.

Terrestrial Laser Scanning; Data Processing; Surveying; HBIM; Ashlar

1 Introduction

Whilst traditional approaches to defect identification and analysis are widely utilised, their results have been empirically shown to frequently yield subjective results and mis-classification [1][2]. Attempts to enhance accuracy have been sought in the use of unifying standards and the creation of a 'common language' for the classification of masonry defects [3]. The difficulties faced by surveyors in meaningfully attempting to accurately and rapidly identify defects make the process extremely time-consuming and therefore problematic when 'upscaling' the survey operations from individual masonry units, within localised regions, to complete façades and ultimately entire buildings. On a more fundamental level, the inability of traditional survey to facilitate the labelling of individual masonry units is of significant concern. Yet, all analysis and intervention flow from accurate initial identification of individual materials and components [4]. Indeed, best practice guidance in the conservation sector [5] proposes that those undertaking visual survey and evaluation of historic masonry fabric adopt detailed pictures of the defective areas that can be supplemented by additional information such as measured dimensional survey and a rudimentary process of manually 'marking up' the images with alternative colours denoting different defects. When seen from the perspective of time, cost, accuracy and reproducibility/transferability, these proceses are increasingly untenable.

More recently, novel reality capture technologies, such as Terrestrial Laser Scanning (TLS) or photogrammetry, deliver coloured dense point clouds which can be used to support surveying activities, such as the identification and semantic labelling of the structural and non structural components. Regarding the digitisation of historic buildings, examples of the use of laser scanners include the work of Wilson et al. [6] which illustrates the potential of this technology with several UNESCO heritage sites.

Beyond the sole recording of buildings and other constructions, the unstructured point clouds produced by these devices can also be used for the generation, and subsequent management, of semantically rich digital representation of buildings [7].

In addition to reality capture technology, Building Information Modelling (BIM) is an effective digital approach to the whole lifecycle management of buildings. Besides new construction, for which BIM is used from the conception stage, BIM can be also applied to historic buildings, where it can play a particularly important role in operational maintenance and repair activities. BIM applied to the specific context of historic buildings has become increasingly accepted as HBIM [8][9].

Pronounced differences are noted between BIM and HBIM insomuch that in new projects designs are digitally conceived by means of BIM and CAD design tools, while BIM models of historic buildings need to be produced to reflect their existing (i.e. 'as-is') state, increasingly using dense point clouds as a reference. Hichri et al. [7] provide a general review of the stages to be undertaken from point cloud to BIM, in a process now commonly termed Scan-to-BIM. Similarly, Macher et al. [8] present an approach to create 3D models of historical buildings by means of point clouds. The authors divide the building in sub-spaces, model surfaces and fit primitive shapes to architectural elements.

The semantically-rich 3D models produced through Scan-to-BIM processes can subsequently be used as a reference to monitor the effects of deterioration. More specifically, decay or change of primary architectural elements or secondary components, such as walls, roofs, etc., can be tracked by means of the processing of newly acquired 3D coloured point clouds and their comparison with the previous known state of the building recorded in the BIM model, using Scan-vs-BIM processes [10].

1.1 Increasing the Level of Detail (LoD) in Scan-to-(H)BIM

Various researchers and practitioners are introducing HBIM to surveys, taking advantage of the structured digital representations of buildings provided by these models [11] [12]. Dore et al. [13] undertook a Scan-to-BIM process for sections of the Four Courts in Dublin and structural damage and decay simulations were applied for conservation analysis. In addition, Oreni et al [14], presented a case study in which HBIM models were generated for digitally surveying an earthquake affected church prior to restoration. This work is particularly interesting in highlighting their approach to the management and evaluation of ashlar columns, whose blocks are individually modelled and their dimensions considered for potential replacement operations.

However, BIM elements, such as walls, typically obtained with these Scan-to-HBIM approaches, do not contain the granularity of composition that is necessary for a detailed annotation and analysis of typical surveys, or require significant manual work to obtain such level of detail. Indeed, surveys may require delineating wall façade defects as effecting a single stone, a cluster of stones (or wall region), or even a part of a stone. There is thus a need for Scan-to-BIM approaches that can efficiently deliver ‘as-is’ semantically-rich 3D models with such higher LoD – in the case of stone walls, down to the individual stones (and mortar regions).

With the objective of automating these segmentation processes, several authors have recently proposed solutions for the computerised segmentation of images [15] or 3D data [16] of various building elements to support the identification of defective regions. Oses et al. [15] present a semi-automatic process for delineating ashlar in masonry walls in 2D images. Whereas Drap et al. [16] identify clusters of ashlar stones in 3D data. Even if these works propose solutions for dividing structural elements (i.e. walls) into smaller parts, an automated stone-level segmentation process would produce higher LoD representations of walls. Valero et al. [17] previously proposed a method for the automatic segmentation of random rubble from point clouds. However, whilst it is recognised as a significant step forward, that approach is not well suited to ashlar wall constructions for which 3D data alone may not be sufficient to robustly segment the wall data (mortar depth profiles are often too well aligned with stone profiles to easily detect the stone boundaries using this information alone).

1.2 Survey Objectivity

Whilst defects are wide ranging, they have been codified into five primary categories in the ‘ICOMOS glossary of stone deterioration patterns’ [3]. These include: Crack and deformation; Detachment; Features induced by material loss; Discolouration and deposit; and, finally, Biological colonisation. These are the broad categories that have been adopted for this research.

The heterogeneity and sophistication of these catalogued defects make their labelling process complex, even for professionals, who can differ in their analysis. For example, historic building walls are composed of hundreds, and in many instances thousands, of unique units (i.e. stones, bricks…), and can be affected by almost countless defects. Sánchez et al [18] proposed a novel strategy to identify, in point clouds, the deformation and erosion of walls and highlight unit clusters (i.e. areas) affected by decay. Valero et al. [4] have recently proposed the use of geometric and colour-related features from individual masonry units relevant to interpretation or conservation purposes, but that interpretation remained manual.

While these recent works investigate the potential of using point clouds to detect wall defects, these remain preliminary in nature. They do not fully automate defect detection and classification, or do this in a limited way, both in terms of the range of defects being detectable and the depth of the classification/analysis.

1.3 Contribution

This paper aims to address the two needs identified at the end of the previous two sub-sections. We first present a novel Scan-to-(H)BIM approach that automatically segments point clouds of ashlar masonry walls into their constitutive units, i.e. stones, and mortar regions (Section 2). Then, we propose a novel machine learning based approach to masonry wall defect classification, that considers both the geometry and colour information of the acquired point clouds, to classify a selective range of common types of masony wall defects (Section 3). The defects are found in relation to the masonry HBIM element and constitutive units, and so can be recorded in a structured manner within the HBIM model, so that the condition of all architectural components can be effectively tracked over time.

For the theoretical presentation of those two novel contributions, Section 4 reports experimental results obtained using real data. Finally, Section 5 concludes the works and proposes directions of future research development.

2 High LoD HBIM Masonry Wall Element

In this work, principal building elements, such as roof or walls, are referred to as *elements*, that can be subsequently segmented into their constitutive sub-elements, named *units*. These would include bricks or stones in the case of walls (See Figure 1). Furthermore, if several contiguous units are affected by the same defects, these should be recorded and studied as a region. Therefore, we refer to several adjoining units composing regions of interest as *clusters*. Finally, certain defects can affect only parts of a unit. We call such region a *sub-unit* region.

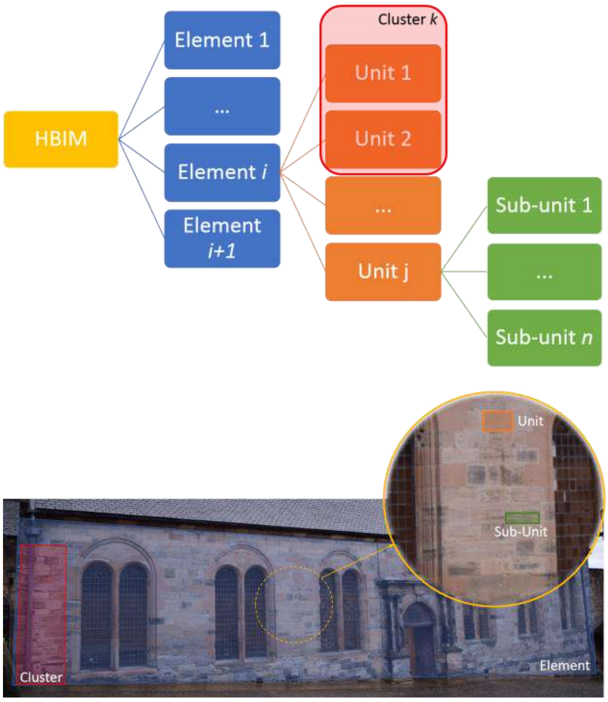

Figure 1. Proposed levels for analysis. Ilustration for a wall

To deliver the hierarchical subdivision described above, a segmentation process was developed to identify the individual masonry units composing the overall element. This method considers colour and 3D information at both local and global level and it is grounded on the analysis of data in the frequency domain. The 2D Continuous Wavelet Transform (CWT) is applied to identify the joints between units and segment individual stones (see Figure 2).

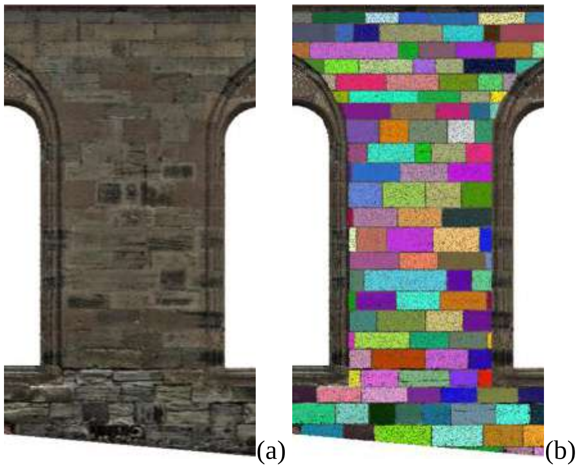

Figure 2. Ashlar masonry wall (a) Coloured point cloud (b) Segmented ashlar units

3 Identification of Defects using Machine Learning

Several geometric and colour metrics are presented in this section, that highlight stone regions potentially affected by decay, at different levels, both unit and sub-unit (Section 3.1). These are used for defects classification by means of machine learning (Section 3.2).

3.1 Metrics for the Identification of Defects

Once units are segmented and labelled, information regarding geometry and colour is extracted from each stone and several parameters are calculated to evaluate its state.

In the case of coursed ashlar, two specific parameters can play an important role to identify decayed units. Regarding geometric-based defects, the evaluation of the roughness of the stone face profile helps differentiate between flat and rough masonry units. Higher levels of roughness can suggest stones affected by deformation and detachment, related in most cases with loss of material. Roughness is calculated as the standard deviation of the distance of the profile points to the profile's mean plane:

$$Ra = \sqrt{\frac{1}{N}\sum_{i=1}^{N}(d_i - \mu)^2}, \text{ with } \mu = \frac{1}{N}\sum_{i=1}^{N} d_i \qquad (1)$$

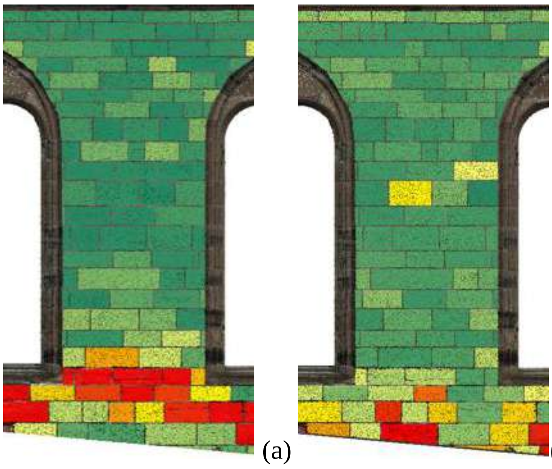
where N is the number of 3D points for the given stone face and d_i's are the projection distances of those points to the fitted plane.

With respect to colour-related defective areas, the analysis of the dispersion of colour in each stone, by means of the calculation of the standard deviation of the hue values within each ashlar unit (Equation (2)), can be used to highlight zones affected by discolouration or other defects associated to color, such as efflorescence or biological colonisation.

$$H_\sigma = \sqrt{\frac{1}{N}\sum_{i=1}^{N}(h_i-\mu)^2}, \text{ with } \mu = \frac{1}{N}\sum_{i=1}^{N} h_i \qquad (2)$$

for which the Red-Green-Blue (RGB) colour data is first converted into Hue-Saturation-Value (HSV) format, using the algorithm presented in [19].

The evaluation of these two parameters can be undertaken at the unit level (i.e. stone), resulting in the generation of two colour maps as illustrated in Figure 3. Figure 3 (a) corresponds to the roughness map, while Figure 3(b) illustrates stones potentially affected by defects related to colour variation. Traffic light colour maps have been used, in which the stones coloured in green are less likely to be affected by decay and the yellow and red ones are potentially defective.



(a) (b)

Figure 3. Geometry- and colour-based parameters (a) Ra (b) H_σ

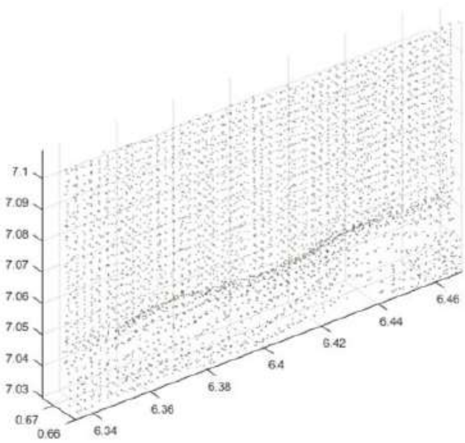
These above parameters and subsequently produced maps are of value for unit-level analysis and are useful to highlight clusters affected by decay. However, a more detailed analysis (i.e. at sub-stone scale) can deliver information about the precise defects which are affecting a specific stone.

The fine dressing of ashlar masonry, especially in polished finishes, facilitates the detection of defective areas. In these cases, the stone profile should fit a plane, with areas potentially affected by geometry-related defects can be found as those containing the outliers. Figure 4 illustrates, for each ashlar, the inliers (in green) and the outliers, which are coloured from yellow to red, according to the distance of the recorded 3D points to the fitted plane. Regions coloured in red are those with a more pronounced loss of material.

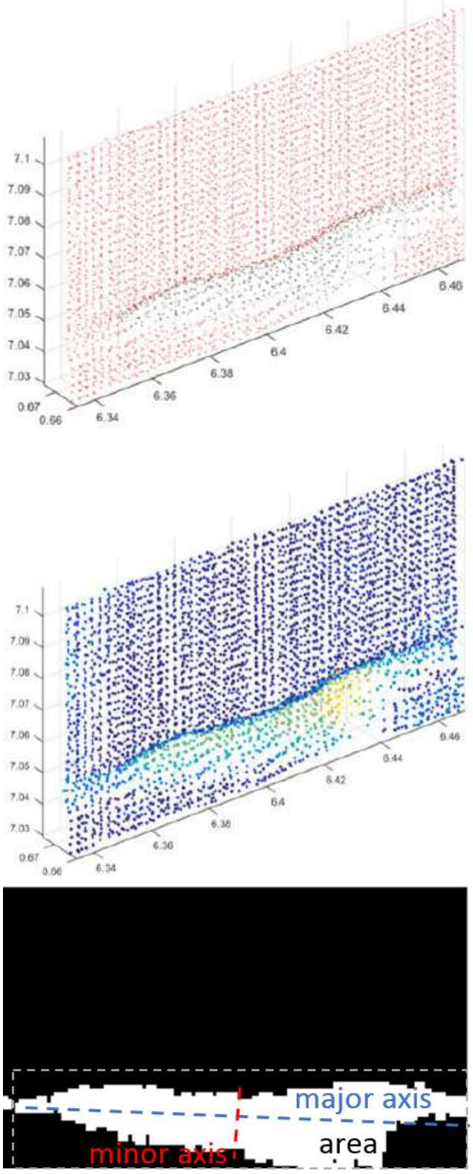
Figure 4. Sub-stone level analysis map

3.2 Machine Learning Approach for Defects Classification

An extended evaluation of the areas containing outliers can be undertaken in order to identify the particular effects affecting the material. Figure 5 (a) illustrates a decayed region of ashlar, where a plane is fitted to the stone and the outliers are considered to be part of a defective area (see darker points in Figure 5 (b)). While 3D coordinates are used to calculate the roughness coefficient (the point cloud is coloured according to their depth in Figure 5 (c)), additional metrics are calculated after the binary image obtained from the 3D point outliers (see Figure 5 (d)).



(a)



(b)

(c)

(d)

Figure 5. Process for parameters extraction (a) Original coloured point cloud (b) Inliers (red) and outliers (gray) after plane fitting (c) Depth map for outliers (d) Binary map created after orthogonal projection of outliers

From the 3D coordinates of the outliers, two metrics are extracted:

- Ra, the roughness coefficient of the defective area, (Equation (1)), and
- The median value of the normal vectors of the outliers with respect to the plane fitting the ashlar.

From the binary map obtained after the projection of the ouliers, the following parameters are considered:

- the number and area of unconnected defective areas (white segments in Figure 5(d)),
- the elongation of the defective areas, which is the ratio of the lengths of the minor to major axes and gives an indication of how ‘oblong’ a defective area is,
- the rectangleness of the defective areas, which is calculated as the fraction of the bounding box covered by the object, and
- the circularity of the defective areas, which is the ratio of the area of the projection of the defective region to the area of a circle with the same perimeter (p), as detailed in Equation (3).

$$C = \frac{4 \cdot area \cdot \pi}{p^2} \qquad (3)$$

From the colour information of the points associated to the defective area, two metrics are extracted:

- H_σ , as detailed in Equation (2).
- Colour lightness. RGB colour data are converted to grayscale [20], and the median value of g_i, (the grayscale value of each point inside the defective area) is calculated to provide information about the colour lightness.

Machine learning techniques are effective tools for classification and analysis. In this work, we propose a supervised learning algorithm to classify masonry units affected by different types of decay, and using the parameters described above. Stones labelled as ‘defective’ by professional surveyors, as illustrated in Figure 6, are used for training the classifier and producing an inferred function that is subsequently employed to automatically label new data.

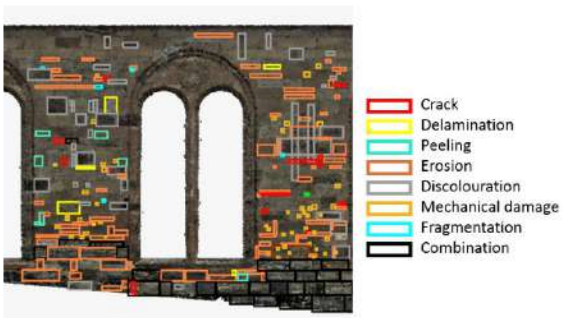


Figure 6. Defective areas labelled by surveyors

The chosen machine learning algorithm may vary depending on the number and nature of samples in the studied dataset and features [21]. In this work, after evaluating the amount of available samples and the extracted features, a logistic regression algorithm has been employed.

4 Experimental Results

The proposed approach has been tested with data from the main façade of the Royal Chapel in Stirling Castle, Scotland. A coloured dense point cloud (see Figure 7) has been produced after merging four scans acquired with a Leica P40 TLS device [22].

4.1 HBIM and Unit-level Maps

The generated point cloud was considered as a reference to create an 'as-is' 3D model of the Chapel Royal's façade. This model, that distinguishes the wall, door and windows (Figure 8) is used as the base of an HBIM model.

After removing the points corresponding to the door and the windows using a Scan-vs-BIM process, the point cloud composing the wall is segmented, producing a database with 1,116 ashlar units, as illustrated in Figure 9.

The points assigned to each ashlar unit are then automatically processed to calculate the parameters mentioned in the Subsection 3.1. Two maps, containing the values of Ra and H_{σ} can be seen in Figure 10.

As can be observed in Figure 10, the bottom part of the façade is found to be potentially affected by both geometry and colour-related defects. Also, the left and right ends of the walls have decayed regions. Physical inspection of the wall confirmed long term deterioration associated with previously defective rain water downcomers, leading to higher fabric moisture contents and subsequent increased incidence of freeze thaw decay processes. In addition, the presence of white 'blooms' were noted and are most likely attributed to salt crystallisation.

Figure 9. Segmented ashlar units

(a)

(b)

Figure 10. Colourmaps generated for the façade. (a) Roughness. (b) Standard deviation of hue values

All produced outcomes in the form of colourmaps, were subsequently added to the HBIM model (see Figure 11) adding information that can be contrasted with the status of the structural components at previous epochs.

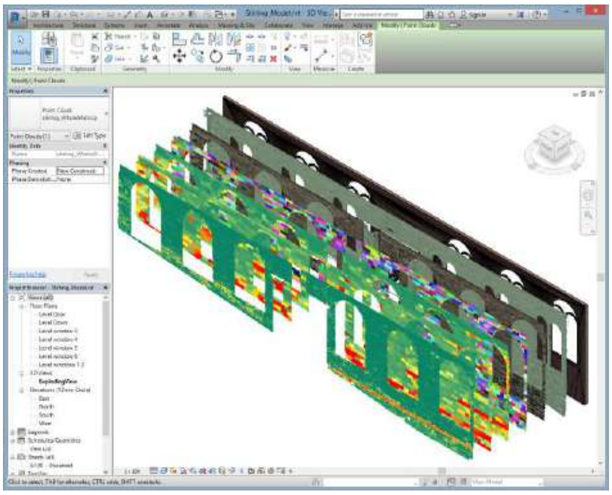

Figure 11. Datasets attached to the HBIM model

4.2 Classification of Labelled Defective Areas

To enhance the rapidity, accuracy and objectivity of labelling, machine learning techniques were developed and applied. The initial classification (i.e. labelling) of defective stones and broader areas was performed by specialist surveyors with expertise in masonry fabric repair and deterioration. The Stirling Castle Royal Chapel's ashlar façade was used and comprehensively surveyed and subsequently adopted to test the algorithms.

As previously illustrated in Figure 6, approximately 230 defective stone areas were labelled by specialist surveyors. Although approximately ten different types of defects were identified, only three of them were representative in significant numbers to be considered in this study: erosion (E), mechanical damage (M) and discolouration (D). The frequency of those most repeated defects is detailed in Table 1.

Table 1 Frequency of defects identified by surveyors in the studied area

Defect	Repetitions
Erosion	77
Mechanical damage	53
Discolouration	43

As previously mentioned in Section 3.2, the logistic regression algorithm was then employed, performing a 'one vs all' training process. For the training process, random samples of these three classes (72 from erosion, 48 labelled as mechanical damage and 38 identified as discolouration), were used as input to the algorithm. A maximum of 50 iterations has been used, with a regularization parameter applied to the cost function.

A total of 15 samples (5 of each class) were included in the test set, obtaining a global accuracy of 93.3% in the classification. More detailed results are summarized in Table 2. Additionally, Table 3 shows recall and precision values for the classification process.

Table 2 Confusion matrix for the classification of defects

	E	M	D	Predicted
E	4	0	0	4
M	0	5	0	5
D	1	0	5	6
Labelled	5	5	5	15

Table 3 Precision and recall values for the different classes

	Recall	Precision
Erosion	0.8	1
Mechanical	1	1
Discolouration	1	0.83

5 Conclusions

A strategy for monitoring the evolution of ashlar masonry walls of historic buildings through reality capture, data processing including machine learning, and (H)BIM models is presented in this paper. Different levels of magnitude are considered to perform surveying tasks: from element to sub-unit levels, several point clouds and maps are produced to illustrate the defective regions of the studied façades. At a sub-stone level, a more detailed analysis is carried out to extract different metrics which are of interest to identify decayed areas by means of machine learning techniques.

A preliminary experiment has been performed with geospatial data from a historic building and the obtained results demonstrate the potential of the proposed methodology.

Abstract –

For successful vision-based monitoring, the camera placement is an important and challenging issue. However, the previous Art Gallery Problem – which is a traditional optimization problem closely similar to the camera placement problem – did not take into account characteristics of construction sites, and thus faced difficulties in placing cameras on site and collecting adequate video/image data of construction activities. To handle the drawback, this paper aims to develop a camera placement optimization framework that considers characteristics of construction sites. The framework consists of two main processes: (1) problem definition and mathematical modeling and (2) optimum camera placement. For the validation, the case study was performed. The results showed the applicability of the developed framework in finding the optimal number, locations, and viewpoints of surveillance cameras for vision-based site monitoring. In conclusion, this research can contribute to propose proper camera placement on construction sites, increase quality of collected visual data, and improve the performance of site monitoring.

Keywords –

Vision-based monitoring; Operation-level; Construction site; Camera placement; Optimization;

1 Introduction

A number of video/image data are collected on construction sites for the purpose of vision-based monitoring. Recently, Unmanned Aerial Vehicle (UAV) is extensively utilized for video/image data collection and analysis in practice [1]. However, practitioners still install surveillance cameras on construction sites for continuous operation-level monitoring. It can be explained that the UAV-based visual data has difficulties to provide the operation-level information (e.g., work time, direct work rate) while it contains more macro, project-level information (e.g., progress measurement) [2]. In contrast, cameras located at construction sites have a capability to capture video/image data involving operation and logistics of input resources such as workers, equipment, and materials [2-4].

For successful operation-level site monitoring, camera placement is a critical and challenging issue to be addressed. In practice, the camera placement is usually conducted manually based on experts' knowledge or experiences. The manual processes make the camera placement to become time-consuming and cost-ineffective. In response to this issue, many researchers have made efforts to solve Art Gallery Problem (AGP) – which is a well-studied open research area that finds the optimal locations of safety guards such that they satisfy the maximum visual coverage in an art gallery. AGP theorems and algorithms are also widely adapted and applied to optimize the camera placement in the visual sensor network domain [5-11]. In the construction domain, Albahri and Hammad [12] attempted to find the optimal camera placement in indoor buildings using Building Information Modeling (BIM).

Even though the previous works showed promising results in finding optimal camera configurations, they focused on the camera placement in controlled, arranged environments for limited purposes. Thus, it is still challenging to determine proper number, locations, and viewpoints of cameras due to various unique conditions of construction sites. To handle such limitation, this paper aims to develop a camera placement optimization framework that considers characteristics of construction sites.

2 Literature Review

In this chapter, the authors review previous works on vision-based monitoring systems on construction sites and previous approaches for solving camera placement problems including Art Gallery Problem.

2.1 Vision-based Monitoring at the Operation-level on Construction Sites

Vision-based monitoring at the operation-level is generally carried out on construction sites for the purpose of safety and productivity management. In the past, project managers directly visited construction sites for gathering operation-level information. However, the manual methods made the monitoring tasks to become expensive and time-consuming [13].

To address the problem, many studies have been performed to develop automated vision-based monitoring systems, which automatically extract safety and productivity information from video/image data. Chi and Caldas [14], for example, presented an image-based safety assessment method for earthmoving operations. In addition to the safety assessment, Kim et al. [15] applied fuzzy inference for supporting immediate risk awareness of workers. Vision-based analysis techniques were also utilized to detect workers' unsafe behavior detection. Han and Lee [16] presented a method that detects unsafe behavior from stereo images. Park et al. [17] developed a vision-based method that recognizes non-hardhat-wearing states of construction workers. Automated vision-based productivity analysis also raised attention. Many researchers focused on developing an activity recognition method for earthmoving equipment; for instance, the method proposed by Kim et al. [18] analyzed interactive operations (e.g., proximity, individual actions) between heavy equipment for recognizing earthmoving activities. Golparvar-Fard et al. [19] used spatio-temporal features and support vector machines to classify actions of earthmoving excavators and dump trucks. Gong and Caldas [20] developed a video-based analysis model for evaluating concrete pouring operations of tower cranes. Bugler et al. [21] also presented a fusion approach of photogrammetry and video analysis techniques for assessing earthmoving productivity.

2.2 Art Gallery Problem for Camera Placement

Art Gallery Problem (AGP) is the well-documented optimization problem of finding minimum number of safety guards and their locations required to cover the interior of an art gallery [8]. Because camera placement optimization has similar natures with AGP [5], AGP-based approaches have been performed to optimize camera networks in various domains.

In the camera surveillance domain, researchers primarily aim to maximize coverage of stationary cameras for indoor building. The cameras were installed to observe pedestrian and unexpected events (e.g., crime, traffic accidents) for security/traffic monitoring purposes [8-9,22-23]. Other researchers also considered Pan-Tilt-Zoom and omni-directional cameras for coverage modeling and maximization [6-7,24]. In recent years, the camera placement problems are extended to multi-objective optimization for maximizing camera coverage and minimizing installation costs simultaneously [5-6,11]. In the construction domain, a few studies have examined the camera placement problem in building environments. The work in [24] visualized and calculated the coverage of multiple cameras in public building spaces. The coverage modeling method presented in [25] used Building Information Modeling (BIM) for a simulation-based optimization and was further developed in [12].

The previous research showed promising results in camera placement optimization for indoor spaces and urban areas. However, it is still challenging to determine proper number, locations, and viewpoints of cameras to be installed on construction sites. To overcome such limitation, this paper develops a camera placement optimization framework considering characteristics of construction sites.

3 Research Framework

The research framework is composed of two main processes. First, we perform problem definition and mathematical modeling. Second, the optimum camera placement is found through site modeling, coverage simulation, and genetic algorithm.

3.1 Problem Definition and Mathematical Modeling

The goal of this research is to optimize number, locations, and viewpoints of cameras that maximizes effective coverage given site-specific constraints (e.g., installable locations). The camera coverage (without occlusions) can be represented with its effective distance and view angle as shown in Figure 1. For the spatial modeling of construction sites, a 2D grid-based matrix was used. The grid size was set as 0.5m x 0.5m based on the expert suggestions during the interview.

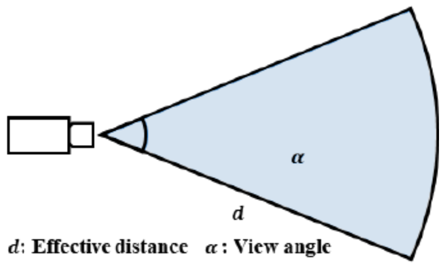

Figure 1. Camera coverage modeling

Next, the mathematical model was developed in order to manage the defined problem as follows.

Objective Functions

$$max\ \sum_{\theta}\sum_{i}\sum_{j} x_{i_1 j_1 \theta_1} e_{i_1 j_1 \theta_1 i_2 j_2} w_{i_2 j_2} \tag{1}$$

Constraints

$$P\sum_{\theta}\sum_{i}\sum_{j} x_{ij\theta} \leq Budgets \tag{2}$$

$$\sum_{\theta} x_{ij\theta} \leq l_{ij}\ for\ \forall i,j \tag{3}$$

$$1 \leq i \leq n, 1 \leq j \leq m, 0 \leq \theta \leq 360 \tag{4}$$

where

$$x_{ij\theta} = \begin{cases} 1, & if\ a\ camera, with\ viewpoint\ \theta, is\ at\ (i,j) \\ 0, & otherwise \end{cases} \tag{5}$$

$$e_{i_1 j_1 \theta_1 i_2 j_2} = \begin{cases} 1, & if\ a\ camera\ (i_1, j_1, \theta_1)\ covers\ cell\ (i_2, j_2) \\ 0, & otherwise \end{cases} \tag{6}$$

$$w_{ij} = spatial\ importance\ weight\ of\ cell\ (i,j) \tag{7}$$

$$l_{ij} = \begin{cases} 1, & if\ a\ cell\ (i,j)\ is\ installable \\ 0, & otherwise \end{cases} \tag{8}$$

The objective function plays a role in maximizing the total weighted effective coverages for vision-based site monitoring. By multiplying the spatial importance weight, possibilities in finding camera configurations that cover targeted monitoring areas can increase (e.g., work zones, travel paths, and material storages). The first constraint (Equation (2)) indicates that the total costs (i.e., number of cameras multiplied by unit prices) should be less than allocated budgets. When considering a camera dimension (around 0.5m x 0.5m) and a grid size, it is necessary to include Equation (3) to ensure that only one camera is located at each cell; however, this constraint can be released if a grid size is set sufficiently larger than a camera dimension (e.g., grid size: 3m x 3m; camera dimension: 0.5m x 0.5m). Equation (3) also explains that cameras should be placed at installable locations. The last constraints are considered for lower and upper bounds of locations and orientations.

3.2 Optimum Camera Placement

The proposed problem-solving method consists of three main modules: site modeling, coverage simulation, and genetic algorithm (GA). First, the site modeling is performed to encode spatial information of the actual construction site. Next, the performance of initial camera placement is evaluated to reproduce better coverage with simulation. GA generates new candidates for camera placement based on the evaluation. Until the terminal condition (i.e., the number of iterations is larger than the pre-determined threshold) is satisfied, the simulation-based coverage evaluation and GA-based reproduction processes are iterated.

3.2.1 Site Modeling

The site modeling creates the site-layout and spatial importance weight maps. First, the site-layout map is generated based on actual site drawings or top-view images. The next step is to create the spatial importance weight map. The spatial weights are assigned as 1, 2, and 3 for normal areas (i.e., background), travel paths and material storages, and work zones respectively. Based on the site modeling, the initialization is carried out. Among the camera-installable locations (e.g., facility boundaries) of the site-layout map, the initial number, locations, and viewpoints of cameras are randomly selected.

3.2.2 Coverage Simulation

The coverage simulation module computes the monitoring performance, total weighted effective coverage, of camera placement through coverage modeling and visibility analysis. The coverage modeling calculates camera coverage without occlusions based on the given camera type (i.e., effective distance and view angle). Next, the visibility analysis is conducted to deal with occlusion effects. Rotation angles to camera locations are primarily calculated for all cells within the coverage. It is then capable of capturing cells in the same line-of-sight when they have same rotation angles. Among the captured cells, cells located farther than any occluded cells are determined as invisible points.

3.2.3 Genetic Algorithm

GA is composed of two main steps: performance evaluation and population reproduction. First, the performance evaluation processes the calculation of objective function values: the total weighted effective coverage and total costs. By using the spatial importance weight map and the measured effective coverage, the first objective function can be determined. It is also possible to compute the total costs by multiplying the number of cameras and its unit price. Based on the acquired results, the population reproduction step is carried out as follows: selection, crossover, and mutation [5]. The selection chooses a subset of chromosomes with higher objective function values from population at the prior iteration, which may result in adoption to the best solution. Afterwards, 95% of the selected chromosomes is proceeded to the crossover and mutation; the other 5% individuals remain to secure the best solutions at the last iterations. Among the 95%, 80% and 20% were further selected for the crossover and mutation respectively. The probability-based uniform selection, the scattered method, and the adaptive feasible method were applied for each process of selection, crossover, and mutation respectively. Moreover, the authors mapped the real-world decision variables (i.e., numbers, locations, and orientations of cameras) into the chromosomes as follows. Each chromosome is composed of 2D locations and orientations. Chromosomes are also generated for all cameras to be installed, which means the number of chromosomes is same as the number of cameras.

4 Case Study

To validate the proposed framework's applicability, the authors performed a case study considering practical conditions of an actual construction site. Since the selected site already had three surveillance cameras for the purpose of vision-based monitoring, it was available to compare the performance of existing cameras and the suggestions based on the proposed method. The method was implemented using MATLAB 2017a on a laptop computer [Intel i7-5500 CPU @ 2.40 GHz, 8.00GB RAM, Windows 10, 64bit].

The case study was applied to the actual site-layout where two buildings were under construction. The site scale was 70m x 30m. There were total three cameras installed. The project manager aimed to mainly monitor work zones, travel paths, and material storages with the maximum budgets of $2,000. They purchased the surveillance cameras with the unit price of $500.

The effective coverage of both existing and suggested camera networks (with three cameras) are visualized with the red lines in Figure 2. The total weighted effective coverage rate (WVCR), calculated with Equation (10), was increased from 45.7% to 87.1% with the suggested camera placement.

$$WECR = \frac{\sum_\theta \sum_i \sum_j x_{i_1 j_1 \theta_1} e_{i_1 j_1 \theta_1 i_2 j_2} w_{i_2 j_2}}{\sum_i \sum_j w_{ij}} \qquad (9)$$

5 Conclusions

This research proposed a camera placement optimization framework for vision-based monitoring on construction sites. To validate the applicability of the proposed framework, the case study was carried out considering actual conditions of construction sites. The performance of existing camera networks and suggested solutions was compared. The results showed the suggested design outperformed the existing camera placement in terms of the total weighted effective coverage rates. With the proper camera placement, it is expected to collect adequate quality of video/image data and support vision-based monitoring tasks successfully.

Several research challenges remain to be improved. For instance, the proposed framework can be applied to diverse construction projects involving various unique site conditions. It is then available to identify and incorporate more various elements in the camera placement framework. Although it is a challenging issue to find proper 2D locations of surveillance cameras in practice, optimization with 3D modeling can be addressed for further studies.

Abstract –

Image-based crack detection methods have been extensively studied due to their cost-effectiveness in terms of data acquisition and processing. However, automated crack detection still remain a challenging task due to complexity of image background and different patterns of cracks. To address these issues, this paper proposes a deep residual network with transfer learning for pixel-level crack detection on road surface images. The network was trained on 71 images of CrackForest dataset and tested on 47 images of it. Experimental results suggest that the deep residual network is superior to the existing algorithms with recall value and precision value of 84.90% and 93.57%, respectively.

Keywords – Crack Detection; Residual Network; Deep learning; Transfer Leaning

1 Introduction

Cracks on a road pavement that are not timely repaired increase maintenance and repair costs due to the acceleration of surface deterioration. To establish a proactive maintenance plan, road inspection data should be obtained frequently. In general, a government agency responsible for road monitoring either manually inspects the status of road networks or by using special road monitoring vehicles equipped with laser scanners, infra-red cameras, or high definition video cameras. However, it is still challenging to timely monitor a significant portion of road networks.

Image processing and machine learning algorithms have been widely studied to detect cracks on road pavement. Radopoulou and Brilakis [1] proposed the pavement management system that automatically detects patches in video frames. The authors used the video acquired by the car's parking camera in patch detection. Ouma and Hahn [2] proposed a pothole detection method on asphalt road pavements using the fuzzy c-means algorithm. The consumer-grade smartphone devices were used as road data collectors for the low-cost automated system. Oliveira and Correia [3] proposed a system for the automatic detection and characterization of cracks on road pavement images captured by a digital camera. These papers shows that the road crack detection methods based on image processing and machine learning algorithms allow frequent updates of road conditions at low cost.

CNN (Convolutional Neural Networks) have been used for road crack detection since CNN demonstrated an excellent performance in ImageNet Large Scale Visual Recognition Competition (ILSVRC) 2012 [4]. Gopalakrishnan et al. [5] used the VGG16 model, a kind of CNN, to identify the presence of cracks in images. Compared with the performance by traditional machine learning methods such as SVM (Support Vector Machine), RF (Random Forest), and LR (Logistic Regression), the CNN model proposed in [5] showed the highest accuracy for crack detection in highway images. Zhang et al. [6] proposed a CNN model with six layers for detecting cracks on road images. They conducted a comparative research with existing algorithms, such as SVM and boosting method, to confirm the superior crack detection performance of the proposed CNN. Wang et al. [7] applied a CNN to detect the existence of pavement crack using two different scales of grid (32×32 and 64×64).

Although the CNNs studied so far have performed well in terms of identifying the presence of cracks in a certain image region, they had a limitation in terms of detecting cracks at pixel-level. Sufficient pixel-level accuracy that can quantify the width, shape, and length of the crack enables detailed analysis of the road surface distress.

In this paper, we propose a deep residual network with transfer learning for pixel-level crack detection. The deep residual network classifies all pixels in road images into cracks and background. To achieve high performance with a relatively small number of training images, this study uses transfer learning, which is a learning method of fine-tuning the weights of a pre-

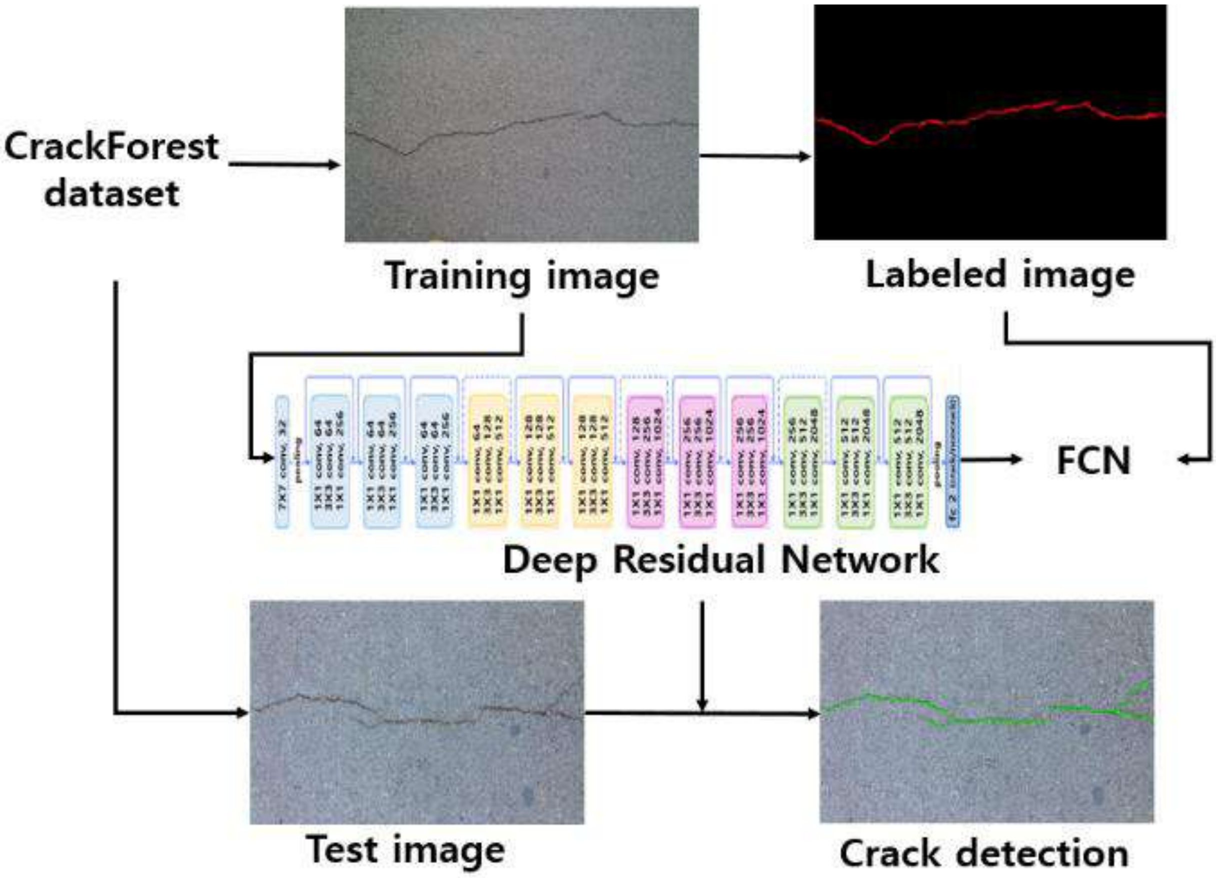

Figure 1. The deep residual network for road crack detection

trained CNN [8]. Experiments are conducted to demonstrate the performance of the proposed network.

2 Deep neural network with transfer learning for crack detection

CNN has been shown to be very effective in processing image data to perform computer vision tasks, such as semantic segmentation, image classification, object detection, and regression. A typical CNN consists of three kinds of layers: a convolution layer, a sub-sampling layer, and a fully-connected layer. The convolution layer applies convolution filters to the input image to produce output images. This layer has parameters such as number of channels, kernel size, number of filters, and stride size. The sub-sampling layer obtains feature maps with a lower dimension using average pooling or max pooling in the receptive field. In a CNN, convolutional layers and sub-sampling layers are typically repeated several times, and a fully-connected layer is placed at the end. The softmax function value of the fully-connected layer is the prediction value of the CNN.

The existing CNNs have the vanishing gradient problem that prevents the front layers of the model from learning in cases where many layers exist. The residual network [9] tried to solve this problem with a novel learning method that trains the network with the residuals–the difference between input and output of each computational block. The residual network with 152 layers shows better performance in large-scale object recognition problems than the VGG network [10] with 16 layers.

Figure 1 represents the proposed network. The network inputs are 480 × 320 × 3 images. The first layer is a 7 × 7 convolution layer with 64 depths and the second layer is a 3 × 3 max-pooling layer to perform down-sampling. The blocks, which consist of a 1 × 1 convolution layer, a 3 × 3 convolution layer, and a 1 × 1 convolution layer, are stacked behind the two layers (7 × 7 convolution layer and 3 × 3 max-pooling layer). An image passed through the 152 layers is reduced to a feature of 15 × 10 size. After that, the method of fully convolution network (FCN) [11] is applied to detect cracks using features extracted by the deep residual network. FCN enables pixel-level prediction by restoring features to original image size using the skip connection, which utilizes the intermediate layers' results and the final features of the residual network. The results of the intermediate layers compensate for losses in the up-sampling process performed by the bilinear interpolation.

A CNN typically require a large amount of labeled images to achieve high prediction accuracy. However, it is difficult to collect hundreds of thousands or even millions of road images and to label them manually. To address this problem, transfer learning was proposed to fine-tune pre-trained weights with big data, such as ImageNet. Unlike existing learning methods that randomly initialize the weights of CNN, transfer learning uses the weights of a pre-trained CNN as initial weights before the training process. Transfer learning has been shown to be useful in solving image classification problems of various domains, such as medical image

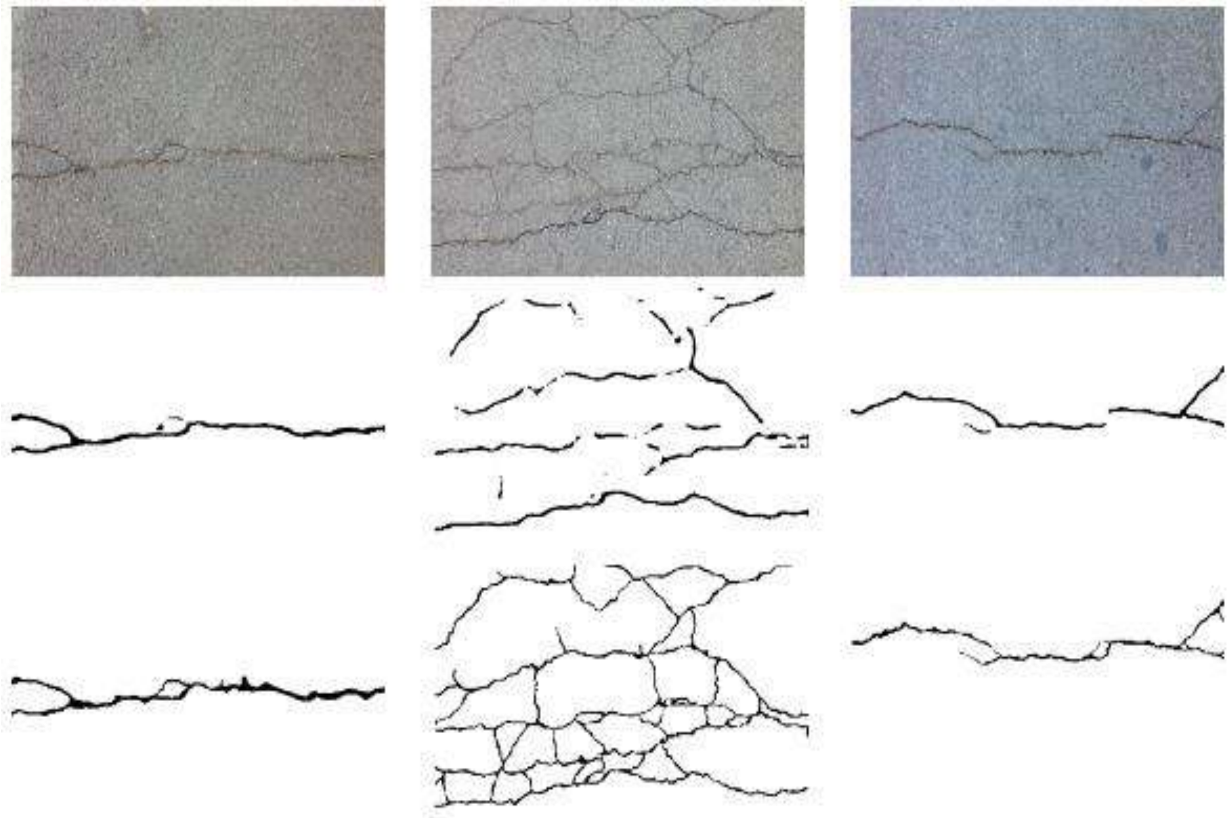

Figure 2. Results of residual network on CrackForest dataset (from top to bottom: original image, network prediction, ground truth)

processing [12]. In this context, we propose a deep residual network with transfer learning. Figure 1 illustrates the training and testing process of the proposed network. In this paper, the residual network with 152 layers, pre-trained by ImageNet dataset were used to detect cracks in images.

3 Experimental study

In this section, the performance of the deep residual network is analyzed. The training and test process of network was implemented in Python code. All experiments were performed on desktops with GTX 1080 Ti GPU and an Intel Core i7-7700 processor. The network was trained with a dataset used for the CrackForest [13], which is the existing crack detection method. The dataset consists of 118 images of the road surface in Beijing city acquired by iPhone5 with focus of 4mm, aperture of f/2.4, and exposure time of 1/134s. The images contain various types of noise, such as oil stains, road-specific textures, and shadows. The resolution of images is $480 \times 320 \times 3$. Each image has a pixel-level ground truth labeled manually. All pixels except for the crack pixels are classified as background.

For direct comparison with the CrackForest algorithm [13], the experimental environment was set in the same manner. The precision, recall, and f1-measure, by examining the correspondence between the predicted pixel and ground truth, were calculated to evaluate the proposed network. We followed the assumption of the CrackForest algorithm that the predicted pixels which are within 5 pixels from the ground truth pixel are considered to be true positive pixels. 71 images of the dataset were used as training data, and the remaining 47 images were used as test data. The results are shown in Fig. 2, and the performance comparison between the proposed network and CrackForest algorithms are summarized in Table 1. Experimental results show that crack detection using the deep residual network is superior to the existing CrackForest algorithms with k-nearest neighbors algorithm (KNN) and support vector machine (SVM).

4 Conclusion

This paper proposes a deep residual network with transfer learning for pixel-level crack detection. The proposed deep residual network demonstrates better accuracy than traditional image processing and machine learning algorithms in pixel-level crack detection. The proposed network is able to quantify the geometry of cracks on various roads by performing pixel-based crack detection with high accuracy. If the network can be utilized in a variety of road image dataset with future studies, it is expected to help the asset managers establish proactive road maintenance strategies.

Table 1. Result evaluation on CrackForest dataset

Method	Precision	Recall	F1
CrackForest (KNN)	80.77%	78.15%	79.44%
CrackForest (SVM)	82.28%	**89.44%**	85.71%
CrackForest (One-Class SVM)	81.25%	86.45%	83.77%
Deep residual Network	**93.57%**	84.90%	**89.03%**

Abstract -

This paper proposes a method for patch-based crack detection of black box road images, for efficient road pavement monitoring. The proposed method is based on deep learning and consists of two modules: road extraction and crack detection. The road extraction module uses the segmentation process of a Fully Convolutional Network (FCN) called FCN-8s to leave only the road area in the image. The crack detection module performs patch-based crack detection on the extracted road area using a convolutional neural network. To the best of the authors' knowledge, the proposed method is the first attempt to detect road cracks of black box images, which are not orthogonal but skewed actual road images.

Keywords – Crack detection; Deep learning; Patch-based analysis; Road surface monitoring

1 Introduction

Proactive road maintenance is an important process for repairing road defects like cracks. For proper maintenance, monitoring of road surface conditions should be performed frequently for large areas. However, it is difficult to efficiently inspect pavement conditions with conventional monitoring methods utilizing inspectors or special vehicles. Recently, mobile devices such as mobile phones and automobile black boxes have become popular. As the performance of the camera mounted on the mobile device increases, it is possible to observe the surface condition of the road by the device attached to the windshield. If a method to utilize this video data for road condition monitoring is developed, significant improvement is expected in the traditional road monitoring method.

Various computer vision algorithms and machine learning based models have been developed for automatic road crack detection. A widely used vision-based crack detection method was to detect the morphological features of cracks by detecting the intensity change of pixels [3,5,7]. Some studies were based on machine learning approaches, which derived features of crack images through a large number of images, and then classified the images into crack and non-crack, or analyzed the types of cracks [4,5,9]. Recently, crack detection methodologies using deep learning have been emerging. Deep learning trains the weights that make up the neural network model based on a large amount of images, and conducts crack detection even with complex backgrounds. The crack detection study using deep learning is divided into patch-based and pixel-based method [1,2,10]. In this study, deep learning based method for detecting cracks in the unit of patch is pursued in black box images.

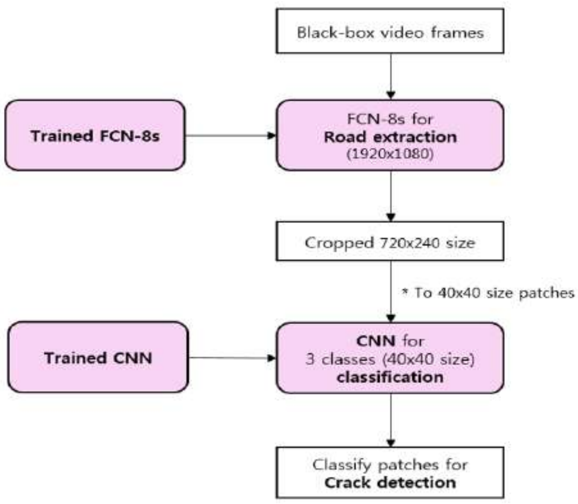

Figure 1. The patch-based crack detection of black box images.

2 System description

Figure 1 shows the patch-based crack detection method proposed in this study, and the method consists of two modules. The first module performs road extraction using a Fully Convolutional Network (FCN) architecture [6], and the second module performs crack detection in the extracted road area using the CNN model suggested in this paper. Cropping is performed between the first module and the second module, in order to limit the area to which the CNN is applied in the extracted road image.

Areas other than roads within a black box road image are not needed when performing crack detection. For the extraction of the road area only, the first module utilizes the segmentation process of FCN-8s [6] which consists of the 13 upstream convolutional layers of VGG16 [8] and an upsampling process. The second module divides the extracted road surface into several small images and then classifies each image into three classes: crack, lane, and others. In this study, a CNN architecture was designed to detect cracks in image patches with a 40 × 40 pixel resolution.

The proposed CNN model consists of five convolutional layers, three pooling layers, and two fully connected layers. The kernel sizes of the convolutional layers are determined considering the small size of the input image. The kernel sizes of the first convolutional layer (C1) and the second convolutional layer (C2) are7 x 7 and 5 x 5, respectively. The kernel size of the remaining convolutional layers (C3, C4, and C5) is 3 x 3. The pooling layers (P1, P2, and P3) are used for maxpooling to reduce the size of the feature map by half. The first fully connected layer (FC1) has 128 channels and the last fully connected layer (FC2) contains three channels for the classification into the three classes. Figure 2 shows more information about the CNN model for crack detection.

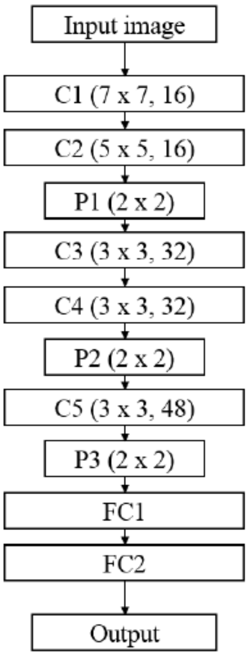

Figure 2. The CNN architecture for crack detection

3 Experiments and Results

The road extraction model was trained with 352 images of 1920 × 1080 pixel resolution, while the CNN model for crack detection was trained with 30,000 images of 40 × 40 pixel resolution. For testing, a total of 50 black box images were used. The black box images were cropped to 720 x 240 pixel size after the road extraction process. In the cropped image, patches that contain non-road areas were excluded from the analysis for crack detection. Consequently, 7259 patches of 40 x 40 pixel size were classified into the three categories. The results of the road extraction were a precision of 98.78% and a recall of 96.13%. In equations (1) and (2), True Positive is the number of patches classified as crack among the real crack patches. False Positive is the number of patches classified as crack among the patches truly belonging to either lane or others. False Negative is the number of patches classified as lane or others when the patches are in fact cracks.

$$\text{Precision} = \frac{\text{True Positive}}{\text{True Positive} + \text{False Positive}} \quad (1)$$

$$\text{Recall} = \frac{\text{True Positive}}{\text{True Positive} + \text{False Negative}} \quad (2)$$

The classification accuracy of the three classes was 91.13%, and the precision and the recall were 88.14% and 72.01%, respectively. The factors that reduce the performance of crack detection are as follows. A patch containing a lane or shadow was, in some cases, misclassified as crack; this is a factor of affecting the precision. On the other hand, patches with blurry cracks or with both cracks and lanes caused the recall to drop.

The results of the road surface extraction and crack detection are given in Figure 3. The middle images in Figure 3 is the result of road extraction and the background pixels are marked with white. The patches classified as crack are indicated with yellow borders in the images on the right side in Figure 3.

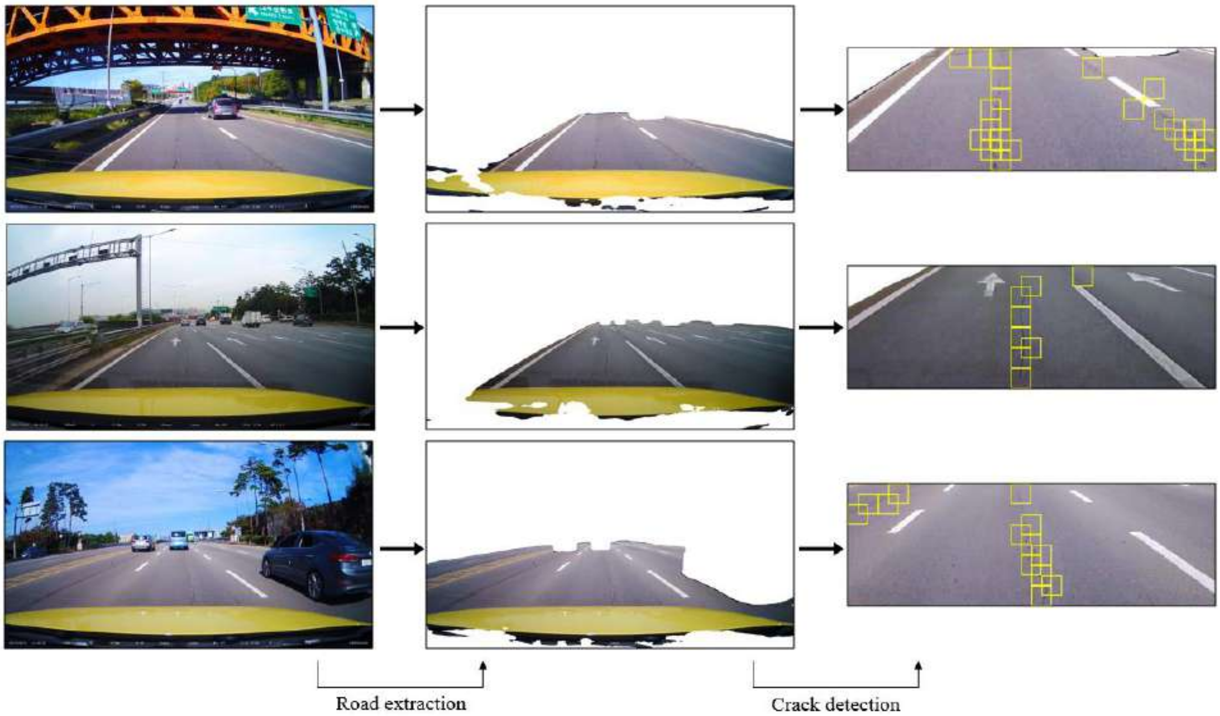

Figure 3. Three example images of road extraction and crack detection; original images (left), road extraction images (middle), and crack detection images (right).

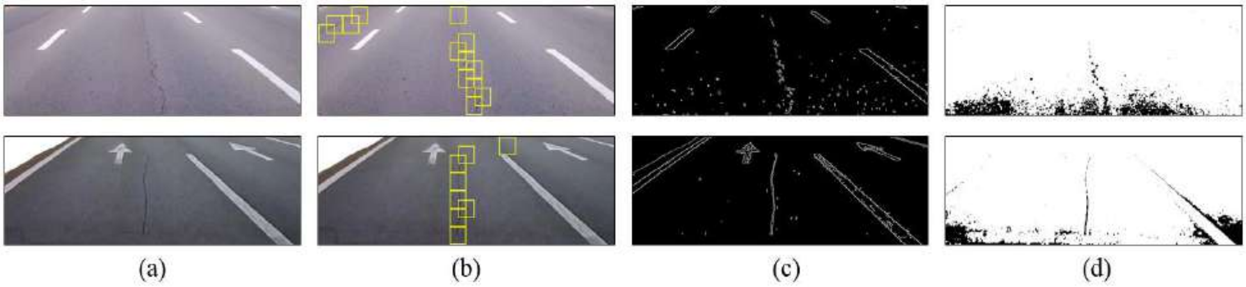

Figure 4. Comparison with other operators for crack detection; (a) original images, (b) proposed method, (c) Canny edge detector, (d) simple thresholding.

Figure 4 shows the comparison of the results of applying the proposed method and other methods to the black box images. In Figure 4(b), the yellow patches were classified as crack by the proposed CNN model. It can be seen that the patches with cracks were well distinguished from the lane and the undamaged road area. Figure 4(c) shows the results of crack detection using Canny edge detector. Because of the large difference in pixel intensity values between the cracks and the surrounding roads, cracks can be detected by the edge detector, but noisy parts of the road surface or lanes can be detected as cracks, as shown in Figure 4(c). Figure 4(d) shows the results of crack detection by simple thresholding. Because cracks are darker than road surfaces, they can be detected when images are binarized with an appropriate threshold. However, since the intensity of the road surface is not constant, areas with dark intensities other than cracks can be mistaken for crack. To detect cracks with an edge detector or thresholding, preprocessing of the input data or post-processing of the output image may be required. However, in the proposed method, no other work is required before and after the crack detection in the extracted road area.

4 Conclusion

This study suggested the use of black box images for effective road maintenance. The black box image has the merit of being easy to acquire; however, the image has a limitation that it is skewed and objects such as other vehicles or buildings are included in it. In this study, we applied the deep learning to extract the road surface from a black box image and detect the crack patches on the extracted road surface. The performance of the road extraction was more than 96% for both precision and recall; it was performed well as a preparatory work for detecting cracks in an image. In the crack detection, the accuracy, precision, and recall were 91.13%, 88.14%, and 72.01%, respecetively. For more detailed analyses, the patches can be categorized into more than three classes or more training data can be used. Using the data of many vehicles equipped with mobile devices as proposed in this study, efficient pavement management can be achieved.

Abstract

The job allocation models used in construction projects have been designed mainly to meet the objectives of the employers such as maximizing productivity and tended to pay inadequate attention to meet the needs and objectives of construction workers. Meeting the objectives of workers, however, is a basic component of corporate social responsibility and vital to improve job satisfaction among construction workers. Among various items on wish-list of workers, availability of career development opportunities in projects stands out as a key factor affected considerably by job allocation decisions. This paper presents an innovative mathematical model for optimization of task allocation in construction projects to maximize the availability of career development opportunities to individual construction workers, paving the way for their career development. A Euclidean distance function in n-space is specified as objective function of career development which measures and compares the distance between ideal skill levels of employees to initial skill levels and developed ones after job allocation. The proposed model is applied to an illustrative case project involving the allocation of tasks to workers with different skill levels in a construction contractor company. Results show a successful task allocation which has contributed to workers' occupational development and made them closer to their ideal skill level.

Construction Industry; Career Development; Mathematical Model of Job Allocation; Corporate Social Responsibility

1 Introduction

The construction industry is one of the extensive global employment sectors which provides career opportunities for a noticeable percentage of the labour market and contributes to a substantial share of the world's gross domestic product (GDP) [1]. As a result, construction industry is acknowledged widely as a fundamental driver of national productivity in most developed and developing countries; and therefore improving the productivity of construction industry through workforce planning has been a major focus of research over the past several decades [2, 3]. Numerous novel conceptual and mathematical workforce planning techniques have been developed to improve the productivity of workers through optimizing the hiring and firing decisions [4], multiskilling strategy [5], training of existing workers [6], optimization of crew composition [7], and optimizing the job allocation [8]. However, while meeting the productivity objectives is crucial, placing the focus solely on productivity and other financial objectives of the employers, has led to a significant level of ignorance with regards to effects that job allocation decisions may have on main players in construction projects, i.e. the workers [1]. One of the direct effects of job allocation decisions on workers is related to amount of career development opportunities made available to them through allocated jobs [9].

Accordingly, job allocation planning provides an opportunity to maximize the availability of career development opportunities for the workers. However, to the best of our knowledge, there is currently a lack of a systematic method to account for career development opportunities in optimizing the task allocation in construction projects. The existing literature on career development opportunities in task allocation to workers is mainly limited to (1) qualitative models of career interests, choice, and development [10-12], and (2) theoretical propositions such as psychological theory of work adjustment [13], and social learning theory of Career Decision Making (CDM) [14]. In the present paper, an innovative mathematical model for optimization of task allocation to maximize career development opportunities available to construction workers is proposed. The proposed model is applied to and solved for an illustrative case project involving the allocation of tasks to workers with different skill levels in a construction contractor company.

2 Mathematical Model Formulation

The model proposed in this study aims at solving the problem of job allocation among available personnel with the objective of maximizing the career development opportunities available to workers. It is assumed that employees begin their career from entry level and promotions to higher levels are based on achieving the experience requirements for different skills required for the level. In addition, it is assumed that the amount and breakdown of the work to be performed, number of available labour forces along with their skills and proficiencies, and their historical learning rates are known or have been previously measured. The objective is to distribute the given workload among individual workers in a way that a majority of workers take a step forward in meeting the skill experience requirements for promotion to the next career level.

2.1 Terminology and Notation

We denote I as the set of primary skills of workers. For instance, if the skillsets required in a building operation include reinforcement iron-working, carpentry, and concrete pouring, these three primary skills are elements of the set I.

The skill level of the worker is denoted by set E. Five stages of skill development is presumed based on the modelling of human expertise suggested by Dreyfus [15]. Description of the abilities and requirements of each skill level are explained in 'Table 1'. Skill level acquisition is mainly assumed by years' experience. First skill level i.e. $\mathrm{e}=1$ indicates a novice worker (0–3 years of experience), $\mathrm{e}=2$ represents a beginner worker (3-7 years of experience), $\mathrm{e}=3$ denotes a competent one (7-15 years of experience), $\mathrm{e}=4$ indicates a worker with proficient skill level (15-22 years of experience), and $\mathrm{e}=5$ indicates an expert worker (22-30 years of experience).

The type of the activity is denoted by set J; e.g. values of $j=1,2,3$ may be assigned when working on columns, beams, and slabs, respectively. In the classification adopted by this study, each activity is comprised of several tasks which are denoted by set M. It is worth mentioning that task $m \epsilon M$ corresponds to one or more required skill(s) $i \epsilon I$.

2.2 Decision Variables and Objective Function

The objective targeted in this study is to maximize the personnel's career development opportunities. The decision variables are the amount of work allocated to each worker in each skill (y_k^i). Based on literature, we assume that promotion of each individual worker to the next career level is achieved through improving his experience in required skills to the minimum level of experience required by the next level position [12]. The enhancement in skill level of individual k in skill i due to performing the allocated job (y_k^i) is formulated by the equation below:

$$S_{ik} = \dot{S_{\imath k}} + \alpha_{ik} \times y_k^i \tag{1}$$

Where $\dot{S_{\imath k}}$ is the initial level of experience of individual k in skill i, y_k^i is amount of work related to skill i which is allocated to individual k, α_{ik} is a coefficient obtained from learning rate of individual k in skill i, and S_{ik} is the improved skill level of individual k in skill i after performing the allocated task.

We assume that each employee has a particular goal in terms of desired job and level in the organizational hierarchy, which we herein define as the ideal job for the candidate. According to Parsons [16], employee's active involvement in selecting their career instead of letting chance to operate in looking for a job, may lead to considerable increase in their job satisfaction and efficiency as well as a decrease in employers' costs. The ideal job for each candidate can be determined based on candidate's desired job or best fit based on various psychological character analyses methods. We assume that the key requirement to qualify for the ideal job is to achieve the required skill levels for the job which can be identified from Human Resource (HR) data and qualification of current/previous individual holding such positions. In this study, parameter $\ddot{S_{\imath k}}$ is defined to represent skill level associated with the ideal job for candidate k. The current skill levels of worker and those associated with the ideal job of the workers are defined by vectors presented in equations (2) and (3), respectively.

$$\dot{S_{\imath k}} = \left(\dot{S_{1k}}, \dot{S_{2k}}, \dots, \dot{S_{\imath k}}\right) \tag{2}$$

$$\ddot{S_{\imath k}} = \left(\ddot{S_{1k}}, \ddot{S_{2k}}, \dots, \ddot{S_{\imath k}}\right) \tag{3}$$

A value of zero for the level of a particular skill is possible and means no experience in that particular skill. A Euclidean distance function in n-space, E^n, is defined to quantify the distance between the current level of skills and the ideal level of skills as defined by equation (4). The distance of each individual k from its ideal job is therefore defined as:

$$D_k = \sqrt{(\ddot{S_{1k}} - S_{1k})^2 + (\ddot{S_{2k}} - S_{2k})^2 + \dots + (\ddot{S_{\imath k}} - S_{ik})^2} \tag{4}$$

Accordingly, to maximize the career development opportunities for each worker, the objective function is defined as follows:

$$\text{minimize } max_{\{k \in K\}}\ D_k \tag{5}$$

Table 1 Different skill levels and their descriptions

Skill level, E	Title of skill level	Description
1	Novice	The worker can assist other experienced workers, and transfer goods.
2	Beginner	The worker can work independently on simple tasks under supervision of a senior worker.
3	Competent	The worker can perform all simple and complicated tasks within his skill range.
4	Proficient	The worker can perform all tasks, within his skill range, quickly and with minimum deficiencies.
5	Expert	In addition to performing all tasks, within his skill range, the worker can supervise other workers.

2.3 Constraints

The constraints considered in this model are presented by equations (6) to (8). Constraint (1) sets the total amount of work allocated to personnel to be equal to the total amount of work available in the project for the entire crew in a particular trade. Judgments of fairness include four distinctive types of perceptions. Distributive justice perception adopted in this study aims at ensuring fair distribution of hiring, promotion, and workload allocation over individuals [17]. Constraints (2) and (3) are defined to account for distributive justice. Constraint (2) ensures that the maximum working hours per week for each worker does not exceed the specified limit value (U_k). Constraint (3) ensures a minimum weekly number of allocated hours of work (L_k) to each worker. In these two constraints, w is total number of weeks in lifespan of the project.

$$Constraint\ (1):\quad \textstyle\sum_{k=0}^{K} y_k^i = H_k \quad ,\forall i \in I \tag{6}$$

$$Constraint\ (2):\quad {y_k^c}/{w} \le U_k \quad ,\forall k \in K \tag{7}$$

$$Constraint\ (3):\quad {y_k^c}/{w} \ge L_k \quad ,\forall k \in K \tag{8}$$

3 Case Study; Results, and Discussion

The illustrative case study considered in this paper involves allocating the tasks in a construction operation to a crew of ten personnel (P_1 to P_{10}). The activity involves three different tasks characterized by six different skill types, presented by S_1 to S_6, with five competency skill levels considered for each skill type. The initial and ideal level at each skill are known for all workers and presented in 'Table 2'. Upper and lower bound of weekly workload of each individual worker are considered as 10 and 60 hours, respectively. COUENNE, an open source code for solving global optimization problems [18], was selected to solve the problems within AMPL framework. Two different scenarios are considered to evaluate the effectiveness of our model in maximizing the career development opportunity as characterized by the distance of each worker to its ideal skill set. In the first scenario our proposed model is used to allocate the tasks, while in the second scenario the tasks are allocated by applying the conventional productivity maximization job allocation approach [8]. The outcome which includes developed skill levels for all employees after job allocation, allocated hours to personnel, and final distances (the distance between developed and ideal skill levels) are presented for both scenarios below.

Table 2 Initial, ideal, and newly developed skill levels along with allocated hours at each skill type

In first scenario job allocation has been performed more uniformly and evenly leading to a wide-ranging and comprehensive skill development of all employees. As it can be seen in 'Table 2', in our model, all employees have received a certain amount of hourly job in at least three skill type and most of them have developed their skill levels for almost all of skill types. On the contrary, in second model, majority of personnel have been allocated a large amount of job in just one skill type leading to overdevelopment of one skill whereas keeping the rest undeveloped.

Results from 'Table 3' indicate all employees have become closer to their ideal skill level after job allocation. However, some subtleties reveal when comparing the final distances derived from two scenarios. Maximum final distances in first and second scenarios for all personnel are 5.96 and 6.77 , respectively, while there is a similar maximum initial distance of 6.93 for both cases. This small change from 6.77 to 6.93 in second scenario, emphasizes the argument that conventional productivity oriented approach does not consider the employee's perspective objectives e.g. career development into optimization planning. In contrast, results of our model indicate a noticeable contribution to career development of employees and their closeness to ideal skillset (%13.9 for 'P_7' and %4.8 on average). Another important advantage of our model is concentration on career improvement of critical employees with longest initial distances to make sure final distance for none of organization personnel does not exceed a threshold value. On the other hand, second model has unnecessarily reduces the distance for employees such as Martin Davidson (P_5) and Michael McCray (P_6) whilst there were people with higher priority for job allocation such as Mike Parks (P_7) and Tom Peterson (P_{10}).

4 Conclusion

In this paper, an innovative job allocation optimization model was presented to maximize the career development opportunities available to the construction workers. Maximizing the career development opportunities available to workers through a systematic workforce planning may lead to considerable increase in job satisfaction of workers and attractiveness of construction industry to skilled workers. The results of the case study presented in this paper showed that implementing our proposed model compared to the conventional productivity oriented model results in a significant improvement in the career development of workers in general and %13.9 advancement in workers' closeness to their ideal skill set in critical employees. In addition, the proposed model allocates the available jobs more uniformly leading to multi-dimensional skill development of employees whereas in the other model, most of personnel have been allocated a large amount of job in just one skill type leading to overdevelopment of one skill while keeping the rest undeveloped. For future studies, work on more complex problems consisting of various construction trades with personnel from different departments within an organization is suggested. In addition, more constraints reflecting time specific and site specific limitations and regulatory conditions can be considered into modelling.

Abstract

Building information modeling (BIM) is a new technology that supports lifecycle information management for buildings. Ontology, derived from philosophy, is another technology utilized to describe real-world entities and to infer their semantic relationships. Each year disasters such as fires, earthquakes and floods affect not only buildings but all occupants inside, and hence, identification of critical building elements and devices vulnerable to a disaster is a must in order to perform countermeasures to ensure the safety of lives and property. At present, many simulation-based tools such as FDS have been successfully employed to mimic the impact of a disaster. Nevertheless, most of such approaches consider only the spatial or geometry data of a building. Other building-related attributes such as materials and equipment that certainly influence how a disaster proceeds have not been thoroughly examined. Thus, this research develops BIM plug-in programs to extract not only geometry but building materials and equipment/devices information in order to craft a disaster-specific ontology. Semantic relationships are modeled using Semantic Web Rule Language (SWRL) constructs, so as to represent the interdependencies among building elements and devices under a given disaster. The combined approach can accommodate not only spatial relationships but functional constraints pertaining to internal building elements and devices. It may help disaster mitigation officials forecast and assess the impact and progress of a disaster. A train station was utilized to demonstrate the proposed approach, with focuses on the fire and flood types of disasters. Better disaster mitigation strategies can be prepared if the proposed approach is adequately utilized.

1 Introduction

Much research on critical infrastructure (CI) can be traced back to U.S. President Clinton's Executive Order 13010, which formally defines CI as the systems that whether real or virtual, the stop and destruction of these systems will have an impact on national society, economic and public health security [1]. The September 11 attacks on the World Trade Center demonstrate the urgent need for subsequent CI-related studies [2-3]. Among CI-related studies, one area of significant importance is about interdependency relationships among CI systems. For instance, according to the survey conducted by Mendonça and Wallace, the total loss of the power, telecommunication, oil and gas, and water sectors in the September 11 attacks due to indirect factors is more than that due to direct factors [4]. The term, CI interdependency, has been coined to denote such a cascade effect because one system failure will often trigger a series of failures of different CI systems. Mitigating the impact of such CI interdependency relationships thus has been regarded as one of the most important tasks during the disaster response phase.

Although it is worthwhile to collect and analyze the interactions of large-scale CI systems at the national level, in practice for a CI owner or operator it may be more useful and desirable to limit the CI scope to all components within a CI system, i.e., investigating the interdependency relationships among all subsystems or components of a given CI system. For instance, a wafer fabrication plant is often a large building with numerous specialized equipment and devices. Such a building is too valuable to be shut down. Thus, when a disaster occurs, one needs to identify vulnerable building elements and devices so as to perform appropriate countermeasures in hopes of mitigating the impact resulting from CI interdependency.

In the architecture, engineering and construction (AEC) sector, building information modeling (BIM) is a new and promising technology and can be defined as a digital representation of the physical and functional characteristics of a facility [5]. In fact, a building's BIM model contains not only detailed geometric information but materials and equipment-related data. Such data sets could be a valuable asset to disaster mitigation; nevertheless, previous research majorly investigates how to extract the geometry information of a BIM model in support of disaster simulation tools such as FDS. During the course of a fire incident, actually both the location and status of each automatic sprinkler device may need to be obtained and analyzed so as to help predict how the fire will proceed. BIM certainly can provide such assistance and requires further investigations.

Ontology comes from the philosophy field. It can be used to represent BIM and disaster-related attributes and to perform reasoning tasks. In other words, if we can build a BIM model close to the real world and transform it into an ontology model with disaster-related concepts, we could apply the ontology model to the identification of critical building elements and devices vulnerable to a given disaster. To this end, the objectives of this research include:

1. Developing a model transformation tool that can extract needed BIM data into the proposed ontology model. The design of the ontology model is based on the disaster-mitigation-related literature. Nevertheless, actual values or individuals need to be generated based on the corresponding BIM model. A computerized tool is developed to expedite such a transformation process.
2. Solving the problem regarding the lack of semantic relationships in the current BIM-based geometry data set. Current disaster simulation tools can extract only the geometry data; however, having such semantic relationships can further improve the disaster simulation process. For instance, currently if a FDS-based tool is supplied with the geometry descriptions of each room or space, since doors or windows inside such rooms or spaces are represented as openings, they are not linked into any wall. Because fire can be prevented from entering another room if a fire-proof door is installed, such information can be easily encoded into a semantic relationship and be used to help the disaster simulation process. Nevertheless, in current geometry data sets derived from BIM tools, no such semantic information exists.
3. Developing rule-based constraints to locate critical building elements and devices vulnerable to a given disaster. Once the semantic relationships can be encoded into the proposed ontology model, one can develop Semantic Web Rule Language (SWRL) constructs to formally describe different behaviors under the context of a different disaster. SWRL constructs are frequently utilized in other domains with ontology models and reasoning tools. Here the SWRL constructs pertaining to functional constraints of a critical building element and devices will be defined.

The manuscript is structured as follows: Section 2 describes important literature to highlight key features of ontology models. Section 3 presents the proposed approach with tools, while Section 4 discusses the application with a real case data set. Finally, Section 5 concludes the research and indicates future research work.

2 Related Work

In the previous research conducted by Leite and Akinci [6-7], they proposed an ontology model with four classes for handling building emergency events, i.e., Content, ContentType, BuildingSystemSupply, and Threat. ContentType is defined as the type of an asset within a building. An asset (represented as Content) in a building must be worth protecting, e.g., a painting or a critical device. These assets require the building to provide some supply (represented as BuildingSystemSupply), which may be water, electricity, gas, etc., to work properly; therefore, asset types and building systems supply form a many-to-many relationship. Additionally, one asset may be subject to one or more threats (represented as Threat). It is hypothesized that the threat posed by a building system is causing the asset to be destroyed or malfunctioned.

In their papers, two types of such damage have been identified. The first one is about spatially adjacent influence, which makes the assets close to the destruction point also damaged. For example, the water leakage event can be expanded from the lowest position of the event. If the leakage problem is not fixed, all the assets close to the event location will be affected. The second type is about connectivity, which means that any system failure resulting from a pipeline can be expanded into other places along the pipeline, so as to create more system failures, such as power failure. In fact, all the systems needing power supply within the circuit loop are stopped. Cascading effects may occur among all the devices and equipment needing such systems.

In order to solve the problem regarding CI interdependency, researchers have utilized the input-output model and obtained positive feedback [8]. However, there are two issues associated with this approach. One is about the difficulty of collection inoperability information for a facility, which is common to almost all CI-related approaches. The other is about the difficult of identifying all relationships between the target CI systems or components. The input-output approach does not provide a clue to such identification; hence, qualitative analysis such as expert evaluations is often utilized and have been criticized for years.

Because BIM contains both geometric and non-geometry information, it could be used to assist in the CI analysis. Based on Leite and Akinci's ontology model, the research team utilizes BIM tools to automatically craft an ontology model representing the spatial layout of a given building. Since it is difficult to manually convert a BIM file to an ontology model, such model transformation tools can not only reduce the conversion time but ensure the quality of the model, which has not been seen or reported in the literature.

3 Methodology

This section will first describe the entire research process. First use the Add-in function of Autodesk Revit 2015, the BIM model editing software. Using Revit API to write the convert program from BIM model to ontology model in Visual Studio 2015. Extract and compile the BIM model information required by the disaster impact architecture into the OWL file format. Then use Protégé 5.0.0 to turn on the converted ontology model. Begin to construct disaster impact rules with semantic web rule language. And use the disaster impact rules to infer the impact of disasters. Finally, we use semantic query web language to present the results through the query.

Autodesk Revit 2015 provides Add-In function. Users can use it to write C # programs with the Revit API for working in Revit. The OWL file format is derived from the RDF file format and is similar to the XML format. Therefore, the convert program is mainly written using the XML library and the Revit API. OWL file format can be divided into declaration area, category area, property area and object area. The declaration area is an OWL file attribute declaring to be used in other areas, such as swrlb, owl, swrl, and protege, and is represented by xmlns: swrlb. Since the OWL file format is not, after all, an XML file format, not all XML libraries are available. This method requires the use of a flexible XML library to successfully write. For example: Some XML libraries have header files that do not allow "<? Xml version =" 1.0 "?>", Which must be added to "encoding" or something else. The category area is a category that is written in the ontology model, for example: the category of the door, denoted by "<owl: Class rdf: ID =" Door "/>. The property area describes the Object Property and Data Property in the ontology model. The difference with the category area is that it needs to define Domain and Range. The object area is Instances that describe the ontology model. The formation of the OWL file format across four regions enables Protégé to access a nearly real-world ontology model transformed from BIM with vast information.

Revit API can be divided into the main categories of objects, names and declarations. An object's category and name are simple compared to the association. From ElementCategoryFilter, you can filter the required object names and categories to IList <Element>. However, it must describe its association with other objects. That is, it must describe what gate is at what wall in the object area of the OWL file. In the program, in addition to using the Insert function to describe what the door is located outside the wall, there is also the use of BuiltInParameter.ELEM_ROOM_NAME and BuiltInParameter.ELEM_ROOM_NUMBER describes the relationship between the object room. Finally, the format in the OWL file is combined with the object information retrieved by the Revit API.

After the process of conversion to form ontology model, you can use ontology editing software Protégé to open it. SWRL is to write rules and make inferences about ontology models. Flooding was used as a case study in this research. First, the categories of disaster impact architecture include doors, walls, rooms, appliances, flooding, sockets and switchboards. Properties then include HasDoor for the door, Height for the flooding height, and DoorFlood for the flooding height of the door. HasDoor is mainly the object-to-object property, and Height is the property of the object and the value. Through the combination of the object and the property, HasDoor describes the framework for analyzing the disaster impact.

Then, in order to set the rules, the pre-defined scenarios need to be designed. Therefore, based on the research needs to infer the impact of flooding, the key is to prove the feasibility of this method, so only in a simple way to infer the flooding, and mainly flooded by the door so highly reduced way to research.

The research will be set to the following assumptions:

1. Assume that the main corridor flooded at a height of 2000mm.
2. The doors have their height reduction coefficient. If the flooding height is 2000mm, the coefficient of the door is 0.8, then after the door, the flooding height is 1600mm.
3. Electrical appliances have their damage height and damage properties. If the damage height of the computer is 600mm and the flooding height is 800mm, then the computer's damage attribute will be YES.
4. Sockets and distribution boards have their own damage properties, and will affect the electrical properties of the stall. If the distribution board is damaged, then all the electrical stalls. If the outlet

is damaged, the appliance associated with it will stop.

5. The rule will deduce that if the flooding height of a certain area is a certain height, it will affect the flooding height of all the places, the situation of electrical damage and stalling.

The research is based on the above assumptions SWRL preparation. It should be noted that the rules of the SWRL because it can only be simple reasoning and no difference set concept. After the rules are written, inferences about the effects of flooding can be obtained, and its process as shown in Figure 1.

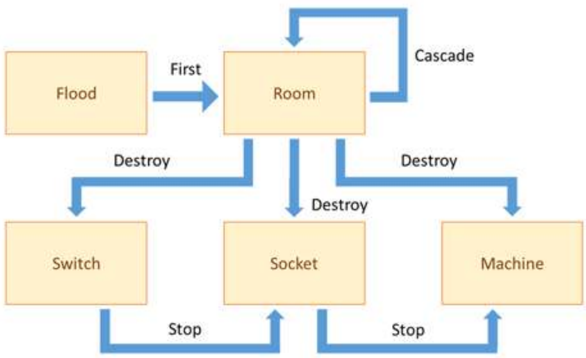

Figure 1. Reasoning Process Diagram

The disaster impact rules of SWRL can be divided into two types, one is to infer the flood level, as shown in Equation 1, and the other is to infer the electrical state, as shown in Equation 2.

Room(?r) ^ HasWall(?r, ?hw) ^
HasDoor(?hw, ?hd) ^
Room(?r2) ^ HasWall(?r2, ?hw2) ^
sameAs(?hw, ?hw2) ^ differentFrom(?r, ?r2) ^
DoorWeak(?hd, ?dw) ^
RoomHeight_1(?r2, ?rh1) ^
swrlb:multiply(?new, ?dw, ?rh1)
-> RoomHeight_2(?r, ?new)

(1)

Machine(?m) ^ MaBreakLevel(?m, ?mabl) ^
MaInRoom(?m, ?mair) ^
RoomHeight_1(?mair, ?rh1) ^
swrlb:lessThanOrEqual(?mabl, ?rh1) ->
MachineDestroy(?m, "1"^^xsd:int)

(2)

Equation 1 first use *sameAs(?hw,?hw2)* to find rooms with the same wall, and then use *HasDoor(?hw, ?hd)* to select the wall has door, and use *differentFrom(?r, ?r2)* to exclude the room itself, and next use *DoorWeak(?hd,?dw)* to get the height reduction factor, and finally get the reasoning result of flood. Equation 2 mainly uses *swrlb:lessThanOrEqual(?mabl, ?rh1)* to compare *MaBreakLevel(?m, ?mabl)* and *RoomHeight_1(?mair, ?rh1).* If *MaBreakLevel(?m, ?mabl)* is less than or equal to *RoomHeight_1(?mair, ?rh1)*, MachineDestroy(?m, "1"^^xsd:int) will be expressed as 1, that is, destroyed.

SQWRL uses MySQL-like settings to further refine the results of SWRL for completeness and alignment. it uses in the research was to reduce the flooding height by using a factor so that the flooding height only decreased as a result of the cascade effect. Therefore, the method of determining the final value is to take the maximum value of the result as its setting criteria. The rule also uses numbers to indicate the stalling and destruction of equipment. If the flooding height reaches its height of damage and stall, set its associated value attribute to 1 to indicate that the device has been destroyed or stopped. Corollary results were generated electrical stall table, electrical damage table, flooded altimeter table, socket damage table, outlet stop table and power distribution board damage table. Equation 3 uses SQWRL to select the flooding height of each room.

Room(?r) ^ RoomHeight_All(?r, ?rh) ˚
sqwrl:makeBag(?b, ?rh) ^ sqwrl:groupBy(?b, ?r)
˚ sqwrl:max(?max, ?b) -> sqwrl:select(?r, ?max)

4 Case Study

The model of Taipei MRT Nanjing Sanmin Station comes from the project and station managers. The station's main body is divided into three floors, ground floor, hall floor and platform floor.

The top floor of the MRT station is the ground floor. It usually has a device to prevent floods. The height of the pump's switch is located at a flood level of 200 years plus 110 cm. The basic height of the entrance also increased. Used to prevent flood entering MRT station.

The hall floor for the main flow through the site. The name of the space through the hall can be divided into recreation room, environmental control room, uninterruptible power system room.

The bottom of MRT station is platform floor. This floor more facilities for the ventilation shaft, exhaust and intake. It is mainly to solve the pressure caused by vehicles entering and leaving the rise and fall. And by air pressure to provide vehicle braking and deceleration features. In addition, this layer is also equipped with pumping equipment, pumping equipment for the entire body of the site. While others are similar to the through-hall, possessing the space for environmental control and power supply system and also based on the symmetry.

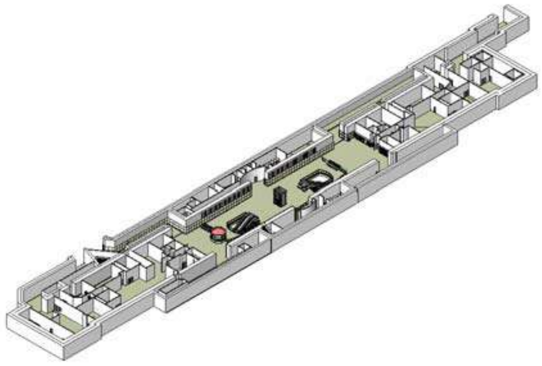

Figure 2. Hall Floor of Nanjing Sanmin Station

However, the details of the platform floor are not clear. And the ground floor only has entrance, not too many objects. Therefore, research proposals, the main reference to about the hall floor. Only in this way can we get the complete and accurate research results.

When the building information model is transformed into the ontology model via Add-in, the model itself is not a model that can be correctly analyzed.

In addition to the designer's design habits may cause differences, but also the following possibilities. First, the BIM software used in this research is Revit, which has the settings for connecting appliances and sockets. However, there is no clear classification of objects requiring electricity, resulting in the need for electricity if not for mechanical equipment, electrical equipment, etc. Objects, are required in the program clearly defined as the need to power the object is also defined in the ontology editor software. Second, most building information models have not yet added switchboards, sockets and electrical appliances. Therefore, the model used for the construction of the Nanjing Sanmin Station in this research has not been provided yet. Therefore, it is necessary to establish electrical appliances in each area so as to understand flooding mechanism is the more appropriate approach, and the ontology model to add, is a more efficient approach.

As shown in Figure 3, this is the result of SWRL reasoning. RoomHeight indicates the water height of the room affected by flooding. RoomHeight_1 indicates the results obtained by cascading the first flood effect. Similarly, RoomHeight_2 is the second time. And RoomHeight_All sets the value of all the water heights. The research is to find the maximum of all water heights because we defined the water height of room comes from the other rooms that would cause this room the highest water height after cascading effect.

However, although SWRL successfully deduced the result, it did not sort it out. So we need to use SQWRL to rank the results we need. As shown in Figure 4, the research continues by writing the SQWRL in SWRL and shows the results in the program, while Figure 5 shows the detailed results. In Figure 5, “1” indicates that the appliance has been damaged, “0” indicates that the appliance continues to operate, and Total_Machine_Stop tab, Total_RoomHeight tab, Total_Socket tab and Total_Switch tab in addition to the Total_Machine_Destroy tab.

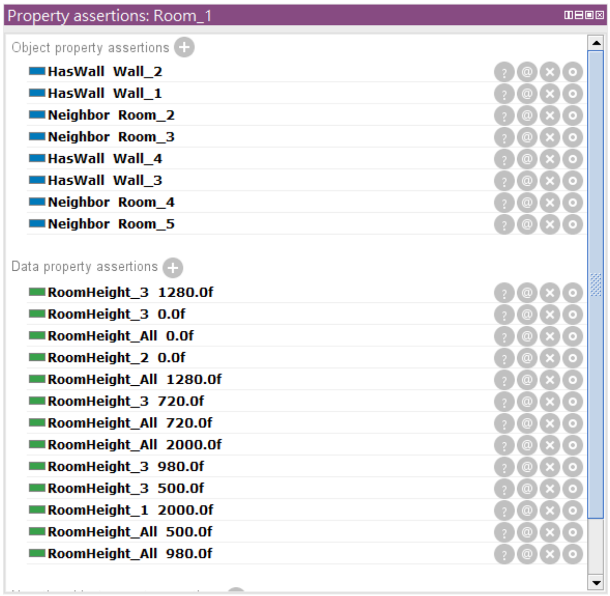

Figure 3. Room_1 Result of SWRL Reasoning

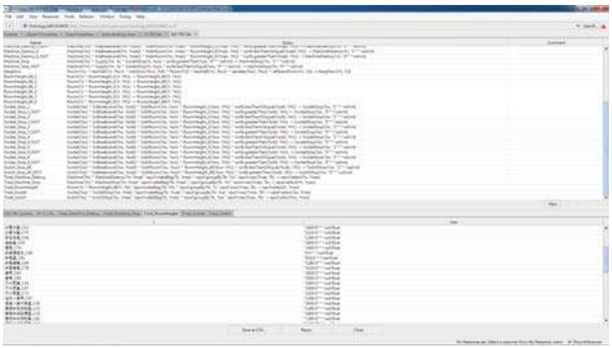

Figure 4. Result of SQWRL Query

5 Conclusions

When analysing the progress of a disaster inside a building, one needs a model representing the building's spatial layout with important building-material-related attributes. Certainly, the Revit tool developed in this research can provide such information. In addition, disaster-specific properties and their interactions with buildings can be modelled using SWRL constructs. Take flooding as an example, one may be able to retrieve watertight doors, sluice gates and pumps information from a building's BIM model. In the future, if this method can be more complete and common method of analysis, or design the user interface to allow users to make self-defined special analysis, and based on this research method, we can analyse all kinds of disasters comprehensively at the same time and use them to get the advantage of more disaster-affected data quickly. Finally, we can analyse the matrix and vector of input-generating model. In addition to contributing to disaster preparedness, expecting to send the results back to Autodesk Revit for visualization will provide a better understanding of the impact of the disaster.

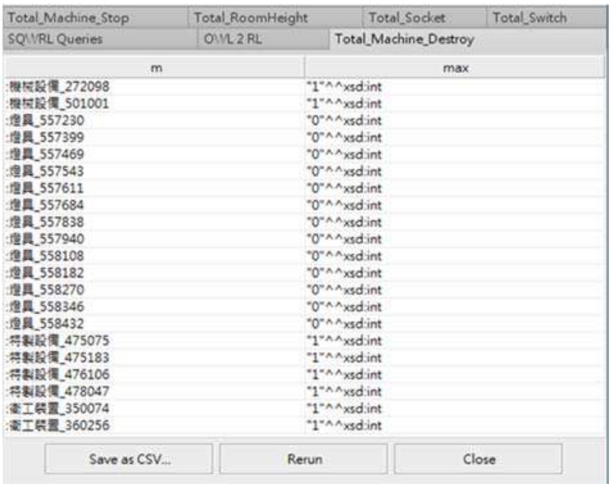

Figure 5. Detail Result of SQWRL Query

Taking the ontology model as the main reasoning can take advantage of the logical relationship between objects. If the building information model as the main body of analysis, in addition to only have to write the program is not good at logic inference analysis, the building information model of the huge information also caused the analysis time-consuming. The ontology editorial software is not only based on the advantages of logical reasoning, but also because of its SWRL and SQWRL, making it easier to write and manage. Taking the information model of the Taipei MRT Nanjing Sanmin Station as an example, the time it takes to open and change is quite time-consuming. Even when operating on a general-purpose laptop computer, it still takes about 3 minutes for the program to open the file, or change the viewing angle to wait 5 seconds. The ontology model of file capacity is better. The file size of the information model of the Taipei MRT Nanjing Sanmin Station is about 2 GB. However, the information extracted by ontology accounts for at most 1 MB, and the difference between the visualizations is not significant. Due to programmatic transformation and the extraction of valid information, it is expedited to research the reasoning. However, the version of Revit API has been greatly changed. Due to the complexity of building information model, the classification of its functions is cluttered and flawed. If this weakness can be solved, Software replacement or version has a considerable improvement, will be able to have more space for this research.

Abstract –

This study suggests an indoor localization method to estimate the location of a user of a mobile device with imaging capability. The proposed method uses a matching approach between an actual photograph and a rendered BIM (building information modeling) image. A pre-trained VGG 16 network is used for feature extraction. Experimental results show that the best image matching performance can be obtained when using features from pooling layer 4 of VGG16. The proposed method allows for indoor localization only by image matching without additional sensing information.

Indoor Localization; Cross-Domain Image Matching; Convolutional Neural Network; Feature Extraction;

1 Introduction

A technique of acquiring the position and orientation information of a person in indoor environment is essential for presenting the information that the person needs at the location. The construction industry utilizes indoor localization technology for maintenance of facilities using augmented reality [4], evacuation route guidance in case of disasters [3], and understanding work situation [1,7].

Vision-based indoor localization estimates the user's location based on visual information obtained from the indoor image. Image-based indoor localization methods can utilize a pre-built image dataset that contains indoor photographs. Since the images in the dataset have the basic information (position and orientation) necessary for localization, the person's indoor position can be estimated by searching the image in the dataset, most similar to the photograph taken indoors. However, it is time-consuming and labor intensive to build datasets of indoor environments for localization.

This study utilizes the BIM (building information modelling) model of a building for its indoor localization, to construct the image dataset. BIM has become increasingly utilized as it is proving its versatile utilities in the construction industry. Since BIM contains a range of information of a building and it is easy to extract information at the location of interest, BIM is also used for localization with sensors [6-8].

This paper proposes a deep learning-based method to estimate the indoor position of a mobile device user, using an image dataset constructed from a BIM model. A deep learning network is an advanced form of traditional neural network, strengthened by the ability to learn important features without relying on human intervention. Image features extracted from a deep learning network are used to compare similarity between photograph and BIM-based images. That is, the visual characteristics of BIM is used for image-based indoor localization, without using additional sensing information.

2 Methodology

The image dataset is constructed by rendering indoor BIM views to images. The rendered images are visually similar to the actual indoor photographs, but there is a difference in style because the domains are different from each other, as shown in Figure 1. The evaluation of the similarity between images for image retrieval is mainly done by comparing their features. Conventional feature extraction methods, such as SIFT (scale-invariant feature transform), have been widely used for the same domain comparison in previous studies.

Figure 1. BIM image (left) and photograph (right) taken from the same location and orientation

This study proposes using the CNN (convolutional neural network) for feature extraction to compare indoor photographs and BIM images. CNN is a kind of deep neural network, appropriate for image processing. It consists of stacked layers and learns to extract meaningful features of images. In a convolutional layer, features in adjacent parts in image are extracted in a form of two dimensional array (feature map) and semantically related features are merged in a pooling layer [5].

Feature maps that passed through each layer of pre-trained CNNs are used as features of images for the cross-domain image retrieval. The CNN network trained for object classification with ImageNet dataset [2], a large image dataset, shows excellent performance in feature extraction even when applied to other datasets [9].

A pre-trained CNN is used to match indoor photographs with BIM images in the dataset based on the similarity between images. The evaluation of the similarity between the cross-domain images for image matching is mainly done by comparing their features with cosine distance. Figure 2 shows the proposed method.

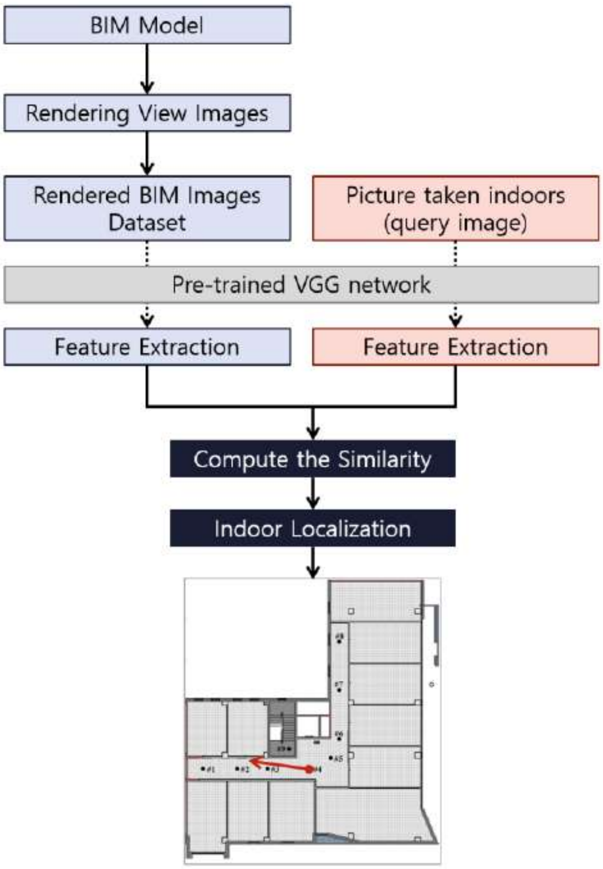

Figure 2. Image matching for indoor localization using BIM and CNN features.

3 Experiment

Experiments were carried out at the North Wing of the 1st Engineering Building of Yonsei University in Korea. As shown in Figure 3, the BIM image dataset for the experiment consists of images rendered in various directions at nine locations.

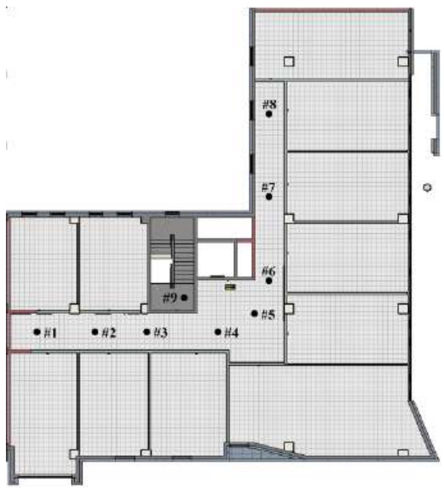

Figure 3. Floor plan of the building where the experiment was performed and the locations selected for view extraction.

Two datasets were created to evaluate the performance of the method. Level 1 dataset contained images with relatively fewer overlapping views as shown in Figure 4(a), and Level 2 dataset contained views in all directions, which resulted in more overlapping views as shown in Figure 4(b). The indoor photographs were taken in the same location and direction as the BIM images of the dataset, and the similarity with the dataset images was evaluated.

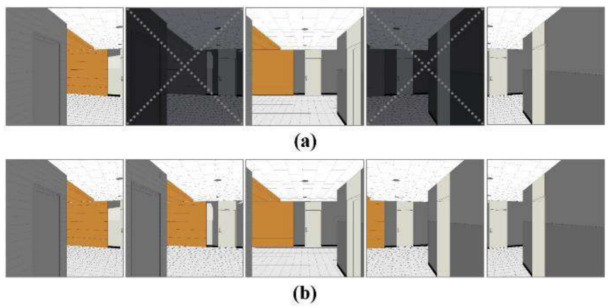

Figure 4. Examples of dataset images; a) Level 1: fewer overlapping views; b) Level 2: more overlapping views.

The VGG 16 network [10] was used as a CNN in the experiment. There are five pooling layers in the VGG

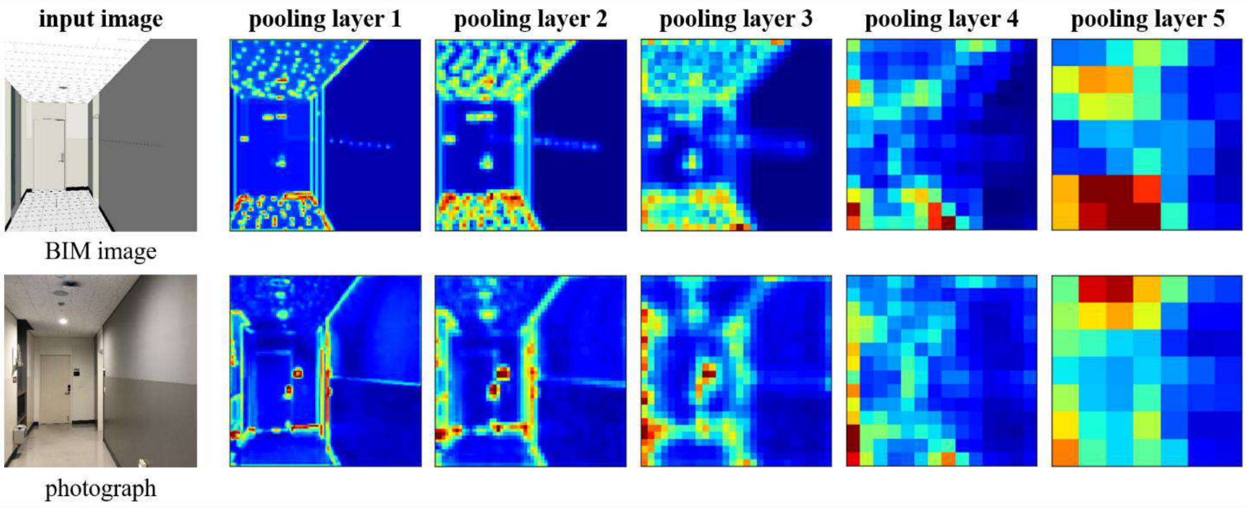

Figure 5. Visualized feature maps of BIM image and indoor photograph

network. The VGG network in the experiment was pre-trained with ImageNet dataset and the outputs of five pooling layers of the pre-trained VGG 16 network were used as features of the image. To evaluate the similarity between the cross-domain images, features from the pooling layer of the same order were employed. For example, the second layer output of the network for the actual photograph was compared with the second layer outputs of the network for the BIM images.

Table 1 shows the results of image matching based on features obtained from each pooling layer of the pre-trained VGG network for the two datasets. When using the features obtained from pooling layer 4, the image matching accuracy is over 90% in both datasets.

Table 1. Experimental Result

Dataset (number of images)	Level 1 (54)	Level 2 (86)
	Accuracy (%)	
Pooling layer 1	64.81	54.65
Pooling layer 2	64.81	52.33
Pooling layer 3	79.63	77.91
Pooling layer 4	**92.59**	**90.70**
Pooling layer 5	74.07	75.58

4 Discussion

Experimental results verified the proposed image-based indoor localization method with the high matching accuracy. The BIM image that was selected as the most similar image to the indoor photograph had the information about indoor location and orientation. In other words, when the matching was correctly done, the position at which the indoor photograph was taken could be estimated by the proposed method.

This study revealed which layer of VGG 16 network extracts the most proper features for matching the indoor photograph and BIM image. Figure 5 exhibits visualized feature maps from each pooling layer when paired BIM image and indoor photograph pass through the VGG 16 network. As the network deepens, it can be observed that features corresponding to large parts of the image are gradually extracted. Through the features obtained from pooling layer 4, which shows the best performance, it can be inferred that a global descriptor representing the structural information of the indoor is suitable for the cross-domain image matching.

As shown in Figure 5, a noticeable difference in the arrangement of colors can be identified in feature maps extracted from the front of the network. In other words, when the domains between images are different, the features that stand out in the images can be different and the difference is more apparent for features extracted from a local area. Therefore, it can be confirmed that the global descriptor is required for cross-domain image matching, and the experimental result verified that the features extracted from pooling layer 4 have the best image matching capability.

The proposed method performed well both in Level 1 and Level 2 datasets. In Level 2, there were images with high degree of view overlap between images and the number of images was about 60% larger as compared with Level 1. However, the accuracy of image matching of Level 2 was not affected much–decrease by 2% compared with Level 1. These experimental results indicate that the proposed method can be applied well in larger indoor environments.

5 Conclusions

This paper proposes an image-based indoor localization method to identify a mobile device user's location and orientation by matching the indoor photograph acquired by the user to the image rendered from the BIM model. Features for evaluating the similarity between the indoor photograph and the rendered BIM image were extracted from the pre-trained VGG 16 network. A field experiment, involving a floor of an actual building, was conducted to verify the proposed method.

This study has three major contributions. First, since the existing BIM model is used, the labor required to construct the dataset is reduced compared to the existing methods. Secondly, the feature extraction layer most suitable for the cross-domain image comparison was identified in the VGG network. Finally, since the pre-trained CNN is utilized, the proposed method can be applied in another place without modifying the network.

As a future study, it is necessary to verify the proposed method with a dataset configured in a more diverse environment. In addition, since using only a single image for localization may have limitation, it can be supplemented by using multiple images for more accurate localization. The proposed method, with the additional research, is expected to improve the traditional facility management process.

Abstract

The emergence of Building Information Modeling (BIM) technology makes the quantity takeoff process faster and more reliable. It helps reduce the effort in cost estimation to survey the cost feedback on alternative schemes in the early stages of design. However, at these stages, the quantity could be absent or in excess because the BIM model has a low level of development (LOD). The building elements that have layered structures such as architectural walls always face such problems. This is because during the construction phase, each layer may have a different dimension. For instance, the height of the interior finish layer of the wall may be shorter than that of the core layer. On the other hand, the walls in a BIM model during the early stages usually have low LOD. Each wall layer is not created separately and some walls may overlap structural elements because the designers need a schematic BIM model that is easy to create and manipulate. This research proposes a method that will improve the accuracy of the wall quantity takeoff in the schematic BIM model by applying the concept of BIM-based clash detection. The proposed method automatically detects the overlapped areas and subtracts or adds the material quantity of each wall layer without the need for editing the BIM model. The now accurate quantities can then be used in the chosen project delivery method where a cost estimation feedback is needed during the early stages of the design process.

Building Information Modeling, BIM, Quantity Takeoff, 5D BIM, Quantification, Early Stages Design, Schematic BIM Model, Clash Detection

1 Introduction

Quantity takeoff is a time-consuming task in the design and construction process. Traditionally, quantity takeoff is done manually based on 2D drawings' measurements. Quantity surveyors need specialized knowledge and experience to understand the set of design drawings; which are a series of 2D projections. They have to understand the design and decide the measurement method to be used for each building element. This process is time-consuming and the results from each quantity surveyor may not be the same.

In a conventional project delivery method or Design-Bid-Build (DBB), a precise quantity takeoff for detailed cost estimation is done after the design phase for bidding. However, there are other delivery methods such as Design-Build (DB) and Integrated Project Delivery (IPD) in which design and construction teams work together as an integrated unit from the onset [1]. One of the goals of these delivery methods is to reduce the projects' cost in order to deliver the project within the owners' budget. An accurate cost estimation during the early stages of the design can help the team to make more informed design decisions [1, 2]. Therefore, precise quantity takeoff during these early stages is important.

The emergence of Building Information Modeling (BIM) technology brings with it a new method of quantity takeoff, called a BIM-based method. This method uses geometry data: such as length, area, and volume as well as the objects information: such as category, name, and level in the BIM model for quantity takeoff. The BIM-based quantity takeoff method is proven to be faster and more reliable than the traditional 2D-based method [3]. However, this is not a straightforward or automatic process [2, 4]. Some quantity can be absent from the BIM model due to the incompleteness of the model compared to the real construction [5]. This issue usually occurs in the early stages of the design; where designers make a rough BIM model in order to explore the design. Some of the data has yet to be defined and some objects may overlap each other causing inaccuracies in the quantities reflected.

Architectural elements that are layered structures always have complications when measuring quantities off of them. For example, architectural walls are non-structural elements which are used to divide or enclose spaces. These walls can be built either between structural frames as an envelope of the building or as interior partitions to separate each room. Architectural walls consist of both a core structure layer which is typically masonry units or stud framing and finish layers which are typically plaster, tiles or wall panels. Each layer has a different size and quantity. For example, the plaster layer height on the interior may only go up to ceiling height whilst on the exterior, it may cover the surface of the beam above (see Figure 1). The measurement variable for the architectural wall materials is an area. In order to measure the accurate quantity of the wall, quantity surveyors have to measure the surface area of each layer separately. They cannot use the core layer area to infer the finish layer areas - as these would differ.

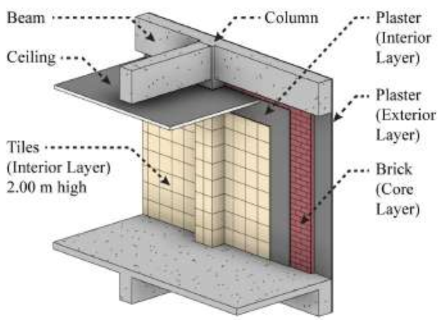

Figure 1. The example of the architectural wall that has four material layers and each layer has a different size and quantity.

In the early stages of the design, which cover the schematic design phase and design development phase, designers use a low Level of Development (LOD) [6, 7] for the wall elements in a schematic BIM model. The walls may overlap structural elements and each wall layer is not created as a separate element. This causes inaccuracies when extracting the wall and wall finishing quantities from the model.

The objective of this research is to find a new method to calculate the quantity of each wall layer in a schematic BIM model. The proposed method will improve the accuracy of the wall quantity takeoff in the early stages of the design when the BIM model is still schematic and is not as detailed. A concept of BIM-based clash detection is applied in the proposed method to enhance the BIM-based quantity takeoff. The scope focuses on architectural walls in a schematic BIM model where walls are at LOD 200 and 300 according to the Level of Development Specification 2017 by BIMForum [7]. The implementation is done by developing Dynamo [8] scripts for Autodesk Revit that can detect the overlapped area and subtract or add the material quantity for each wall layer. With this method, the chosen project delivery system such as DB or IPD will benefit from the accurate quantity takeoff for cost estimation in the early stages of the design. Furthermore, the designers or modelers can edit and adjust the BIM model easily since this method does not interfere with the original BIM model.

2 Literature Review

The strength of BIM is in its ability to share the same information among different disciplines. Hardin [1] discussed the uses of BIM in four types of project delivery methods, namely Design-Bid-Build (DBB), Construction Management at Risk (CM-at-Risk), Design-Build (DB), and Integrated Project Delivery (IPD). In the DBB method, the potential of BIM is limited because no information is shared between design teams and contractors during the design phase. Conversely, the use of BIM fits well in the CM-at-Risk, DB, and IPD methods because there are more integration and collaboration between the design and construction teams from early on. Consequently, the construction costs can be estimated during the design phase in order to verify whether or not the design is within the projects' budget.

According to Eastman et al. [2], the use of BIM for accurate quantity takeoff and cost estimation in the early stages of the project is most valuable. It is stated that "Today's use of BIM is typically limited to the late phase of design and engineering or early phases of construction. Use of BIM earlier in the design process will have greater influence on cost."

Although BIM-based quantity takeoff is reliable [2], some deviation still occurs due to practical and technical issues. With regards to the practical issues, the quality of the BIM model is a major concern [9]. Olsen and Taylor [5], interviewed general contractors and reported that up to half of the data, including architectural finishes, is absent from the BIM model because the model does not have enough detail yet. As for the technical issues, there are three causes. Firstly, some BIM software products do not have the specific modeling tools for some building elements. For example, there is no modeling tool to create formwork or rebar in ArchiCAD software [4]. Secondly, the software calculation method for some elements is incorrect [3]. And thirdly, some of the data is lost when transferring the files between BIM software products [2].

Several studies have been done on the improvement of BIM-based quantity takeoffs. Monteiro and Martins [4] explored BIM-based quantity takeoff using ArchiCAD software. This study showed that some elements could not extract the desired quantities. It was suggested to use another modeling tool in order to get the desired quantities. For example, using slab and wall tools to create stairs in order to get the volume of concrete needed. Kim et al. [10] proposed a BIM-based quantity takeoff method for building interior from a given space or room. Cho and Chun [11] proposed methods for estimating the cost of reinforced concrete structures in the design development stage by quantity takeoff and quantity prediction using data mining. Choi et al. [12] developed a quantity takeoff system that can estimate the quantity of the building frame in the early stages of the design. Rajabi et al. [13] developed a system that can estimate the quantity of mechanical, electrical, and plumbing in the early stages of the design. Lee et al. [14] studied a method to analyze the construction productivity. This study developed formulas to calculate structural formwork quantity by considering the overlapped area of concrete.

Although studies exist for quantity takeoff of many building elements, there has yet to be any research concerning the quantity takeoff for architectural walls.

3 BIM-based Quantity Takeoff Software and Its Limitation

BIM-based quantity takeoff is related to the Level of Development (LOD) of BIM elements. According to the Level of Development Specification Guide [6], LOD is divided into six levels. These are LOD 100, 200, 300, 350, 400, and 500. No standard exists to select the LOD for each BIM element in the phases of a buildings' lifecycle [6]. However, the study by Grytting et al. [15] concluded that in the early stages of the design, the LOD of BIM elements ranges from LOD 100 to LOD 300. Therefore, the proposed method used in this research is made for the wall at LOD 200 and LOD 300 since there is no definition of a wall at LOD 100 in the Level of Development Specification. The wall at LOD 200 is a generic wall with no material layers and the wall at LOD 300 is a single wall element with defined layers of core structures and finishes [7].

The early stages of the design are divided into two parts; a schematic design phase and a design development phase. In the schematic design phase, the designers may choose the walls at LOD 200 and make them penetrate columns and overlap with beams and floors of the level above. This is because schematic models need to be created and edited easily. When the design is then moved on to the design development phase, the designers may change the walls to LOD 300.

There are numerous BIM software tools on the market that can perform a quantity takeoff. However, this study makes use of Autodesk Revit software as it is currently the most popular BIM software for architectural works [5, 16, 17] and can perform a quantity takeoff efficiently.

Autodesk Revit has a schedule feature which extracts quantities in two different ways: by quantities and by material takeoffs. Quantity takeoff schedules extract data properties from the Revit elements. Material takeoff schedules extract data properties from the sub-components or materials of the Revit elements. Both quantities and materials can be extracted from architectural walls in Revit. If the wall layers are defined, the area of each material layer can be seen in a material takeoff schedule.

The investigation using Revit software reveals that when walls overlap with structural frames, the graphic shows the walls as being trimmed. When in fact, the area of the walls has not been deducted yet. Designers will then have to manually separate walls from the structural frames. One way to do this is to use the Join Geometry tool to create a cut between the walls and the structural elements. This tool will cut away the overlapped area of the walls. The quantity result is shown in Figure 2. However, editing every wall is time-consuming and the material quantities of the finish layers are still inaccurate. The areas of the interior and exterior finish layers that cover the surface of the structural elements are absent because the walls have already been cut with the structural elements (see red line in Figure 2).

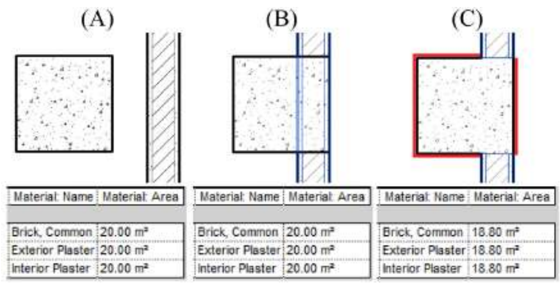

Figure 2. (A) Wall material area when the wall is outside the column. (B) Wall material area when drawing the wall through the column. (C) Wall material area decreased after using the Join Geometry tool. The red line shows the areas of the finish layers that are missing from the model.

Bečvarovská and Matějka [3] suggested that BIM models need to be made as close to the real construction as possible in order to perform an accurate quantity takeoff. Nevertheless, editing the model or creating each wall layer separately is time-consuming and impractical for the early stages of the design as the design will change many times.

4 Proposed Method

Every element in a BIM model is an object with semantic properties that represent the element in the real world. The semantic properties of each element, such as category and type can be used for multiple benefits. One benefit is that it can be used for checking the intersection between objects which is called BIM-based clash detection [2].

To improve the accuracy of the architectural walls quantity takeoff, the proposed method would apply the concept of BIM-based clash detection to assist in the BIM-based quantity takeoff. The main idea is to use the information from clash detection to subtract the exceeded quantity or add the absent quantity.

The implementation of the proposed method is done using Autodesk Revit 2018 with a Dynamo extension. Dynamo [8] is a visual programming extension in Revit that allows users to create algorithms to process data or geometry from the Revit model. Each function and variable in Dynamo is represented by nodes. Each node can be wired together to perform operations. The group of nodes can be packed into collections of nodes called packages. Packages can be published to the Dynamo website and shared with the online community.

The method for calculating the area of each layer of the architectural walls is divided into two sections: the calculation method for the core layer and the calculation method for the finish layer.

4.1 Calculation Method for the Core Layer of the Walls

The core layer of the architectural walls is the structure of the walls. The most common materials used for the core layer are masonry units such as bricks or concrete blocks and stud framing such as wood or metal studs. Generally, the core layer does not cover or intersect with other objects, thus the idea is to find the area of the wall that intersects with other objects such as columns, beams, and floors.

The workflow in Dynamo begins with the input of element categories from the Revit model. The categories are walls, structural columns, structural framing, and floors. The overall process is shown in Figure 3.

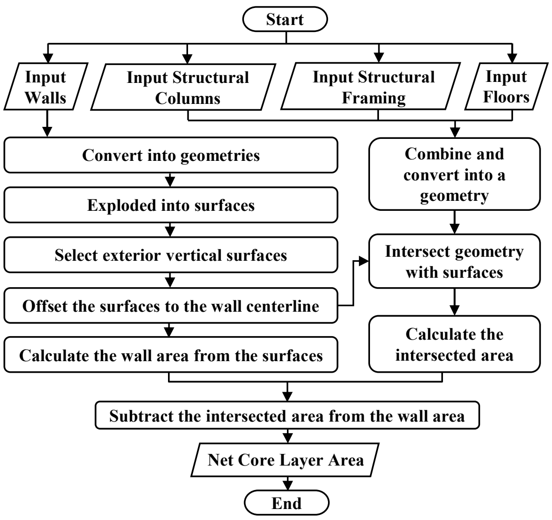

Figure 3. The flowchart diagram of the calculation method for the core layer of the walls.

The structural columns, structural framing, and floors will be combined and converted into a geometry. This geometry will be used to check the intersecting area of the walls.

The walls will then be converted into geometries and exploded into surfaces. The exterior vertical surfaces will be selected and offset to the wall centerlines. These surfaces represent the core area of the wall. They will be intersected with the structure geometry.

The intersected surface will be shown in the 3D view and the intersected area will be calculated and subtracted from the wall area. The result is the net area of the core layer (see Figure 4).

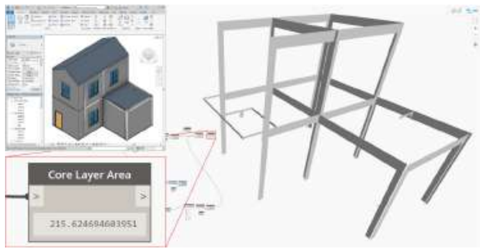

Figure 4. The surfaces of the walls that intersect with columns, beams, and floors are shown in Dynamo. The net core layer area of the wall is calculated.

4.2 Calculation Method for the Finish Layers of the Walls

Finding the area of the finish layers is more complex than the area of the core layer. This is because there are multiple scenarios for each type of finish layer depending on the materials used and the design. Usually, the materials of the finish layers are dependent on the material of the core layer.

The walls that have stud framing at their core, usually have wall panels as the finish layer. Examples of wall panels are wooden planks, gypsum board, fiber cement boards, and cladding. The area of the wall panels is usually equal to the area of the stud framing core as the panels attach to the studs. In this scenario, the same method used for calculating the core layer can be applied to this type of finish layer.

On the other hand, the walls that have the masonry at their core will usually have plaster as the finish layer. In some cases, tiles, wall paint or wallpaper will form the second finish layer on top of the plaster. The plaster, tiles, wall paint, and wallpaper usually only cover the surface of the structural elements that the walls cut through. Furthermore, on the interior, the height of the finish layers may not be as tall as the core layer. The height may only go up to the ceiling or it could have a custom height (see Figure 1). These scenarios need different methods to calculate the finish layer area.

The calculation method for the finish layers of the walls is divided into three parts: the method for the exterior finish layer, the method for the interior finish layer, and the method for the custom height interior finish layer. The concept of clash detection is still used here. Room elements in Revit will be used to check whether the surface of the wall is exterior or interior. The structural elements that intersect with the wall will be used to calculate the covered surface area of the finish layer.

4.2.1 Calculation Method for the Exterior Finish Layer of the Walls

The exterior finish layer is the wall layer that covers the outside surfaces of the building. The materials of these layers are typically plaster, tiles, cladding, or wall paint. This method is developed for the scenarios where the exterior finish layer covers the entire area of the exterior surfaces. The wall surfaces and the structural element surfaces that are exposed to the exterior are included in this method. However, it excludes the surfaces of the roof as well as the top and bottom surfaces of the floor, which typically have other materials.

The workflow in Dynamo begins with the input element categories from the Revit model. The categories are walls, structural columns, structural framing, floors, and rooms. The overall process is shown in Figure 5.

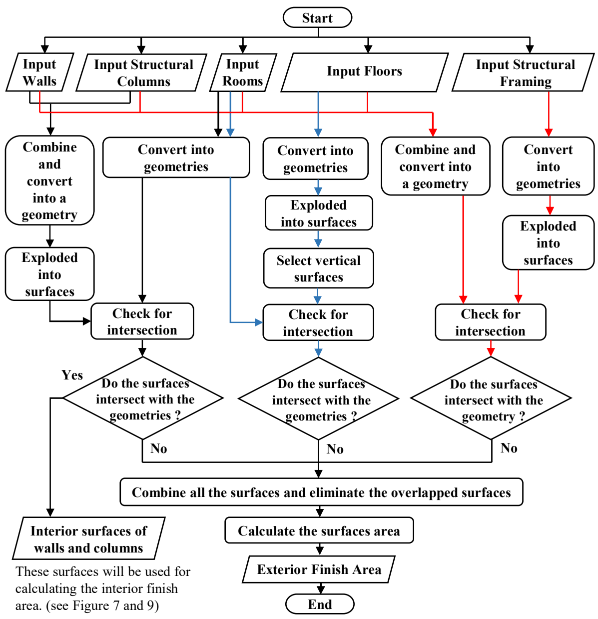

Figure 5. The flowchart diagram of the calculation method for the exterior finish layer of the walls.

In the first step, the walls and structural columns from each floor level will be combined and converted into a geometry. This geometry will be exploded into surfaces and each surface will be checked with the room geometries. The surfaces that intersect with the room will be interior surfaces which will be used for calculating the interior finish area. The surfaces that do not intersect with the room will be exterior surfaces which will be used in the final step.

The second step is to find the surface area of the structural framing (beams) that are exposed to the exterior. The walls, structural columns, floors, and rooms will be combined into a geometry. This geometry will be checked with the structural framing geometries that are exploded into surfaces. The surfaces of the structural framing that do not intersect with the geometry will be used in the final step.

The third step is to find the surface area of the floor edges that are exposed to the exterior. The floors will be converted into geometry and exploded into surfaces. The vertical surfaces will be selected. The rooms will be used to check and eliminate the interior vertical surfaces of the floors such as the interior hall and stairways. The remaining surfaces will be used in the final step.

The final step is to combine all the surfaces from the first, second, and third steps. The result is the surfaces of the wall, structural columns, structural framing, and floor edges that are exposed to the exterior. Thereafter the overlapped surfaces will be deleted. The remaining surfaces will be used to calculate the area of the exterior finish layer of the walls (see Figure 6).

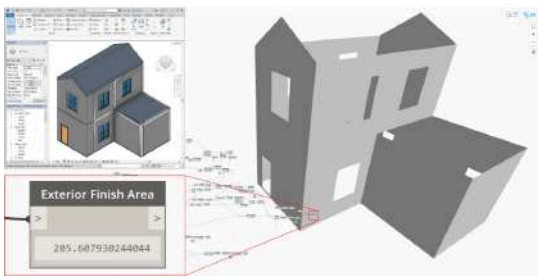

Figure 6. The surfaces of the exterior finish layer and the calculated area are shown in Dynamo.

4.2.2 Calculation Method for the Interior Finish Layer of the Walls

The interior finish layer is the wall layer that covers the inside surfaces of the building. This layer usually covers the surface of the walls and columns in the rooms. The height of this layer usually attaches to the top of the ceiling or the underside of the above levels' beams or floors if there is no ceiling in these rooms.

The interior surfaces of the walls and structural columns from the first step of the calculation method for exterior finish layer of the walls will be used. The overall process is shown in Figure 7.

In order to set the height of the interior finish layer, the Limit Offset property of each room must be set to the ceiling height or the desired height.

The rooms will be converted into geometries. These geometries will be used to subtract the height from the interior surfaces of the walls. The outcome surfaces will be used to calculate the area of the interior finish layer of the walls (see Figure 8).

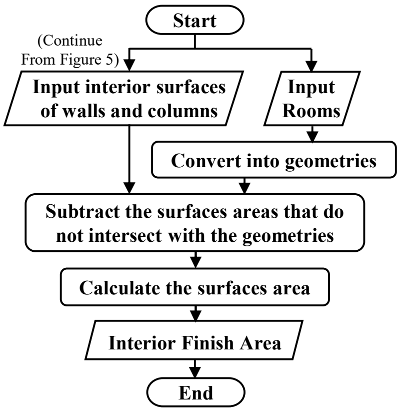

Figure 7. The flowchart diagram of the calculation method for the interior finish layer of the walls.

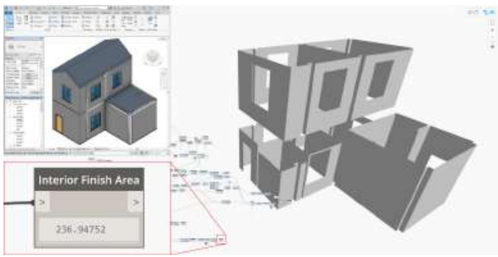

Figure 8. The surfaces of the interior finish layer and the calculated area are shown in Dynamo.

4.2.3 Calculation Method for the Custom Height Interior Finish Layer of the Walls

The interior finish layer may have a second layer. For instance, restrooms or kitchens may have a tile layer on top of the plaster layer. Sometimes the height of this layer will not go up to the ceiling height or up to the underside of the above levels' beam or floor.

The method is similar to the calculation method for the interior finish layer of the walls, but instead it will only calculate the areas for the selected rooms. The overall process is shown in Figure 9.

The desired rooms will be selected by inputting the rooms' name. The selected rooms' boundaries will be converted into surfaces. The surfaces will be extruded into 3D geometries. The height of the geometries will be controlled by the Number Slider node. These geometries will be used to subtract the height from the interior surfaces of the selected rooms. The outcome surfaces will be used to calculate the area of the custom height interior finish layer of the walls (see Figure 10).

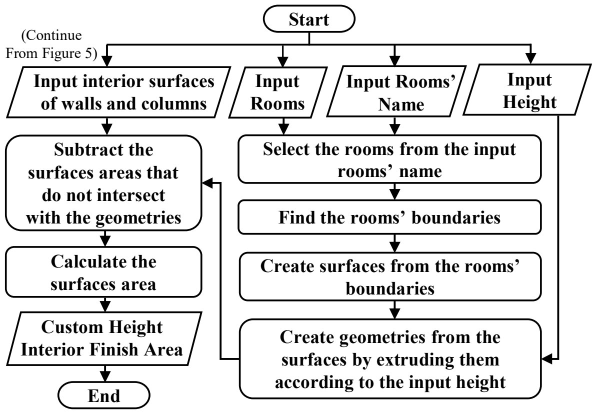

Figure 9. The flowchart diagram of the calculation method for custom height interior finish layer of the walls.

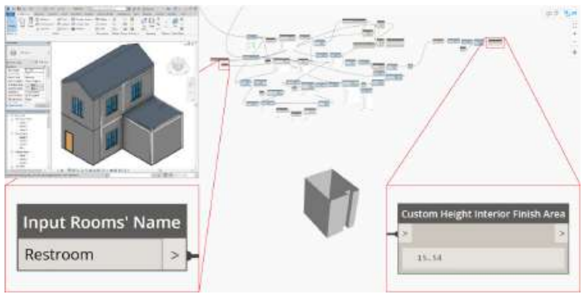

Figure 10. The interior surfaces of the restroom and the calculated area are shown in Dynamo.

5 Implementation and Validation

The implementation is done using two buildings as case studies. Two versions of BIM models were made in Autodesk Revit 2018. One is the schematic model for testing and the other is the detailed model for validating.

The two buildings are different in shape and number of floors, but wall materials, structure type, and level heights are at the same settings. The buildings have reinforced concrete columns, beams, and floors as its structure. The walls are brick masonry with plaster that covers the exterior and interior surfaces. The brick layer is 70mm thick and the plaster layer is 15mm thick. The restrooms have the tile layer on top of the plaster layer which is 10mm thick. The height of the tile layer in the restrooms is at 2.1m. The ceiling height of the restrooms is at 2.3m. The ceiling height of the other rooms is at 2.6m.

In order to compare the quantity of each wall layer, the wall at LOD 300 is used for the schematic BIM model. The walls are single elements with three layers; the core layer, the exterior finish layer, and the interior finish layer. The total wall thickness is 100mm. The walls are created by drawing through structural columns and overlapping with beams and floors. The developed Dynamo scripts are used to find the area of the core layer, exterior finish layer, interior finish layer, and a custom height interior finish layer in the restrooms (see Figure 11). The wall material takeoff from Revit will be compared with the result from the Dynamo scripts.

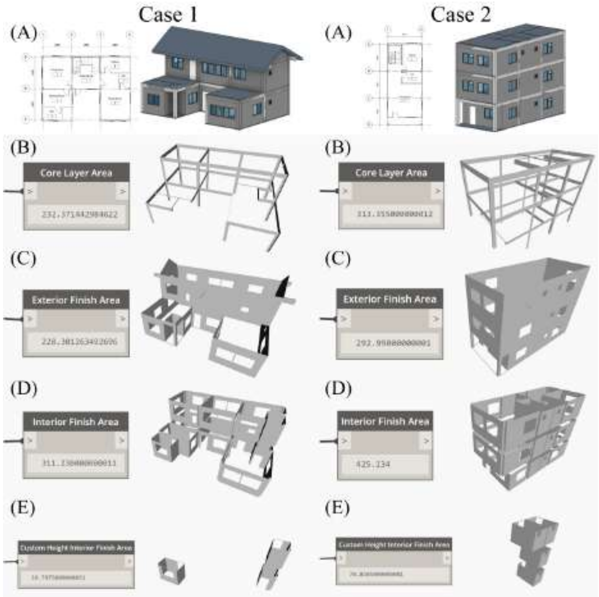

Figure 11. (A) The schematic BIM models of the two buildings. (B) The area of the core layer in Dynamo. (C) The area of the exterior finish layer in Dynamo. (D) The area of the interior layer in Dynamo. (E) The area of the restrooms' interior layer in Dynamo.

In the detailed BIM models, each wall layer is created separately. The height and the thickness of each layer are defined (see Figure 12). The material takeoff is done in Revit and the result will be compared to the result from the schematic BIM models.

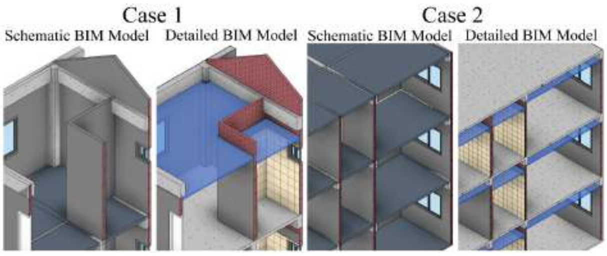

Figure 12. The comparison between schematic BIM models and detailed BIM models.

Table 1 and Table 2 show the comparison of the material area from the detailed BIM models, the schematic BIM models as well as the Dynamo scripts. The case number is written in the parentheses after the name of the wall layers. The results from the detailed BIM models form the baseline of this comparison. The results from the Dynamo scripts when compared to the baseline have about a ±1% deviation, which is acceptable. The deviation is caused by the thickness of the material layers in the detailed BIM models. On the other hand, the results from the schematic BIM models have a significant deviation.

Table 1. Comparison result between detailed BIM model and schematic BIM model

Wall Layers	Detailed BIM Model	Schematic BIM model	% Deviation
Core (1)	234.60 m^2	299.31 m^2	-27.58%
Core (2)	315.95 m^2	391.08 m^2	-23.78%
Ext. (1)	226.08 m^2	299.31 m^2	-32.39%
Ext. (2)	291.00 m^2	391.08 m^2	-34.39%
Int. (1)	314.65 m^2	299.31 m^2	4.88%
Int. (2)	426.83 m^2	391.08 m^2	8.38%
Tile (1)	39.55 m^2	N/A	N/A
Tile (2)	70.50 m^2	N/A	N/A

Table 2. Comparison result between detailed BIM model and Dynamo scripts

Wall Layers	Detailed BIM Model	Dynamo Scripts	% Deviation
Core (1)	234.60 m^2	232.37 m^2	0.95%
Core (2)	315.95 m^2	313.36 m^2	0.82%
Ext. (1)	226.08 m^2	228.30 m^2	-0.98%
Ext. (2)	291.00 m^2	292.99 m^2	-0.68%
Int. (1)	314.65 m^2	311.23 m^2	1.09%
Int. (2)	426.83 m^2	425.13 m^2	0.40%
Tile (1)	39.55 m^2	39.80 m^2	-0.63%
Tile (2)	70.50 m^2	70.85 m^2	-0.50%

6 Conclusion

The proposed method for calculating the area of each layer of the architectural walls is executed in Dynamo - a visual programming extension in Revit. Each Dynamo script is designed to calculate the surface area in a specific scenario. For example, if designers want to find the area of the exterior paint, they will use the script that calculates the exterior finish layer. If designers want to find the area of the interior plaster, they will use the script that calculates the interior finish layer. If designers want to find the area of the interior wall panels that only attach to the stud framing layer, they will use the script that calculates the core layer.

The results from the Dynamo scripts are accurate when compared to the results from the detailed BIM model. With this method, the designers who work in the early stages of the design can know the accurate quantity of the architectural walls and finish layers without having to make a detailed BIM model. The model can easily be edited while the designers get instant feedback. The accurate quantity of the walls and finishes can be used to estimate the building cost in the early stages of the design process for the project delivery methods which have higher collaboration between design and construction teams, namely DB and IPD.

However, these Dynamo scripts still have their limitations. The scripts cannot find the area of the surface if there are multiple materials used. For example, if the tile layer has two types of tiles, the scripts cannot separate the areas of each type. In this case, a detailed BIM model is needed for the accurate quantity takeoff.

In future research, the implementation will need more case studies for validation and the Dynamo scripts will need to be improved. There are three possible features to improve on in the future Dynamo scripts. Firstly, the Limit Offset property in each room should be adjusted automatically. As of now the user still has to edit the Limit Offset property to match the ceiling height manually, - which is error-prone. Secondly, the adjustable height of the custom interior finish layer should be limited to the ceiling height or floor-to-floor height. Lastly, in the case that there are many wall types in the building, the user should be able to select the wall type that will be used in the calculation.

Abstract –

Retrieving proper accident cases and extracting risk factors from them are crucial for construction safety management. However, the process was often challenging due to unstructured properties of text data in accident reports, which caused limited, inefficient, and non-consistent information retrieval and knowledge gathering. To overcome the problems, this research aimed at developing a semantic search system to retrieve proper accident cases based on user's deliberate intentions and to extract safety risk factors automatically using Natural Language Processing. The performance of the system prototype was evaluated by construction practitioners with promising results for more usable construction accident database development (i.e., thesaurus) and efficient accident analysis using the thesaurus.

Keywords –

Construction Accident, Safety Management, Semantic Search, Natural Language Processing

1 Introduction

The construction industry is known to be one of the most dangerous industries. According to the Korea Occupational Safety & Health Agency (KOSHA), 29.3% of occupational accident occurrences (26,570 records) were from construction sites in 2016. Moreover, the number of victims by the construction accidents has been steadily increasing for the last three years [1].

The Korean Society of Civil Engineers (KSCE) published a research report of which contents insisted that construction accidents showed similar patterns in occurrence. The patterns consist of (1) what caused the accident, (2) where it occurred, (3) when it was, and (4) how the results came out. These attributes are referred to construction accident risk factors one by one: (1) hazard object, (2) hazard position, (3) work process, and (4) accident result [2].

Since the construction accidents occur in similar patterns, many studies determined that it is possible to prevent construction accidents by identifying and eliminating the risk factors by analyzing similar cases [3,4,5,6,7]. For this reason, retrieving proper cases and extracting risk factors are crucial to preventing construction accidents.

To support academic and industrial efforts on accident analysis, two public institutions operate and manage construction accident databases. One is KOSHA, a database run by itself, and another is Construction Safety Management Information System (COSMIS), run by Korea Infrastructure Safety Corporation (KISTEC). The integrated data of the two databases cover more than 4,000 records of historical construction accidents.

However, the construction accident cases are written in the form of text document which is difficult to be managed and analyzed [8]. The situation generates some troubles in searching and analyzing accidents. The search algorithm implemented on the current database follows binary search "same or different", hence it could only retrieve results exactly matching the given query word by word precisely. This might limit useful information of previous cases, especially due to many synonyms and natural languages used in the construction domain, which would be used as basis for conducting construction accident analysis [9,10]. Besides, accident analysis process would be inefficient and the results could have non-consistency due to laborious task such as perusing numerous accident reports and labeling risk factors manually [11,12,13].

Taken altogether, analyzing construction accident cases based on current databases is difficult due to the unstructured properties of text documents. To overcome these problems, the research aimed at developing a semantic search system supporting two major functions: to retrieve proper cases based on user's deliberate intentions and to analyze accident cases by extracting risk factors automatically.

Accessing KOSHA and COSMIS, the research collected 4,263 reports of construction accidents which had occurred from September 1 1990 to October 18 2017. Natural Language Processing (NLP) was used to manipulate the text data of the reports and conduct the research. Meanwhile, the research adapted pre-existing risk categories identified by the Construction Risk Factor Profile [2] in order to define the labels of construction accident risk factor as mentioned in the first paragraph.

2 Research Methodology

2.1 Web Crawling

Construction accident reports were collected from KOSHA and COSMIS websites by the web crawling method which is a web-based process that accesses websites and collects target data [14]. Websites are usually constructed with Hypertext Markup Language (HTML), a standard language of websites used to specify detail features of entries such as position, font, color, and size. Once the web crawler is set to extract certain information, it finds the tags (e.g., <position>, <font>, <color>, <size>, etc.) and takes the information from each tag.

The process consists of two steps: (1) list page parsing and (2) target page parsing [15]. In the first step of list page parsing, the web crawler (i.e., web crawling algorithm) extracts Uniform Resource Locator (URL) links of target pages from the list page that covers the user's query. Afterwards, during target page parsing, the web crawler extracts actual data from the target pages. The procedure is provided in Figure 1.

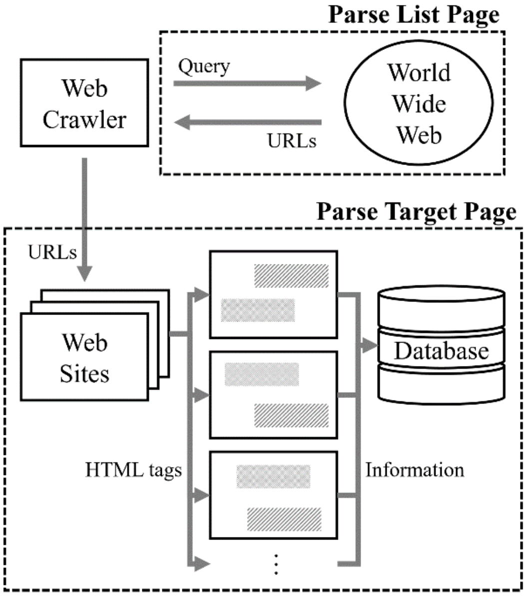

Figure 1 Web Crawling Procedure

2.2 Preprocessing

Text data preprocessing was conducted in order to convert raw data into an understandable format for the computer by splitting text strings into several valid words [15]. In this research, the preprocessing was composed of four steps. First was data cleaning; all punctuation marks were eliminated since those non-verbal items were worthless to understanding the text data. Second was tokenizing; every sentence from accident reports was split into a single word (i.e., token) based on space marks. Third was normalizing; each token was converted into its canonical form. Fourth and the last was stopword removal. Stopwords (i.e., less informative tokens) including grammatical components and person's name were removed to improve data quality. For instance, a sentence "During installation process, John lost his balance and fell down." would be converted into "installation process lose balance fall down" after preprocessing as explained in Figure 2.

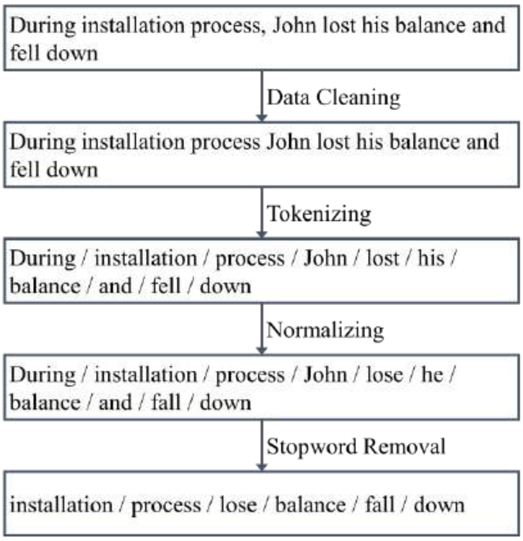

Figure 2 Procedure of Text Preprocessing

2.3 Query Expansion

For the purpose of including the user's deliberate intention to queries, the newly developed search system is able to expand the given queries using the thesaurus [16]. According to ISO 25964-1 standard, a thesaurus is a kind of advanced dictionary containing additional information such as the synonym, hypernym, and hyponym of each term [17]. Generally, plenty of advanced search engines already have been adopting query expansion using a thesaurus to overcome uncongenial result problems [18,19]. The research established a construction accident thesaurus using several construction dictionaries and a list of similar terms derived from the Word2Vec algorithm.

Specifically, twelve construction dictionaries with the total of 15,564 terminologies were adopted to the system. The construction dictionaries represented term relationships in the construction industry (e.g., synonym, hypernym, hyponym.), hence query expansion using dictionaries could be regarded as considering the relationship of meanings between terms.

Word2Vec is an algorithm which creates a corresponding vector for each term based on distribution similarity of surrounding terms [20]. For instance, in the two sentences "A worker got hurt on head" and "A worker got injured on hand", the term "hurt" and "injured" will be mapped close to each other since the surrounding terms are very similar. Consequently, it could be deducted that the Word2Vec algorithm clustered terms using the similarity of term usages which existed in the accident reports.

2.4 Frequent-based Search

The last steps to the search algorithm include assessing relevance of documents and returning the search results. To get a quantitative achievement in relevance assessment of documents, the research adopted a frequency based ranking method called BM25 which considers two frequency indicators – Term Frequency (TF) and Inverse Document Frequency (IDF). TF is the number of occurrences of a term in a document, which implicates the importance of a term. That is, the larger the TF is, the more important the term is. However, if a term exists in every document, then the term cannot be used as a distinctive feature for judging the importance among documents. For this reason, IDF, an inverse number of documents which contain a certain term, was designed to normalize the scale effect of TF [15,21]. Since higher BM25 score means the document is more relevant to the query, the accident reports are sorted in descending order.

After identifying user-wanted accident reports based on the BM25 score, predetermined four kinds of risk factors were extracted by conducting Named Entity Recognition (NER). NER is a text classification method which labels each term with informative categories such as person's name, place, object, action, and so on [22]. Among existing NER algorithms, the research employed Conditional Random Field (CRF) to determine each term's label on the basis of conditional probability of the surrounding terms, hence had been showing the highest performance at text labelling [23]. The conditional probability of each class y for a target token is calculated as Equation (1), where Y represents a set of labels (i.e., set of risk factors) X represents a sequence of observations which equals to the surrounding terms. On the right side of the Equation (1), t_j and s_k represents feature functions of which output is 0 or 1, λ_j and μ_k are weighting values for each feature function, and Z(X) is a constant normalizing the maximum probability as 1. Consequently, the target token was labelled by the class with the largest probability as provided in Equation (2), where y^* indicates the label of the target. The correct dataset was constructed by 51 rules which labelled terms related to risk factors from each sentence base on the relationship between sentence elements [24].

$$P_{\Lambda}(Y|X) = \frac{1}{Z(X)} \exp\left(\sum_j \lambda_j t_j + \sum_k \mu_k s_k\right) \tag{1}$$

$$y^* = \underset{Y}{argmax}\, P_{\Lambda}(Y|X) \tag{2}$$

3 System Prototype

A system prototype was developed to test the proposed methodology and evaluate the results. Figure 3 provided the result page of the system prototype with the query "타워 크레인 추락" which means "Tower

Crane Fall" in English. The system prototype was developed by localhost, which means only local computers have authority to access. This is to block unwanted users, since the research is in experimental stage.

When a user gave a query "tower crane fall" as an input, the system preprocess the query with data cleaning, tokenizing, normalizing, and stopword removal. The query would be divided into two tokens "tower crane" and "fall", then expanded based on the thesaurus to various queries: "tower crane", "crane", "lifting equipment", "lift", "T/C", "coping", "jib", "winch", "falling", "drop", "collision", "fall beneath", etc. The expanded queries were visualized in the top of the prototype as the red box in Figure 3. One of the most powerful text visualization tool, Word Cloud, was applied to show the queries, of which the font size indicates importance and leverage [25,26].

After searching and ranking appropriate documents with the queries based on the BM25 score, the system retrieved the most proper accident reports right below the Word Cloud. The accident name and short description of each case are provided in rows as marked with the dark blue box in Figure 3. For detailed information, users can access the original report simply by clicking the case.

Eventually, the CRF model extracted risk factors from the text data of retrieved reports. The risk factors (i.e., hazard object, hazard position, work process, and accident result) were provided on the right side of accident descriptions, marked in orange, light blue, green, and purple boxes each. For instance, the first case was "Haeundae I-park tower crane collapsed" of which content was that "Jib of tower crane collapsed due to sudden gust". The risk factors of this case were identified as "jib" for the hazard object and "collapse" for the accident result. As some of accident reports did not specify every risk factor explicitly, several blanks existed in the result.

Figure 3. Layout of System Prototype

4 Validation

4.1 Validation of Query Expansion

The retrieval results based on query expansion were validated in qualitative approach using Normalizing Discounted Cumulative Gain (NDCG), a commonly used approach to evaluate information retrieval results. NDCG examined whether relative documents were ranked high in the retrieval result by comparing documents from the result and correct set at every rank position p [27]. The NDCG is defined as Equation (3), where rel_i is the relevance of the result at position i and $|REL|$ represents the number of relevant documents up to position p [28].

$$NDCG_p = \frac{\sum_{i=1}^{p} 2^{rel_i} - 1 / \log_2(1+i)}{\sum_{i=1}^{|REL|} 2^{rel_i} - 1 / \log_2(1+i)} \quad (3)$$

To secure testing set, one query and 10 documents were given to each of 4 questionnaire groups composed of 4 construction practitioners with less than 5-year work experience. Then, each group ranked the documents based on the relativity of documents with the given query with 5-point scale: '5' represents the very high level relevance and '1' represents the very low level. NDCG score was calculated using the ranked results for four queries. Finally, the research compared the retrieval results with the testing set which questionnaires ranked and quantified the difference based on NDCG. The scores of each query were 0.98, 0.98, 0.94, 0.98, where 1.00 represents a consensus and otherwise 0.

4.2 Validation of Risk Factor Extraction

In the first step, the relevance of correct set generated from rule-based approach was verified. Same questionnaires with the former step were involved to label every risk factor from 101 documents. Then, the results of rule-based labeling were compared to the results of human-based. As a result, the rule-based approach showed an average accuracy of 93.75% establishing its relevance as training set for the CRF model. Specifically, labeling of hazard object scored 96% (82 from 85), hazard position 87% (46 from 53), work process 95% (82 from 86), and accident result 97% (98 from 101) which are provided in Table 1. The population of each risk factor would be different since not every accident report contained all of the risk factors. Since the relevance scores were considerably high, the CRF model, trained by the rule-based labeled data, must be trained attentively.

Table 1 Verification of Rule-based Labeling

Risk Factor	Relevance of Rule-based Labeling	
Hazard Object	82 / 85	96 %
Hazard Position	46 / 53	87 %
Work Process	82 / 86	95 %
Accident Result	98 / 101	97 %

Next, the labeling results of the CRF model were validated using the remaining 10% of data based on precision and recall of each risk factor. As provided in Table 2, most of the precision and recall scores came out to be sufficient to insist the feasibility of the system. Even though the recall rate of the hazard position was evaluated quite low, the overall results showed promising applicability of the proposed system. The precision and recall rates would become higher as the accident reports are accumulated constantly.

Table 2 Validation of CRF Model

Risk Factor	Precision	Recall
Hazard Object	0.95	0.68
Hazard Position	0.93	0.52
Work Process	0.86	0.74
Accident Result	0.99	0.90

5 Conclusions

Analyzing construction accident cases is crucial for safety management, since construction accidents occur in similar patterns which could be represented by hazard objects, hazard positions, work processes, and accident results. However, the current databases collecting accident reports have limitations to retrieve and analyze accident cases due to unstructured properties of text reports. This research thus developed a prototype of semantic search systems that retrieve similar cases based on the user's deliberate intentions and analyze accident cases by extracting risk factors automatically by applying text-mining techniques.

The developed system would have several contributions to both of industrial and academic sectors. For the industry level, the system would help provide accident references for safety managers to explain the causes of accidents and precautions to prevent them by applying the developed thesaurus and NER. For the academic level, the research identified relationships between keywords that exist on construction accident reports by using the Word2Vec algorithm and eventually explained the feasibility of NLP-based text analyses for better construction safety management.

6 ACKNOWLEDGMENT

This research was supported by a grant(16CTAP-C114956-01) from Technology Advancement Research Program (TARP) Program funded by Ministry of Land, Infrastructure and Transport of Korean government and Seoul National University Big Data Institute through the Data Science Research Project 2017.

Abstract –

This paper presents the results of the practical learning experience when combine three different school level students to learn open infrastructure building information modelling (infra BIM) and automation during OuluZone workshop week. Students started to build Speedway track in OuluZone test centre with one-week resources with the help of experts from industry and teachers. In addition, for students, ten different tricks were designed to present the tasks of the responsible person on the construction site. The idea of tricks was to teach students how these experts are using open infra BIM construction automation in their work. Infrakit, which is open infra BIM cloud service, was used to connect automation systems together. Based on the one-week workshop experience including questionnaire study answers and the results of pre-test and exam for students, it can be concluded that this type of practical learning is an effective way to teach open infra BIM based automation to students.

Keywords –

Automation, Education, Infrastructure building information modelling (infra BIM)

1 Introduction

The construction industry has started to found the advantages of use building information modelling (BIM) as a tool for managing the process of design, construction, and across the supply chain. The top five advantages of using BIM has found to include scheduling, communication, visualization, coordination, and clash detection [1]. The other reasons for the grow of BIM are application of technologies and innovations, which integrates the construction process not only buildings but also in infrastructures, such as transportation (roads, bridges), energy (power generation plants), utility (networks/pipelines), recreational (parks, stadiums) and environmental (managing flood and coastal defences). [2] In fact, BuildingSMART Finland has a forum which is responsible for the development of the infrastructure BIM (infra BIM). [3] However, there are still some obstacles to adopt BIM within architecture, engineering, construction, owner, and operator (AECOO) industry, such as technical barriers, legal and liability issues. Besides those, there is also is a need for training, education, and regulations [4]. BIM teaching in educational institutions will be grown due to the recommendation of European Union [5]. There are courses offered by private companies for professionals who want to update their knowledge in the field of infra BIM, or graduate as BIM coordinator, however these courses are relatively expensive. Therefore, universities and polytechnics are starting to provide BIM courses for construction and architecture students. [6]

Education in Universities and Universities of Applied Science schools is often lecture-based, instructor-centered pedagogical models. Courses can be included lectures and exercises with detailed spots. Practical knowhow about infra BIM and automation students is gained mainly from summer jobs, since the lack of money is prevented this type of practical learning from schools. However, the authors' opinion is that practical learning is vital to understand the theory as well as to learn new technologies and how to collaboration with expertise in the field. These skills can help students to find their future jobs. The idea that student can use learned information from teacher to real world challenges and problems have found to be excellent, but a challenging way to be as deep learning of the subject, and found a promising option for BIM education [7, 8]. BIM should be teaching as a process improvement methodology rather than only a technology. Giving students real word problems and active learning experiences will encourage to self-directed learning and critical thinking [9].

There is relatively rare any collaboration between school levels. Some articles are about the connection of courses between universities or different topics, such as BIM and sustainability [10, 11]. The objective in OuluZone+ project (started in March 2017 and ended in December 2017), which is presented in this article, was to connect the special open BIM and automation expertise of three different educational level institutions and to utilise their resources, and to be a practical learning experience for students, as well as for teachers, too. The goal was to plan, implement and evaluate the OuluZone workshop week in OuluZone test centre. Before the one-week workshop in OuluZone test centre, the students were trained in the lectures to understand the basics open infra BIM and automation knowhow from to implement the workshop. The goal during the OuluZone workshop week was that students use their know how from lectures and build the Speedway-track with one-week resources with the help of expertise from school and from industry. Findings and lessons learned from the practical learning experience are presented in this article.

2 Finnish Educational Framework System

In Finland after finishing the mandatory basic education at age of 15, the student can select different educational paths. Infra BIM related courses offered at all levels after basic education. However, there is rarely any collaboration between the school levels.

The goal of the OuluZone+ project is to develop research, development, and education environment for open infrastructure BIM is between the institutions of The University of Oulu, the Oulu University of Applied Sciences (OAMK), and Oulu Vocational College (OSAO). These institutions are presenting the three different level that is collaborating in the OuluZone+ project.

Before the workshop week in the OuluZone test centre, students learn practical knowledge in selected courses, presented below, in each institution. Teachers are using both cognitive and behavior approach to teach BIM to students [10]. This means that the theory of BIM is learned by lectures but also from experts from industry.

For a Masters Degree students of Technology there is a five-credit course called "Information modelling and automation building construction and maintenance", at the Department of Structures and the Construction Technology Research Unit at the University of Oulu. During the course, the students are trained to learn the Novapoint boulevard program, RTK-GNSS positioning techniques, Novatron's 3D machine control system using a mini excavator, and the use of the Infrakit in the real-time control of the site. Annually, the course has an average of 10-15 graduate civil engineer students.

For engineering students at the Oulu University of Applied Sciences (OAMK) there is a five-credits course entitled "Infra BIM modeling and building a construction project". At the start of the annual course, OAMK has about 80 engineering students and 40 master students. For masters students there is a course called "Computer modeling at infrastructures". The teaching of measurement techniques has unfortunately decreased in recent years due to teacher resources, and it has been integrated more into other courses. AutoCAD Civil3D is used to teach boulevard design.

The Oulu Vocational College (OSAO) provides teaching for construction machinery and lorry drivers as well as logistics instructors. The basic education for young people is three years, with a one-year course of about 20 students; thus a total number was 60. In addition, adult education includes some 40 students. OSAO has four different machines (three excavators and one wheel loader) on the campus of Haukipudas with Scanlaser Oy's and Novatron Oy´s 3D machine control system installed in educational use. In addition, the University of Oulu maintains a Sunward mini excavator machine, where Novatron Oy's 3D machine control system, at OSAO's premises at Haukipudas. Several test simulators as in Figure 1, which estimate performance and gives feedback to the user. The test simulator is integrated into Leica's 3D machine control system so that the simulation corresponds to a truly genuine environment. The scope of the 3D Driving tutorial for construction experiments is 15 competence points.

Figure 1. Test simulator (Tenstar) integrated to Leica's 3D machine control system to practice the use of excavator.

3 Development of the Education Workshop for Open BIM Based Construction

3.1 Tools for Implement Ouluzone Workshop Week

The OuluZone test centre is a place located around 30 minutes away from the city centre of Oulu built by the City of Oulu. In OuluZone test centre, one can do activities such as motor sports, research, and education.

The OuluZone workshop week, the construction site was decided to be the Speedway track, and the beginning of its cutting operation. The geometry of Speedway-track was first done in traditional 2D drawings. The total length of the track is 437m in with a straight line of 65m. The 3D model of the Speedway track (Figure 2) was made in Mitta in open file formats such as DXF and LandXML. It was calculated that the weight to be cut was 7848 m^3, filling 7727 m^3 and surplus mass 100 m^3.

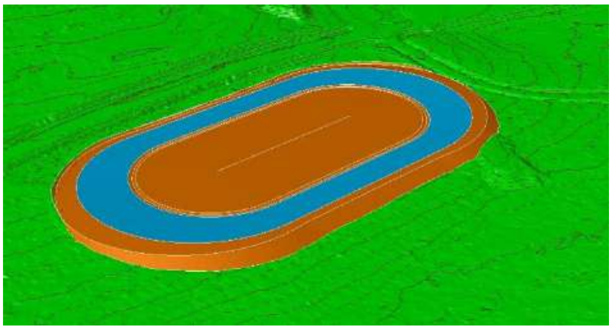

Figure 2. Speedway-track in 3D DFX format (Mitta Oy).

For practical implementation in OuluZone test centre, it was decided that OSAO brought necessary machineries and dumper trucks to start the Speedway-track building. The University of Oulu organized other necessary infra building information modelling (infra BIM) and automation technologies and systems. To support the development of education, technology companies and key infra actors were challenged to bring their technology.

Based on authors previously projects [12] and experiences Infrakit have been found to reliable. That was the reason why Infrakit (www.infrakit.fi) was used as an open infra BIM tool for real-time monitoring of Speedway-track progress and for quality checking. In addition, Infrakit can be integrated into many machine control systems such as Trimble, Topgeo, Leica Geosystems, and other software. In Figure 3. shows how different automation systems of Novatron are connected real time to Infrakit and used to share data between a designer, project owner, site foreman, machinery and surveyor. The students and teachers had an Infrakit-training day before the OuluZone workshop week. The goal of Infrakit-training was to present to the audience, how the Speedway project is set up in Infrakit. In addition, meaning coordinate systems, designed files in correct formats and other necessary information needed in the beginning of the construction site was also presented.

Figure 3. Automation system and operation models (Novatron Oy).

All the measurement devices, such as RTK-GNSS-tablet, and mobile devices, meaning the android guidance system in trucks, tablets for construction leaders, and laptops that were used on the Speedway construction site are integrated into the collaboration cloud via Infrakit internet system. The other necessary equipment needed in Speedway-track construction site were RTK-GNSS-base station, three to four pieces' reference points around the Speedway track, machines with 3D-guidance systems both Scanlaser and Novatron, Leica-robot tachometer, Trimble R10–RTK-GNSS-system with Infrakit, a video camera connection, and Drone-monitoring. In addition, there were two excavators, wheel loader, and two trucks from OSAO.

3.2 OuluZone Workshop Week Preparation for Students

The OuluZone workshop week was 30 October to 2 November 2017. During this period, all the students and teachers had a common information event about the workshop days in OuluZone test centre in the University of Oulu, two working days Speedway-track contract site in OuluZone test centre, and a finally enclosing day in OAMK.

There was pre-test at the beginning of the week and end exam at enclosing day, both were based on Common Infra BIM Requirements (YIV2015) [13]. The result of the pre-test and exam was analyzed. In addition, during the enclosing day the students and teacher was answered in questionnaire study regarding: 1) what was successful, 2) how OuluZone workshop week can be developed, and finally 3) to give the school grade from 1 to 5.

The amount of students was 6, 41, and 13 from the University of Oulu, OAMK and OSAO, respectively. The students from OSOA were decided to be responsible for working machines. They started two weeks earlier of the preparation of the workshop week. The students learned the basics about positioning, charting, coordination systems, and GPS measuring. These profession skill demands are part of their degree and were estimated during the workshop week.

Students from University of Oulu and OAMK were divided into 10 groups' occasional order. To students, 10 different tricks were planned:

1. Construction' head manager
2. Site foreman
3. Designer
4. BIM coordinator
5. Excavators, trucks, and wheel loader drivers
6. Surveyor
7. Construction consultant
8. Construction security officer
9. Speedway Project owner
10. Drone-monitoring

The purpose of each trick was present the tasks of the responsible person on site, and how they are using open infra BIM in their own work. The responsible person on the trick was professionals from industry (Mitta Oy, Leica GeoSystems Oy, Destia Oy, Novatron Oy, and Infrakit Oy), or were a teacher from the University of Oulu, OAMK, or OSAO. The connection of ten tricks to open infra BIM is shown in Figure 4.

Figure 4. Ten tricks for students during the OuluZone workshop days in OuluZone test centre.

During the OuluZone workshop days, the student group visit each trick about 25 minutes. During this time, the students heard about the work of the responsible person and had a possibility to ask. Each student was to give a paper and pen to do his or her notes for example to write a report to the teacher. Transfer time one trick into other was about 10 minutes.

3.3 Objectives to OuluZone Workshop Working Days

The objective of the first workday in OuluZone test centre was to practice and to understand how the open infra BIM is used on Speedway track site. The following things are expected of students to learn:

- How is the map of the Speedway track site, machine control system and realization measuring recorded?
- How can all the experts on the Speedway track site communicate each other in real time and do changes if needed?
- How is the schedule of the Speedway track, and the calculation of masses done based on the model?
- How the information from Scanlaser's or Novatron's Guiding 3D systems in excavators can be used for the controlling?
- How is the quality check of the excavator done by measuring the cutting surfaces continuously?
- What is the reason to measure separate "point of reference" of RTK-GNSS systems?
- What is the reason to use Drone-plane to follow and control the progress of the construction site?

The objective of the second workday in OuluZone test centre was the automation change and problem scenarios. The aim was for the student to understand why the information model needs to be monitored and why it must react whenever possible changes occur. The following possible problem scenarios were planned and what must be done:

- The excavator is excavated (intentionally) 10 cm too deep. The actual point is stored, whereby the error should be detected by the Infrakit system (supervisor) and reacted to it or interrupted the excavation
- Adding a drum scraper model to the excavator machine control system. The background map shows it. The driver and the manager should observe it and ask for this model from the site manager who request a template from a road designer.
- Some layer thickness is incorrectly a type cross section; the automation operator should note and request a repair from the designer, or be repaired by the automation operator.
- The excavator driver x reports the observed rock surface and asks the job director for blasting operations.
- A person appears on site without any safety equipment. The supervisor suspends the work situation, removes the person and orders the contractor for the sanction.
- Failure of the vehicle and the working machine, condition check, etc.

4 Results and Discussion

At the beginning of the OuluZone workshop week, the students were given a simple pre-test based on Common Infra BIM Requirements (YIV2015). The pre-test contained 10 question and there were four answer options in each question. The pre-test was given to Monday and the answers were collected next day. The correct answers were told after the students' answers was given. Of 32 results, the average degree was 6.34 with the standard deviation 3.08 (Figure 5). The result indicates that students were learned something about the infra BIM during the lectures.

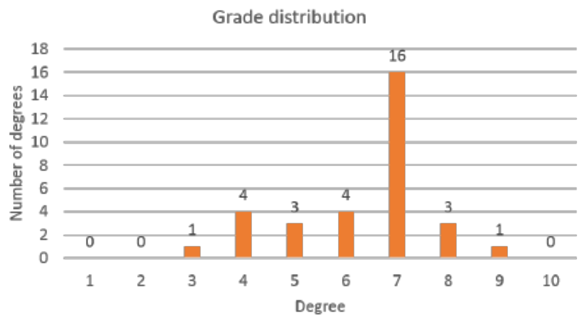

Figure 5. The 32 result of pre-test the average degree was 6.34 by the standard deviation 3.08.

During two OuluZone workshop days, the team of five to six students was visiting ten different tricks. The first day was training and the second day focused on the solving problems. Students were heard more how the experts were using Infrakit in their job function. Construction head manager (trick 1) explained how he is using Infrakit to budgeting, scheduling, and quality control. His responsibility is also the orientation of the workers on the construction site. The site foreman (trick 2) explained to students what responsibilities it is needed to keep high quality on the site based on YIV2015. Designer (trick 3) collected and checked the Speedway-model and delivered those files in Infrakit. He also controls and updates the machine 3D-guidance systems. One task for students was to calculate the quantity of masses if a blasting job was needed. BIM-coordinator (trick 4) explained to students why separate RTK-GNSS systems was needed and why "the point of references" was done. He also showed how the calibration of the guidance system was done. The excavator driver (trick 5) showed the student how the Scanlaser guidance system was used when cutting process is going on. The driver also showed how the quality check was done by measuring the cutting surfaces continuously. The job of the surveyor (trick 6) was to measure and maintain reference points and safe the collected data to Infrakit. The construction consultant (trick 7) also used power point slides to explain more detail their work, and what must be considered scheduling and budgeting. Examples of real problems how heavy rain can stop the construction site was explained. The construction security officer (trick 8) showed in the first day relevant video about safety issues in the construction site. The next day, the student's task was to point out errors and give solutions to solve the problem. The Speedway Project owner (trick 9) followed the project via Infrakit. He also used drone monitoring (trick 10), especially the schedule and mass control. Figure 6 presents students visiting tricks 5 and 6 to learn more about how to measure "the point of reference” and the 3D machine control systems of Scanlaser and Novatron in excavators.

Figure 6. Trimble R10-RTK-GNSS-system (trick 6) and Bobcat excavator with both 3D-guidance systems of Scanlaser and Novatron (trick 5).

The students were possibility to ask questions and do some tasks during their visits in tricks. The communication between experts was done via chat service in Infrakit, but also mobile phone, and face-to-face meeting. The students followed the Speedway site progress and saw the progress of the site, and how it was recorded into Infrakit in real-time (Figure 7).

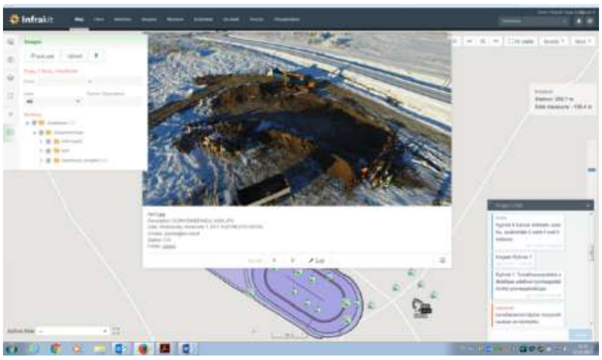

Figure 7. Speedway project in Infrakit. Pictures from Drone-plane (trick 10) are recorded and thus the site can be monitor in real-time for example in mobile application.

During the workshop days, the teachers and the experts were evaluated the student groups based on their activity and spontaneous. The level of groups was variable. Some groups were relatively silent and as opposite, there were relatively good groups. Students were not informed of the evaluation, which could explain the difference between groups. There was no competition.

The last day of workshop week was the event for discussion and feedback. Similar type of exam than the pre-test was for students. The students were not informed of the exam, so they could not be prepared themselves for it. Based on 49 results returned it can be said that the degrees were higher than pre-test degrees (Figure 8). This time, the average degree was 7.67 with the standard deviation 2.63.

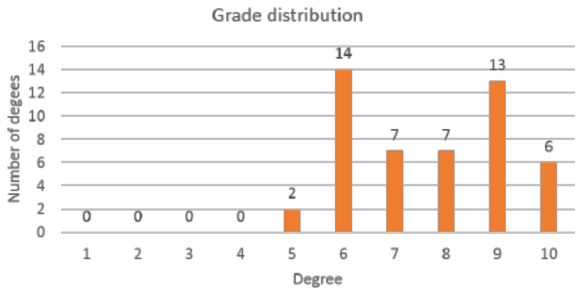

Figure 8. The 49 result of exam of final day. The average degree was 7.67 by the standard deviation 2.63.

Feedback from students, teachers and experts was collected during the enclosing with day questionnaire study. In addition, a questionnaire in e-mail was used, since most of the experts did not have time to participate in enclosing day. Based on the answers of the questionnaire studies, the successful thing during the workshop was the collaboration between the students of University of Oulu and OAMK. The students worked and motivated each other. The students think that the experts brought much more information on different situations on working life, skills versatility, advice, and new perspectives. In addition, the reason why in the construction site is needed so many expertise was clarified.

There were also things what should be developed for the next OuluZone workshop week. Since the OuluZone workshop week was organized the first time, it was rather difficult to estimate how much time is enough on each trick. Some of the tricks can be merged together and some other can give more time. Infrakit was acting a major role during the workshop, however some students think that the information obtained was repeating itself. Maybe next time it would be a good idea to give some small tasks like budgeting or calculation. However, it must be sure that students are learned those before workshop and tested their skills during the workshop.

Based on the 49 questionnaire study answer, it can be stated that overall the whole experience was successful. Overall the grade from the first workshop was 3.42/5 the standard deviation 3.56. For the reason for good experience from this first OuluZone workshop week, it has been decided to continue to organize OuluZone workshop week in year the 2018, too. Based on the feedback, the workshop week is changes so that there will be three working days instead of two. During the first two days, students will be trained to take the charge of the Speedway-track construction site under the supervisor. The idea is for motive students to learn open infra BIM and automation to take subject seriously.

5 Conclusion

In this article, it is reported the results from the OuluZone workshop week. Students from three different levels i.e. University of Oulu, Oulu University of Applied Sciences (OAMK), and Oulu Vocational College (OSAO) were guided through open infra BIM based Speedway construction automation with the help of the experts from industry and teachers.

During the OuluZone workshop days, students learned by doing what are the tasks of the responsible person on the construction site, and how they are using open infra BIM and automation. In addition, the problem solving on the construction site was found to be an interesting way to learn in collaboration of other students and experts of industry and teachers. Based on the gained feedback, this type of practical workshop was an excellent way to bring novel knowhow from industry to improve education in courses.

Therefore, it can be concluded based on the results of pre-test and final exam as well as questioner study that practical learning is an effective way to teach open infra BIM based construction automation for students. The collaboration between three school levels will be continued in next improved OuluZone workshop week in the year 2018.

Acknowledgements

The authors would like to acknowledgement all the students and teachers from University of Oulu, Oulu University of Applied Science (OAMK), and Oulu Vocational College (OSAO) that took the courses and participating to OuluZone workshop week. Authors are grateful to the experts from industry Mitta Oy, Destia Oy, Infrakit Oy, Welado Oy, OuluZone Operointi Oy, Novatron Oy, and Leica GeoSystems Oy, for provided the feedback on their experiences and for brought their technology. BusinessOulu is also acknowledged for their great support on this workshop. This OuluZone+ project was financed by European Regional Development Fund (A71660). Finally, the BIM4PLACEMENT ERASMUS+ project (2016-1-IT0-KA202-005399) has had a great importance of the success of the project and this paper.

A Methodology for the Development of Interoperable BIM-based Cyber-Physical Systems

F.R. Correa[a] and A.R. Maciel[a]

[a]Department of Construction, University of Sao Paulo, Brazil
E-mail: fabiano.correa@usp.br

Abstract –

Building Information Modeling (BIM)-based processes are increasingly being adopted worldwide. With it, possibilities to exploit digitization had been appearing for the AEC sector. In that context, the present work aims to investigate how, and in which form, a Cyber-Physical System (CPS), one of many different but complementary technologies associated with the future of manufacturing, could be employed in the Construction industry. Recognizing that the core of CPS should be the dynamics of construction processes, the initial focus is in how to develop Process Data Models (virtual) that could communicate with Product Data Models (BIM models), and receive/send data in almost real-time from/for the existent hardware (sensors and actuators) in the physical production processes. This article present some preliminary work based on the standardized methodology of IDM/MVD, which are part of the buildingSMART solution for interoperability along with Industry Foundation Class (IFC) data schema. The proposed methodology considers an IDM modelled in Business Process Modeling and Notation (BPMN) language in such detail as to expose the workflow of production. The contribution in this context is in mapping production processes in BPMN notation into Petri Nets (PN) semantics. Petri Nets are an adequate model to construction processes, with precise semantics and largely used in the simulation of discrete events. With PN models it would be possible to develop the BIM-based control strategy, and test and implement it in real controllers. An illustrative example is provided in the context of automating cut and bend of rebar.

Keywords –

Cyber-physical systems; IDM-MVD; Construction Simulation; BIM

1 Introduction

Building Information Modeling (BIM)-based processes are increasingly being adopted worldwide. It could be viewed as the digitization phenomena that allows further adoption of technologies related to the automation and employment of robots in the Construction industry [1].

However, BIM models, with probably rare exceptions, are in reality Product Data Models [2]. For the effective introduction of automation technologies, it would be necessary to have, explicitly, Process Data Models [3]. Automated Construction [4], in its core, should be about control systems for production processes. Advanced applications of automation and robotics in construction already emphasized this notion [5].

In that context, the present work aims to investigate how, and in which form, a Cyber-Physical Systems (CPS) could be employed in Construction. A CPS could be viewed as a control system, which integrates the cyber world of computational models of products, process, organization behind production, supply-chain, and so on, with the physical world of sensors monitoring material, equipment, manual labor, machines and robots, and its actuators. It is a complex field of research that is in its infancy.

Towards a viable development of such a CPS, it would be economical to adopt open standards and current industry practices. Industry Foundation Class (IFC), both a data schema and a file format to exchange building information of its entire lifecycle, is becoming a *de facto* open standard for the interoperability in the aforementioned processes.

The focus is in how one could develop, in the interoperable scenario proposed by buildingSMART, a process (virtual) model that could communicate with Product Data Model (BIM models) and the hardware/software in the production processes.

This article present some preliminary work based on the standardized methodology of IDM/MVD, which are part of the buildingSMART standards, and are used to specify a subset of IFC entities. First, an IDM should be modelled in Business Process Modeling and Notation (BPMN) language, in such detail as to expose the workflow of the production process. Then a map between BPMN and Petri Nets, an adequate model to construction process with precise semantics and used in simulation of discrete events [6], is applied providing the basis for implementing a CPS.

An example is provided in the context of automating cut and bend of rebar.

2 Cyber-Physical Systems in Construction

Cyber-Physical Systems (CPS) is probably one of the most important technology associated with the current Industry 4.0 paradigm for manufacturing, because it is the integration of many of them. Implementations of such systems are already happening in the manufacture industry, mostly in automotive and aerospace.

One way to see it, is that it enables the integration between the virtual world (digital models and simulations) with the physical world (by means of sensors – Internet of Things/Industrial Internet – and actuators – Automation equipment and robots). The necessity of integration between different systems, or islands of automation, is not new.

Depending on the way cyber-physical system is defined or approached, one could find many or few research articles in the literature. If bidirectional data transfer between computational platforms with virtual models of construction and the construction field is sufficient to have an effective CPS, there is plenty of works dealing with monitoring the work done on site with different sensors [7]. However, to consider that it is necessary to have an actuator receiving commands to control some equipment on-site, it is hard to find one approach that integrate automated equipment with BIM models. Considering the evolution of the employment of robots on the field [8], it would be interesting to study the impact of CPS system in this context.

In [9], two scenarios are proposed that could employ CPS in Construction, based on the view that a CPS is a bidirectional data transfer: steel placement and light fixture monitoring and control.

In this article, it is considered that a CPS could be viewed throughout one spectrum of possibilities, which could become more functional or important as it integrates more technologies, such as sensors, automated equipment/robots, data analytics, simulation of construction process, and so on.

However, it is advocated that independently of the level of development of the CPS, the essential point for the integration is the virtual model of the different construction processes, in which it would be the bi-directional link. Henceforth, the necessity to study how to represent the knowledge of construction processes inside BIM platforms.

3 Construction Simulation with Petri Nets

It is important to note that BIM models are Data Product Models. Analyzing IFC Schema, although it is possible to instantiate processes, there are not standard construction processes already present in the schema, as are the building components used to design and construct a building.

Some author emphasize the difference and necessity of product and process model [2]. Mostly, the referred authors calls that approach Virtual Design and Construction (VDC), although the process model adopted many times are not a computational model.

To have the ability to simulate, analyze, and optimize production processes are the main drive for the importance of the process digital model. And as the simulation will be the core of a CPS, the kind of digital model should have characteristic appropriated for control systems.

Petri Nets were considered adequate to model and simulate construction processes, which presents a high degree of concurrency and synchronization.

A Petri Net is a tuple, given by [10]:

$$N = (P, T, \mathrm{E}) \quad \textbf{(1)}$$

where: P is a finite set of places; T is finite set of transitions; and E is the incident relation, representing the set of directed arcs connecting places to transitions and vice-versa, given by:

$$\mathrm{E} \subseteq (P \times T) \cup (T \times P) \quad \textbf{(2)}$$

There is also a token, a mark inside places, to represent the dynamics of the net. One transitions only occurs if there are token in every place connected to it. And if a place is connected to two transitions, and both could fire, a decision should be made.

3.1 Types of Petri Nets

There are many different formalisms to define Petri Nets with added capabilities: *Colored Petri Nets* [11], *Hierarchical Petri Net* [12], *Controllable Petri Nets* [13], and on. It is not the objective of this work, in this initial research, to define which one is more adequate to the cyber-physical system in hand, at that time. It will be considered in the following discussion a regular Petri Net.

Construction Processes would be experimented with **untimed models** with Petri Nets, as there exists an order in the events that occurs for the production of building components. Where there will be necessity to develop the control of the manufacturing process, it will be the **Control Theoretic Approach**, where there is a “model of the plant dynamics and a specification for the desired closed-loop behavior”. “There is a clear distinction between the plant and the controller and the information flow between the plant and controller is modeled explicitly” [10].

The main problem would be to create such Petri Net based on construction information, inside the current practices present in BIM implementations

4 Interoperability with IFC: IDM/MVD Methodology

Industry Foundation Classes (IFC) are both a schema for the entities of the products of the AEC industry and a file format to exchange those data product models. It comprises the entire lifecycle of a building.

The main concern with working with IFC is its complexity and size. buildingSMART is the international organization behind the efforts to promote open-BIM. As a building traditionally is represented by a set of BIM models, one for each discipline, those models are used in exchanges between different professionals to promote cooperation and concurrent work.

In each exchange, only part of a given model is needed. buildingSMART have being promoting the methodology of creating different Model View Definitions (MVD), that are a pre-defined subset of the IFC Schema, with agreed representation for the allowed entities.

However, there are few MVDs available, and this is part of the misconception that IFC do not work out-of-the-box in practice. Software vendors are certified as IFC exporters based on Coordinating View exchange (one MVD), which is not appropriate, for instance, for energy analysis.

Part of the cause for the existence of few MVDs is difficulty of the process of creating one and making it official at buildingSMART [14]. The methodology consist in first creating an Information Delivery Manual (IDM), basically a diagram in BPMN (Business Process Modeling Notation) notation, which all professionals could understand, and based on that, translate each piece of information, based on MVD Concepts.

Considering this scenario, where the different professionals involved in Construction are more comfortable in developing models using a language such as BPMN than Petri Nets, in this article it is proposed that a map between both models should be a solution for that.

As IDM is a high-level representation of a construction process, it should be exploited in the open-BIM scenario to produce process models.

5 Proposed Approach for CPS in Construction

The end of the spectrum of possibilities (most advanced) of CPS in Construction, should consist in a scenario with automated or semi-automated fabrication, with employment of machines or robots – as is currently more common in off-site production.

However, the proposed approach of this article contemplates a modular solution, around BIM models:

- A module for the simulation of construction processes in the form of a Petri Net (built upon the respective IDM diagrams) – which is considered here to be core of the CPS;
- A module for monitoring the construction processes, using whichever sensor (RFID, Ultrawide-band, laser scanners, Images, and so on). It feeds the CPS (or the platform using BIM models) with (possibly, real-time) data;
- A module for (Big) Data Analytics, based on the dynamics of the construction process and the BIM Models;
- A module for automatic decision-making routines, given to construct management personnel, or, direct control commands to machines in on- and off-site.

In that way, it aims to provide an enhancement of the employment, and existence of BIM implementations. Its most distinct characteristic is to associate the **process data model** with a CPS system, which connects and integrate with other technologies used by the enterprise.

In its simpler incarnation, it would be a way to monitor, with the capabilities of each sensor employed, what really happens on-site (off-site), so that it could be used as data to act more quickly to solve problems, and to study ways of optimization of the processes.

5.1 CPS: From IDM to Petri Nets

The idea is not new; neither was it developed by the present authors. However, upon finding previous work [15] on the subject, BPMN mapping in Petri Nets, it was considered a matter of investigation of its adequacy, in a scenario where some construction processes are currently being modelled in BPMN, and it is a language more closer to the background of the team of professionals involved in Construction industry.

IDMs are currently created using BPMN language [16]. The main problem with BPMN is that it inherits and combine constructs from different graph-oriented process definition languages with other features, drawn from a range of sources [15], and could produce semantic errors. Mapping it in Petri Nets allows the verification of its consistency. However, the main interest of Petri Nets for the proposed approach is that it is largely used to model and control manufacturing processes.

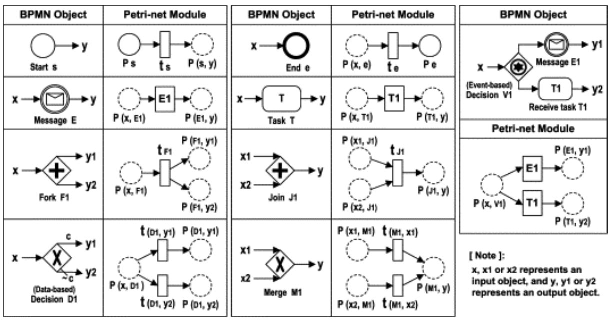

Figure 1. List of symbols considered and mapped into Petri Net constructs [15].

In [15], the authors provided a mapping between BPMN notation and Petri Net, which is adopted in this work as is (Figure 1). A subset of symbols from BPMN notation were considered, and it is compatible with symbols used for the IDM / MVD specification [16].

5.2 Example: Process for Automated Cut and Bend of Reinforcing Bars

5.2.1 IDM / MVD for Automated Cut and Bend of Reinforcing Bars

As the authors of the present article are working in the development of a IDM / MVD for the automated cut and bend of reinforcing bars as a BIM process [17][18], it was decided to use this scenario to illustrate the mapping between IDM (BPMN) to Petri Nets (Figure 2).

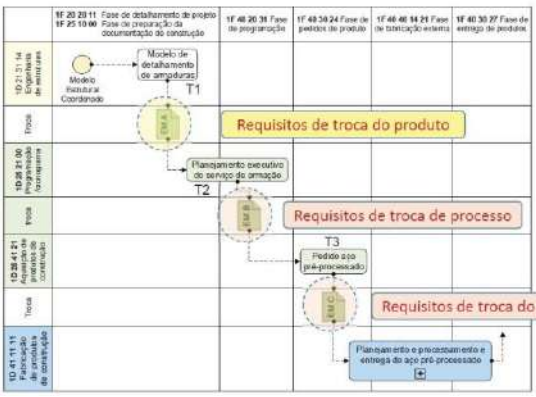

Figure 2. Example of an IDM in BPMN language for the Automatic Cut and Bent of rebars.

The IDM is the business process in BPMN notation. It contemplates 5 phases (Design Detailing and Preparation of Construction Documents; Programming; Product Orders; External Fabrication; and Product Delivery) and 4 disciplines (Structural Engineering; Schedule Programming; Acquisition of Construction Product; and Fabrication of Construction Product), following codes from NBR 15.965 (a Brazilian standard, based on Omniclass). In addition, it represents three exchange requirements: T1 (product), T2 (process), and T3 (order).

The level of detail achieved (and it is that way throughout this development in Construction industry) in modelling IDM for MVD specification is not enough for it be immediately mapped (and be relevant) in a Petri Nets, as it do not exposes detail of the fabrication process.

5.2.2 Sub-process: Fabrication of Reinforcing Bars

In the industrial process of cut and bend of reinforcing bars (rebars), there is a team dealing with orders received (containing delivery date and reference drawings for rebars processing). This team does a preliminary analysis of the order (reference drawings missing, errors in data filling in the forms), and contacts the client if necessary. If everything is correct, the next stage is to send forward the orders and the reference drawings (Rebar Detailing Project) to the scheduling team, which will transcript design data to production (geometry and quantities of each bend format). That information is entered in the production management software of the service (cut and bend) provider.

In the sequence, the Production Planning and Control starts. In general, large cut & bend providers have many equipment working simultaneously. Each equipment works with a specific diameter of steel bars, and have restrictions of bend shape that it could process (for example, maximum length of the bar to be bend).

Also, a pool of orders is stablished to achieve a given volume of production, to keep the line operating continuously, and to make some optimization in reducing possible lengths of lost from the raw material [19].

5.2.3 BMPN diagram of the fabrication process

For this example, it will be considered just one machine operating, starting from the point where the previous dynamic description ends. There are different types of machines that produces reinforcing bars [20], and here it will be considered types A or B machines (Figure 3).

Figure 3. Schnell's A type machine.

Therefore, it was developed a prototype of a sub-process for the task that appears in blue in Figure 2, with the right amount of detail, to provide a BPMN notation (Figure 4). The model considers orders arriving in regular intervals. Given the availability of appropriate reinforcing bars (same diameter and material as ordered), the processing of rebars remains active due to place rebars_batch.

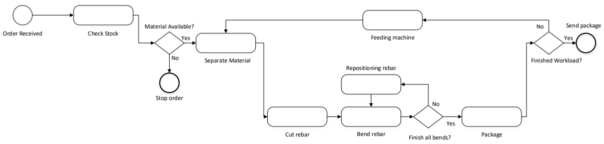

Figure 4. Sub-process for the fabrication of reinforcing rebars.

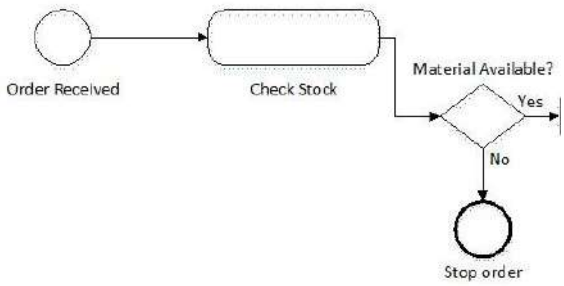

Figure 5. Initial part of the BPMN for Automated Cut and Bend of Rebars.

In the sequence (Figure 5), an order received (*Order Received*) is the start of the modelled process. The task *Check Stock* check if the material to attend the arrived order is available in the stock. Then, a gateway divides the flow: is there is material, then order follows along the path; if not, that is the end of the process (*Stop order*).

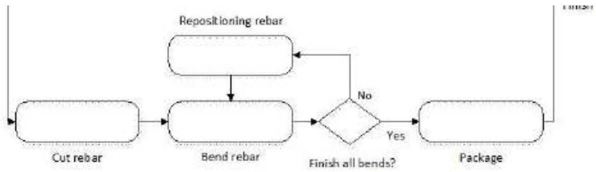

Figure 6. The part of the process were the rebars are cut and bend, following specification in BIM model.

After the gateway, there is a task (which is not represented in Figure 6) called *Separate Material*, in which the raw bars from the specified material are separated and brought closer to the machine. Then happens the tasks *Cut rebar* and *Bend rebar*. As could be more than one bend for each rebar, there is another gateway to check if all bends for that rebar were done (*Finish all bends*). If not, there is a task named Repositioning rebar, as an operator sometimes exist to conduct the positioning and gives command to the machine make another bend. When all bends were done, the flows goes to the *Package* Task.

Figure 7. Final loop to produce all rebars of a given order.

From *Package* task, there is a final gateway (Figure 7) that checks if all rebars of the given order were produced. If yes, then the flows and the process ends at *Send Package* (end node). If not, it goes to the task *Feeding machine* and then again to *Separate Material*, and the process of cut and bend of the rebar starts again in another rebar, which were previously separated.

5.2.4 Mapped Petri Net

Applying to this model the map presented in Figure 1, the Petri Net represented in Figure 8 is obtained.

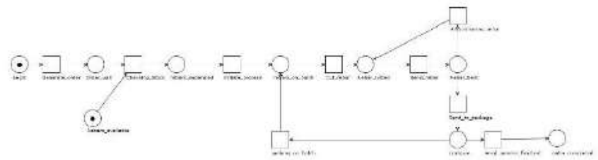

Figure 8. Petri net derived from BPMN subprocess.

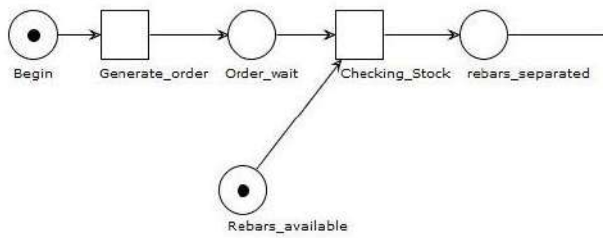

Figure 9. Initial part of the Petri Net mapped from BPMN diagram.

The token are added from simulate the dynamics of the net: one token to start the process (*Begin*), as an order arriving, and one at place *Rebars_available* (Figure 9).

The transition *Generate_order* is active and fires. Token moves to *Order_wait* place. The transition Checking_Stock become active, as there are tokens in both predecessor places (*Order_wait* and *Rebars_available*), and the token moves to *rebars_separated*. Note that the net will not work again, even with the arrival of another order, because rebars_available must also receive another token. The connection of this process with other dependent was not modelled.

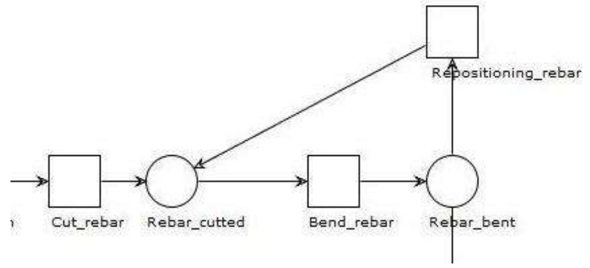

Figure 10. The cut and bend activities represented in the Petri Net.

Figure 10 do not show that after the place *rebars_separated* there are a transition *intiate_process*. After it, there is a place (that also not appears in the above figure) called *rebars_on_batch*. The token in this last place, activate the transition *Cut_rebar*, flows to *Rebar_cutted*, and then fires *Bend_rebar*, ending in the place *Rebar_bent*.

In the place *Rebar_bent* there is the possibility for two transitions to occur: *Repositioning_rebar*, if there are more bend to be made in the rebar, or *Send_to_package*, if this rebar is finished. If it is not finished, the transition *Repositioning_rebar* is activated and the token goes back to *Rebar_cutted*.

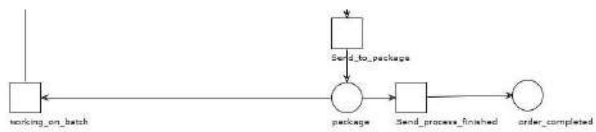

Figure 11. End of the process.

Figure 11 starts with the fire of transition *Send_to_package*, when all bend are made at the rebar. The token at *package* activates both *Send_process_finished* (if all rebars on the order were fabricated) and *working_on_batch* (if there still rebars to be fabricated). If the last transition is fired, it returns to place *rebars_on_batch*, and initiate again the cut and bend dynamics. If all work on that order is done, it fires Send_process_finished and goes to *order_completed*, with the simulation ended.

6 Results

In order to, somehow, validate the mapping (beyond test its dynamics in a software), one Petri Net was elaborated beforehand, and its dynamics tested with WoPeD (Workflow Petri Net Designer). The modelled Petri Net is represented in Figure 12.

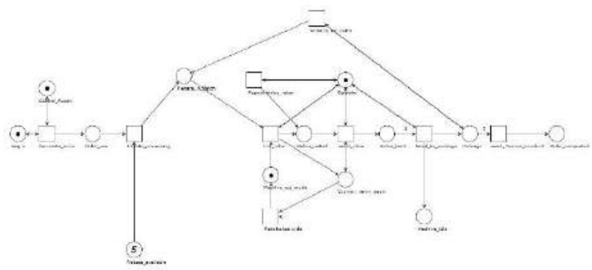

Figure 12. A previously modelled Petri Net for the same purposes.

Figure 13 represents the initial part of the process, with orders arriving; this part of the model was taken from the simulation presented at [21].

Figure 14 shows the cut and bend process of each reinforcing bar. First, the machine is in cut mode, and the operator is available. Then, the machine changes to bend_mode, and the operator makes the repositioning of rebars for further bends, until the number of bends are completed. The machine goes to idle state, and then back to cut mode.

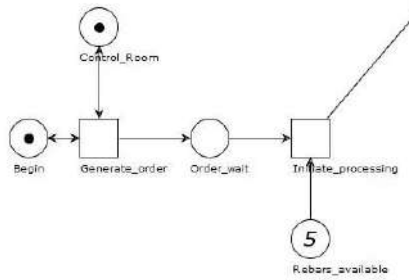

Figure 13. Petri net model for automatic rebar cut and bend (this part of the net is inspired by [21]).

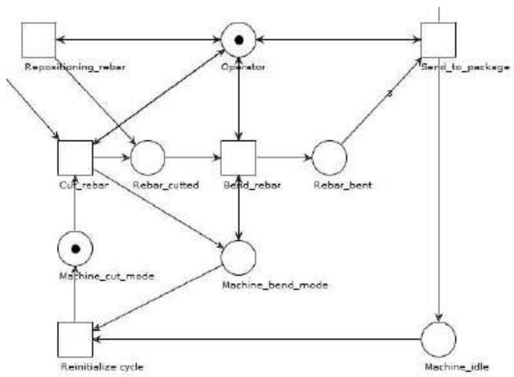

Figure 14. Processing of reinforcing bars.

At the same time, the first piece of the order, remains in the package, and maintain the rebar supply available to process new rebars in the same batch (Figure 15). The transition send_finish_process has precedence and stops further processing. The loop initiate again with a new order.

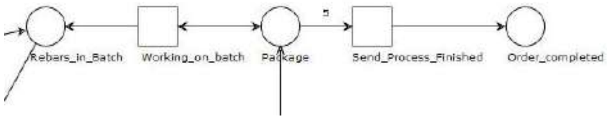

Figure 15. Final part of the model.

It is interestingly that where modelling the same process in BPMN, many details, such as the existence of an operator, and the difference in the type of machine (using one for bend and other for cut), are abstracted generating a simpler and functional network.

7 Conclusion and Future Works

This paper proposed the use of IDM/MVD workflow to start the development of a process model in Petri Net formalism. The objective in creating such model is that it could integrate information from BIM models and sensors and actuators signals for the plant process, obtaining a kind of cyber-physical system. This area is very promising, but the results are still preliminary.

The experiment of developing a simulation of construction processes as the core of a cyber-physical system was presented.

The focus of the article was in testing the relevance in using available IDMs, elaborated for BIM processes purposes, to produce one representation, Petri Nets, that allows to test its dynamics, and even its control strategy.

Initial results, were positive, as the mapping between IDM (in BPMN notation) produced Petri Nets more simple and functional when compared with a previous Petri Net elaborated from zero.

Another result is that the level of detail present in current IDMs ([14] was also analysed) is not sufficient for the proposed approach. But it is not difficult to proceed in the same notation to model sub-task or sub-activities to expose details of the fabrication processes.

Finally, a workable dynamic model in Petri Net probably needs more characteristics than BPMN could model. It should be considered a starting point to further develop to include controlled process, or a controller explicitly.

Interestingly, to produce from zero a Petri Net for this fabrication process, the resultant net was more complex, because many more details were inserted in its elaboration (and it was an iterative process) to achieve the right dynamics in the Petri Nets. When modelling with BPMN, it was easier to achieve a diagram that was translated in a simpler Petri Net, with about the same dynamics.

In the end, there was not necessary to deal with orders that necessitate different number of bends, or work packages with different number of rebars. In the mapped solution, this aspects was abstracted of the net, although it has the same dynamics.

Abstract –

We discuss the idea of developing Information Modeling (IM) for an existing underground facility so that it can be efficiently utilized as a laboratory for testing automated machinery in tunnel construction and mining.

The currently existing underground laboratories are located in old mines or underground storage facilities of which there exists usually only rough 3D CAD drawings, often done with geological modeling software. We discuss the relevant information content to create a useful IM for the purpose of the R&D of tunnel construction and mining equipment. We also present the current status of the IM, created in Lab 3 at 990 m depth in Callio Lab, the new underground laboratory in Pyhäsalmi mine in Finland.

Keywords –

Information modeling, IM, BIM, Underground facility, Underground laboratory, automation, robotics, mining, tunneling.

1 Introduction

Several underground facilities of old mines, nuclear waste storage facilities or extensions of road tunnels have been utilized as a laboratory for the research or development of activities, which specifically require underground conditions. Such activities include for example basic research of physics [1], geophysics [2] mining and tunneling equipment automation as well as education of mining engineering (for example in [2] and [3]) or even experimental food production [4]. Some of the major manufacturers, such as Sandvik or Atlas Copco, have excavated their own underground facilities for the testing of tunneling equipment and robotics [5].

When converted to laboratory use, an underground space is essentially turned into a building, where people work and spend substantial amounts of time in environments, which should be characterized similarly to office buildings or normal laboratory facilities. However, there are no standards for the conversion of an underground facility into a work place. The purpose of this study is to test the idea of creating an Information Model (IM), similarly to normal Building Information Modeling (BIM). We discuss specifically the case of creating a test laboratory for the research of tunneling automation and robotics and the benefits of the approach both from the user's point of view and the infrastructure provider's (the operator of the underground laboratory) point of view. We also present the results of a proof-of-concept experiment to make an IM, using the Industry Foundation Class (IFC) [6] data format, for the creation of an office in the Lab3 facility of Callio Lab at the 990 m depth in Pyhäsalmi mine.

2 Callio Lab

The tunnel network of Pyhäsalmi mine extends down to 1430 m depth, making it the deepest metal mine in Europe. The main ores, excavated since 1962, have been copper, zinc and pyrite. However, the current forecast is that the ore reserves are going to be exhausted by the end of 2019 and the mine is due to a closure.

Because of its depth and the extraordinarily large tunnel network, created during the 66 years of underground operations, the mine has hosted a variety of research activities since 1995. The modern and extensive support infrastructures both on the main service level, at +1400 m depth, and on the surface, provide a great platform for developing the mine into a versatile underground laboratory.

In 2015, the municipality of Pyhäjärvi started the project Callio (the name Callio is derived from Finnish word *kallio* meaning *bedrock*) to co-ordinate and develop the underground laboratory activities in the mine under the brand name Callio Lab [7]. During 2015-2017, the non-mining activities included the research of mining vehicles, radiation shielding systems, particle physics detectors and an observatory for cosmic rays and even an experimental farm for growing green vegetables and potatoes in underground conditions [8][9].

In 2017, Callio Lab had four dedicated Lab facilities on the levels +75 m (Lab 1), +660 m (Lab 4), +990 m (Lab 3) and +1430 m (Lab 2) depths of the mine .(Fig 1.).

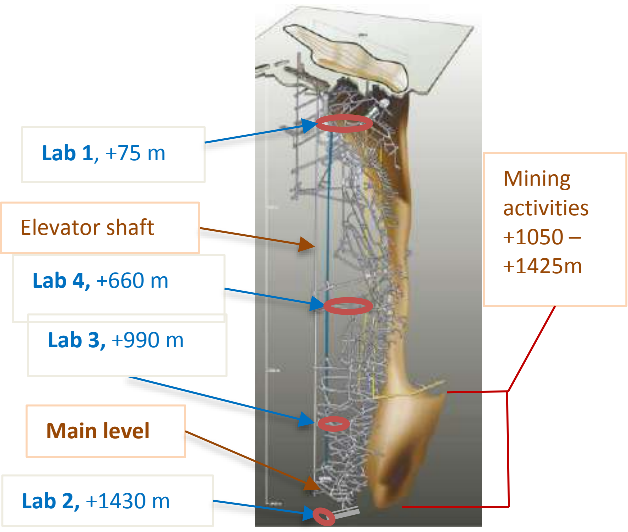

Figure 1. Cross section of the Pyhäsalmi mine. The brown column represents the ore deposits.

The main level is accessible with a mine elevator, hoisting people at 12 m/s and reaching the surface in 3 minutes. All levels are accessible with an 11 km long, truck-sized incline, which takes about 30 minutes to drive from the surface to the 1400m level. The rock conditions are uniquely stable and the rock mechanical tensions thoroughly investigated for the laboratory use, especially in the bottom part of the mine [10].

3 Testing of mining equipment, tunnel construction machinery and robotics in an UL

The creation of a possible standard IFC data model for underground laboratories requires a combination of different approaches:

- A mine model, mainly as a tool for the transportation and excavation of ore, described in the terms of geoscientific modeling, such as Geospatial Information Systems (GIS) [11][12]
- Underground tunnels, modeled as infrastructures for the transportation of people, machinery, mining and tunneling equipment (Infra IM) [13]
- Underground laboratory as a working space, with a BIM comparable to facilities in normal buildings.

For example, Fraser [14] has pointed out that the broader adoption of the IM in the mine environment is still an unchartered area of opportunity for interoperability and equipment standards for testing of both mining and tunnel construction automation. Tunnel construction and mining industry should see similar benefits as do building construction in general by adopting the use of BIM. In Europe this can be seen as an extension to open data concept of BIM, in Australia it's part of the "*Common Mine Model"* [15]. Automation and robotics can be linked via this concept as well. Mine geoscience and geophysics applications would be eventually natural additions to these studies.

Based on the discussion with the representatives of mining and tunnel industries, we propose that an IM of a tunnel construction or mining technology test facility could provide at least (but not limited to) the following types of information:

Objects

- Tunnels, which are available as test areas for mining or tunneling vehicles
- Electrical outlets, WiFi or cable connection to the internet, water supply, compressed air
- Location of rescue services with rescue chambers or other emergency services
- Offices, control rooms for operators and service areas, such as cafeteria, conference room, rest room, etc.
- Material handling spaces, for example concrete mixing
- Vehicle maintenance spaces
- Storage rooms
- Doors
- Roads and parking areas
- Elevator station or other transportation

Information tagged to the 3D model or the objects

- Mine driveway inclines
- Characteristics of the rock and surfaces
- Special areas available for blasting, drilling, installations
- Average ambient temperature
- Moisture, dust
- Other sensory information
- Specific rock mechanical considerations, such as tensions or fracture

The goal is that the comprehensive information modeling makes it easier for users to plan their test programs: How to make the automated tunnel construction or mining machinery to navigate better in tunnel networks, how to plan the testing and how to arrange the safety and facility maintenance procedures for the personnel.

Also from the underground laboratory operator's point of view, the Information model provides clear benefits:

- Better service to the customers, which helps to make the underground laboratory more competitive
- A methodology to take new tunnels into use more rapidly
- A tool for Facility Management (FM) of the underground facilities.

4 Information Modeling of Lab 3 of Callio Lab

As a proof of concept to study the viability of making an IM into an existing underground facility, we created and IFC model based on the existing 3D mine model provided by the Pyhäsalmi mine's surveying department and using existing software tools.

The Information Modeling for Callio Lab was started on the level +990 m in the Lab 3 tunnel (Fig. 2) by designating it as "office".

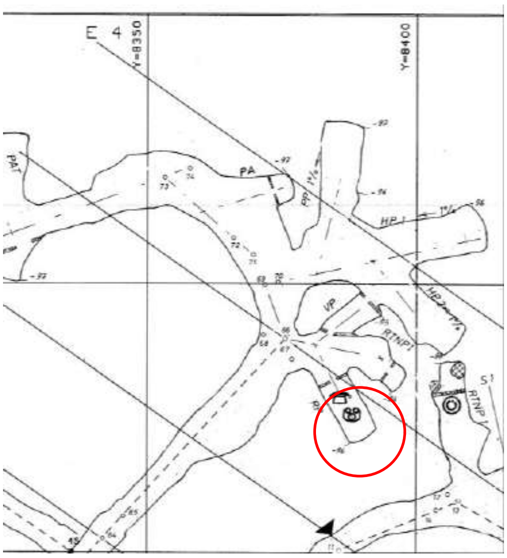

Fig 2. The location of Lab 3 in +990 level shown inside the red circle.

The IFC file for the "office" in Lab 3 was created with Autodesk Revit (Fig 3), so that it relates each object type from the building information model to the corresponding IFC entity (*e.g.* ifcWifi, ifcDoor, ifcElectricalOutlet, [16]). The IFC file can then be saved and edited as an external text file and it is possible to add simple meta-data to an IFC file.

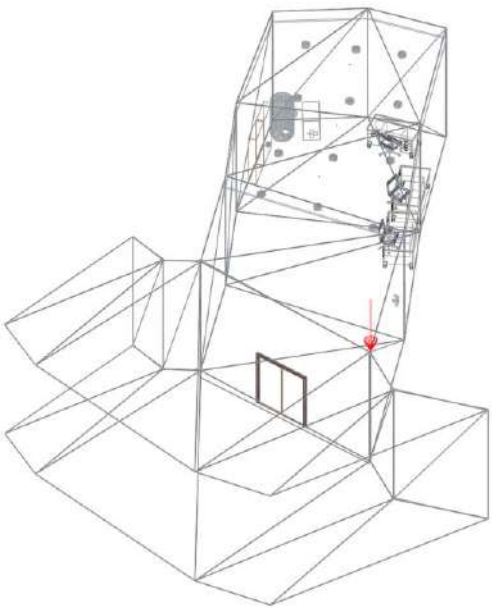

Fig 3. The Lab3 office model in co-ordination view of Revit.

However, the creation of the office based on the existing data was not straightforward. The mine's structures are modeled with Surpac geological surveying modeling software (Fig 4.) and importing the point mass information into Revit required and intermediate step of creating a tool for the conversion of data with Autodesk Dynamo.

An even bigger problem was that the resolution of the mesh in the mine model was at best of the order of 1 m, which may turn out to be insufficient for some users. The way to achieve a better resolution would then be to make laser scanning in the location (see for example Makkonen [17] and [18].

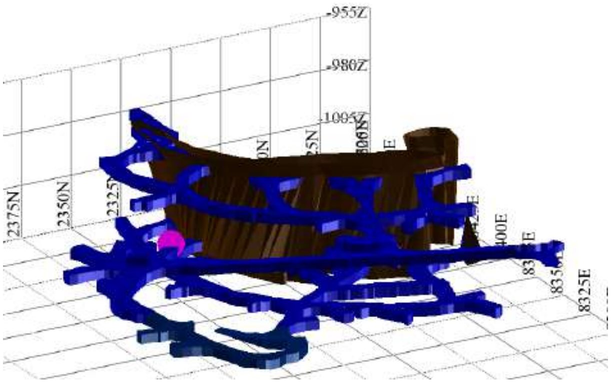

Fig. 3. The Surpac 3D plot from level +955 m to +1030 m. The location of Lab 3 is indicated with the pink ball. The black area in the background represents the ore reserves.

The work is continuing by developing the IM further. The next steps could include the creation of more objects and by tagging more information also to the adjoining service roads and tunnels. The new objects can include warning lights, valves related to plumbing location of escape pots (locations with reserve air) and available sensory information. Eventually the information shall include information about the inclination of tunnels and characteristics of wall surfaces for tunnel construction robotics.

5 Conclusions and future work

The information modeling of Callio Lab, based on the existing Surpac models of the Pyhäsalmi mine was demonstrated to be a viable possibility, although not straightforward. Based on the discussions with a tunnel construction company and a mining company we also reviewed the information, which would be useful for an IM of a testing platform of underground construction and mining automation.

The work shall continue by developing the underground laboratory IM further and implement especially the information, which is relevant for the testing of automated tunneling and mining machinery. Then we plan to collect feedback from the current users of Callio Lab and other companies in the industry. The work shall be conducted partly within the framework of the project BSUIN - Baltic Sea Underground Innovation Network, an ERDF funded Baltic Sea Region INTERREG program for developing services and technical characterization of six underground laboratories in the Baltic Sea Region in EU and Russia [19].

For the parties interested in utilizing Callio Lab's facilities, there is an open call for expressions-of-interest, accessible at Callio Lab's web page [20].

Acknowledgements

The authors wish to acknowledge the municipality of Pyhäjärvi, Pyhäsalmi Mine Oy and Normet Oy for valuable discussions and encouragement and European Union's Interreg Baltic Sea Region's Programme for supporting the work.

Abstract

Occupant comfort plays an important role in office buildings in terms of environmental, social, and economic aspects. Facility managers need to evaluate occupant feedback to moderate the negative consequences on office users and ultimately on the corporations that occupy office spaces. However, in the current facility management systems, occupant feedback is not effectively collected and evaluated; thus, facility managers cannot utilize this information in making critical decisions when operating, maintaining and retrofitting office facilities.

This paper presents the initial results of an ongoing research study, which focuses on integrating occupant feedback with Building Information Model (BIM) for assisting decision-makers in the facility management phase. The first step of this research study was to identify the information items that are required to represent occupant feedback for effective use in the facility management phase. To identify the required information items, interviews were performed with office users at ten office buildings and use cases were developed. To validate the use cases, interviews were performed with twelve facility managers. The aim of this paper is to present a sample of the use cases developed and describe the occupant feedback information flow observed in the office buildings. The results show that the occupant feedback data include detailed information related to: (1) location where the problem is observed, which is represented by building, and/or floor, and/or room, and/or façade, and/or table/zone/region depending on the case; (2) location of the user, that is represented by building, floor, room, table/zone/region, (3) source of the problem that is represented by type of building element and related building element, (4) source location, which specifies the location of a problem source that is different than the location where the problem is observed, and (5) time.

Keywords – Occupant Comfort; Facility Management; FM; Building Information Modeling; BIM; Use Case.

1 Introduction

Effective utilization of occupant complaints and feedback is crucial for successful operation, maintenance and retrofitting in offices. Many studies reveal the effects of occupant comfort on energy efficiency [1]; [2]; [3]; [4], employee health and well-being [5]; [6]; [7]; [8]; [9] and employee productivity [10]; [11]; [12]; [13]; [14]; [15]. Currently, to regulate indoor environment during design, operation and retrofitting in office buildings, occupant comfort standards (e.g., ASHRAE 55, EN ISO 7730) are used [16]. However, due to the variations in individuals' sensation levels, there is a poor relation between comfort conditions defined in the standards and the comfort conditions perceived by the occupants [17]. Occupant comfort and satisfaction increases when the occupant evaluations on performance parameters, such as thermal, visual, acoustic comfort, are considered by facility managers [18]; [19]. To measure functional comfort and identify possible workspace features which slows down or demotivates employees, collection of feedback from occupants is critical [20].

Collection of occupant feedback is currently performed by post occupancy evaluation (POE) tools, which are a type of building performance evaluation system. POE is defined as the "examination of the effectiveness for human users of occupied designed environment" [21]; [22]. The current POE tools, however, are lacking extensive inquiry about occupant satisfaction parameters [23]; [24], location based (spatial) occupant feedback [25] and easily understandable visualized data analysis and representation formats for facilities management (FM) [26]; [27].

Building Information Modeling (BIM) constitutes an effective platform to represent and analyze occupant feedback in facilities management. Although the need for BIM in facility management (FM) has been acknowledged by researchers and practitioners [28]; [29]; [30]; [31]; [32] BIM is still not being effectively utilized in this phase, including retrofitting activities [33]; [34]; [35]. FM is still dominated by corrective maintenance and there is under-utilization of preventive, predictive, and condition-based maintenance in facility management despite the use of advanced FM programs [36].

The study explained in this paper proposes to integrate BIM and occupant feedback to assist facility managers in making critical decisions in FM, including retrofitting activities, as well as preventive, predictive, and condition-based maintenance in office buildings. The first step of this ongoing study was to identify the information items that are required to represent occupant feedback for effective use in the FM phase. To identify the required information items, interviews were performed with office users at ten offices and use cases were developed based on those interviews. The aim of this paper is to present a sample of the use cases developed and to give an overview of the information items required to represent occupant feedback in the office buildings.

2 Literature Review

As part of the literature review occupant comfort, post occupancy evaluation (POE) and its relation to FM, existing POE tools, and FM & BIM & POE integration topics are investigated.

2.1. Occupant Comfort

There are three basic pillars of the effects of occupant comfort in office buildings. These are social, economic and environmental dimensions. The social dimension includes the well-being and health of employees. It is proved that the well-being and health of employees are directly related with the work environment comfort conditions [37]. One of the main disruptions among the employees is caused by indoor air quality. Adequate ventilation, pollutants and moisture level in the air are the key factors affecting the employee health in an office environment. Also, lighting, high level of noise and vibrations directly affects the employee's psychology. As a result, disturbing environmental conditions slows down the work rate of employees and increases the amount of mistakes due to distraction. It is observed that the absenteeism rate due to health issues is lower in offices which satisfy occupant needs; therefore, the employee productivity in such offices is comparably higher [38]; [39]; [40]. Design-related comfort aspects such as indoor air quality, noise control, thermal comfort, privacy, lighting comfort, spatial comfort and noise comfort designate the level of employee performance. It should be highlighted that physical environment of the office affects 15-20% of productivity of personnel; therefore, productivity constitutes the economical aspect of comfort condition by eventually affecting the company financial-wise [41]; [42]; [37]. The environmental effects of occupant comfort level are also investigated in the literature. It has been identified that the occupant comfort dissatisfaction leads to inefficient use of building systems and causes an increase in building's energy consumption [18]. If the environment is designed to meet the requirements of the occupants and if the occupants understand how the building operates and how the controls systems are used, then it is possible for the occupants to contribute to lower building energy use [18]; [19]; [43]; [44].

The occupant comfort condition standards are used to regulate the indoor environment during operation and renovation periods of office buildings; however. There is a poor relation between comfort conditions defined in the standards and the comfort conditions perceived by the occupants since the sensation level of every individual is different [17]. Especially the evaluations of occupant feedback on performance parameters such as thermal, visual, acoustic comfort, indoor air quality, space usage and occupant control increases the occupant satisfaction [18]; [19]. Collection of feedback from users is vital to measure functional comfort and to identify possible workspace features which slows down or demotivates employees [20].

2.2. Post Occupancy Evaluation (POE)

During the occupancy phase of the buildings, the building performance evaluations (BPE) are conducted via post occupancy evaluation (POE) tools. Post-occupancy evaluation (POE) is the process of obtaining feedback on a building's performance after it has been built and occupied. In the literature, POE tools are named as Occupant Satisfaction Measurement Tools, Indoor Environmental Surveys or Building Performance Evaluation Surveys. By collecting factors, such as energy consumption, building use, maintenance costs or user satisfaction, POE allows various and continuous improvement possibilities in buildings. Moreover, because of the advances in technology, POE transformed into a knowledge tool than a diagnostic tool in time. Generally POE tools consist of three core parts: questionnaires, bills and metrics, physical measurements (optional) [45]. The results of the questionnaire surveys enable the determination of indirect parameters and characteristics, such as individual characteristics of the occupants and their personality. The physical measurement enable the determination of direct parameters, such as air temperature, relative humidity, air velocity, globe temperature, CO_2 concentration, illuminance levels etc. Also, bills and metrics include documents related to energy consumption of the building and blueprints of the building.

2.3. Importance of POE in FM

British Institute of Facilities Management has defined

FM as "the integration of processes within an organization to maintain and develop the agreed services, which support and improve the effectiveness of its primary activities" [46]. Facility planning (space management); health, safety, security; maintenance management; and work environment comfort conditions are the main aspects of FM, in which cleaning services, support services, property services, catering services, security services, etc. are provided.

In the current FM applications, IT systems are effectively used in many service areas, such as maintenance and space management. However; work environment comfort conditions are only detected via sensors and POE is not integrated with this data. FM receives the occupant feedback not as a continuous information source, but only as the source of some work orders, which are supposed to be closed after fulfilling required maintenance. In fact, occupant feedback plays an important role for the management of work environment comfort conditions by the facility managers, and there is a need for advanced approaches for effective collection of occupant feedback data.

2.4. Existing POE Tools

There are many POE tools developed over the years focusing on different building types. Various methods and techniques were developed to extract user requirements regarding safety, health, comfort, functionality and efficiency, and aesthetic quality of buildings, and to identify defects in the system [47]. POEs are powerful tools for demonstrating whether or not building programs are delivering best value and for identifying areas for improvement. Currently, architects, built environment professionals, industry bodies and even clients prefer building evaluations through POE since they can see the benefits of evidence-based decision making in achieving their organizational goals. However the current POE tools are lacking some crucial features such as (1) extensive inquiry about occupant satisfaction parameters, (2) spatial occupant feedback, and (3) visualized representation of easily understandable data analysis results.

1. In POE measurement graphs, there is no extensive inquiry about occupant satisfaction parameters which are the indicative of occupant satisfaction. In the research studies, it is found that the satisfaction level of the occupants is measured using several parameters, but the dissatisfaction of the occupant or the reason of the complaint is not interrogated [23]; [24]. Lack of details constitutes a problem in case of a need for detection of specific problems.
2. The evaluation tools are not collecting spatial occupant feedback. The spatial information can enrich the feedback data and point out the building element related to the complaint. This information cannot be delivered to decision makers; therefore, a historical occupant feedback platform does not exist. It is known that linking the performance data to occupant location increases the system efficiency [25]. In a previous study, Hua et al. (2014; 2015) linked the occupant feedback to building spaces (i.e., rooms). However, this approach is not sufficient for open office environments and homogenous evaluations cannot be performed since usually open offices are large areas. Also, it is not possible to give feedback about the common areas other than offices.
3. There is lack of data analysis and representation of analysis results in the systems. In the current systems, the data obtained from evaluation system is not reflected in the facility management application [26]. The greatest obstacle is that the data is not processed and analyzed in a way that the decision makers need and not presented in an easily accessible, refined and visualized way [27]; [26].

2.5. FM & BIM & POE Integration

BIM is a process which uses 3D, parametric and object-based models to create, store and use coordinated and compatible data throughout the life cycle of a facility [48]. The system goes beyond a visual modeling by means of 3D numerical modeling feature. It is a multifunctional management and information exchange tool which can contain all the information for manufacturing. Also, the information embedded in BIM models can be used for the operation of the facility [49]. Thanks to the developed exchange formats such as IFC Standards, data exchange between BIM tools is possible [50]. BIM integrated FM systems utilize effective decision making during operation and retrofit phases and consequently increases the building performance and occupant satisfaction [51]. The usage of BIM in FM bridges the information gap between the authorities in design and construction phase and the owner. It helps to reduce the costs since the data is ready to use and easy to reach in the model. Also, the models can be integrated into building automation systems which helps the FM to manage the buildings more effectively. Lastly, by enabling faster analysis and correction of problems, it helps to improve building performance and therefore the occupant comfort. In recent years, it has been emphasized that a BIM-integrated FM system is needed for delivering facility performance data more effectively to decision-makers in FM or retrofitting processes [25]; [52]; [53]; [54]; [55]; [56]. The application of such a system is not reported in any of the studies, even though the required approaches are proposed frequently.

3 Method

To identify the information items that are required to represent occupant feedback, the current information flow between employees and facility managers are investigated for reporting of complaints and feedback. A set of interviews were performed and use case scenarios were developed based on these interviews. Ten office employees, who work in ten offices in different companies, participated in the interviews. All office buildings chosen for the study have automation systems for HVAC control and operated by professional FM firms, but are diverse in terms of size, type of offices (cellular/open-plan), type of activities, facades, finishing materials, energy efficiency levels and none of them have BIM models. All the office users were asked four open-ended questions;

1. What kind of complaints did you report before?
2. Whom did you report your complaint?
3. Which communication method(s) did you use to report your complaint?
4. Which information did you provide to the authorities about your complaint?

According to the information obtained during the interviews, thirteen use case scenarios that represent occupant feedback/complaint information flow were developed. For each use case scenario, a use case diagram using Unified Modeling Language (UML) was created.

To validate the use cases that were developed, use case scenarios and UML diagrams were presented to twelve facility managers. Their feedback was received via interviews and reflected in the use cases. The methodology is also shown in Figure 1.

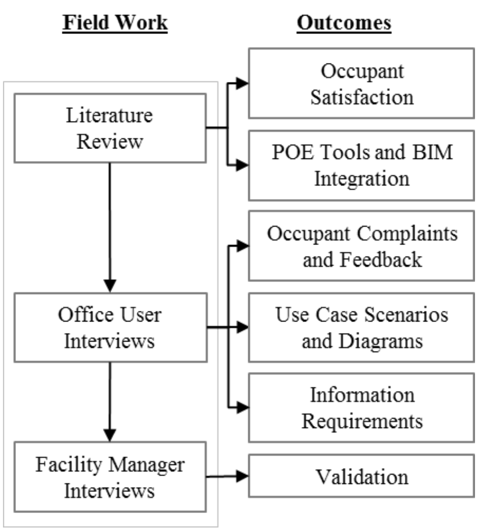

Figure 1. Methodology flowchart

4 Results

Out of thirteen use cases that were developed via interviews with office occupants and facility managers, three of them are provided as a sample in this paper. Information requirements that were identified from the use case as an outcome were presented along with each use case scenario.

Use Case Scenario 1 : Indoor Air Quality – Odor

Actors: Employee, facility manager, technical staff

Triggers: The employee realizes that there is an unpleasant odor in the office coming from the cafeteria.

Scenario: The employee realizes that there is a bad smell in the office coming from the cafeteria. He calls the facility manager and complains about it. The facility manager directs a technical staff team to the entrance floor to make an inspection about the complaint. After the inspection, the technical staff offers the construction of an automated door between the Blue Zone (offices) and the corridor that opens to the cafeteria. The facility manager accepts the offer and as a solution the door is constructed.

Outcomes: Building, Floor, Zone, and Source Location (different room for problem source, ex: cafeteria)

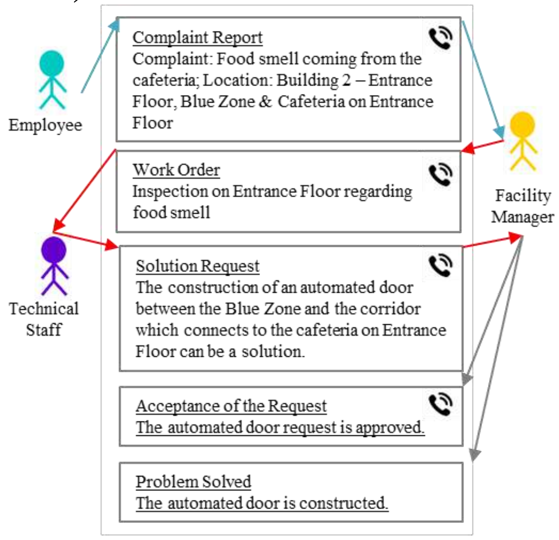

Figure 2. UML diagram of use case scenario 1

Use Case Scenario 2: Visual Comfort – Reflection

Actors: Employee, facility manager, administrative affairs manager

Triggers: The sunlight is reflecting on the computer of the employee and the employee cannot see his screen

Scenario: The sunlight is reflecting on the computer of the employee and the employee cannot see his screen.

He reports this problem to the facility manager. The facility manager comes to the office of the employee and inspects the problem on site. After identifying that the problem is observed between 11:00 and 15:00, the facility manager decides that there is a need for a window shade. The facility manager calls the administrative affairs manager, reports the problem and requests a window shade for office X. The administrative affairs manager accepts the request of window shade procurement. The facility manager purchases the window shade. By using the window shade, the employee prevented reflection on his screen between 11:00 and 15:00 while working at his computer.

Outcomes: Floor, Room, Region, Table, Facade, Time.

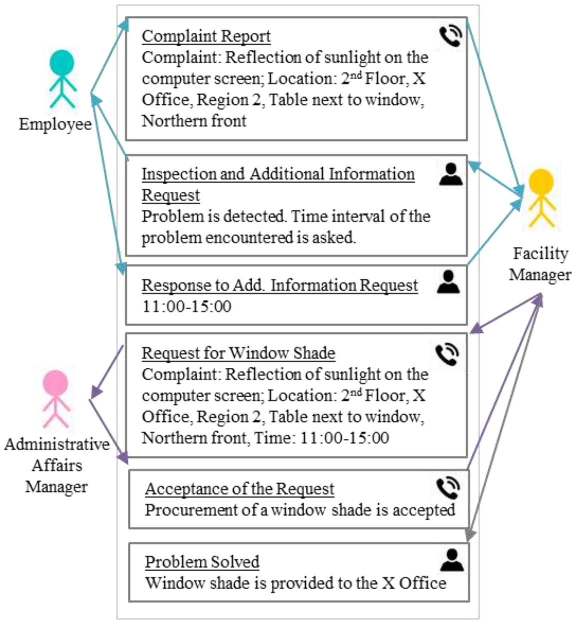

Figure 3. UML diagram of use case scenario 2

Use Case Scenario 3: Indoor Air Quality – Odor

Actors: Employee, facility manager, technical staff

Triggers: The employee thinks there is a bad smell coming from the air-conditioning (AC)

Scenario: The employee reports his complaint via a phone call about the unpleasant odor coming from air-conditioning to the facility. The facility manager directs a technical staff to do an inspection. The technical staff changes the filter in the air-conditioning unit and reports back to facility manager. The facility manager notifies the employee about the maintenance work.

Outcomes: Floor, Room, Building Element Type, Related Building Element (Building Element Location)

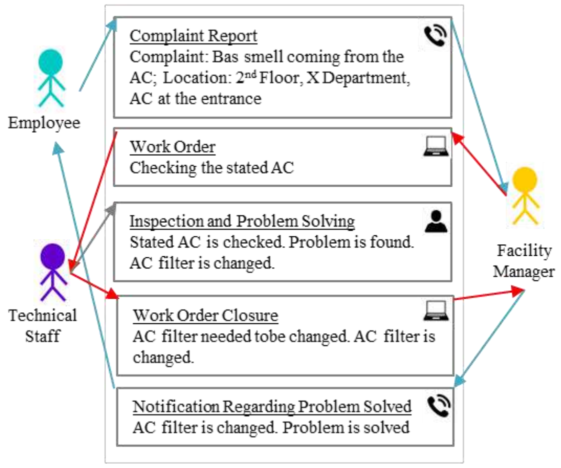

Figure 4. UML diagram of use case scenario 3

The use cases demonstrate that information requirements are different for each case. From use case scenario-1, *building*, *floor*, *zone*, and *source location* outcomes are obtained. Building, floor and zone represent the different granularity of location information of problem. The source location specifies the location of a problem source that is different than the location of the occupant. In the case of the unpleasant food smell in the office area, cafeteria represents the source location whereas the office represents the room/zone/region where the office user works.

From use case scenario-2 *floor, room, region, table, facade,* and *time* information requirements are gathered. Floor, room, region and table represent the location of the user. Since the complaint is related with a certain building frontage, the façade where the problem is observed is needed as well. Lastly, time stamp is important since the complaint is time dependent.

The information outcomes of the use case scenario-3 are *floor, room, building element type,* and *related building element (building element location).* Floor and room gives information regarding user location. Since the complaint is related to a certain building element, the type and exact location of it are needed as well.

Table 1. Information requirement outcomes of use case scenarios

Use Cases	Building	Floor	Room	Table	Region	Zone	Facade	Building Element Type	Related Building Element	Source Location	Time
1	x	x				x				x	
2		x	x	x	x		x				x
3		x	x					x	x		

Information requirements gathered from the use case scenarios are summarized and listed below:

- Location where the problem is observed (represented by building, and/or floor, and/or room, and/or façade, and/or table/zone/region depending on the case)
- Location of the user (represented by building, floor, room, table/zone/region)
- Source of the problem
  - Type of Building Element
  - Related Building Element
- Source Location
- Time

5 Conclusion

This paper presents the initial results of an ongoing research study, which focuses on integrating occupant feedback with Building Information Model (BIM) for assisting decision-makers in the facility management phase. The first step of this research study was to identify the information items that are required to represent occupant feedback for effective use in the facility management phase. The aim of this paper is to present a sample of the use cases developed to identify the required information items and describe the occupant feedback information flow observed in the office buildings.

The use cases demonstrate that information requirements are different for each case. The identified information items are: (1) location where the problem is observed, which is represented by building, and/or floor, and/or room, and/or façade, and/or table/zone/region depending on the case; (2) location of the user, that is represented by building, floor, room, table/zone/region, (3) source of the problem that is represented by type of building element and related building element, (4) source location, which specifies the location of a problem source that is different than the location where the problem is observed, and (5) time.

The next step of this study is to determine how the required information items are represented in IFC and if necessary, how IFC should be extended to represent those information items. Future work includes developing a prototype that collects occupant feedback from the user, stores in BIM and presents to the decision-makers for effective facility management.

Automatic Reassembly of Fragments for Restoration of Heritage Site Structures

Sivapriya V[a], Madhumitha Senthilvel[a] and Koshy Varghese[a]

Abstract –

A major bottleneck activity in the process of restoration of Heritage Structures is the reassembly of its fragments. Computer-aided reassembly could assist in finding the relation between them thereby reducing time, manpower and potential degradation to fragile fragments. Using geometric compatibility between the adjacent fragments as the central idea, a reassembly framework for a three-dimensional shell is proposed as a logical extension of the two-dimensional framework. Edges are extracted as polygons and relevant features are computed at each of its vertices. Sequences of the match for two fragments in the feature space are found using a modified version of Smith-Waterman Algorithm. Each match is assessed using a connectivity score. The final choice of best match is left to the user by displaying the resultant assembled fragments of prospective candidates along with the score. After pairwise matching, the global reassembly is done through a clustering-based method. This framework can handle fragments even with curved edges which can be reasonably approximated by a set of edges. We verify the methodology using a simulated dataset for both 2D pieces and a shattered 3D surface object.

Fragment automatic reassembly; Partial Curve matching; Feature extraction; 3D Reassembly; Heritage Restoration

1 Introduction

A large number of fragments are discovered during archaeological excavations and heritage site restoration tasks. Finding their relative positions is a very laborious yet crucial step. Manual methods are time-consuming, demands the construction of special supporting structures, labor intensive for heavy fragments and can potentially damage the fragile pieces during the process.

With advancements in technological developments to digitalize objects, computers can aid to a great extent in automating the process. [2] talks about the methods and technologies available for three-dimensional digitization of objects and monuments. [3] introduces a 3D digitizing pipeline for cultural heritage where they brief about polygonizing the point cloud to mesh to represent the geometry of the object.

This problem is similar to solving a three-dimensional jigsaw puzzle. There are a variety of approaches to solve the problem. The fragmented pieces themselves contain the clue for solving it. The clue varies from colour compatibility in the case of paintings [4], incisions on the surface for stones, marble veining directions [6], hand impressions on pottery [7] etc. Sometimes the clue also comes from knowing the end result like in the case of Skulls where similarity matching could be performed with the standard template to reassemble [8]. For highly eroded fragments, reassembly can be performed with the objective of maximising its packaging efficiency.

Unlike paintings, unearthed and abandoned fragments of buildings do not have colour or colour variations. Neither do we have a clear idea of the end result of the structure after reassembly of the fragments. The scope of the paper is to assemble pieces which have retained their geometric information without making any assumptions about the reassembled piece. We follow a framework for assembling pieces in two dimensions making use of only its geometry by contour curve matching. This has applications in assembling flat fragments like the fresco, walls. We then, logically extend the framework to assemble a three-dimensional surface object. Applications include reassembly of surfaces like domes, thin shell structures etc. This paper aims to help archaeologists reassemble interactively with user involvement only in the approval stage.

2 Related Works

The problem of reassembly has different approaches and is dealt in different ways depending on its applicability for each scenario. Every problem is essentially three dimensional. But some problems can be converted to two dimensions. Instances like flat fragments where the third dimension is uniform and does not exhibit appreciable variation belong to this category. Square type jigsaw puzzles involve utilizing boundary pixel values as the parameter to search among other pieces since there is no variation of shape along the edges [10]. Geometric reassembly dates back to 1964 where Freeman et al. encode the boundary as chains and partially matches chainlets through features for a commercially produced jigsaw puzzle [9]. As mentioned in [11], generalized reassembly is different from the jigsaw puzzles because of the uncertainty in the endpoint, unlike jigsaw puzzles where the delimiting point is fixed. The combination of geometrical and colour matching is very suitable to handle fragments of paintings.

A significant project in this domain was The Digital Forma Urbis Romae project where reassembly of marble pieces belonging to a giant map of Rome is attempted [6]. The clue, in this case, is contained in the incisions of the surface. Prediction of the pattern of the adjacent fragment based on the boundary drawings and searching for it through a number of pieces had resulted in significant improvements in its reassembly. Additional constraints come from the nature of the material - marble veining direction. Here we seek to reassemble apictoral fragments which provide us with no other clue than its edge contour. A similar problem was attempted in [12] and [13] where the fragments were converted to invariant features and compared in the feature space. Different features, the way matches are detected and their global reassembly methods are explored in various works.

In case of surface fragments like potteries, the two-dimensional simplifications do not hold. Some authors make use of the symmetry of objects by utilizing the thickness profile to reassemble pottery [5]. In this paper, we look at a generic case of reassembling 3D surface object without utilizing any information other than its edge information. Thus the proposed framework can handle missing pieces since it relies only on the strength of edge matching.

The extent of automation also varies for different works. A few works require the user to specify initial constraints like iso-planarity, adjacency while others do not involve the user at all and perform a completely automatic reassembly [12] [14]. We use very low user intervention in the following processes: (1) to finalize the pairwise and (2) reject the match when overlaps occur during global reassembly.

3 Framework

This paper aims to propose a 3D surface object reassembly framework by extending that of a 2D reassembly and verifying both the frameworks using a simulated dataset. The steps involved in the framework are described in the following sub-sections.

3.1 Extracting the Contour

The only piece of information we extract from the fragment is its contour. We attempt an apictoral reassembly. While extracting the boundary, we observed many consecutive 'almost' collinear points in the contour, which created a lot of edge jaggedness. This can be seen in Figure 1. We use Douglas-Peucker Algorithm to remove these points which do not contribute significantly to the matching process [17]. This reduces the processing complexity significantly. The choice of the threshold given as an input to the algorithm should be optimum since smaller values can be less effective and higher values can alter the shape of the fragment itself making it less suitable for the further process.

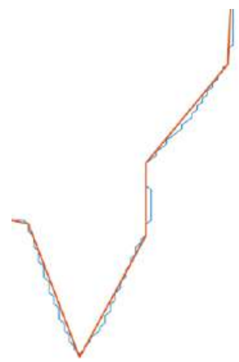

Figure 1. A fragment - Input to the Douglas Peucker algorithm (green) and output (red) with threshold = 0.01

3.2 Feature Extraction and normalization

With this reduced number of points in the contour which better capture the shape variation, we extract the following features based on [12] at every vertex:

I. Log of mean of edge lengths
II. Log of Absolute Value of signed curvature
III. Internal angle

For fragment i, let Fi_c contain the features extracted from the contour clockwise and Fi anticlockwise. The perimeter of each fragment is also stored in PM.

Distances in the feature space are highly dependent on the scale of each feature. Thus, to obtain uniformity, we use min-max normalization.

3.3 Pairwise matching

We use a modified version of Smith Waterman algorithm to match the two fragments i and j using Fi_c and Fj_a or Fi_a and Fj_c [15]. Two vertices are said to be same if their Euclidean distance in the feature space is less than Φ.

The endpoint to break the matching sequence is, cyclic matching i.e., we duplicate the sequence and append it to then end, and then match the sequence by removing repetitions [13]. The output of this is a list of matches between the fragments. The sequences greater than a minimum connectivity value C(i,j) as defined in [12] is stored in G.

$$C(i,j)= \frac{\text{Length of common boundary}}{\text{Minimum (PMi, PMj)}} \quad (1)$$

The transformation in the 2D space is estimated, checked for overlaps after transformation and displayed along with the connectivity value to the user to finalize the match.

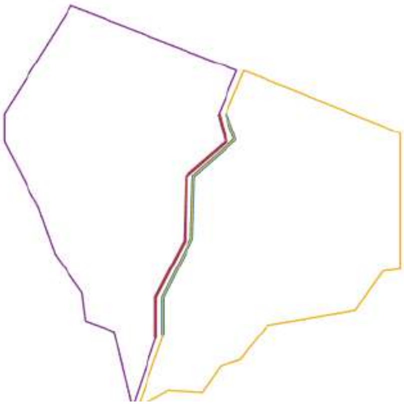

Figure 2. Fragment 2 and 3 pairwise match with Φ=0.05

3.4 Global reassembly

The order of assessment and reassembly of fragments is essential since wrong matches at initial stages potentially lead to error accumulation. Initially, connectivity score is found for all possible pairs of fragments (highest of all the matches for the pair of fragments is chosen). As proposed in [12], we use an agglomerative clustering algorithm. Pairwise matching is continuously performed for the pairs in decreasing order of their connectivity. The scores are not calculated after each iteration significantly reducing the computational requirement. After the reassembly, the fragments merge and form a single piece. Now, if any fragment is left over, the connectivity is recalculated considering the assembled fragment as a single fragment because the newly formed fragment structure might pose a good match to the leftover fragments. For our test dataset, a single iteration is adequate to assemble all of the fragments when we follow the approach of following the decreasing connectivity order. The assembled structure is shown in Figure 3.

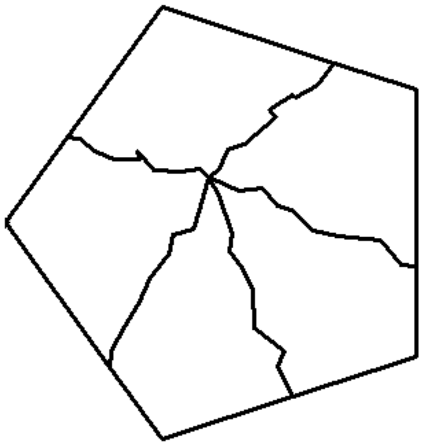

Figure 3. Assembled fragments

4 Extending towards a 3D case

The framework is easily and directly extendible to a 3D scenario. The input model now contains information in three dimensions. Techniques and technologies available to produce the digital representation of solid objects and monuments are discussed in [2]. The kind of features we compute now would differ because of the third dimension.

4.1 Creating the dataset

A unit sphere was created and shattered into 10 pieces using the 3D computer graphics application Autodesk Maya. They were randomly translated along three axes and rotated at different angles. Each individual piece is stored separately and labeled for further processing.

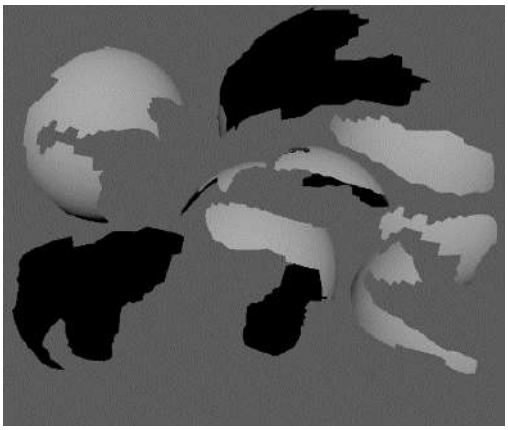

Figure 4. Input fragments

4.2 Extracting the contour

The created fragments were stored as object files (.obj) since it stores the mesh representation of the object as a set vertices with their coordinates, set of edges making up each triangle. Edges which are not common to two triangles indicate the end of the surface and are extracted to form a closed figure. Douglas Peucker algorithm is modified to be applied in three dimensions to smoothen the curve. As mentioned earlier, the threshold value decides the extent of smoothening and is necessary to maintain it constantly for all pieces. For our dataset threshold (th) was chosen as 0.005. The number of vertices constituting the contour drop drastically and hence makes the processing easier.

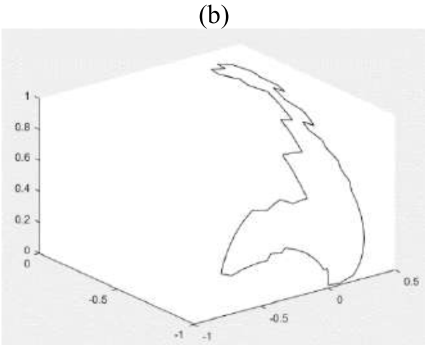
(b)



(c)

Figure 5. (a) Fragment when generated (b) Its mesh representation and borders highlighted (c) Extracted contour as the output of Douglas Peuckar algorithm with threshold th = 0.005

4.3 Feature Extraction

Features extracted for a 3D polygon at its vertices are different from that of a 2D polygon owing to its non-planar nature. Every curve representing a fragment has a set of points P_1, P_2 … P_n. Each point has the location in the form of 3D coordinates associated with it. We use the numerical approximation used in [18] and [19] for each of the feature defined for a smooth curve.

The features extracted here are:

1. Curvature: It measures the amount of deviation of a curve from a straight line. Mathematically, it can be obtained by calculating the reciprocal of its radius. The numerical approximation for curvature is

$$\alpha_i = 4 \cdot area_i / (a_i \cdot b_i \cdot c_i) \qquad (2)$$

where

$area_i = \sqrt{(s_i \cdot (s_i - a_i) \cdot (s_i - b_i) \cdot (s_i - c_i))}$

a_i = Distance between P_i and P_{i-1}

b_i = Distance between P_i and P_{i+1}

c_i = Distance between P_{i-1} and P_{i+1}

$s_i = 0.5 \cdot (a_i + b_i + c_i)$

2. Derivative of Curvature: This measures the rate of change of curvature with respect to arc length. This can be numerically approximated by

$$\beta_i = \frac{3 \cdot (\alpha_{i+1} - \alpha_{i-1})}{2 \cdot a_i + 2 \cdot b_i + d_i + e_i} \qquad (3)$$

where

d_i = Distance between P_{i-2} and P_{i-1}

e_i = Distance between P_{i+2} and P_{i+1}

3. Torsion: This is an indicator of the curve's non-planarity by measuring the speed at which the osculating plane rotates along the curve. A numerical approximation is given by

$$\gamma_i = 0.5 \cdot (\gamma'_i + \gamma''_i) \qquad (4)$$

where

$\gamma'_i = (6 \cdot H'_i) / (\alpha_i \cdot e_i \cdot f_i \cdot g_i)$

f_i = Distance between P_{i+2} and P_i

g_i = Distance between P_{i+2} and P_{i-1}

$H'_i = 3 \cdot V'_i / area_i$

$$V'_i = \frac{\det(P_{i+2} - P_{i-1}, P_{i+2} - P_i, P_{i+2} - P_{i+1})}{6}$$

$\gamma''_i = ((6 \cdot H''_i)) / ((\alpha_i \cdot d_i \cdot h_i \cdot j_i))$

$\gamma''_i = (6 \cdot H''_i) / (\alpha_i \cdot d_i \cdot h_i \cdot j_i)$

h_i = Distance between P_{i-2} and P_i

j_i = Distance between P_{i-2} and P_{i+1}

$H''_i = 3 \cdot V'' / area_i$

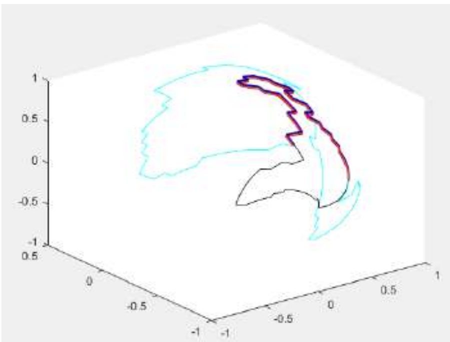
$$V''_i = \frac{\det(P_{i-2} - P_{i+1}, P_{i-2} - P_i, P_{i-2} - P_{i-1})}{6}$$

Here we take the average of γ' and γ'' to avoid introducing asymmetry in our calculations. As [16] states, only the above three metrics are enough to parameterize a Euclidean signature since they are the fundamental signature invariants. Feature extraction is done both clockwise and anticlockwise.

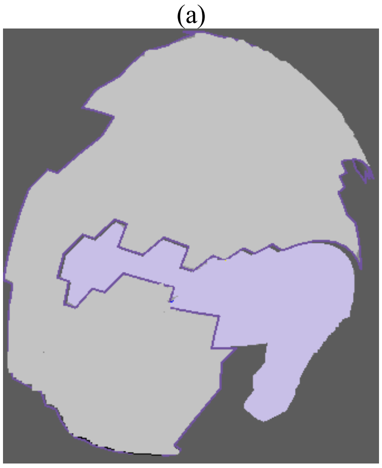
4.4 Pairwise Matching

We use the modified form of Smith Waterman algorithm like in the previous case except for the features matched. Two points A (α1,β1,γ1) and B (α2,β2,γ2) of two different fragments score a similarity score of 1 if the distance between them in the feature space is less than the threshold. For matching fragments i and j, features extracted clockwise for fragment i and counterclockwise for fragment j or vice versa is given as input to the algorithm.

A connectivity score as defined in (1) is evaluated for each pair and values below μ=0.1 are discarded. Once a good match (> 0.1) is found, the appropriate 3D transformation of one of the piece is estimated and made to merge with the second fragment and displayed (as shown in Figure 6) for the user to approve the connection. Once approved, the connectivity score and the start and end vertices of the matching part is stored separately.



(a)



(b)

Figure 6. Pairwise matching of fragment 2 and 8. (a) shows Fragment 2 (cyan) and Fragment 8 (black) with the matching portions of the fragments in blue colour and red colour respectively. (b) shows the three-dimensional merged fragments after translation

Table 1. Matrix showing the connectivity values of fragments (a) as estimated by the algorithm and (b) as calculated while creating the fragments. The rows and columns indicate fragment number. (c) shows the percentage error in connectivity value for each pair.

Observed Connectivity values for pairs of fragments									
	1	2	3	4	5	6	7	8	9
1									
2	0.127								
3	0.129	0.138							
4	0	0.163	0						
5	0	0.25	0.209	0					
6	0.313	0	0	0	0.306				
7	0.142	0	0	0.26	0	0.336			
8	0	0.556	0.298	0	0	0	0		
9	0	0	0	0.472	0.253	0	0	0	

(a)

Actual Connectivity values for pairs of fragments								
1	2	3	4	5	6	7	8	9
0.161								
0.288	0.1865							
0	0.2498	0						
0	0.2917	0.2502	0					
0.369	0	0	0	0.377				
0.26	0	0	0.311	0	0.3995			
0	0.6161	0.3435	0	0	0	0		
0	0	0	0.524	0.318	0	0	0	

(b)

Percentage Error in connectivity values for pairs of fragmnets									
	1	2	3	4	5	6	7	8	9
1									
2	20.97								
3	55.13	26.01							
4	0	34.75	0						
5	0	14.3	16.47	0					
6	15.13	0	0	0	18.88				
7	45.41	0	0	16.37	0	15.89			
8	0	9.755	13.25	0	0	0	0		
9	0	0	0	9.992	20.44	0	0	0	

(c)

The maximum error in the connectivity value was 55% (for fragment 3 with fragment 1) and the minimum was 0% (for multiple fragments as shown in Table 1c). This maximum value occurs when nearly half the original connection was undetected by the algorithm. The minimum value indicates a perfect fit.

4.5 Global reassembly

For each pair of fragments, the connectivity value calculated and approved by the user is recorded in the form of a matrix as shown below. The values less than 0.1 are reported as 0 as shown in Figure 7. The connectivity values obtained for our dataset as shown in the figure indicate that each fragment has found a strong connection with atleast one other fragment implying if no overlaps detected, just one iteration is enough to assemble back all the nine fragments.

Starting with the pair having the highest connectivity value, each pair is transformed and merged. At any point throughout the global reassembly process, the user can intervene and undo a merge if any sort of wrong overlaps is visually detected.

A major advantage is that the connectivity value need not be calculated over and over again. Since there were no overlaps, in one iteration all of the pieces were assembled back to form the assembled object as shown in Figure 7.

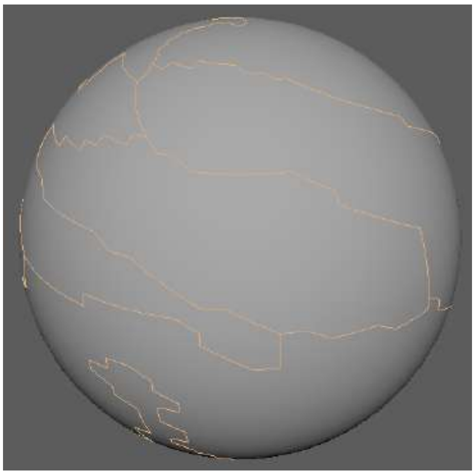


Figure 7 Assembled fragments

5. Results

From table 1c and Figure 7, it can be seen that despite having error values for pairwise connectivity, the sphere was assembled correctly because the location of matches detected were correct though only partially matched. The reasons for a partial match of the common curve could be because of the quality of the image processed and stored as vertices, choice of threshold given as input to Douglas Peucker algorithm or the sampling rate of points along the boundaries of the object.

6. Conclusion and Future work

A framework for re-assembling 3D surface object as an extension of the 2D reassembly framework was proposed and verified using simulated datasets. The merits of this framework are manifold. It is an unsupervised reassembly where the reassembled structure is not known prior to the process. The global reassembly does not compute the connectivity values after each pairwise merging reducing computational requirement. Additionally, while the user involvement was minimal, this involvement along with the cluster-based merging process prevented error accumulation. For the given dataset, the reassembly was completed in the first iteration. This way, an efficient tool for the archaeologist to speed up the reassembly is put forward.

In future work, the proposed framework will be tested on a real datasets where the fragments are not predefined by the user. This methodology can be used in addition to features extracted from fracture surfaces for validation while reassembling a solid object.

Abstract

The goal of this study was to identify any potential benefits drone technology offers in the surveying industry as compared to traditional methods. Drone technology has advanced rapidly over the past decade, offering greater capabilities every year. These technological advances were the inspiration for this research, with an ultimate desire to identify current survey process improvements. The research was carried out in an interview format with professionals from companies offering services within this industry. It was found that replacing traditional surveying methods with drone technology results in overall cost savings for the company and increased efficiency by their field crews. These findings provide significant data for companies with surveying service offerings as operating expense reduction and efficiency increases are realized following the implementation of this new technology.

Keywords –

Drone; Unmanned Aerial Vehicle; UAV; Surveying; Construction

1. Introduction

Arguably, one of the most important factors determining the result of a construction project is site and building surveying. The surveying & mapping industry had a value of $6.672 billion in revenue in 2016. This market peaked in 2007 at $8.173 billion and fell hard following the financial crisis. With the construction industry on an upward trend again, the surveying and mapping industry has followed suit [6].

Profitability, accuracy and efficiency are critical aspects to the overall quality of the construction project, requiring that the project be complete per the construction documents and that the initial land surveys were exact. This is regularly done and tracked with surveying equipment to ensure project components are in agreement with where the project is proposed to end up. Traditional surveying not only requires that expensive instruments be used and maintained, it can also be a relatively slow process.

Current human surveying crews are required to perform numerous equipment set-ups in order to achieve total visibility of a site. Often, many obstructions come into play on active construction sites, which in turn require even more station arrangements for the crews. For each station set-up the crew is required to do, productivity drops and costs quickly escalate due to this lost time. If a crew is not physically surveying or mapping, that time spent setting up or reviewing data can be viewed as lost time. Each new set-up requires the equipment to be moved, re-leveled, and back-sights must be shot.

Enter the use of drones; what was initially a military tool, advancing to a toy for people to enjoy has now become a critical tool for the construction project process. Drones were introduced to the construction industry as a means to photograph projects through construction and at completion. They provided project teams an opportunity to access a "bird's eye" view of their construction site at a rather minimal cost. Through the advancement of technology, however, developers have found a way to utilize drones to analyze what they are seeing and provide a report to the team. The many new uses will continue to grow as drones become more common and the governing rules ideally continue to adapt and loosen.

The new, highly advanced drones available on the market today offer technology that can take the place of former surveying crews and be operated by a single individual. Partnered with a tablet and application, the drone can provide real-time surveys of the geography or structures being assessed. Not only this, operators can also program a route for the drone to take, ultimately mapping the survey process before it even begins [7].

This research investigated if drones provide both a cost and time savings for companies in comparison to traditional surveying crews. New technology theoretically should lead to increased productivity, efficiency and reduced costs to surveying companies. Potential roadblocks were also researched to determine what might currently be decisive factors pushing surveying companies away from the new technology. Some publications have been accessed to provide further sustenance to this research.

Additionally, the biggest cost savings we suspect/anticipate was in the form of reduced labor hours. Surveying companies should be able to cover more sites, meaning increased productivity. This might allow them to reduce their number of crews since they can now cover more ground with fewer people, ultimately reducing their expenses on equipment. In addition, drones typically only require a single operator, while survey crews typically are comprised of two people, although a surveyor could work alone if needed.

2. Literature Review

The construction industry has unfortunately gotten a reputation of being sluggish, plagued with inefficiencies and ultimately resistant to change – mostly because those that make up the industry are technology adverse and believe that doing things the way that they've always done them is perfectly sufficient. This is not a new trend but one that has seen decades come and go. Technology, however, has refused to accept this fact and has made data collection, organization and sharing impossibly easy; so easy that it would be self-destruction for a modern firm to not take advantage of profit margin protecting efforts that are now available.

Because our research has highlighted the many uses, advancements in time savings to the planned schedule, improved material, safety and job-site monitoring and continual ingenuity and innovation for the use of Unmanned Aerial Vehicle (UAV) technology, we have found it imperative to research and discuss some of the many ways industry has decided to implement UAV use and improve their business.

There were many examples of the bird's-eye visual and with "Job Site Monitoring: There is huge potential here. As it stands, flying a UAV over people is not allowed without a permit, but the Federal Aviation Administration (FAA) works with applicants who are willing to prove their processes are safe (and who have proper liability insurance)" [2]. This may be one of the largest issues currently facing drone implementation in surveying. The FAA has some restrictions governing who can use drones, for which purposes, when they can be used and why the use is necessary for their business. If companies are required to go through too intensive of a permitting process for each site they intend to survey, it is safe to assume many companies will remain with traditional technologies and processes already discovered and controlled. Additionally, there are other risks and costs associated with making sure that the proper liability insurance is maintained and covers all of the evolving hazards and threats that continue to develop on the surveyed site/location.

While traditional methods may be slightly more time consuming in the field and require data compilation following the survey, this might still be a better option than using drones if flight restrictions remain at the current level. It would take additional full-time staff to continually work through the permitting process for each site requiring clearance. It will be interesting to see where time takes this particular issue and if organizations will deem it valuable to invest this level of attention from their firm and the potential profit realized for the given project.

"According to a March 2016 report from Goldman Sachs, construction will be the largest use case for commercial drones in the immediate future, generating \$11.2 billion of the projected \$100 billion in global spending over the next five years" [3]. This is an exciting fact for our research. Over 10% of commercial drone spending in the next five years will be focused directly on construction. This indicates a growing demand for the services and shows a bright outlook for the technology.

Companies clearly see an advantage to using the new technology; it can only be expected to get better as technology advances continue to surface. UAV training entities and software leaders continue to evolve and present products to an industry that has resisted this type of change for so long. We believe that the numerous software products used by various stakeholders to realize simple collaboration within a project will become an issue of focus that competing software organizations will seek to find appropriate (streamlined) solutions for and that eventually an answer will inevitably emerge. We also believe that consistent FAA standards and subsequent workforce training will eventually saturate the industry to further stabilize the technology and encourage complete business adoption.

"Drone technology is moving extremely fast. It's very possible many surveyors would rather hire a service provider to collect data than invest in a tool that can be obsolete in as little as six months. They may also consider short-term leases to ensure their technology is relatively current or just rent a drone when needed" [5]. The continuous advancements in drone technologies and their uses deter many companies from potentially purchasing new drones as they would rather have subcontractors or other firms collect the data or simply wait until the drone market steadies more. There are fears that drones are merely a phase in surveying technology evolutions and some companies may not feel comfortable investing such large capital resources in technology that could possibly soon be out of date and not produce the anticipated or desired return on investment (ROI).

"They are finding a much higher return on investment due to more accurate data being accumulated by fewer people in less time with quicker results. Not working with a modern surveyor employing the best techniques is far too expensive a proposition for many companies, and they are finding the change worthwhile" [4]. Drones help in collecting accurate data relatively inexpensively. There seems to be an upward trend in organizations attempting to use drone technology because companies that have switched to the technology are able to provide accurate data that is collected by fewer people and in noticeably less time.

"The number of surveyors is actually projected to decline by two percent from 2014 to 2024 because of improved surveying technology" [5]. Thanks to advances in surveying technology, the physical number of surveyors is projected to decrease by two percent. According to the US Department of Labor, there were 44,300 surveyors in the United States in 2015. With these projections, as the industry continues to grow, the number of employees will actually drop by nearly 9,000 positions. While this is an unfortunate outlook for the job market, this projection provides a bright outlook to the industry regarding advances in technology drones can bring to the surveying industry.

3. Research Methodology

Our research included a combination of scholarly and trusted online article sources and one-on-one interviews conducted directly by our group. In most cases, we were able to speak directly with the manager of the department that operates the drones or with the individual who utilizes the drone in their daily tasks. In other instances, we emailed these same stakeholders; the same ten (10) questions were used in both scenarios. We've attempted to resolve with our research these two fundamental questions:

1. Have drones provided surveying companies with cost savings over their traditional surveying efforts?
2. Has the use of drones in surveying provided increased efficiency and productivity for their organizations?

3.1. Expert Interviews

In order to provide high quality responses to the aforementioned research questions, the group undertook a research method geared towards interviews. Approximately twenty-five (25) organizations were initially identified to interview. These companies were believed to have utilized human work crews at some time to capture surveying data and information and have since switched over to some degree to the use of drone technology. Of the twenty-five (25) companies chosen, we received feedback from seven (7) of those groups. The eighteen (18) that did not participate had varying reasons for not providing feedback. The large majority felt some of the information being requested was proprietary and preferred not to answer. The others either did not respond promptly within our research timeframe or they did not respond at all. Upon contacting the companies, the team conducted an interview with the following questions:

1. When did your company begin to incorporate drones in surveying procedures?
2. What kind of drones are you using?
3. What is the average upfront cost of the new technology per drone the physical drone and any necessary software?
4. Have you noticed a cost savings after switching to drones?
5. What was the deciding factor to switch to this surveying technology?
6. Have you noticed an increase or decrease in productivity with the new technology?
7. Approximate percentage of increase/decrease?
8. Do you have any reservations in using drones versus traditional human survey crews? Are you concerned about data quality?
9. Are there any legal or logistic hurdles that need to be overcome?
10. Are there any additional services your company has begun offering with the addition of this new technology?

The questions were not strictly seeking numerical responses, which makes visual comparison difficult through diagrams and charts. Often, the interviews were largely conversation based with in-depth dialogue regarding each question to better understand the industry. While we made efforts at extracting hard numbers from the responses, the majority of our data is dialogue from those conversations. With the responses from these interview questions, we have reviewed the data to identify trends. These trends will be used to answer the research questions, and will ultimately lead the team to providing a final decision on the thesis. In addition, the team will look into potential risks associated with drones, the evolving legal and regulatory compliance linked with their use, and the conceivable advancements this technology is sure to bring.

3.2. Research from One-on-One Interviews

Within our research we found that the organizations that we received responses from all in fact used a traditional (human/manned crew) form of surveying prior to their implementation of UAV equipment. There was one relatively early adapter who began their use in 2011. However, the other six respondents stated that they began to use drones in 2015 or 2016, four companies and two companies respectively. Likewise, most organizations made a significant upfront financial investment for the drone itself and the associated software packages; in some cases, this also included any initial training as well.

The average cost per drone varied greatly from company to company, however, it appears that companies typically spend between $40,000-$60,000 per drone including any software. Those drones that are being purchased and used also proved to be anything but standard; we found that the following drones are being used: the DJI Phantom 4 Pro, Trimble UX5, Skycatch, Firefly VTOL, Matrice 100/600 series, 3DR Solo, Sensefly eBee, Inspire 1v2, Pulse Aerospace Vapor 55, Albris and even some custom-made drones. The lack of "industry standard" when it comes to drones made comparing apples to apples difficult in regards to the cost of the upgrade. The number of drones needed, the capabilities of those drones, and the financial resources available among other factors seemed to cause a wide variation in the upfront capital expenditures by the companies interviewed. A larger sample size with more refined financial questions would further narrow in on costs associated with this technology upgrade. Nonetheless, valuable data was gathered from the seven respondents, which effectively illustrates that there is no standard practice currently in place within the surveying industry.

The amounts spent on these technologies, we have discovered, also depends on the type of surveying products that will ultimately be produced. In our research efforts, we found a nice sampling of organizations that produce small to large scale surveying projects. The

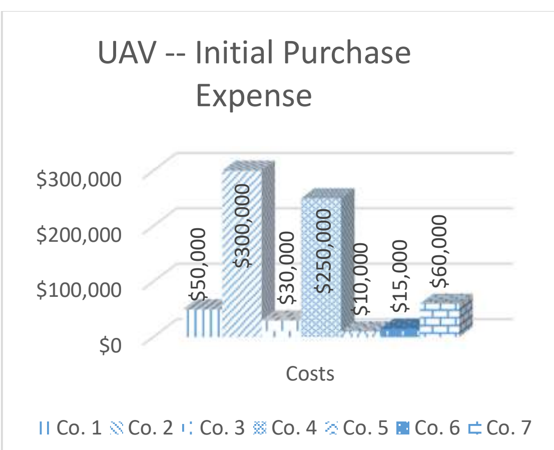

Figure 1. Graph depicting the initial costs associated with acquiring the equipment to begin surveying using drone technology.

higher the initial upfront costs, the larger the scale of surveys performed and vice versa. For instance, "Co. 2" spent approximately $300,000 for their UAV equipment and classifies their expenditure along military-grade alignment. "Co. 2" uses their drones to cover several miles, similarly to manned helicopters that were previously used for surveying projects that cover hundreds of acres. Other organizations have varying levels in scale of this and their initial expense also reflect the measure of surveying projects that they perform. Some organizations perform more of the marketing, or monitoring, type of project and the UAV's that are able to fly and hover lower to the ground are more useful for their requirements. Still others have been used to perform the more traditional construction surveying projects of parking lots, pre-construction and construction monitoring and 3D & 4D imaging – and these constitute the more average, mid-range expenditure.

One of the desired research outcomes was to determine if drones provided companies a savings in time and money. According to the interviews conducted, every company said the use of drones has reduced costs on many, if not all projects. In addition, many companies saw an increase in productivity at least by 50% through the implementation of drones; mostly these increases in productivity are exampled by their ability to take on more work with the same human workforce. One interviewee stated this productivity increase is thanks in large part to improved workflows and overall efficiency with the surveying being done from above, rather than on the ground.

Most of the companies interviewed stated that one of the primary deciding factors to incorporate drones in their company's operations was due to the anticipated cost savings. It appears that each company had done rather extensive research prior to taking this step forward in technology. Other recurring factors that pushed companies toward the technological upgrade included increased efficiency, enhanced safety for those manned work groups on the ground, improved precision and detail, while still others knew that the industry was progressing to this technology and was dedicated to take advantage of the advancements it offered.

The other desired research outcome previously identified by our group, was to ascertain potential legal or logistical issues that are present with drones that were not previously considered. The largest legal matter mentioned by companies was flying restrictions. It takes logistical planning with the Federal Aviation Administration (FAA) for airspace planning prior to the act of surveying. Although the FAA regulates airspace usage and logistics, one company interviewed by the group felt that those regulations were not enough for this new niche within the surveying industry. The person interviewed identified that there is "a growing concern that unskilled people are using the technology without grasping the complete knowledge of what needs to be done to produce quality work. As this happens, it will push back the industry and build a rift with the public against the new technology. There should be regulations and a licensing board [established]." It appears, according to these comments, that drones with surveying capabilities are too accessible to the general public that could allow anyone to buy one, advertise as a "surveyor" and perform poor quality work. This would be significantly detrimental to the industry, driving a wedge between the new technology and potential clients.

Drones do have identified risks associated with their use and organizations have decided to use the art of collaboration to minimize their exposure. Some of the alliances include partnering with entities that have specific drone insurance to help absorb some of the risks or with firms that employ individuals with aviation knowledge and experience (licensed pilots). In other examples, collaborators may also use UAV equipment that is different from what the original organization may own, which ultimately improves their capacity and the product deliverable and quality; while the other gains access to additional markets.

At this time, companies did not appear to have any reservations in utilizing UAV/drone technology. Some of these entities expressed skepticism that sat in the back of their minds surrounding the new technology, however each company seemed to have their own set of checks to ensure accuracy was of the highest quality and improved the overall industry, trade and public perception.

The final finding from the interviews showed that there are two companies that have not added additional services to their product offerings after supplementing their fleet of equipment with drone technology. While still the majority of companies interviewed have taken on different types of projects from their original surveying work. Some of the new contributions included buried pipeline mapping using thermal sensors, before & after work pile photography and wildlife conservation type projects. Others have found that inspection photos and thermal imaging are great ancillary products to be offered in tandem with their main services; however, they have focused on offering their services to new industries that have not used Light Detection and Radar (LiDAR) technology before. Most have found that having the technology is actually more of an expansion of their market instead of the actual services that they are able to offer.

And still others have decided that the drone itself is considered a "new" service offering from their original organizational structure. They have been able to offer services to "site prep" companies, which basically are tasked with moving large amounts of dirt from the site. One company is now able to monitor the dirt being removed and mark it or data point it over the period of time, as well as offer a visual image of the site. It is noted that companies tend to like the visual and bird's eye view and this fact offers a marketing tool opportunity or communicable image of what a company actually performs.

Finally, those entities that have offered an altered service mix note that they are better able to understand a number of technologies due to the drone. It's possible, not as a direct result, drone technology has inspired all within the company to be more creative and dynamic. This is because of the seemingly ever-expanding nature of the drone concept. These companies are currently pursuing sales in the Thermal, Multi and Hyperspectral, LiDAR and Normalized Difference Vegetation Index (NDVI) markets using drones.

For those who did not alter their product mix, this came as a bit of a surprise to the group as we anticipated seeing some service expansion or minimally some alteration. It does appear, however, that the addition of drones has provided both cost and time savings to all of the companies that are providing surveying services and throughout the interviews, these organizations expressed being pleased with their expenditure and identified noticeable overall improvements.

4. Conclusions

We have discovered that the organizations that we have interviewed, as well as the subsequent research we performed, made one point abundantly clear and that is that introducing drone/UAV technology to their firm has found cost savings and improved project scheduling. As discussed throughout the paper, we have highlighted the labor/crew hours that have readily been absorbed by most firms by increased projects, improved safety and job-site related efficiencies, increased collaboration and potential new product offerings.

Our group has set forth to explain the cost savings organizations have found because of their use of drone and UAV technology versus the more traditional ways to survey sites of varying forms. We planned to explore the potential differences of productivity in surveying using drones versus traditional surveying methods. The biggest cost savings we found emphasized by the interviewed companies were in fact in the form of reduced labor hours; or, it was often times quantified by increased project/job capacity.

We also discovered that because surveying companies were able to cover more sites, they were able to illustrate specifically that productivity increased substantially and warranted the implementation of new products or overall organizational growth.

Again, these forms of increased productivity were demonstrated in some ways by the reduction of crews since these specific companies were then able to capitalize on more ground with fewer people in the crew, which ultimately reduced their expenses on equipment as well as for other manual surveying procedures and continued training. In addition, drones typically only require a single operator, while survey crews typically are comprised of two or more people, although a surveyor could work alone if needed.

Again, drone and UAV technology present their own list of challenges and business structure necessities. FAA regulations, improved insurance and safety procedures, as well as the continued expense for training in an ever-evolving technology and market/industry are all examples of the new issues to be monitored and controlled by organizations. These potentially, and arguably, are substantially less taxing on a company than the traditional way of conducting surveying projects on the construction site. We believe that our research has exhibited the increased efficiencies and financial savings that have been realized by those innovative companies that invest in the drone technologies.

Abstract –

Building Information Modelling (BIM) has been implemented by architecture, engineering and construction (AEC) firms since it effectively manages and integrates information throughout the building life cycle bringing long term benefits compared to existing practices. BIM models serve as communication between design and construction phases. These models are used to determine geometry details, resolve constructability problems, track the types of materials, represent functional characteristics, and produce workflows among others. However, the benefits of BIM have not been fully extended to the operations and maintenance phase. Once the building is finished, the owner still needs the handover of paper documents to complete the information required to support the facility management phase. Therefore, to help owners extend information support throughout the building life cycle, this study proposes a process model to collect information required for facility management and incorporate it into BIM. A Construction Operations Building Information Exchange (COBie) approach is used to capture essential information to support facility management as it is created in design and construction. By capturing all the information, owners may be able to directly import data into maintenance management systems to support facility operations. Future directions are also discussed.

Keywords –

COBie; Facilities management; BIM; Integration

1 Introduction

Architects, contractors, consultants, and operators from many disciplines generate information in a variety of formats while designing and constructing a facility [1]. Once the facility is constructed, the information required for facility management is given to the owner for future operation, maintenance and decision-making. This information referred to as the as-built documents is compiled by the design team and is intended to show the actual location of systems and components in the building. However, the as-built documents are often poorly structured, missing, inaccessible or incomplete making it difficult for facility operators to locate necessary information and understand design objectives during their building operations tasks [1]. As-built documents should be planned to document the constructed state of a facility and reuse all the design and construction information as it is created to support facility management. To efficiently reuse all the information it is not only necessary to gather all the documents generated during design and construction, but to integrate them in a data set in order to support life-cycle operations and maintenance.

Relevant documents not incorporated in the data set and properly integrated may preclude equipment maintenance, preventive operations and other facility management goals. These goals may be achieved by considering the owner's requirements such as safe functional systems, life-cycle costs savings, extended equipment life, and reduction of unscheduled shutdowns and repairs [2]. The Computer-aided facility management (CAFM) is a widely applied approach used to support facilities management by information technology. CAFM systems track and maintain floor plans, building information, space usage, and occupancy data among others [10]. However, the value of these systems is limited since no party is assigned to update the data and information can only be distributed to facility management operators. The Computerized management maintenance system (CMMS) is a software package that upholds the information about the maintenance operations and schedules maintenance activities [3]. The CMMS improves uptime, establishes preventive maintenance, organizes work orders, help management make informed decisions, and allows data to be also useful when dealing with third parties. However, there is still some information essential for facility management that needs to be transcribed to be used for facility management since CMMS does not support related document linking. As a result, if a building wants to implement an effective management operations plan, the gathering and integration of data as it is created during design and construction is required.

The integration of information has been addressed by the integrated document management approach such as the Electronic Document Management Systems (EDMS) which is a very efficient approach to manage large numbers of documents in a systematic way [1, 4]. It has also been addressed by the model based approach defining data models such as Building Construction Core Model, Industry Foundation Classes and CADD/GIS data standards [1]. This approach is to produce documents automatically through query of an integrated representation and to communicate and exchange information across AEC disciplines.

There have been some practical changes and trials using BIM for better information transfer for facilities management. Recent developments have shown that after the completion of construction, many projects now require BIM-based documents for handover. For instance, efforts include FMie by buildingSMART [22], CAD technologies [13], building automation systems (BAS) [15]. Some countries have also mandated BIM-based documentation. In the UK, the government is pushing to implement BIM Level 3 by making mandatory that a data model can be accessed and modified in a single source (e.g. common data environment or open BIM) [21]. In the US, the requirement is a non-uniformed deliverable using a number of formats specified by the General Services Administration (GSA) [13].

However, the current procedure to integrate information lacks of a tool that helps decision makers organize knowledge on the various types of information generated during the building life-cycle to make reliable decisions and increase the life-cycle of the facility. An operational system design needs to be implemented if BIM is to integrate an effective design and support facilities management [12,21].Therefore, to help decision makers gather relevant information for facility management, this paper describes a process model to integrate information under a Construction Operations Building Information Exchange (COBie) approach. The process model describes the procedure to capture information and how to implement the COBie data set into a CMMS. In other words, the procedure traces information from its delivery by design and construction phases through its incorporation into the operations system and finally delivery to the owner. As the use of smart technologies is becoming more common in buildings, there is a need to transform FM data so that it can be integrated with smart devices. This needs changes both in the schema level of COBie and data translation effort so that the FM data can be exchanged through a network instead of just spreadsheets or IFC files. This paper discusses the process model to capture information and how to implement the COBie data sets and its future direction.

2 Data requirements for facility management operations

The Facility management and operations phase orderly controls activities required to keep a facility in an as-built condition while continuing to maintain its original productive capacity [3]. The objectives of this phase are to extend the useful life of assets, assure the optimum availability of equipment for production, ensure the safety of personnel using facilities, guarantee customer satisfaction, and provide healthy spaces [1, 2, 3]. In order to comply with the objectives, facility managers must reuse effectively a wide scope of information created during design and construction by different parties to support operations and maintenance [1]. The information required to support facility management produced during the design phase includes material types, floor characteristics, building functions, floor plans and systems. Later, during the construction phase information required includes equipment lists, connections between equipment, product data sheets, warranties, preventive maintenance schedules, and submittal register among others [1, 2]. Today, directives have been created to establish goals for reduction of energy and water consumption and to improve sustainability goals for both new and existing facilities [12,13]. These directives not only affect how facilities are designed and constructed but also how they will be operated and maintained [2, 10]. The operations and maintenance activities will be guided to minimize operating costs while increasing occupant's productivity, improving energy performance, water consumption, indoor environmental quality and materials use [5]. As a result, other sources of data such as whole-building cleaning issues, waste stream water management programs, recycling programs, exterior maintenance programs, and systems upgrades will also be needed to perform facility management in buildings. New sustainability requirements affecting facility maintenance and operations include can be found in the Whole Building Design Guide [2] and the leadership in energy and environmental design (LEED) rating system for existing buildings operations & maintenance (LEED-EBOM) [5]. Although the requirements and amount of information to operate and maintain a facility is increasing, facility managers lack of a tool to help them organize knowledge on the various types of information generated during the building life-cycle. The purpose of integrating information is to enable all the documents produced during the design and construction phases to be stored in a single integrated database [1, 4]. The database contains the information generated in drawings and text documents. By accessing to the database, information on any particular building component can be retrieved and exchanged since data is standardized. In addition, information can be displayed in different formats allowing different parties to still use different software [2]. Representation of all the information needed to describe buildings throughout the whole design and construction process has been an objective for applying information technology (IT) in Buildings [6]. Informative case studies for BIM implementation for FM are detailed in [10-15, 18].

3 Building information modelling and COBie overview

The BIM is a tool for digital representation of physical and functional characteristics of a facility and it serves as a shared knowledge resource for information about a facility [7]. BIM represents real world elements as 3D objects. In addition to geometry details, other information is attached to these objects such as cost estimates, manufacturers, fire rating, and schedule among others [1, 4, 7]. Additionally, they have been used to solve constructability problems, conduct interference analysis and perform scheduling during the preconstruction phase [7]. These 3D models serve as a tool for communication between planning and design phases. However, BIM is rarely used during the post construction phase to address facility management issues [1, 7]. A substantial amount of information is still collected and transferred to the owner in boxes. Therefore, an approach to data collection that is incorporated into a BIM model is required.

Data collection can be completed using a COBie approach. The COBie is an approach to enter data just as it is created during design, construction and commissioning (Cx) phases. In other words, the information required by COBie is not different from the information already supplied in the design and construction contracts by all the parties. Since different parties use different software, they need to interact with COBie, as this information can be displayed in various formats [2]. All the formats provide an interoperable view of the underlying information specified by COBie and COBie can be customized to support specific requirements of an owner or a facility. Therefore, COBie allows having a one data set with different views enhancing the value of connection information and creating meaning since exchange is possible [2]. COBie's exchange specification is intended to transform existing deliverables into deliverables that contain the same information but in a new reusable format. COBie data includes spaces and zones of the facility, equipment and its location, submittals, instructions, tests, certificates, maintenance and safety protocols, start-up and shut-down procedure and resource data for the related activities [12]. Additionally, COBie data eliminates the reproduction cost for paper files, uses current software to deliver electronic handover information, ensures collaboration and integration of all project partners and improves the roll of construction submittals in construction handover [2, 7, 11].

4 Documentation process

The COBie approach begins early in the design phase and goes through the commissioning phase (see Figure 1). The starting point of COBie is when the owner determines the objectives of the facility and states the requirements. Once the specific requirements are determined, the design phase starts. In the early design, the facility naming and the vertical and horizontal spaces that are needed are defined. Additionally, the different types of systems to satisfy the function of each space such as ventilation, mechanical, plumbing and electrical are also defined. COBie information in the design planning stage is provided via a listing of facility, number of floors, spaces in each floor, functions of spaces, and product and equipment types for each space. After the design planning stage information is provided, the information of the coordinated design such as name of equipment, equipment systems, space zoning, space layout, and location is provided. At last, the information of the final design stage is provided which includes design document register, as-designed equipment properties, product and data schedules and the equipment connection model.

After the design phase information input is completed, the construction phase information takes place. Builders provide not only the approved submittal documents but also all the information to complete the equipment data such as component systems, manufacturer, model, serial number and tag numbers. Later in the commissioning phase, job plans, warranty and parts documents and resources are also provided. Additionally, updates space functions and area measurements and operations and maintenance documents complete the commissioning documentation. As noted in Figure 1, the information integration is cumulative. In other words, the information is transferred from the early phases of the process to the late phases to improve decision-making. Therefore, COBie database gathers the accumulated information produced in each phase. For all of the information provided to be integrated into COBie, COBie specifications have to be followed within the existing contract specification [8]. This specification requires the handover of COBie information in the spreadsheet XML format at each phase. The COBie specification is implemented within the context of the existing specifications or performance based. Performance based specifications deliver information not as a stand-alone data, but as data that can be further incorporated to measure and quantify the building's performance [8]. Quantifying the building's performance enhances architectural design since the facility is measured in terms of the owner's specific requirements [12, 17].

5 The integration approach

The decision on how to create COBie data is based according to the firm's software and in many cases other firms are contracted to create it. COBie can be created using COBie compliant software, development of transformations of existing data into a COBie compliant file and direct use of the COBie spreadsheet [8,13]. Due to the variety of parties, a combination of these methods is usually followed to create the COBie deliverables. If the first method is used, the use of the software must be combined with manual configuration of the BIM software. This process can be performed using two different approaches. The first approach consists of producing a COBie file that complies with the buildingSMART international's facility management handover model view (MVD) definition specification for industry foundation classes (IFC) building information model (BIM) files [12].

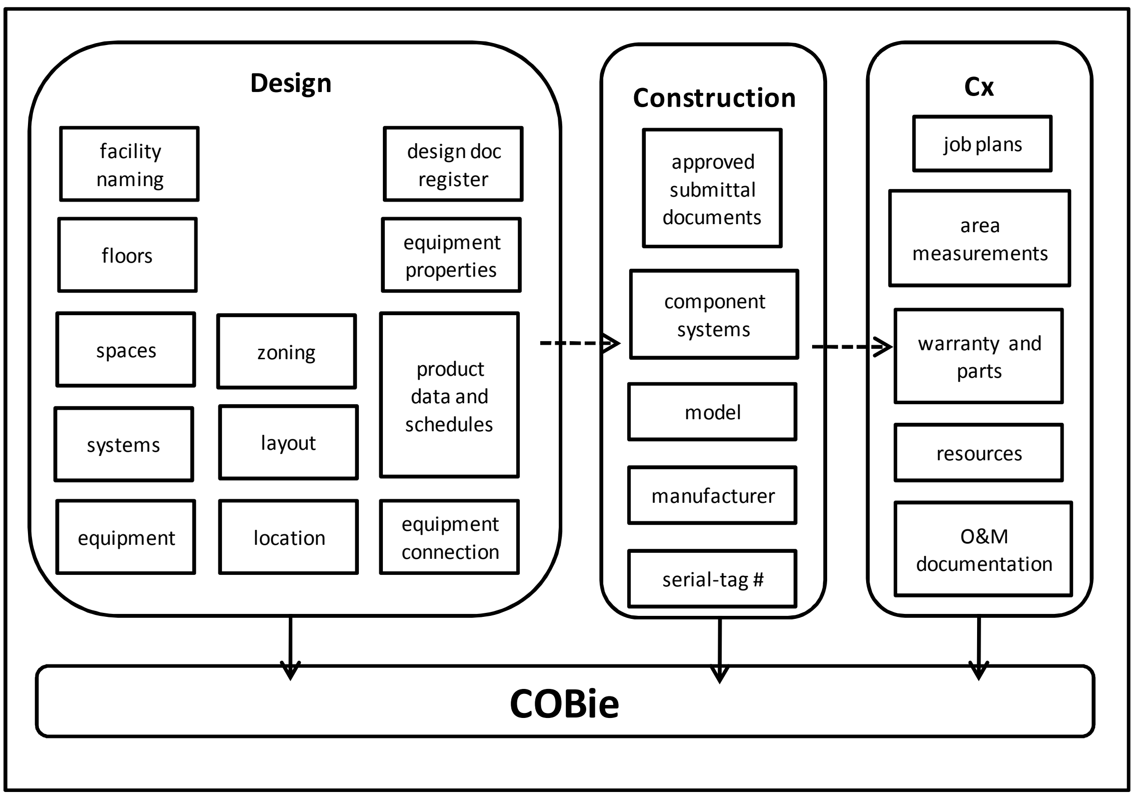

Figure 1. COBie approach. Adapted from WBDG, 2018.

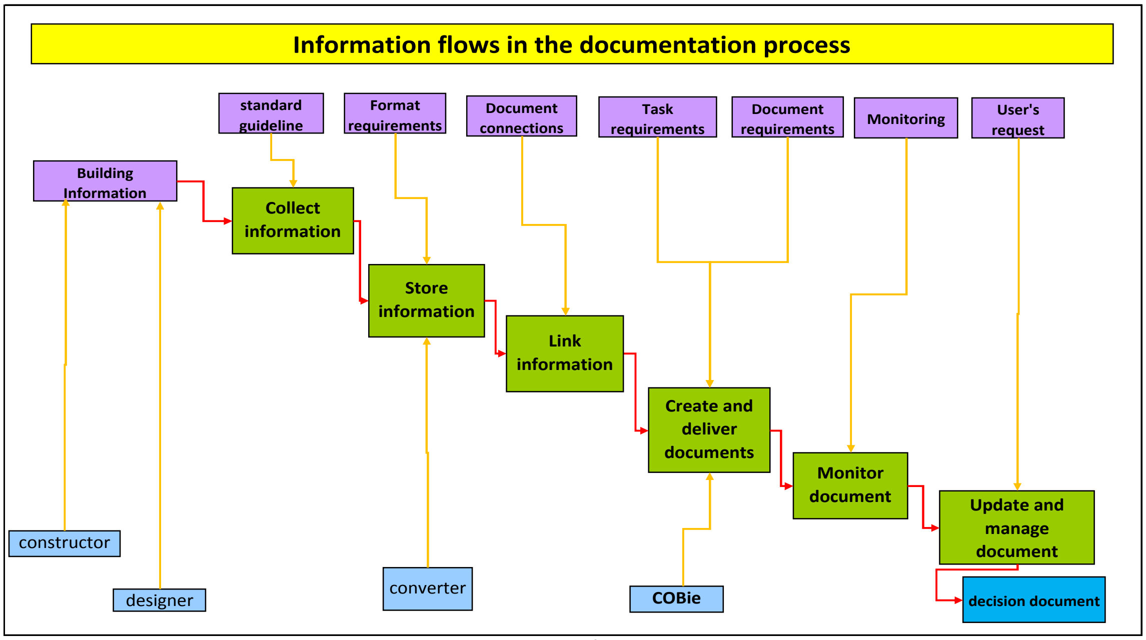

Figure 2. Adapted from Song et. al 2002

The COBie files produced have no technical difference with the MVD files, but to ensure compliance with the COBie contract language, the project parties must deliver the COBie formatted files. For that reason, a translation between the IFC files into a COBie formatted file is required [8]. The alternative approach needs the use of applications able of producing a file in the COBie spreadsheet format. The spreadsheet format of COBie is a modified version of Microsoft Excel spreadsheet which allows handling and saving of information as an Excel XML file format. As of December 2014, all software produced through the MVD will require some minimal manual adjustment to comply with COBie. Products from vendors who have completed COBie challenge can be found in the Whole Building Design Guide [2].

The second method to produce COBie files is based on capturing the information directly from the software tool in which it was created and the documents already containing the COBie information. For instance, applications containing equipment and room lists have most of the information required by COBie. For the case spreadsheets under a specific format are created, the spreadsheets' information is organized by hand or using other software. Afterwards, COBie information can be created using the exporting capabilities in the software. Finally, the third method is the input of the information in the COBie spreadsheet. By using this spreadsheet, the parties of the project can directly verify the accuracy of the information before submitting the COBie deliverable.

With all the information integrated into COBie, the COBie data is completed and can be used to support the facility management operations. Figure 2 shows the information flow in the documentation process. The building information is the initial input. This information is later collected, stored and linked (using COBie). COBie deliverables are the monitor document and this data set needs to be updated and managed to become the decision document.

The process model framework shown in Figure 3 supports the decision maker in the process of facility management planning. The framework illustrates how the process of data integration is supported by using tools and software. In the data input module information is collected, in the integration module the interoperability procedure and integration of documents into COBie occurs using an integration model of heterogeneous databases, then in the standardization module the translator is checked for compliance and finally in the operation module the standard format document is given to the owner or decision maker.

Since COBie data can be directly imported into the CMMS, no further standardization is needed and the complete facility operation and maintenance plan can be effectively controlled using the CMMS.

The integration module is the main enabler of this process model. This module uses an XML schema mapping using ifcXML (XML-based data interoperability) for querying and integration of data from heterogeneous data sources containing facility operations and maintenance information. The ifcXML is an implementation of the ISO-10303 Part 28 Edition 2 standard that provides an XML schema specification of the IFC schema through an automatic conversion from the IFC EXPRESS (ISO 10303 part 1) representation [22]. The integration framework for heterogeneous data sources has been the center of many database studies and the XML-based integration model dealing with transformation of heterogeneous data has proven to be effective in many prior studies [23, 24, 25]. The ifcXML schema provides both IFC interoperability features and XML-based data integration capabilities. Using ifcXML schema, data from diverse sources such as design, construction, and commissioning stage will be integrated and maintained in an XML-based database following IFC data model and will then be configured and mapped to COBie dataset.

6 Limits and benefits

Implementation of the process model described may be successful if parties involved in construction rethink and reorganize the building process throughout its life-cycle. Collecting and storing information in the minimum required format to then integrate it into COBie format might require new responsibilities and costs. The process of capturing information may need new personnel and training. It may also need agreement among the owner and AEC parties in the procedures to be implemented.

BIM has the potential to change the way construction is performed and documented. The transition requires a complete shift through all the phases of the building's life-cycle. BIM could become the data source of information including facilities management [16, 19]. The advantages of BIM include improvements in productivity as compared to other practices. Though, there are no reliable methods to measure the benefits of BIM and quantify the results of the new practices. Therefore, there may be some building participants who may still refuse to use BIM models and integrate information to improve the way construction is performed [17]. The process model described has demonstrated COBie data as a practical solution to the current problems of the as-built documents in order to support facility management. The benefits of using the process model include delivery of necessary and concise information, easy access to related information, enhanced collaboration between the parties, and provide reliability of information among others.

7 Discussion and conclusions

A number of studies on integration of information have been carried out, indicating the use of approaches to manage and compile facility operations and maintenance documents in a systematic way as well as models to integrate information and produce new formats. Although the integration of information has been approached by considering standards that may facilitate the input of information, the owner who is the final user of the format has not been considered. Owner's still receive information in boxes and have to gather and re-organize the information since it was usually produced by different parties using different software. In addition to the owner's need to translate information, the as-built documents are often poorly structured, missing, inaccessible or incomplete. Gathering this information is expensive and at the end is not a reliable database since it differs from the actual construction.

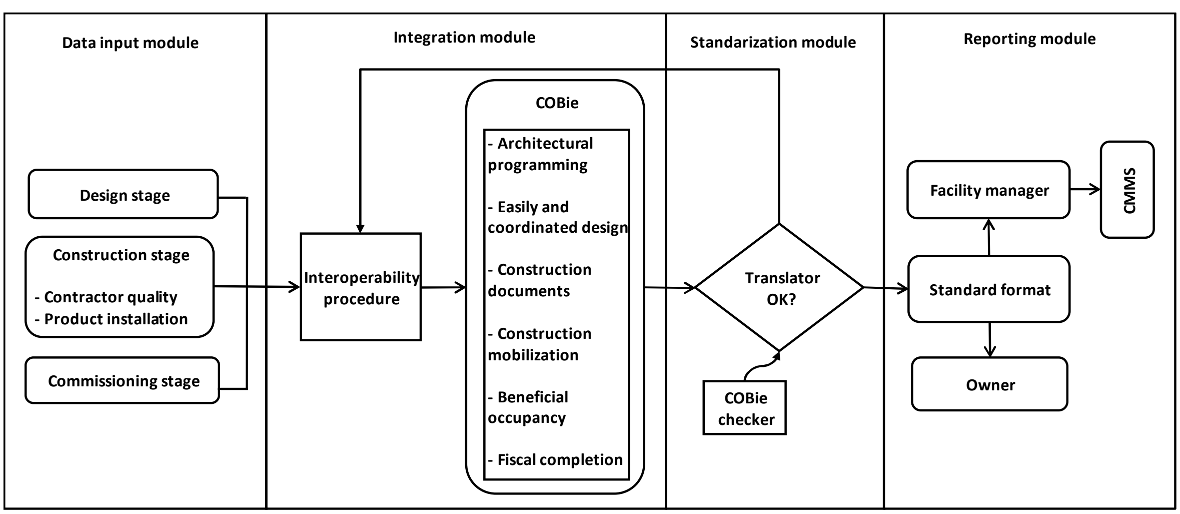

Figure 3. Process model framework

Therefore, an integration approach is needed to help owners support facility management operations with reliable data. COBie data set was developed to deliver accurate information to the owner in a format that can be used for facilities management.

The process model framework described in this study can help gather information and bring significant positive changes to the actual process of facility operations and maintenance activities. Its usefulness lies in the opportunity to include in the integration process information just as it is created in the design and construction phases. The possibility for all the different parties to include information from different software and different formats may help improve the quality of the as-built documents. As-built documents can be created and intended to reuse efficiently design and construction information to support operations and maintenance. Through COBie standards and the well-developed software products available in the market to transform documents into COBie documents, the benefits of information integration of a building can be realized. As a result, the process of facility management may be simplified and accelerated. COBie data set may broaden the capabilities of the decision-making process by allowing owners and facility managers to efficiently use reliable data without needing to gather and translate information.

The applied process model incorporates all the information of a building relevant to support facility management operations. The information is then integrated through an interoperability procedure to convert it into COBie information. Afterwards, a COBie check is run to verify the translators work properly. Once the check is concluded, the deliverables of COBie are ready to be used by owners to assist decision making in facility management operations. The implementation of the proposed process map and application case for indicating the actual uses of this process map is a future study.

As electronic environments increase, the range of document formats expands overwhelming users with information and making the retrieving information process effortful. Therefore, it is necessary to understand the information integration tools in order to help users benefit from all the information provided and successfully implement it to accomplish their tasks. The process model described in this study may contribute to benefit the integration of information for facility management operations. By investigating the products available that have applications capable of producing the format needed by the final user, information databases could become valuable tools to assist in operations in an ever-expanding range of options. As the use of smart technologies is becoming more common in buildings, there is a need to transform FM data so that it can be integrated with smart devices. This needs changes both in the schema level of COBie and data translation effort so that the FM data can be exchanged through a network instead of just spreadsheets or IFC files [9, 17, 20]. The understanding of demand and needs within building construction enhance consumer satisfaction contributing on how to make practices remain viable and useful for the construction sector.

Abstract -

Rock-wise objects made after natural disasters must be removed by construction machines which are maneuvered by human beings. In that case, from the viewpoint of preventing a secondary disaster, the construction machines are preferable to carry out the task autonomously or by remote operation. We take aim at autonomous tumbling operation by a mobile robot with dual arms to move a rock-wise object. In previous study, a path planning algorithm for an object in tumbling operations had been presented. The order of the selected ridge line determines the path of the object. Next, trajectory planning of forces and arm tips of the robot is necessary for autonomous motion. In this paper, we present a method for determining the combination of action points by analyzing the tumbling operation. First, we derive relational expressions of force for the rotational motion of the object. Conditional expressions are set for making stable operation. Then, the problem is solved as a nonlinear optimization problem by evaluation function of force. The constructed algorithm derives optimal trajectory planning of forces and arm tips. Finally, the usefulness of the algorithm is shown by a numerical example.

1 Introduction

After the wide-scale landslides are caused by a natural disaster such as an earthquake or a concentrated downpour, rock-wise objects generated by the disaster must be removed by construction machines which are maneuvered by human beings. In that case, from the viewpoint of preventing a secondary disaster, the construction machines are preferable to carry out the task autonomously or by remote operation. In this paper, we describe automation of removal work. Grasping and lifting-up motion are a common handling to remove objects, and easy to move the object. However, if the object is too large or heavy for the machine to grasp and carry, removal work by this operation is difficult. On the other hand, graspless manipulation such as pushing, tumbling, and pivoting are effective methods to handle the object in the case mentioned above [1]. Since these operations are performed while the object is in contact with the environment, they are not necessary to support all the weight of the object, and their energy is less than the energy of pick-and-place operation. In addition, pushing, tumbling and pivoting operations have different characteristics, so by combining these operations it is possible to flexibly manipulate the object. Therefore, many studies have been aimed at assisting the grasping operation or the pick-and-place operation for the assembly work of parts [2] [3] .

On the other hand, we take aim at autonomous tumbling operation by a mobile robot with dual arms to move rock-wise objects. In previous study, a path planning algorithm for an object in tumbling operations had been proposed [4] . The study dealt with a problem to move a rock-wise object approximated as a convex polyhedron around a desired position by tumbling operation. And a method for planning semi-optimal path represented as a selection order of the edge for a tumbling operation to minimize a predefined performance index was presented. Next, trajectory planning of forces and arm tips of the robot is necessary for autonomous motion. In this paper, we present a method for determining the combination of action points by analyzing the tumbling operation. The above method is possible to obtain the optimum trajectory planning that suppresses the excessive internal forces on the object.

In the next chapter, related studies are described. In the chapter 3, the initial setting of the problem and the coordinate system are explained. Derivation of relational expressions of force for the rotational motion of the object, and conditional expressions for making stable operation are described in the chapter 4. Determination of the combination of action points is solved as a nonlinear optimization problem by the derived equation and evaluation function of force. Also, we reduce variables to solve the problem of multivariable. For all combinations of action points, a convergence analysis is performed, and an algorithm is shown for deriving the optimal trajectory planning of forces and arm tips in the chapter 5. In the chapter 6, the usefulness of the algorithm is shown by a numerical example, and the conclusion and the future work are described in the chapter 7. However, the trajectory planning doesn't consider the characteristics of the robot except for two arms.

2 Related work

Sawazaki et al. analyzed three kinds of tumbling operations, and showed the feasibilities of them by carrying out the tumbling operation with multi-jointed robot fingers [5]. In contrast to the proposed method, which is an analysis based on a two-dimensional plane, this study extends the analysis to three dimensions in order to deal with the shape like a rock-wize object. Y. Maeda et al. proposed a method of motion planning of multiple robot fingertips for graspless manipulation including tumbling operations [6]. By considering whether each robot finger should be position-controlled or force-controlled, this method can obtain robust manipulation plans against external disturbances. Since large numbers of lattice points obtained by discretization of the configuration space are used as candidates of action points, it is theoretically possible to construct a plan for objects of any shape. However, in exchange for that, it takes a lot of calculation time. Therefor, in this paper, candidates of action point are narrowed down to cover a complicated shapes like a rock-wize object.

3 System initialization

3.1 Assumption

The assumptions in the tumbling operation are as follows.

- The operation is performed on a horizontal floor.
- The rotational motion of the object is slow and is regarded as quasi-static. Therefore, the inertia term is excluded for the motion of the object.
- The object is a convex polyhedron. Therefore, the object rotates around one ridge line on the bottom of the object.
- The friction coefficient generated at the contact portion is constant and it is possible to estimate approximate values from knowledge of the site.
- No-slip occur between the object and arm tips or a floor.
- The middle point of the ridge line is a position of action point. However, the middle point of the ridge line which is the bottom surface of the object is excluded from the action point.
- The initial state of the object is when the bottom surface and the floor surface are in contact with each other. Further, from Figure 1 the operation of rotating from the initial state to the other bottom surface and the floor surface around one ridge line is defined as "single tumbling operation".

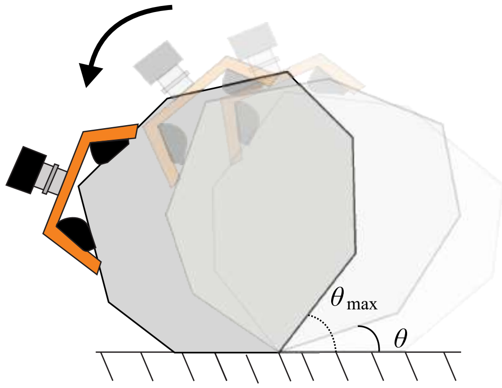

Figure 1. Single tumbling operation

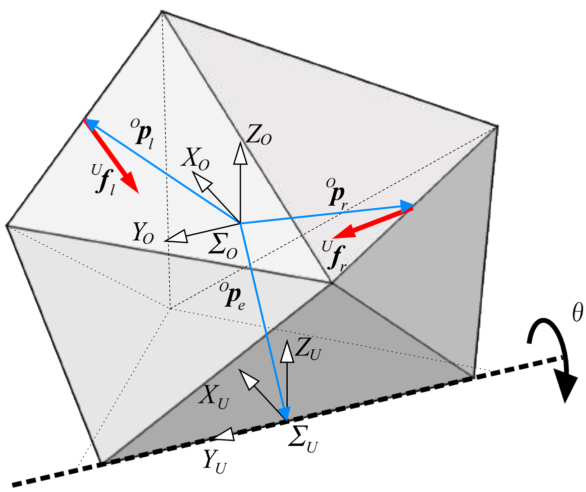

Figure 2. Coordinate system in object

3.2 Setting of the coordinate system

As shown in Figure 2, two coordinate systems, which are orthogonal and right-hand ones, are defined for calculation. The coordinate system Σ_O is fixed on the object, and its origin is located at the center of gravity of the object. The coordinate system $\Sigma_U(O_U - X_U Y_U Z_U)$ is defined with the middle point of the ridge line in the rotation axis as the origin. The Z_U axis is in the upper direction, and the X_U axis is in the advance direction of the robot. In the initial state of things, the postures of Σ_U and Σ_O are equal.

4 Problem formulation

4.1 Relational Expression of force

The external force on the object is denoted as ${}^U\boldsymbol{f}_i = \left[f_{ix}, f_{iy}, f_{iz}\right]^T$ $(i = r, l)$, where r and l indicate right and left quantities in the robot. Also, M is the mass of the object, $\boldsymbol{g} = [0, 0, g_z]^T$ is the gravitational acceleration, and $\boldsymbol{N} = \left[f_{fx}, f_{fy}, N_z\right]^T$ is the reaction force given from the floor surface. When two action points are selected and a tumbling operation is performed around the Y_U axis, relational expression of force is expressed as follows.

$$ {}^U\boldsymbol{f}_r + {}^U\boldsymbol{f}_l + M\boldsymbol{g} + \boldsymbol{N} = 0 \quad (1) $$

Further, the position of the action point is ${}^O\boldsymbol{p}_i = \left[{}^Op_{ix}, {}^Op_{iy}, {}^Op_{iz}\right]^T$ $(i = r, l)$, the position of the center of gravity is ${}^O\boldsymbol{p}_e = \left[{}^Op_{ex}, {}^Op_{ey}, {}^Op_{ez}\right]^T$, and the minute torque is $\boldsymbol{d\tau} = \left[0, d\tau_y, 0\right]^T$. Moreover, denoting the action point expressed in Σ_U as ${}^U\boldsymbol{p}_i = \left[p_{ix}, p_{iy}, p_{iz}\right]^T$ $(i = r, l)$, and the rotational matrix from Σ_O to Σ_U as ${}^U\boldsymbol{R}_O$,the equation of the torque on the tumbling operation is expressed as follows.

$$ {}^U\boldsymbol{p}_r \times {}^U\boldsymbol{f}_r + {}^U\boldsymbol{p}_l \times {}^U\boldsymbol{f}_l - {}^U\boldsymbol{R}_O{}^O\boldsymbol{p}_e \times M\boldsymbol{g} = \boldsymbol{d\tau} \quad (2) $$

$$ {}^U\boldsymbol{p}_i = {}^U\boldsymbol{R}_O({}^O\boldsymbol{p}_i - {}^O\boldsymbol{p}_e) \quad (3) $$

$$ {}^U\boldsymbol{R}_O = \begin{bmatrix} cos(\theta) & 0 & sin(\theta) \\ 0 & 1 & 0 \\ sin(\theta) & 0 & cos(\theta) \end{bmatrix} \quad (4) $$

Forces are applied from the arm tip to the object as shown on the left side of Figure 3. In this case, we assume that the resultant force of ${}^U\boldsymbol{f}_a$ and ${}^U\boldsymbol{f}_b$ is ${}^U\boldsymbol{f}_i$. Also, it is assumed that the plane and the ridge line are in contact. Therefore, the action of force around the ridge line is expressed as shown on the right side of Figure 3. The unit direction vector of bisector of the inner angle in ${}^U\boldsymbol{p}_i$ is ${}^U\boldsymbol{n}_i = \left[n_{ix}, n_{iy}, n_{iz}\right]^T$ $(i = r, l)$, and the coefficient of friction between the object and the arm is μ_{rob}. From the angle α between $\boldsymbol{f}_i$ and $\boldsymbol{n}_i$, the condition for not causing slip between the object and the arm tip is expressed by the following Equation (5).

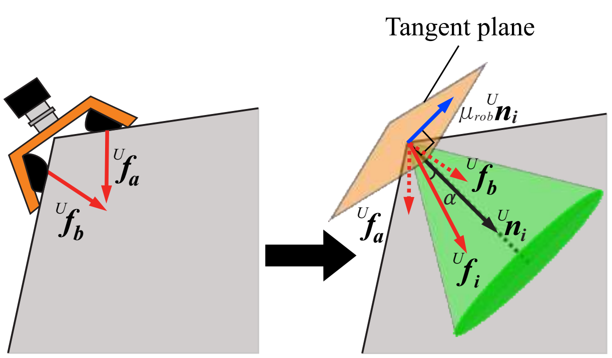

Figure 3. Relationship between force and friction cone at action point

$$ \frac{|{}^U\boldsymbol{n}_i||{}^U\boldsymbol{f}_i|}{\sqrt{1 + \mu_{rob}{}^2}} - {}^U\boldsymbol{n}_i \cdot {}^U\boldsymbol{f}_i \leq 0 \quad (5) $$

Further, the condition for not causing slip between the object and the floor surface is given by Equation (6) from the μ_{env} which is the friction coefficient between the object and the floor surface.

$$ \sqrt{f_{fx}{}^2 + f_{fy}{}^2} \leq |\mu_{env} N_z| \quad (6) $$

4.2 Formulation of problem to determine action points

In order to determine the optimal combination of action points, we define constraint equation and evaluation functions. The optimum solution in this paper means the combination of action points that can perform the tumbling operation with a force as small as possible. Therefore, the evaluation function on the magnitude of force is set as in Equation (7).

$$ f({}^U\boldsymbol{f}_r, {}^U\boldsymbol{f}_l) = |{}^U\boldsymbol{f}_r|^2 + |{}^U\boldsymbol{f}_l|^2 \quad (7) $$

By solving the nonlinear optimization problem shown in Equation (8), the problem of determining the action point is solved.

$$ \begin{array}{ll} \text{minimize} & f({}^U\boldsymbol{f}_r, {}^U\boldsymbol{f}_l) \\ \text{subject to} & h({}^U\boldsymbol{f}_r, {}^U\boldsymbol{f}_l) = 0 \\ & g({}^U\boldsymbol{f}_r, {}^U\boldsymbol{f}_l) \leq 0 \end{array} \quad (8) $$

$h({}^U\boldsymbol{f}_r, {}^U\boldsymbol{f}_l)$ and $g({}^U\boldsymbol{f}_r, {}^U\boldsymbol{f}_l)$ represent the equality constraints of Equation (1) and (2), respectively, or the inequality constraints of Equation (5) and (6).

However, it is desirable to improve computation efficiency as much as possible for multivariate analysis, so we will reduce variables. First, Equation (9) can be obtained by balancing the force in the Y_U axis direction of Equation (1) with only the external force related to the arm tips.

$$ f_{ly} = -f_{ry} \quad (9) $$

From Equation (9), one variable can be removed from the problem. Furthermore, there are five remaining variables, and there are three equations from Equation (2), so it is possible to reduce up to three variables.

For example, simultaneous equations for three variables are expressed as follows.

$$\begin{bmatrix} f_{rz} \\ f_{lx} \\ f_{lz} \end{bmatrix} = \boldsymbol{A}_0^{-1} \begin{bmatrix} -(p_{rz}-p_{lz})f_{ry} - Mp_{gy}g_z \\ -p_{rz}f_{rx} + Mp_{gx}g_z + d\tau_y \\ p_{ry}f_{rx} - (p_{rx}-p_{lx})f_{ry} \end{bmatrix} \quad (10)$$

Further, $\boldsymbol{A}_0$ is shown below.

$$\boldsymbol{A}_0 = \begin{bmatrix} p_{ry} & 0 & p_{ly} \\ -p_{rx} & p_{lz} & -p_{lx} \\ 0 & -p_{ly} & 0 \end{bmatrix}, |\det \boldsymbol{A}_0| \neq 0 \quad (11)$$

Three variables can be reduced by incorporating f_{rz}, f_{lx}, f_{lz} into the evaluation function or inequality constraint condition respectively. However, an inverse matrix of $\boldsymbol{A}_0$ is necessary for satisfying Equation (10). In a similar way, there are ten combinations when reducing three variables from five variables. Furthermore, determinants of $\boldsymbol{A}_{\mathrm{j}}(\mathrm{j} = 0, \ldots, 9)$ are as follows.

$$\begin{cases} \det \boldsymbol{A}_0 &= p_{ly}(p_{rx}p_{ly} - p_{lx}p_{ry}) \\ \det \boldsymbol{A}_1 &= p_{ry}(p_{lx}p_{ry} - p_{rx}p_{ly}) \\ \det \boldsymbol{A}_2 &= (p_{rx}-p_{lx})(p_{rx}p_{ly} - p_{lx}p_{ry}) \\ \det \boldsymbol{A}_3 &= p_{ly}(p_{ry}p_{lz} - p_{ly}p_{rz}) \\ \det \boldsymbol{A}_4 &= p_{ry}(p_{ly}p_{rz} - p_{ry}p_{lz}) \\ \det \boldsymbol{A}_5 &= (p_{rz}-p_{lz})(p_{ly}p_{rz} - p_{ry}p_{lz}) \\ \det \boldsymbol{A}_6 &= p_{ly}(p_{lx}p_{rz} - p_{rx}p_{lz}) \\ \det \boldsymbol{A}_7 &= p_{ry}(p_{rx}p_{lz} - p_{lx}p_{rz}) \\ \det \boldsymbol{A}_8 &= (p_{rx}-p_{lx})p_{ry}p_{lz} - (p_{rz}-p_{lz})p_{rx}p_{ly} \\ \det \boldsymbol{A}_9 &= (p_{rx}-p_{lx})p_{ly}p_{rz} - (p_{rz}-p_{lz})p_{lx}p_{ry} \end{cases} \quad (12)$$

However, when neither p_{ry} nor p_{ly} has a value, in other words when both Y_U components of the action point are included on the origin of Σ_U, variables can not be reduced by the method like equation (11). At that time, if we substitute $p_{ry} = 0$ and $p_{ly} = 0$ for Equation (2), f_{ry} is expressed by Equation (13).

$$f_{ry} = \begin{cases} \frac{Mp_{gy}g_z}{p_{rz}-p_{lz}} & (p_{rz}-p_{lz} \neq 0) \\ 0 & (p_{rx}-p_{lx} \neq 0) \end{cases} \quad (13)$$

In addition, in order to determine one variable, it is divided into two cases as follows.

$$f_{rx} = \frac{p_{rx}f_{rz} - p_{lz}f_{lx} + p_{lx}f_{lz} + Mp_{gx}g_z + d\tau_y}{p_{rz}} \quad (14)$$

$$|p_{rz}| \geq |p_{lz}|, p_{rz} \neq 0$$

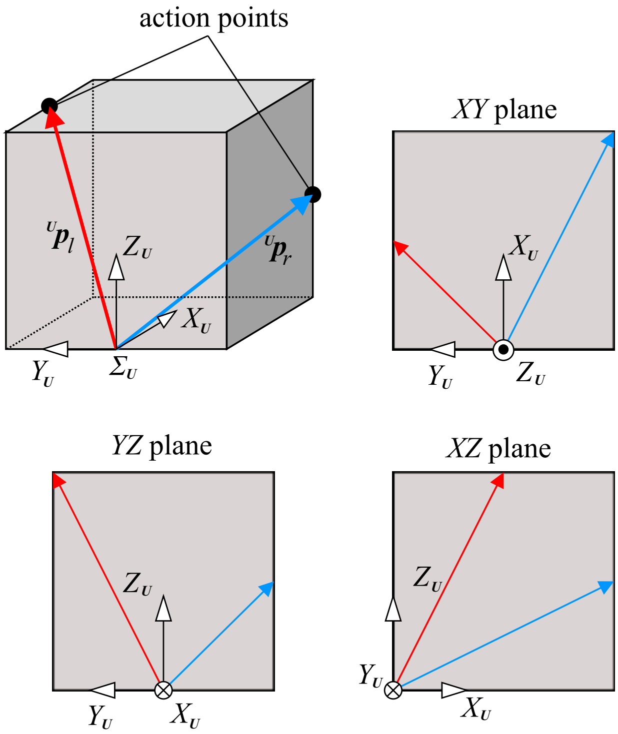

Figure 4. The positional relationship between the action point and the origin of Σ_U on each coordinate plane

$$f_{lx} = \frac{p_{rx}f_{rz} - p_{rz}f_{rx} + p_{lx}f_{lz} + Mp_{gx}g_z + d\tau_y}{p_{lz}} \quad (15)$$

$$|p_{lz}| \geq |p_{lz}|, p_{rz} \neq 0$$

Next, the case where the Y_U component of one of the at least two action points does not exist on the origin of Σ_U will be described. In this case the determinants of equation (12) are narrowed down by using the geometric characteristics of the object. As an example, suppose two action points are selected in a cubic object as shown in Figure 4. Also, in Figure 4, the positional relationship between the action point and the origin of Σ_U is shown using the projection of each coordinate plane. It can be seen that a part representing the outer product is included in part of the Equation (12). When no outer product exists, the two vectors overlap each other, or they are in a parallel relationship. Since there is a possibility of obtaining a singular point of a determinant by a combination of action points, conditional branching is necessary to reduce variables. In this case, we select the determinant taking the maximum value and reduce the variables. Furthermore, based on geometrical characteristics, the condition that no outer product exists in the coordinate plane is only when the action point of the same point is selected, so the determinant to be calculated can be narrowed down.

Therefore, reduction of variables are determined only by the determinant shown in Equation (16).

$$\begin{cases} \det \boldsymbol{A}_1 &= p_{ry}(p_{lx}p_{ry} - p_{rx}p_{ly}) \\ \det \boldsymbol{A}_3 &= p_{ly}(p_{ry}p_{lz} - p_{ly}p_{rz}) \\ \det \boldsymbol{A}_5 &= (p_{rz} - p_{lz})(p_{ly}p_{rz} - p_{ry}p_{lz}) \\ \det \boldsymbol{A}_7 &= p_{ry}(p_{rx}p_{lz} - p_{lx}p_{rz}) \end{cases} \tag{16}$$

In the Equation (16), we select the determinant that has the largest value of determinant and reduce the variable.

From the above, we solve Equation (8) after reducing variables. Furthermore, variables to be reduced depend on the position of action points. When solving based on the above method, it means that there is no feasibility of the tumbling operation unless equation (8) converges.

5 Algorithm of trajectory planning

An algorithm was constructed to determine optimal combination of action points from the problems described in the previous chapter. The flowchart is shown in Figure 5, and one ridge line which is the rotation axis of the object is set beforehand.

First, convergence calculation of Equation (8) is performed for the selected two action points. At this time, if an executable solution of the tumbling operation is not obtained, another combination of action points is selected. On the other hand, when Equation (8) is satisfied, 1[deg] is added to the rotational angle θ, and the convergence calculation of Equation (8) is performed again. When θ which is the rotation angle of the object reaches θ_{max}, this means that single tumbling operation can be executed to the end.

Then, by using the value of the evaluation function of Equation (7), the combination of the optimum action points is determined. The optimal combination is determined by comparing the sum of the evaluation functions obtained after the convergence calculation. However, the trajectory planning obtained by this algorithm does not include the operation of changing the action point in the middle of single tumbling operation.

6 Numerical example

Our planning algorithm is implemented on Windows using C language. We used IPOPT (Interior Point OPTimizer) [7] , which is a library suitable for large-scale continuous optimization problems. For the convex polyhedron shown in Figure 6, the combination of action points in single tumbling operation is determined. The object used in the experiment is a wooden polyhedron with size 0.32 × 0.29 × 0.28[m], M= 2.0[kg], g =

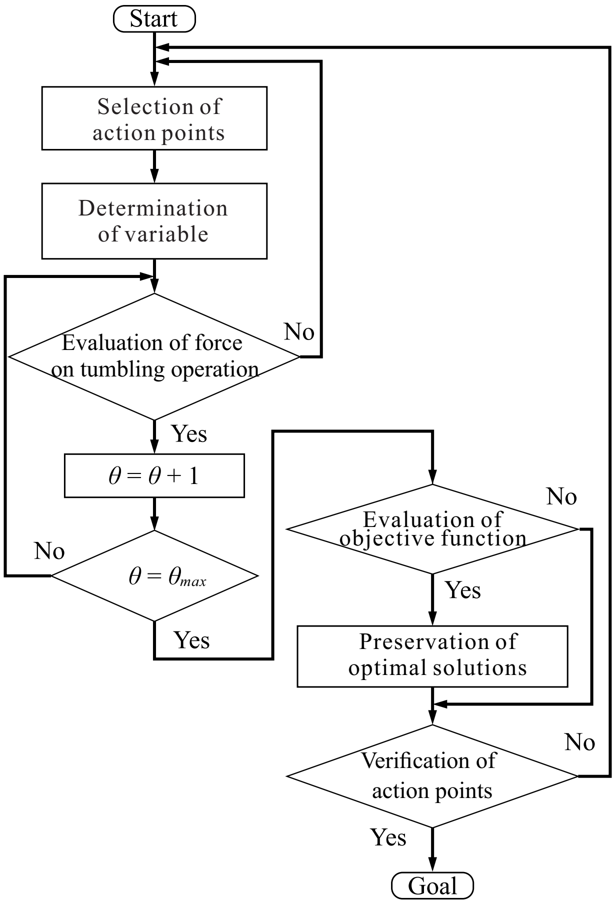

Figure 5. Flow chart for selection of action point

9.80665[m/s^2], θ_{max}=47.2[deg] and the friction coefficients are μ_{rob} = 0.5 and μ_{env} = 0.5, respectively. Figure 6 shows the object of a convex polyhedron. Since the object has twenty plane faces and the ridge line of the bottom surface is excluded, there are 27 action points. The combination of the action points obtained by the implemented algorithm is also shown in Figure 6.

Figure 7 shows the norms of force required for single tumbling operation for each θ, and Figure 8 is shown the planning trajectory of tumbling operation. In addition, as can be seen from Figure 7, when comparing the force acting on the object, the tumbling operation can manipulate the object with a smaller force than $Mg/2$ = 9.80665[N]. In the tumbling operation, it can be seen that the left and right forces fluctuate as θ increases.

We presented an impedance control of a mobile robot with dual arms for a three-dimensional tumbling operation [8] . Also, experimental verifications were conducted and its results were shown the effectiveness of the proposed algorithm. However, trajectory planning of this paper doesn't consider the characteristics of the mobile robot. Therefore, in the future, it is necessary to construct the

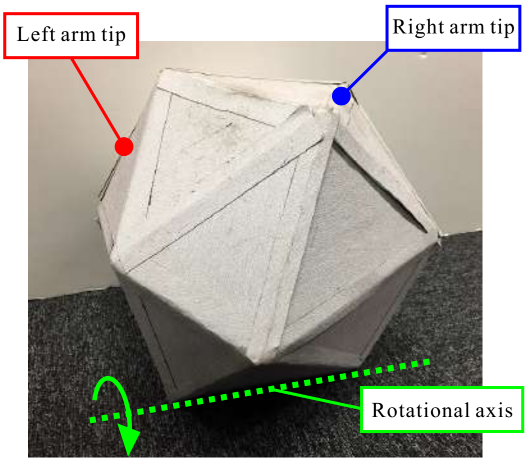

Figure 6. The appearance of the object

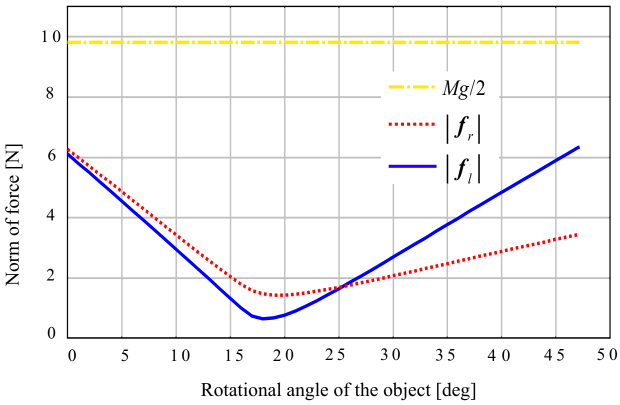

Figure 7. Result of tumbling operation and $Mg/2$

trajectory planning including characteristics of the robot.

7 Conclusion

In this paper, we presented the method for determining the combination of action points by analyzing the tumbling operation. We solved this problem as a nonlinear optimization problem by the evaluation function and the constraints on relational expression of force. From the characteristics of geometry, we showed effective reduction method of variable against multivariable problem. Finally, the usefulness of the algorithm was shown by a numerical example. As a future works, we will attempt to construct a trajectory planning that considers the robot's hand position and posture. Currently, we are trying verification experiments based on this algorithm by a mobile robot with dual arms.

Abstract

Building Information Modeling (BIM) is a technique in which a three-dimensional (3D) building model is constructed and designed in a computer. In recent years, BIM has been widely used in design and construction phases, but it has not been widely used in operation and maintenance phases, which account for the largest part of the building life cycle. The information required in BIM is different in each of the phases of design, construction, operation, and maintenance, and there are many pieces of reproduced information, making it difficult for managers to utilize the information. Although a number of studies have been conducted on combination of BIM with various technologies such as Internet of Things (IoT) and advanced sensing equipment in operation and maintenance, and interlinking of the obtained information with BIM information, there have been difficulties in commercialization and field application. This study aims to determine the problems found in previous studies and propose a fusion process in which new technologies adopt and utilize virtual reality techniques such as augmented reality (AR), mixed reality (MR), and head-mounted displays (HMDs) in existing maintenance work, thereby increasing maintenance work efficiency and further improving the utilization of BIM.

1 Introduction

1.1 Research Background and Purpose

The fourth industrial revolution (Industry 4.0) will bring about various technological changes in a variety of industries including the building industry, which has been affected by Industry 4.0 in many areas. According to ‘IoT Analytics’, seven main technologies that will lead Industry 4.0 are cyber physical systems, cloud computing, big data, system security, 3D printing, augmented reality (AR), and humanoid robots. The number of patent registrations for these technologies has increased by approximately 12 times between 2010 and 2015 [1]. The Gartner Hype Cycle for Emerging Technologies in 2017(Figure 1) reported that AR technology has already passed through ‘the peak of inflated expectations’ where excessive interests are concentrated and has entered the ‘trough of disillusionment’ where investments occur in corporations that own actual technologies, and it forecasts that virtual reality (VR) and AR will grow explosively until 2021 [2].

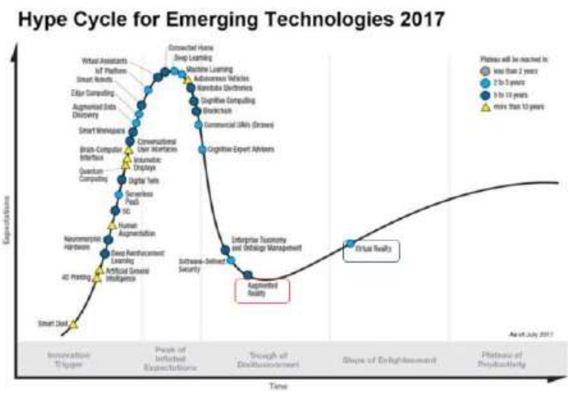

Figure 1. Augmented Reality / Virtual Reality in Hype Cycle (Panetta, 2018)

With the advancement of these technologies, a variety of new technologies have been combined in the building industry as well. Through the utilization of Building Information Modeling (BIM), information in the life cycle of building projects from design, construction, operation and maintenance, demolition, and remodeling can now be managed. To utilize this informatization model, requirements of BIM attribute information for each phase need to be specified and development and promotion of BIM libraries and standard formats are required. In addition, a process improvement for efficient BIM technology application is needed. In this regard, related studies have also been conducted actively. It is now time to consider how BIM information is efficiently created and fused with other new technologies (IoT, 3D printing, AR/VR) and utilized. Facility management (FM) accounts for 85% of the building life cycle cost (LCC) [3]. On-site facility data visualization and real-time collaboration function utilizing AR technology will change the maintenance work process and significantly benefit economy in terms of LCC viewpoints. Nonetheless, compared to the design and construction phases, few studies have been conducted on the applications of state-of-the-art technologies such as AR and VR to the maintenance work process.

Thus, this study identifies a trend of BIM and AR/VR technologies and determines an information linking method as one of the studies on smart FM for automation management and efficient execution of maintenance on facilities. It also proposes a smart maintenance work process that is applicable to smart FM systems by deriving user tasks where BIM and AR/VR technologies need to be applied in existing maintenance work.

1.2 Study method and procedure

This study adopts the following methods to enable smart FM work execution with applications of BIM and AR/VR technologies in FM of the building sector of public facilities. First, the existing maintenance work process is analyzed through a literature review. Through this analysis, the problems of existing processes are derived, and technical solution methods are searched. Second, component technologies of open BIM and AR/VR and Head Mounted Display (HMD) devices for visualization implementation are analyzed to derive applicable technologies and devices for smart FM. Third, a new work process for smart FM is proposed and detailed use cases for workers to execute the process are divided. Finally, the applicability of the technologies is determined through simple prototype implementation for each phase in the processes.

2 Research Trends

2.1 Building maintenance using BIM

The advantage of applying BIM to the maintenance phase is that it can utilize analysis data for purchase procurement of machine equipment, control systems, and other products and it can check whether all systems are correctly operating after buildings have been completed. It can also play a role as an interface for sensors and remote operation management of facilities, and real-time monitoring on control systems through providing accurate information about space and systems [4]. The BIM for FM is a sole information basis that provides a manual for building users. This can help the location of models such as facilities, attachments, and furniture to be recognized visually and can support contingency planning, security management, and scenario planning [5]. As described above, several studies have been conducted actively to draw out the advantages of BIM application to FM as much as possible.

A study by Yu et al. developed a data model, FMC, that can extract the required information from Industry Foundation Classes (IFC) for information compatibility of BIM data with FM [6]. A study by Mendez proposed functions that can be utilized by BIM in the maintenance phase and developed a web-based prototype to improve utilization of BIM data [7]. East and Brodt developed a spreadsheet-based data exchange format, COBie, to solve inefficiencies due to unnecessary information in maintenance among information sets created during design and construction phases [8]. A study by Burcin et al. defined a level of BIM recognition in the maintenance phase through expert interviews, applicable areas, required data and processes for successful implementation of BIM [9]. Lee et al. attempted to improve a facility maintenance system through benchmarking of the COBie system [10] and Choi et al. conducted a study to implement a FM system for sewage treatment based on COBie [11].

Most of the previous studies on FM utilizing BIM are focused on interoperability with FM systems and a measure to link data that are produced during design and construction phases, as well as being directed toward application of BIM to FM systems and commercialization.

2.2 Utilization of AR/VR technologies in the building industry

The trend of utilizing AR/VR technology in the building industry is reflected in the focus of most studies being on analysis of applicability of virtualization technology in the early days. Hammad presented the applicability of AR technology to field tasks of infrastructure [12] and Kwon analyzed considerations in the development of wireless technology-based AR-applied systems in terms of display, tracking, and servers. Afterward, a study on presentation of AR system prototype for inspection of steel column construction was conducted [13][14].

A variety of studies have also been conducted in relation to VR technology. For example, decision-making support through virtualization and simulation has been studied. Kim utilized VR technology in a system that evaluated a road scenery design and selected the final alternative based on superior scenery, technicality, and environmental criteria [15]. A study by Choi implemented a cloud-based BIM platform by which construction site environments could be experienced indirectly through simulations [16].

For studies on AR authoring tools, AR modeling through capturing and rendering of exterior structures in real time and a 3D modeling tool called 'Tinmith', which was manufactured to provide interaction between user and AR directly, can be found [17]. More recently, prototypes that can be applicable to real construction sites have been developed. For example, Dunston used a head mounted display (HMD) to represent a 3D computer-aided design (CAD) model on an actual real background, thereby conducting a study on AR-CAD that found a spatial interference on the drawings in the design phase [18]. Moon et al. implemented an AR prototype that can select the position of a tower crane appropriately in a high-rise building construction site and conducted a verification procedure through actual building drawings [19].

The analysis results in previous studies showed that the utilization of AR/VR technology in the building industry has enabled efficient construction management by recognizing design drawings intuitively by users. Four-dimensional (4D) BIM based on existing virtual environments has lacked reflection of actual construction site conditions. Thus, if AR technology that reduces a cognitive resistance is applied to maintenance sites, its value and utility would be significant in terms of productivity improvements.

3 Theoretical Discussion

3.1 Open BIM and IFC standards

In terms of commercial CAD systems, BIM technology has been advancing continuously. However, the most difficult limitation in BIM application is data compatibility. BIM platforms can share all information throughout the building life cycle in their unique data formats. However, the absence of standard formats and data access methods can create a problem in BIM data exchange between CAD systems. To overcome this problem, the Industry Foundation Classes (IFC) have been applied as a standard data format to exchange and share BIM data.

The IFC are a neutral data model rather than a proprietary model of a specific software vendor. They have been developed by the International Alliance for Interoperability (IAI), buildingSMART, to facilitate data compatibility for information sharing and exchange between application tools used in the building industries. They have been developed as standardized data sets for data compatibility between application tools. OpenBIM is an initiative of buildingSMART and several leading software vendors using the open buildingSMART Data Model [20]. Based on openBIM, several public project order issuing institutions in the USA and Europe require openBIM-standard-based delivery. The BIM-based public project orders in North America and Europe have been expanding throughout the world.

The AR/VR-based smart maintenance process proposed in this study utilizes openBIM for data interoperability.

3.2 AR/VR technology

The component technologies of AR applied to building industries that were analyzed in the previous studies can be summarized as follows.

- GPS-based technology: user location is recognized using GPS technology and registration to real environment can be done by projecting a 3D model to a pre-calculated location through the display.
- Vision-based technology: feature points are recognized based on images inputted to the camera and camera position is calculated to register a 3D model with a real environment.
- Real-time 3D recognition technology: real spaces are recognized and interpreted to align virtual objects in real spaces.
- Positional tracking technology: accurate tracking data values of user's position are reflected in the display in real time.
- Head tracking technology: can make a virtual object transit not only by position detection of the user according to movement in the real space but also by detection of head movements even when staying in the same position.
- Gaze (pupil) tracking technology: tracks the focal points of the pupils of eyes in real time using image processing, or can be implemented by a specific transmitter.
- High transparency technology: it overlays the view in the real space and the virtual object image naturally to project the light reflected in the real space to the retina.

The features, advantages, and disadvantages of AR/VR as virtualization technologies utilized in the building industries in construction sites are as follows.

- HMD hardware is needed to block the field of view in the real space as a technology that uses a 100% virtual image rather than a real image.

- It can provide various angles and stereoscopic effects through computer graphics, but it lacks site reality compared to AR.
- It is a technology that overlays 3D virtual images to real images. It requires a coordinate recognition technology of device medium or a rotation sensor to accurately overlay virtual images to positions in the real space.
- It has the advantage of delivering site-based selected information realistically, but has a limitation in recognition accuracy due to various site obstacles.
- It can be superior in providing indoor information of a completed building where the surrounding environment is stable.

This study aims to improve efficiency and productivity of maintenance work. To achieve this, it utilizes basic components and element technologies of AR/VR technologies.

4 OpenBIM-Based Smart FM

4.1 Overview of smart FM

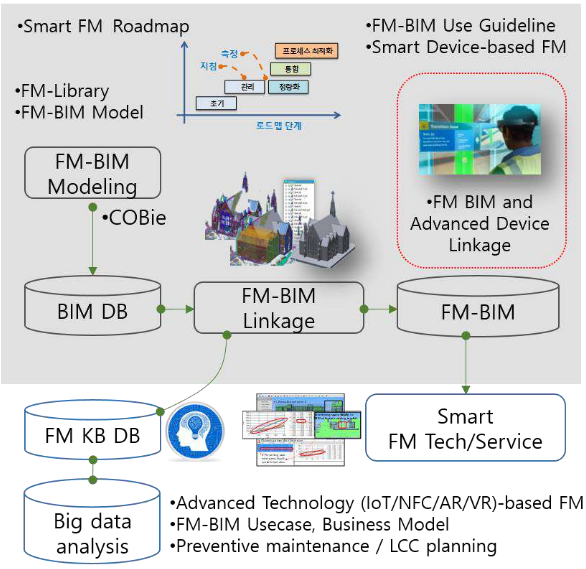

Figure 2. Smart FM technology development for advanced device and data analysis

The smart FM proposed in this study is a platform that employs the IoT, cloud, big data, and mobile (ICBM) basis technologies. It has the following major technologies.

- Scan/reverse design technology (SCAN-BIM, BIM model reverse design technology)
- Intelligent FM BIM technology (cloud/big data/intelligent model/BIM data analysis technology)
- Smart field FM BIM technology (IoT/VR/AR-based BIM FM)

The smart maintenance process proposed in this study is based on smart field FM BIM technology. It aims mainly to support site work. Figure 3 shows a diagram of the improved maintenance work flow.

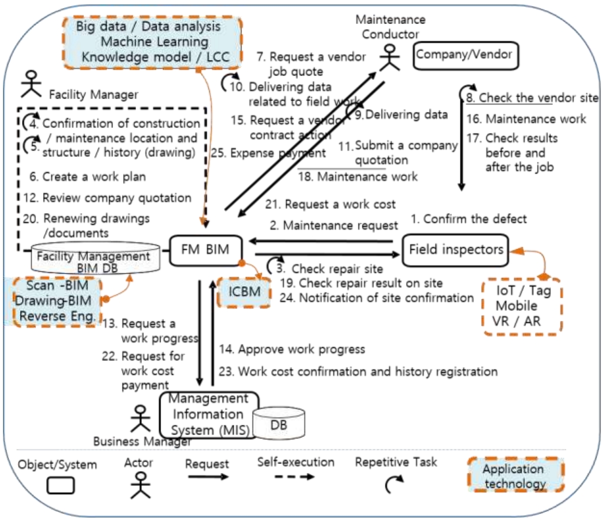

Figure 3. Maintenance work flow diagram in Smart FM

Through the ICBM platform-based FM BIM system that manages the facility management database in the center, variably distributed data can be gathered and processed as a hub for each request.

4.2 Existing maintenance work process

The routine maintenance inspection work processes of various facilities are investigated through a literature review and worker interviews. The maintenance work process differs depending on facility uses and sizes. Thus, this study limited the use and size to public facilities of less than five stories. The general maintenance work process is:

1. Establishment of inspection plan
2. Discovery/investigation of abnormality and defects
3. Determination of maintenance work schedule through safety diagnosis; and then if required
4. Repair work.

When utilizing BIM, histories of facility maintenance can be included and utilized in the BIM data. It is also differentiated from existing maintenance work processes by its process of automatic extraction of various statistical data and establishment of preventive repair plans as well as its conducting visualization simulations after repair work is complete. The as-is process of various maintenance works is divided into tasks for each user and is represented in Figure 4.

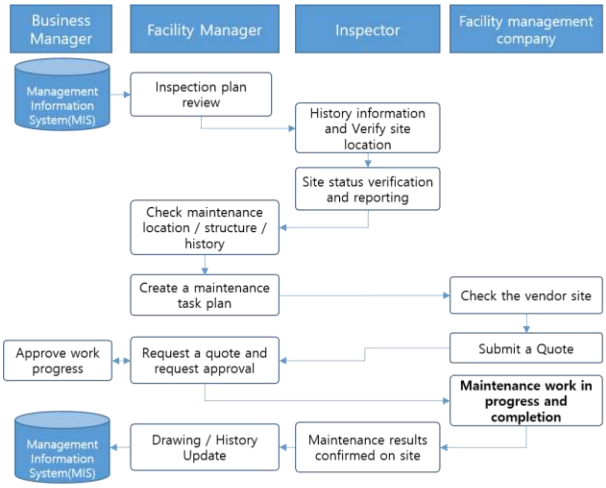

Figure 4. As-is process flow diagram of maintenance work

The facility manager then reviews the inspection plan and the inspector conducts inspection at the site based on the plan. Afterward, facility manager checks the history of maintenance and conducts maintenance, and the facility management company rechecks the site. When the facility management company submits a quote, the facility manager checks the quote. Once the executive manager approves the work, the facility management company can start the maintenance work.

4.3 Improvements in the AR/VR technology application process

Previously, data such as drawings, history information, and related documents were distributed and stored during facilities maintenance work. In addition, when facility defects occurred, it took a lot of time to search history information, drawings, company information, site location, and MIS history information. This was one of the main factors hindering work efficiency. The inefficient process with iterative tasks and sequential progress is improved through AR/VR technologies to produce an improved to-be process as shown in Figure 5.

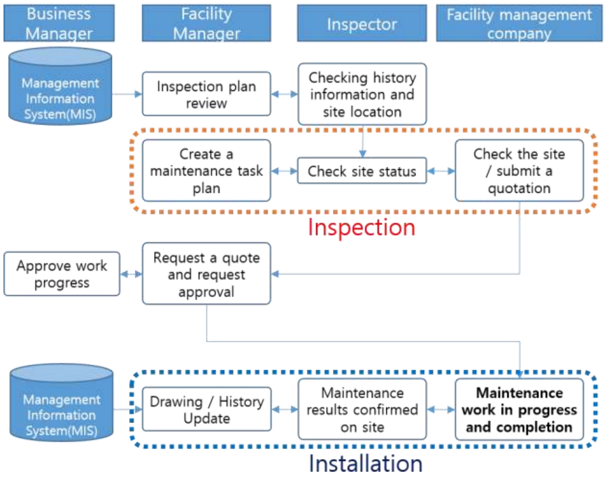

Figure 5. To-be process flow diagram of maintenance work

If VR virtualization technology utilizing BIM model spatial information is applied to review the work of the facility manager inspection plan, the inspector's history information and site position verification work can be done simultaneously. If AR technology is applied to a process when an inspector verifies a facility status at the site, the facility manager and facility management company can share the site conditions in real time and collaboration work for maintenance can be achieved. If AR technology is applied even when the facility management company does maintenance work, follow-up work of the inspector and facility manager can be done simultaneously. The utilization scenarios of the proposed system are shown in Figure 6 for different technical areas.

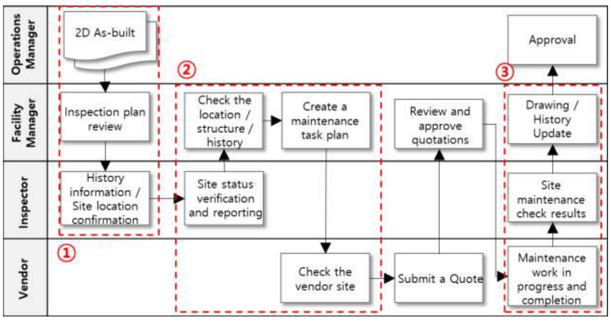

Figure 6. Utilization scenarios of the proposed system

The core technologies in the visualization process for each space through VR are as follows.

- Reference information system by phase
- Information division and information sharing process
- Indoor positioning technology

- Marker-indoor positioning integration technology

The core technology in the real-time collaboration process through AR visualization are as follows.

- VR/AR-based surveillance construction support technology
- 3D information + AR overlaying technology
- 3D data conversion technology for AR/VR

Table 1 Key issues and core technologies in the proposed maintenance work

① Space-specific visualization through VR	
Key issues	• Mapping of attribute information and mapping of necessary information to shape information • The user/manager side information process must be established & information control • Real-time management technology through history management based on current location information
Core technology	• Step-by-step reference information system • Information Segmentation and Information Sharing Process • Indoor Positioning Technology • Marker - Indoor positioning integrated technology
② Real-time collaboration through AR visualization	
Key issues	• The Inspector provides real-time information on the target location and history for checking the status of the object, • Real-time sharing of real-time information through 3D visualization
Core technology	• Surveillance-based support technology based on virtual / augmented reality • 3D Information + AR Overlaying Technology • 3D data conversion technology for AR / VR
③ Site-based update of historical information	
Key issues	• Check the real-time field status, upload and save the inspection contents, update historical information by each type of work • As-built model update through on-site information update
Core technology	• Data lightening support technology • 3D contents update process and technology based on reverse design • IoT information-based control technology for managers

4.4 Implementation of the improved process

An openBIM dataset of public facilities of five or fewer stories was utilized to implement the proposed AR/VR-based smart maintenance process. Table 2 shows the data and programs used to verify the applicability.

Table 2 Data and tools used for validation

Data and Tools	Programs and contents
BIM Dataset	Autodesk Revit(rvt), LOD500(BIM for FM)
Geometry models converted to IFC standards	VR development tool	Unity
VR HMD	Microsoft Hololens
AR development tool	ARtoolkit, Android studio
AR HMD	Vuzix M100

To implement a VR virtualization prototype for prior inspection planning review and site location verification work (Figure 7), a model library for each maintenance target object should first be extracted from BIM information, and converted into model data for each space. The above process is required to use the 'Unity' VR implementation authoring tool. Any openBIM dataset can be acceptable. A VR prototype is complete for maintenance area visualization if spatial and object data are combined in Unity and camera and moving travel paths are set up followed by building into a preferred platform. To demonstrate this, Microsoft's 'Hololens' was used as an HMD.

For the implementation of AR technology-applied process, a maintenance history information overlay function and a real-time communication function were implemented through the open source programs 'ARtoolkit' and 'Vuzix M100', and Android SDK.

Figure 7. Validation of AR/VR based maintenance task through simple test

5 Conclusion

This paper proposed a process to apply AR/VR technologies to site maintenance work in the openBIM-based smart FM system. A survey analysis was conducted regarding existing BIM-based maintenance and AR/VR research in building industries. Along with surveys on openBIM and AR/VR technologies, a method to utilize them in maintenance work was derived. Finally, a process by workers and technology systems was proposed for AR/VR-applied maintenance work, and this was implemented as a prototype.

As a result, the utilization of AR/VR technologies in the maintenance work enabled fast and accurate decision making. With BIM data that can replace existing two-dimensional drawings and AR technology that can visualize information through overlay, inefficient re-work elements can be removed. In addition, since openBIM datasets created in the construction phase are utilized, it has the advantage of requireing little resource input for technical application. It can also improve accuracy and reliability of maintenance work results by minimizing interventions based on individual subjective judgments through real-time site circumstance sharing and collaboration functions via HMDs.

However, since the scope of this study was limited to the maintenance of public facilities of five or fewer stories in the building sector, the study results cannot be applied to other purposes and larger facilities. If maintenance work is extended to mechanical, electrical, and plumbing (MEP) facilities, the required BIM information can be extensive, and lightweight data are therefore needed. Thus, for future study, the following topics can be selected: definition of classes for attribute information visualization and BIM models for each facility of various sizes and uses, measures to link HMD and IoT sensing data, ensuring connectivity with actuators, and technical advancement of marker recognition with regard to maintenance targets.

Abstract –

As the importance of maintainability for the energy efficiency of industrial plants is emphasized, thermographic inspection has been widely used as a key technique. However, the thermographic inspection cannot provide clear information due to the limitation of low resolution in inspecting wide areas where the worker cannot acquire data in close, such as hazardous environments and the ceiling with pipelines. Therefore, this paper proposes a resolution enhancement method for thermographic inspection in industrial plants based on deep convolutional network. The proposed network involves patch extraction and representation, non-linear mapping, and reconstruction. The proposed method was validated with 210 thermal images obtained from real cogeneration plants. Experimental results show that the method can provide the clear boundaries of instruments with an average PSNR of 32.51, which is superior than the bicubic interpolation of 29.92. The proposed method can be implemented in energy efficiency monitoring and automatic defect detection for thermal inspection in industrial plants by helping to detect defects that can be unchecked in low resolution images.

Keywords –

Thermographic inspection; Industrial plants; Resolution enhancement; Convolutional deep networks

1 Introduction

As demand for electricity increases, the importance of the energy efficiency of an industrial plant becomes a critical issue. Chen et al. [1] demonstrate that the energy efficiency of industrial plants can be achieved through efficient maintainability. With emphasis on the importance of maintainability of industrial plants, many non-destructive evaluation techniques have been proposed as an efficient maintenance method to detect defects in industrial instruments. However, as industrial plants become larger and more complex, most non-destructive evaluation techniques require significant labor resources for maintenance. This may result in insufficient information for evaluation, which makes it difficult to achieve corrective action for defects at optimal times [1]. In addition, most non-destructive evaluation techniques expose the worker to hazardous environments by requiring them to closely approach and inspect the instrument [2]. In this context, thermographic inspection enables short but reliable inspection by allowing the worker to inspect energy efficiency for many areas at a distance without needing to access instruments during maintenance [3, 4].

Despite the advantages of thermographic inspection, thermal images have limitations due to their low resolution. When inspecting areas of industrial plants where a number of instruments are installed, a thermal image with insufficient resolution cannot provide clear information on critical defects. This problem can cause the inspector to be unaware of a critical defect and leave the defect unchecked. Unchecked critical defects cannot only lead to energy losses of industrial plants, but also have far-reaching consequences. In order to ensure the resolution of the thermal data, acquiring data from close to the instruments is inefficient and impossible in pipelines installed on the ceiling or in hazardous environments that people cannot approach. In this context, it is necessary to enhance the resolution of the thermal image for thermographic inspection in industrial plants.

Over the past few years, some studies have been carried out to enhance the resolution of thermal images to address these low-resolution limitations [5-8]. Recently, with starting with a study by Dong et al. [9], the deep learning method has been successfully applied to improve the resolution of a single image, so many studies using deep convolutional networks have been actively conducted [10-12]. Choi et al. [12] have demonstrated that a convolution neural network can be successfully applied to thermal image enhancement.

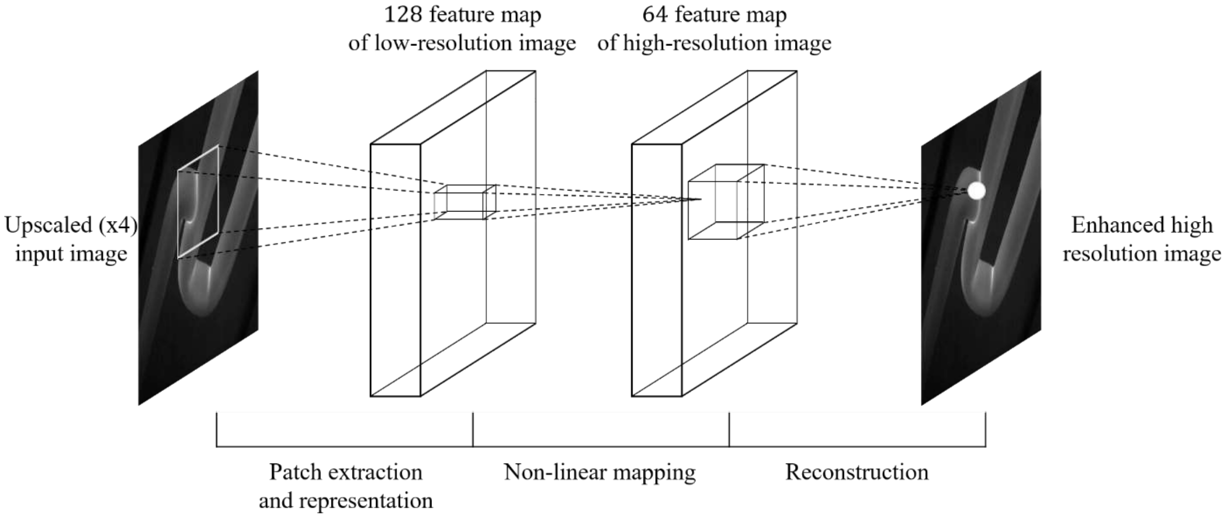

Figure 1. Network structure for super-resolution of thermographic inspection

However, Choi et al. [12] used an RGB (red-green-blue) dataset converted to gray scale as a training dataset. This process cannot be applied to thermographic inspection that utilizes the thermal value of acquired data, because it can distort acquired thermal values guided by the RGB image. Therefore, none have studied the method that can enhance the resolution of the thermal image for thermographic inspection in industrial plants. This study proposes a thermal image enhancement method for efficient thermographic inspection of industrial plants based on deep convolutional networks. The proposed method was evaluated by using a thermal dataset obtained from actual industrial plants.

2 Methodology

For resolution enhancement of thermographic inspection, this study uses a deep convolutional network inspired by C. Dong et al. [9, 10]. The configuration of the network is outlined in Fig. 1.

2.1 Proposed Networks

In pre-processing, the input image with low resolution is upscaled to the desired size of the high-resolution image using bicubic interpolation. This study used only gray channel for the input image by extracting temperature value from raw images. After pre-processing, there are three convolution layers that are patch extraction and representation, non-linear mapping, and reconstruction separately.

In the first layer, patch extraction and representation operation extracts overlapping patches from the upscaled image and represent each as high-dimensional vectors. In this paper, we use a larger network with the filter number of the first and second layers, because a superior performance can be achieved by a larger network [10]. We applied 128 filters with a size of 9 × 9 in the first layer. Therefore, output is generated as a 128-dimensional feature map. In this layer, the Rectified Linear Unit (ReLU) [13] is used as an activation function. In the second layer, each of the high-dimensional vectors from the first layer is mapped onto another high-dimensional vector. This operation is equivalent to applying filters with the size of 1×1. We set the number of filters as 64 in this operation. In the last layer, the enhanced output image is generated by aggregating the representations from the second layer. This layer operates as like the average pooling layer in traditional methods.

2.2 Training

This study used the 205 thermal images with resolution 640×480 taken from a cogeneration plant as training dataset. Figure 2 shows some examples of the training dataset. For training, the high-resolution ground truth images are cropped as sub-images with the size of 33×33 and the stride of 14. The sub-images are blurred using Gaussian kernel and sub-sampled by the upscaling factor of four. Finally, sub-images are generated by upscaling using bicubic interpolation with the same factor.

In the training phase, the parameters as weights and biases of filters are optimized in a way that minimizes loss. In this paper, mean squared error (MSE) is used as the loss function between input low-resolution images and the high-resolution images that are ground truths.

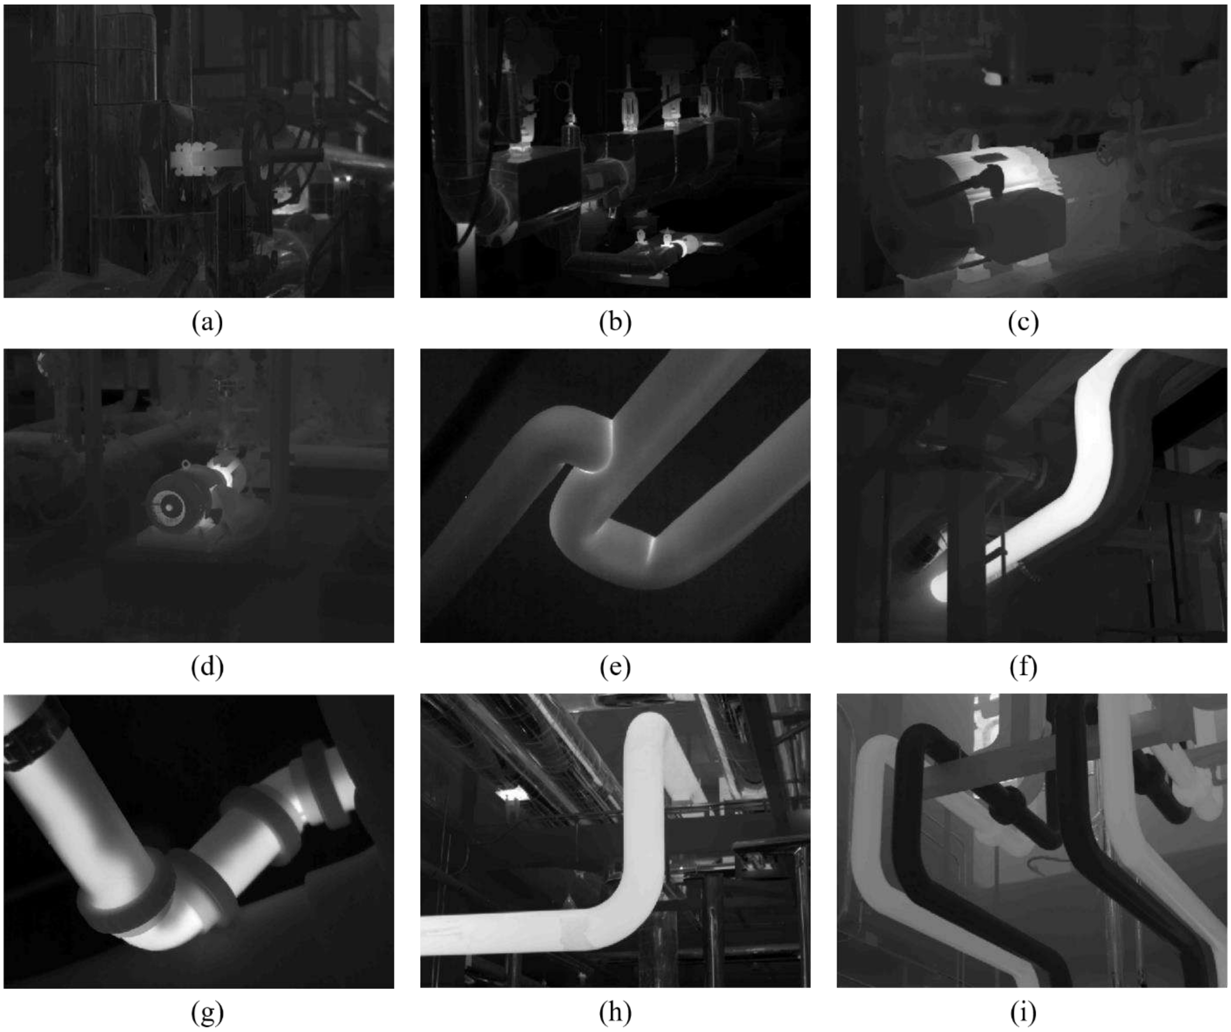

Figure 2. Examples of thermal image from cogeneration plant: (a) – (d) instruments; and (e) – (i) pipelines.

The loss function of MSE is below:

$$L(\theta) = \frac{1}{n}\sum_{i=1}^{n} \| F(X^i;\theta) - G^i \|^2 \qquad (1)$$

where θ is the parameters consisting weights and biases of filters, n is the number of training samples, $F(X^i;\theta)$ is i-th reconstructed image and G^i is a ground truth image. Therefore, the parameters are updated so that $F(X^i;\theta)$ is reconstructed close to G by calculating the loss every time it iterates from end to end. The parameter optimization is held by using stochastic gradient descent with back-propagation. We used a learning rate of 10^{-4} for the first and second layers. The smaller learning late of 10^{-5} is used for the last layer as suggested in Dong et al. [9].

3 Experimental Results

To measure the performance of the resolution enhancement, we employed peak signal-to-noise ratio (PSNR). The PSNR is the most common quantitative evaluation of resolution enhancement [11,12]. For evaluating the proposed method, five thermal images from real industrial plants were used a test dataset (Figure 3 (a)). We compared the performance of the proposed method with bicubic interpolation which is one of the baseline method in resolution enhancement [12,14].

Figure 3 shows the resolution enhancement results of the proposed method. We used the model obtained at 2×10^6 iteration of the proposed networks. As can be seen in Figure 3 (d), a much sharper image is produced using the proposed method compared to input image (b)

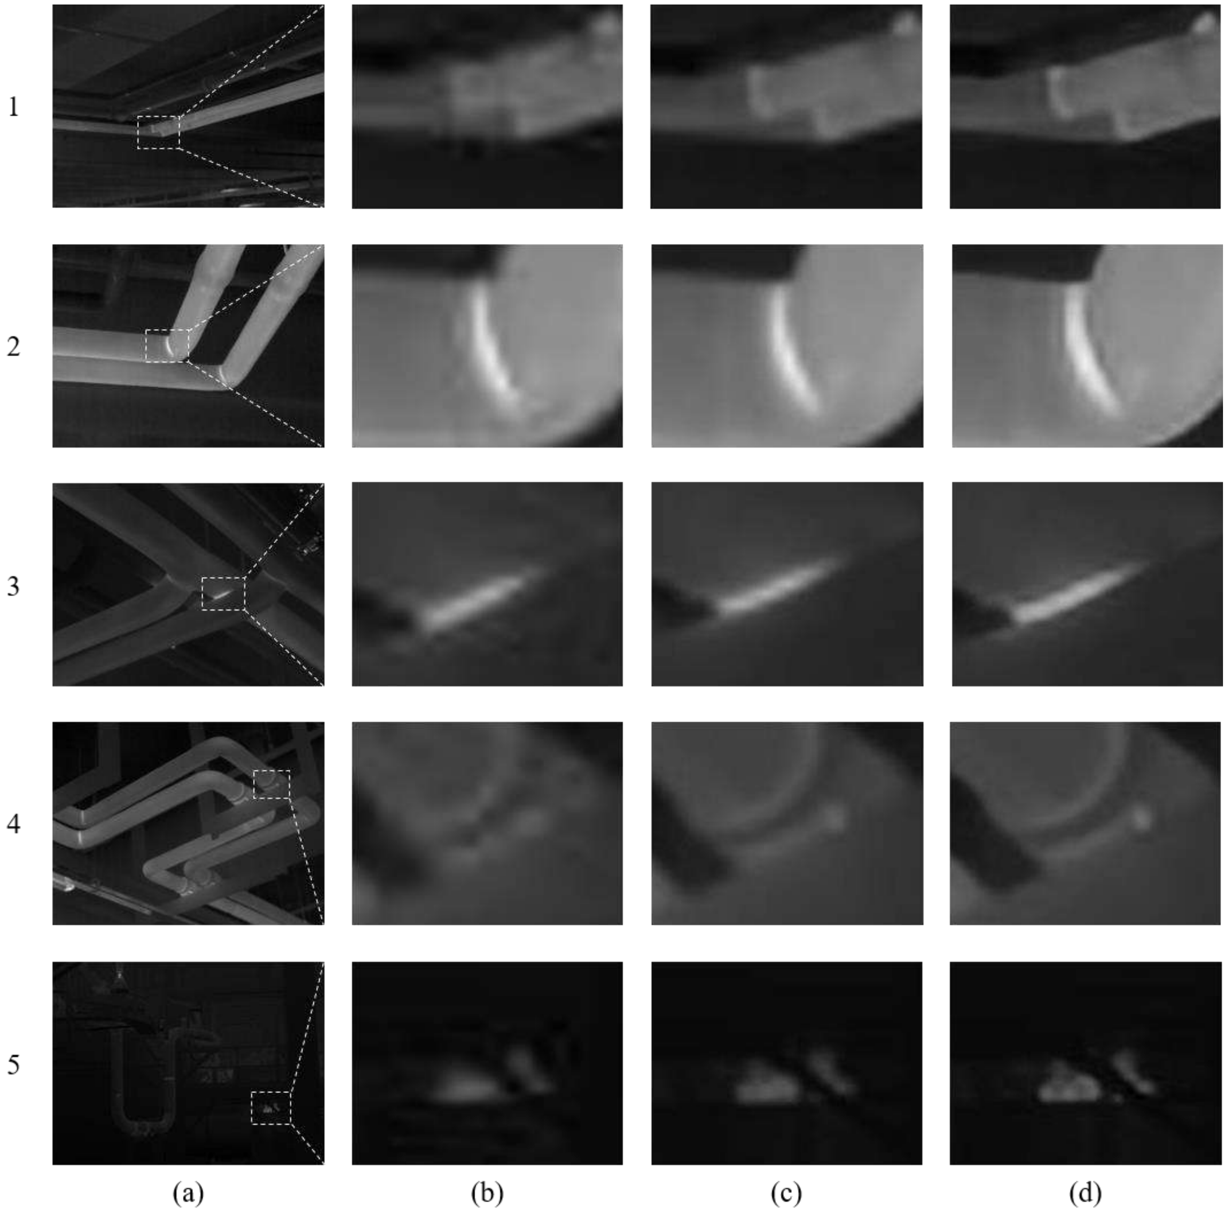

Figure 3. Resolution enhancement results of five test images: (a) ground truth; (b) input; (c) bicubic interpolation; and (d) proposed method

and bicubic interpolation (c). This shows that blurry boundaries of defects and other instruments in input low-resolution thermal images can changed to clear boundaries through the method proposed in this study. Table 1 shows the quantitative results as average PSNR for test dataset. For each test image, the PSNR of the proposed method shows the superior performance over bicubic interpolation. Therefore, the results show that the proposed method for resolution enhancement can be effectively applied in thermographic inspection for industrial plants.

Table 1 Resolution enhancement results (PSNR)

Test images	Bicubic	Proposed
1	38.88	41.23
2	38.33	40.94
3	42.52	44.39
4	39.03	40.89
5	45.59	46.33
Average	40.87	42.75

4 Conclusion

This study proposed a method for thermal image resolution enhancement using deep convolutional networks, with the goal of providing clear information about instruments installed in areas where it is impossible for workers to acquire data from nearby, such as pipelines on the ceiling or instruments in a hazardous environment. The experimental results show that the proposed method could produce a far clearer thermal image of actual industrial plants. The proposed method is expected to help identify the defects of instruments that may not show up in low-resolution thermal images. In future research, we will focus on automatically detecting defects based on the improved data using the proposed method.

Abstract –

The objective of this research is to evaluate vision-based pose estimation methods for on-site construction robots. The prospect of human-robot collaborative work on construction sites introduces new workplace hazards that must be mitigated to ensure safety. Human workers working on tasks alongside construction robots must perceive the interaction to be safe to ensure team identification and trust. Detecting the robot pose in real-time is thus a key requirement in order to inform the workers and to enable autonomous operation. Vision-based (marker-less, marker-based) and sensor-based (IMU, UWB) are two of the main methods for estimating robot pose. The marker-based and sensor-based methods require some additional preinstalled sensors or markers, whereas the marker-less method only requires an on-site camera system, which is common on modern construction sites. In this research, we develop a marker-less pose estimation system, which is based on a convolutional neural network (CNN) human pose estimation algorithm: stacked hourglass networks. The system is trained with image data collected from a factory setup environment and labels of excavator pose. We use a KUKA robot arm with a bucket mounted on the end-effector to represent a robotic excavator in our experiment. We evaluate the marker-less method and compare the result with the robot's ground truth pose. The preliminary results show that the marker-less method is capable of estimating the pose of the excavator based on a state-of-the-art human pose estimation algorithm.

Pose Estimation; Stacked Hourglass; Excavator

1 Introduction

Due to the hazardous working environment, construction site has a higher rate of fatalities and injuries throughout the industry [1]. On average, 53% of the fatal accidents that happen on construction sites are either struck by vehicle or equipment overturns and collisions [2], which causes almost $13 billion in extra cost per year [3]. Blind spots around the equipment are the main cause of such accidents [4]. When workers need to interact with the equipment on job sites, the equipment operator sometimes cannot locate all workers nearby and the workers also cannot locate the equipment components clearly. The prospect of collaborative human-robot teams on construction sites further heightens these concerns and highlights a need for developing on-site articulated equipment pose estimation methods. The pose of the construction equipment, such as an excavator, can be described as the angle between each component and the 6 degree-of-freedom (6 DOF) coordinates. Therefore, determining each joint location and the angle between each component is the primary goal of the machine pose estimation, as shown in Figure 1.

Figure 1. Excavator pose is determined by identifying its joints and components.

In the real practice, two types of pose estimation methods are used on construction equipment, namely non-visual sensor-based and vision-based pose estimation method. For sensor-based pose estimation methods, Inertial Measurement Unit (IMU), Global

Positioning System (GPS), Wireless Local Area Network (WLAN), Radio Frequency Identification (RFID), and Ultra-Wide Band (UWB) are mainly deployed on equipment and construction site. IMU sensors need to be mounted on excavator joint components to measure the angle [5], which has drift issues [6]. GPS is known for outdoor used only [7], which is not suitable for some indoor construction site. WLAN system requires significant amounts of effort for calibration [8]. RFID and UWB methods both require sufficient preinstalled tags and readers on equipment and infrastructure [9–11]. They generally suffer from missing data issues [12] and are inadequate for pose estimation [13]. In addition, most of these methods cannot provide orientation information directly, except for IMU, are not suitable for construction scenarios.

On the other hand, vision-based pose estimation methods are capable of analyzing position information as well as orientation information directly from input data, such as videos or point clouds. These methods generally recognize construction equipment on site [14–17], then estimate their 6 degrees-of-freedom (6 DOF) pose [18,19], which can be categorized to two different group: marker-based and marker-less pose estimation. The marker-based pose estimation method recognizes all the markers mounted on equipment and estimates the pose by their geometric relations [20,21], whereas the marker-less pose estimation method directly extracts image features and estimates the pose by them [18]. The marker-based method has been extensively applied in indoor localization and facility management [22,23]. Similar to sensor-based pose estimation method, they also require preinstalled markers on equipment and environment.

In addition to the marker-based method, the marker-less pose estimation method only requires an on-site camera system, which is common on modern construction sites. Feature descriptor based is the first type of marker-less pose estimation method, such as Histograms of Oriented Gradient (HOG) [16], 3D principal axes descriptor (PAD) [14], Iterative Closest Point (ICP) [24], or Viewpoint Feature Histogram (VFH) [18]. Convolutional Neural Networks (CNN) is another type of pose estimation method [25], which has higher performance (accuracy and speed) in comparison with all other vision-based methods, especially for human pose estimation. Therefore, in this study, a CNN based marker-less pose estimation system is presented, which can distinguish excavator joint components and estimate their poses in images. This system is built on a state-of-the-art human pose estimation network [26,27] and trained on an excavator image dataset collected in a factory setup lab environment. The excavator pose in this research is defined as the boom, stick, and bucket pixel-wise 2D location.

2 Marker-less Pose Estimation System

Our marker-less pose estimation system is developed based on a state-of-the-art human pose estimation algorithm, namely stacked hourglass network by Newell et al. [26,27]. This network scales the training image into different resolution and captures features, then combines the information together to predict the pose. Compared with the human pose, the construction equipment pose is much simpler, thus requires less information across different image resolutions. The detailed network architecture is further discussed in the next section.

2.1 System Network Architecture

We modify the stacked hourglass network to fit our target construction machine, mainly excavator. Unlike the complicated human skeleton, excavator pose only requires identifying three components, which are bucket, stick, and boom, as shown in Figure 1. Therefore, the complexity of the network needed is much less than the original network. Figure 2 shows the network architecture. Two convolutional layers followed by a max pooling layer are first applied to the training image, which shrinks the image down to the size of 64 pixels. Then three subsequent convolutional layers upscale the image to the size of 256 pixels before the hourglass module. Finally, three hourglass modules, output prediction modules, and residual link modules are used in the network. All the convolutional layers are followed by ReLu activation function, with stride 1 except the Conv1 layer with stride 2, and with batch normalization except the convolutional layers in the output prediction module.

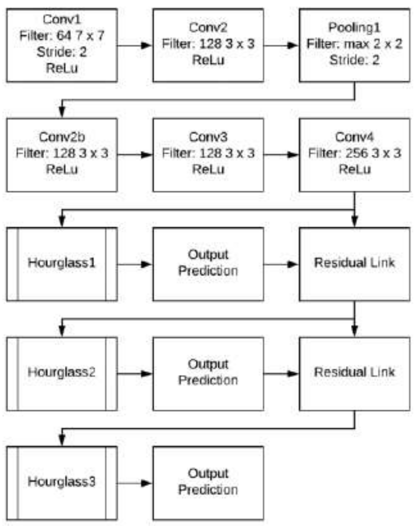

Figure 2. Full system network architecture, 3 hourglass modules are used in our system.

The hourglass module is the main part to collect features across different resolution, which is illustrated in Figure 3. The input passes into two parallel routes. In the first route, only one convolutional layer is applied to upscale the input to the size of 256 pixels. In the second route, one max pooling layer followed by three convolutional layers are applied to downscale the input to the size of 384 pixels, then resized to the size of 256 pixels, as the first route result. Finally, two route results are added together through elementwise summation to generate the output. This can preserve the global feature and capture the local feature as well. In the Hourglass2 and Hourglass3 module, we change the Conv_low2 layer to another hourglass module. This recursive hourglass module will increase the output size for more features.

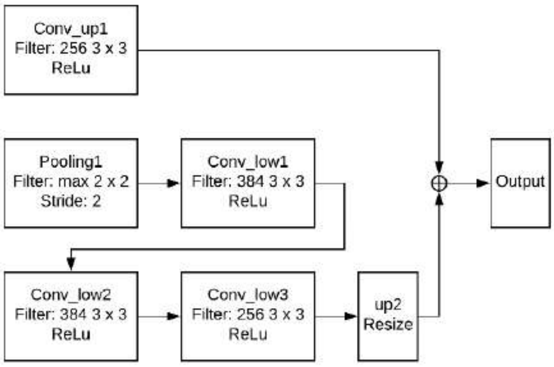

Figure 3. Hourglass module architecture, convolutional upscale and downscale layers are the main features of the hourglass shape.

The output prediction module and residual link module are applied after the hourglass module, as shown in Figure 4. Two convolutional layers are used in the output prediction module to generate the heat map of the possibility of the location of each joint. Figure 5 shows the concept of the prediction heat map. Each red dot represents the highest probability of each joint location from which we can estimate the pose, as shown in Figure 1. The final layer is a one-by-one convolutional layer, which aims to calculate the possibility across the depth of the output of the Conv5 layer. On the other hand, the residual link module combines the output from the previous hourglass and after the output prediction module to generate the input for next hourglass. The repeated hourglass and residual link module can preserve the spatial location and relation of each feature and apply to the final prediction step.

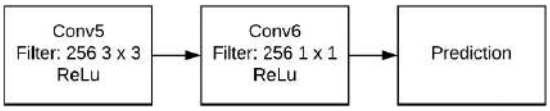

Figure 4. Output prediction layers, the previous hourglass prediction results are added with current output prediction.

Figure 5. The concept of the prediction heat map. Each red dot represents the highest probability of each joint location.

2.2 Training Details

We use the L_2-norm loss function to train our network, as shown in (1):

$$L_2(\hat{X}_p, X_L) = \sum \left(\hat{X}_p - G(X_L)\right)^2 \tag{1}$$

where $\hat{X}_p$ represents the predicted pose and X_L represents the labeled ground truth training data, $G(\cdot)$ represents the Gaussian kernel function with 1-pixel standard deviation. The loss function directly calculates the error between training and predicting image.

We implement the network system by modifying the original network using PyTorch [28] and the loss function described above. The network is trained on an excavator image dataset, which we collected from a factory setup lab environment with a simulated excavator and real construction site with real excavators. All the hyper-parameters are set the same as in [27]. The excavator dataset contains 1,000 training images and 500 testing images aligned with their pose annotating data. The detailed lab environment setup is discussed in section 3.

3 Experiment

We collect the image data from a factory setup lab environment and from real construction sites. The dataset is separated into training and testing groups. The algorithm is trained by the training group and evaluated by the testing dataset.

3.1 Implementation

We used a KUKA 7 DOF robot arm to simulate the excavator and capture the image of the robot arm with different poses. The upper arm represents the excavator stick and the lower arm represents the excavator boom. A bucket is mounted on the robot arm for a more realistic simulation. Figure 6 shows the simulated excavator in a factory setup lab environment. In order to control the robot as an excavator, the profile of the mounted bucket must remain perpendicular to the ground level. We controlled the robot arm to perform several excavator tasks such as digging, moving, or unloading.

Figure 6. The simulated excavator by a robot arm mounted with an excavator bucket.

We used a Point Grey camera to capture the image of the simulated excavator. The camera was deployed in 5 different location and orientation near the excavator to increase the variety of the dataset. A total of 1,000 images were collected; 750 of them were used as training images and 250 of them were used as testing images. Figure 7 shows an example of the simulated excavator dataset with different camera location and orientation. The joints of the simulated excavator were labeled in 2D pixel-wise location via MATLAB code. The structure of the annotation data is the same as the well-known human pose dataset (MPII) [25].

To increase the variety of the dataset and augmented the background of the dataset, we also collected image data from the real construction site with real excavators, as shown in Figure 1. A total of 500 images were collected; 250 of them were used as training images and 250 of them were used as testing images.

Figure 7. Example of the simulated excavator dataset with different camera location and orientation.

4 Results

We evaluate the proposed method by comparing the prediction results of the testing images and the ground truth. Figure 8 demonstrates the results of the excavator pose estimation. The green, blue, and red line are corresponding to the bucket, stick, and boom prediction. These two images are in the testing dataset. We also evaluate the Euclidean distance between the predicted joint location and the ground truth joint location, and the error percentage of the predicted component length and the ground truth, which can be seen in Table 1 and For the error percentage of the predicted component length and the ground truth, we only evaluated the lab dataset because the length of each robot arm component is known but the real site excavators are unknown. The result is shown in Table 2. The error percentage of the boom and stick is about 35% to 45%, and the bucket is 62%. The reason for the high error percentage in the bucket case is the occlusion issue. When the bucket is blocked or out of range, the predicted bucket location will be far away from its true location. In addition, the ground truth length of the bucket is short, which increases the differences between the ground truth and the false predicted result. Figure 9 shows two results of false prediction caused by occlusion.

Table 2. The average Euclidean distance between the lab testing dataset and ground truth is 50.05 pixels and between the real site testing dataset and the ground truth is 71.95 pixels. The bucket location has the highest error because the bucket is blocked (occluded) or out of range in some of the image. The model still tries to find the location in these cases, which increases the error

distance. The error in the real site dataset is higher than the lab dataset. This is because the real site dataset has a greater variety of excavators and backgrounds. Only some of these variations were included in the testing dataset, so this caused a decrease in accuracy.

Table 1. Results of the average Euclidean distance (pixel-wise) between the predicted and the ground truth joint location.

(pixels)	Lab Dataset	Real site dataset
Boom	42.01	67.12
Boom Stick	45.37	59.99
Stick Bucket	44.68	65.67
Bucket	68.13	95.03

Figure 8. The result of the excavator pose estimation. On the top is the simulated excavator and on the bottom is the real excavator.

For the error percentage of the predicted component length and the ground truth, we only evaluated the lab dataset because the length of each robot arm component is known but the real site excavators are unknown. The result is shown in Table 2. The error percentage of the boom and stick is about 35% to 45%, and the bucket is 62%. The reason for the high error percentage in the bucket case is the occlusion issue. When the bucket is blocked or out of range, the predicted bucket location will be far away from its true location. In addition, the ground truth length of the bucket is short, which increases the differences between the ground truth and the false predicted result. Figure 9 shows two results of false prediction caused by occlusion.

Table 2. Results of the error percentage of the predicted component length and the ground truth.

(%)	Lab Dataset
Boom	46.8
Stick	34.3
Bucket	62.8

Figure 9. The result of the false prediction, both are out of range (top) or blocked (bottom).

Based on the evaluation results, occlusion is the primary issue of the proposed system, which can be tackled by increasing the number and variety of the training dataset. Another problem is the multiple excavator situation. The proposed system can only identify one excavator pose. If there are two or more excavators in the image, the result will fail. We will design a new network or method for multiple excavator situation in the future work.

5 Conclusion

In this research, we proposed and evaluated a vision-based marker-less pose estimation system for construction robots, for which we used an excavator as our test-bed. The excavator boom, stick, and bucket joint positions are estimated with pixel-wise coordinates. We adapted and modified the state-of-the-art human pose estimation convolutional network, i.e., the stacked hourglass network, for our application. Three stacked hourglass modules and two residual links are included in the network. The network model is trained on an excavator dataset, which we collected and annotated from a factory setup lab environment with a KUKA robot arm representing an excavator from a real construction site. The results showed that the system can estimate the boom and stick joints but had higher estimation error for the bucket location due to the occlusion issue. Therefore, for the future work, more training image data with higher variety will be collected. We will also modify the proposed network to adapt to the multiple excavator situation. The comparison between the proposed system and the sensor-based system will be conducted as well.

Abstract -

This paper discusses the results of a survey regarding state of the art and possible future opportunities for the application of robotic technologies in the construction industry. The survey was conducted by submitting two distinct questionnaires to Arup's[1] most experienced technical and business leaders. The first questionnaire was designed in order to understand the state of the art of robotic technologies in the construction industry, while the second one aimed at identifying promising application scenarios from both the industry and the research point of view. The paper discusses how the questionnaires have been designed and presents the corresponding results.

Keywords -

Robotics; Construction industry; Construction Robots;

1 Introduction

The first applications of robotic technologies to the construction industry were designed in Japan during the 70's, in order to improve the quality of prefabricated elements for modular residential buildings. Since then, robots started spreading in the construction industry, slowly moving from factories to actual construction sites [1, 2, 3]. Differently from other industry fields, where the introduction of robotics technologies radically changed the way human workers operate, the construction industry has not fully experienced its "robotic revolution" yet. As a result, various operations that require high power and/or high accuracy (such as panel positioning, plumbing, material handling) are still manually performed by human workers in very inefficient and dangerous ways. Not by chance, some studies strongly suggest that productivity in the construction industry has been declining over the last decades [4] and that the conventional construction paradigm has reached its technological performance limit [5]. Even though the barriers that are preventing robots to spread within the construction industry are well known, some recently emerged trends started fostering the adoption of novel technologies.

As far as scientific research is concerned, there is no doubt that also the robotics community has demonstrated a growing interest towards applications in the construction industry in the last 15-20 years. Not by chance, the number of scientific publications targeting construction scenarios has experienced a significant growth over the last two decades, as it is demonstrated by Figure 1. From the application point of view, these scientific publications have confronted almost every construction-related application context. Naturally, heavy-duty operations have been tackled, like for instance façade installation [6, 7, 8], forestry [9], mining [10] and generic earthworks [11, 12]. Several solutions have also been developed in order to facilitate inspection of buildings and infrastructures [13, 14, 15]. Finally, in accordance with the trends that will be introduced in the following sections, more recent contributions tackled novel application contexts like for instance realization of wooden buildings [16], interior and exterior renovation [17, 18, 19, 20], additive manufacturing [21, 22] and also decommissioning of nuclear power plants [23, 24].

On the other hand, as far as research topics are concerned, construction-related contributions have explored both consolidated and recent topics in the robotics field: inverse kinematics calculations [25, 26], control architectures [27, 28, 29], trajectory planning algorithms [30], teleoperation strategies [31, 32], Human-Machine Interfaces (HMIs) [33, 34], autonomous vision [35, 36], [37], usage of Unmanned Aerial Vehicles (UAVs) [38]. Another topic that is worth mentioning is represented by the integration with Building Information Modelling (BIM) [39, 40, 41].

Given this scenario, it is clear that both a thorough review of the state of the art of robotic technologies in the construction industry and a detailed assessment of their implementation at different stages of the construction process could be beneficial to identify future research directions and to steer future development activities. With this in mind, the authors realized a survey in order to (i) draft a detailed picture of the state of the art, (ii) identify promising application contexts from both the industry and the research point of view and (iii) underline what skilled professionals expect from robotic technology in the con-

struction industry. In detail, the survey has been realised by submitting two distinct questionnaires to Arup’s most experienced technical and business leaders. The first questionnaire aimed at defining the current scenario, while the second one aimed at identifying possible future opportunities. This paper discusses how the questionnaires have been designed and presents the corresponding results. Section 2 deeply discusses barriers, drivers and trends that are influencing the adoption of robotic technologies in the construction industry. Then, Section 3 introduces the first survey and presents the corresponding results, while Section 4 describes the methodology and the results of the second survey. Finally, Section 5 reports some hypothesis regarding future opportunities.

2 Robotics in the Construction Industry

As mentioned before, the spreading of robotic technologies within the construction industry has historically encountered strong resistance, due to several well known barriers. Nowadays the situation is rapidly changing thanks to some recently emerged drivers that are accelerating innovation processes within the construction industry. Moreover, these drivers originated some clearly recognizable trends that are changing the way buildings are planned, built and maintained. In the remainder of this Section these barriers, drivers and trends are explained in detailed.

2.1 Barriers

The main factors that have prevented the spreading of robotic technologies in the construction industry can be listed as follows:

- **Site-related Challenges**: the inherently unstructured nature of construction sites prevents straightforward integration of robotic technologies already used in factories;
- **Sceptical Attitude**: the main stakeholders involved in the process (construction companies, clients and regulatory bodies) are characterized by a strong tendency to stick to well consolidated practices rather than to innovate and adopt novel technologies;
- **Complexity of the Supply Chain**: the number of different stakeholders and the fragmentation of the supply chain entails a strong inertia towards innovation due to extremely varying interests and needs;
- **Variety of the Markets**: regional markets have intrinsic differences (regulations, cost of materials, cost of workforce, quality requirements for products, etc.) that imply different requirements;
- **Variability of Buildings Typologies**: every building can be considered as unique due to the many differences that apply to its shape, materials, components used and locations. Consequently, flexible and easy to adapt technologies are required.

2.2 Drivers

Moving to the drivers that are fostering innovation processes within the construction, the following ones were identified:

- **Scarcity of Resources**: cost of materials traditionally used for construction purposes is increasing, while availability is decreasing;
- **Urbanization**: in order to build within densely populated urban areas it is necessary to rationalize the way buildings are designed and to employ compact and flexible machines in the construction process;
- **Ageing Workforce**: construction workers are rapidly ageing and technologies that can reduce physical effort and fatigue will be increasingly needed;
- **Connectivity and Convergence**: construction workers are becoming more and more used to new technologies, thus making it easier for them to adapt to the introduction of robots in their workplace;
- **Environmental Friendliness**: construction sites will need to progressively reduce polluting emissions, thus fostering the diffusion of electric powertrain systems;
- **Safety**: safety-oriented technologies will play a crucial role in reducing the number of accidents and injuries, in line with latest safety regulations.

2.3 Current Trends

Finally, robotics-related trends that are currently gaining momentum in the construction industry include:

- **Additive Manufacturing**: 3D printing simultaneously allows to rationalize the consumption of resources and to customize products to specific needs;
- **Internet of things**: the possibility to continuously acquire and share data is enabling novel paradigms, like for instance remote control of machines and predictive maintenance;
- **Integration with BIM**: the availability of 3D and 4D (time) information models will foster robotization of construction sites by making all the design information and the data collected on-site available in real-time to construction robots. As a result, quality of planning, construction and maintenance processes will increase, while execution time will decrease;
- **Augmented an Virtual Reality**: integration of AR an VR will improve training strategies and allow effective remote operations of robots [42, 43, 44];
- **Circular Economy**: construction industry is moving from a linear consumption model (use-consume-dispose) towards a circular one (use-recover-recycle). In this context automation and digitalization will act as key enablers.

3 First Survey: State of the Art for Robots in Construction

The first survey aimed at understanding the current occurrence of advanced construction machines and robots in key construction sectors, through the life-cycle of a project. To do so, a decomposition of the construction process life-cycle has been proposed, as well as six different application sectors have been prioritized for the investigation.

3.1 Construction Process Life-cycle

The default life-cycle of a construction project can be decomposed into the following main phases (see also Figure 2):

- **Site investigation**: this phase includes any action to assess the status of a construction site both for existing buildings/infrastructures and new built. It could include scanning of a building interior, inspection of basements as well as geotechnical survey;
- **Demolition**: this phase includes the set of actions needed to demolish a portion or a whole of a building/infrastructure. Might also include disassembly when possible and requested by the project;

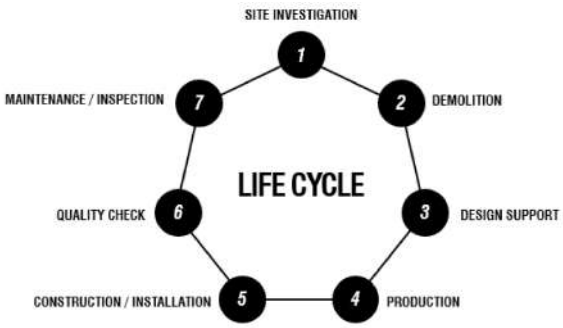

Figure 2. Construction Process Life-Cycle.

- **Design Support**: this phase includes actions to allow a more precise and actual design process, allowing the designer to know more details about any pre-existence at building/infrastructure or site level;
- **Production**: this phase includes the set of actions performed in the making at either the component or at the system level. For the purpose of this paper, we refer to production specifically for in-factory processes;
- **Construction / Installation**: this phase includes the set of actions performed during either the construction or the installation of a building/infrastructure portion or its whole. For the purpose of this paper, we refer to construction and installation referring to on-site processes;
- **Quality Check**: this phase refers to the actions performed at completion of the construction and installation process to assess the quality and the right execution of the process;
- **Maintenance / Inspection**: this phase includes the set of actions to assess the status of a building/infrastructure until its end of life.

These phases are seen as the most meaningful, and those ones where a construction robot could have a significant impact.

3.2 Priority Sectors for Application

On the basis of their experience and market knowledge, Arup's experts identified a set of high priority sectors for application in construction to be investigated within the survey. As shown in Figure 3, these sectors are:

- **Building Cladding**: this sector includes all the parts (components and systems) used at the level of the building envelope being this of any size, form and complexity, from small rain-screen panels to large unitized façade panels;

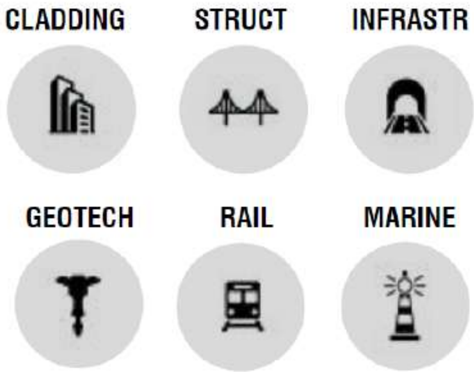

Figure 3. Priority Sectors for Application.

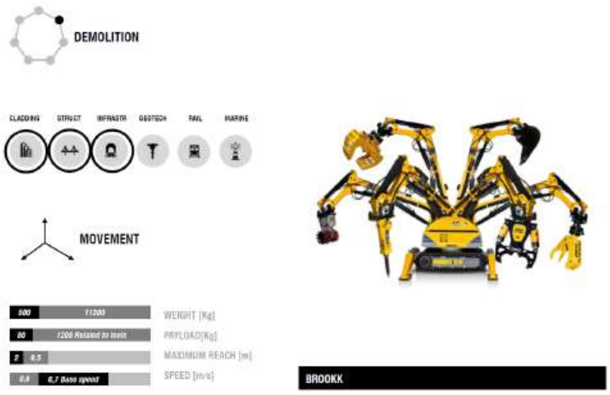

Figure 4. First Survey: remotely operated demolition machines produced by Brokk.

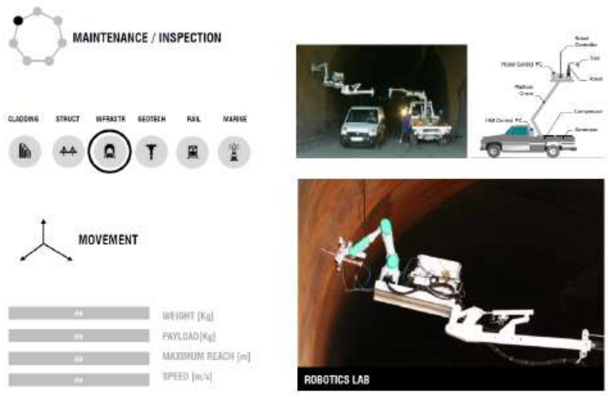

Figure 5. First Survey: Tunnel inspection robot developed by Universidad Carlos III de Madrid.

- **Building Structures**: this sector comprises all the parts (components and systems) used to provide adequate structural performance to a building;
- **Infrastructures**: for the purpose of present research, we considered this as the sum of the parts (components and systems) used to make a tunneling project;
- **Geotechnical Engineering**: for the purpose of present research, we considered this as the sum of the processes necessary to perform surveying and construction of underground areas or parts of a building/infrastructure;
- **Railway**: for the purpose of present research, we considered this as the sum of the parts (components and systems) used to make a railway project;
- **Marine Engineering**: for the purpose of present research, we considered this as the sum of the processes necessary to perform surveying and construction of marine and cost areas or parts of a submerged building/infrastructure.

3.3 Examples of Case Studies

In order to clarify the methodology used to conduct the survey, two distinct case studies have been reported here. The first example refers to the line of remotely operated demolition machines realized by Brokk[2]. Figure 4, shows some data regarding weight ($500 - 1300\ kg$), maximum payload ($80 - 1200\ kg$), maximum reach ($2.00 - 9.50\ m$) and travelling speed ($0.60 - 0.70\ m/s$) of the different machines. More interestingly, the diagram also reports the result of the survey in terms of mapping between the specific case study and life-cycle phases (in this case only demolition), and between the machine and the corresponding sector (cladding, structural and infrastructural engineering).

[2]Brokk's website: `http://www.brokk.com/`

A different case study is described by Figure 5, where an example of tunnel inspection robot is considered. Clearly, this case study robot has been matched with the maintenance/inspection phase and with the infrastructural engineering sector.

3.4 Survey Results

During the survey a total of 52 construction robots have been identified and categorized by Arup's consultants. Figure 6 shows the final results of the investigation from a tow-fold perspective. In the heptagon on the left, case studies were mapped to the different phases of the construction life-cycle. Data show that the vast majority of currently available construction robots are strongly focused on maintenance and installation tasks. As far as inspection tasks are concerned, the spreading of robots is almost surely due to the possibility to take advantage of high position accuracy in order to automate repetitive and specific tasks. Moving to installation tasks, the possibility

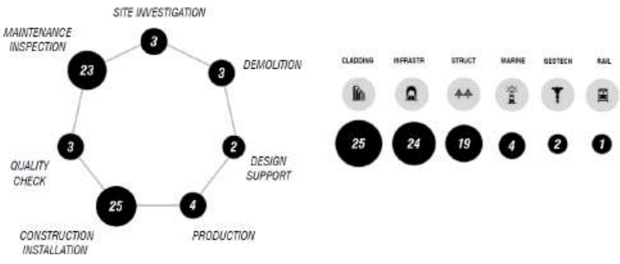

Figure 6. First Survey: overall results.

to move relatively low (high) payloads with high (limited) accuracy is particularly appealing. Notably, the survey identified a low number of robotic applications in the design support, production and in the quality check phases. This is possibly due to some of the aforementioned barriers: sceptical attitude towards new technologies, complexity of the supply chain and heavily unstructured nature of on-site operations.

Moving to the diagram on the right, where the identified case studies were mapped to the considered application sectors, it can be seen that several robots were found in the cladding, infrastructural, and structural sectors, while very few examples exist in geotechnical, railways, and marine engineering. A possible interpretation of these data consists in relating the number of technologies with the features of the corresponding working environment. In other words, the more the environment is unstructured and exposed to dust and weather conditions, the more difficult it is to realize robust and effective robots. It is worthwhile to mention that, as shown in Figure 4, a single robot can be mapped to one life-cycle phase (application sector) or more.

4 Second Survey: New opportunities in the construction industry

The second survey had a different ambition, namely to identify where the highest potential is currently seen within the building life-cycle and according to the six priority sectors identified before. To reach this goal, Arup's experts have been asked to assign a score to the relevance of robotic technologies, in the specific sector, at a specific life-cycle stage. Possible scores were:

- **High**: 3 points;
- **Medium**: 2 points;
- **Low**: 1 points;
- **Not Applicable**: 0 points.

Then, they were requested to evaluate, in each sector and using the same scale, the impact of robotic technologies on the following key indicators:

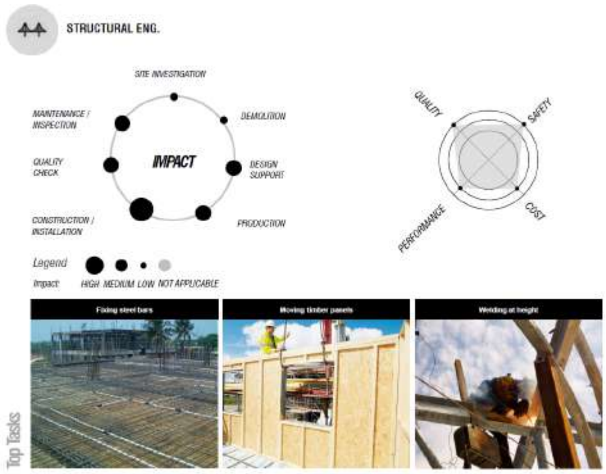

Figure 7. Second Survey: Structural Engineering sector.

- **Quality** of the construction;
- **Safety** within the construction site;
- **Cost** for the operations;
- **Performance** of the construction.

4.1 Examples of Application Sectors

In order to demonstrate how the authors conducted the second survey, data regarding two different application sectors are detailed in the following. The first one pertains the structural engineering sector. As it can be seen in Figure 7, the impact of novel robotic technologies in this sector is considered as "high" in the construction / installation phase, "medium" in design support, production, quality check and maintenance phases, and "low" for all the other phases. Arup's experts also evaluated a high impact in terms of safety and quality metrics, and a medium impact on cost and performance. As far as types of operations are concerned, some promising tasks identified in this sector are fixing of steel bars, placing of wooden elements and welding at height.

A different example is displayed in Figure 8, where the infrastructure sector is analysed. The impact of innovative technologies has been considered as "high" in almost all the phases, except production ("medium") and site investigation ("not applicable"). As far as key indicators are concerned, the result is the same with respect to the previous example. Finally, the most interesting tasks to automate are concrete spraying, tunnel inspection and tunnel boring.

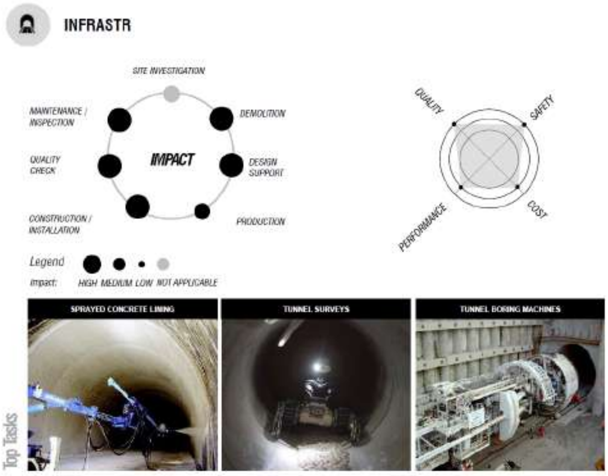

Figure 8. Second Survey: Infrastructure sector.

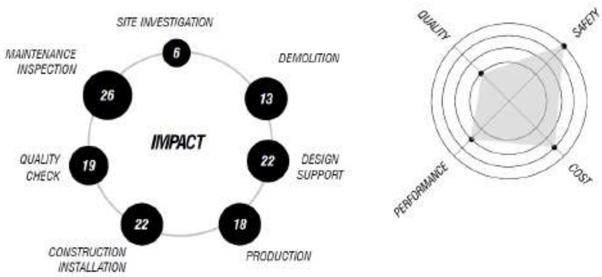

Figure 9. Second Survey: overall results.

4.2 Survey Results

In order to sum up the results of the second investigation, the two diagrams contained in Figure 9 have been realized. The one on the left shows the overall relevance of hypothetical new robotic applications to be implemented at the different stages of the construction life-cycle. Global scores have been computed by averaging the total scores assigned to each life-cycle stage over the different application sectors. Having in mind the results of the first survey (see Figure 6), the fact that maintenance and installation are confirmed to be the top-two phases comes at no surprise. Furthermore, the fact that a significant potential has been identified in the design support, production and quality check phases is in line with the conclusions of the first investigation. Finally, also demolition has been judged as an appealing stage since, in the context of a circular economy, the idea itself of demolition changes from destruction to de-construction, thus making position accuracy a valuable advantage.

On the other hand, the diagram on the right shows the average score assigned to each key indicator. According to Arup's experts, novel robotic technologies will have a substantial impact on safety and cost (which is quite straightforward). On the other hand, a lower impact is foreseen in terms of quality and performance, mainly because the capability to deal with heavily unstructured environments is still an open issue from both the research and the industry point of view.

5 Conclusions

This paper presents a survey activity aimed at defining a clearer picture of the current scenario of robotic in the construction industry. The investigation also intended to identify future opportunities for research and development activities. The survey involved Arup's most experienced technical and business leaders and was performed by means of two distinct questionnaires. The paper motivates the design of these questionnaires, presents some example of detailed analysis and discusses the overall results. In the end, Arup's experts identified demolition, design support, production and quality check as the construction phases where new robotic technologies could have larger impact in the next few years, in terms of improved safety and reduced costs and across several application sectors. Clearly, in order to develop such machines, the capability to robustly perform complex tasks inside heavily unstructured environments remains the most demanding challenge to tackle from the research point of view.

Recognition and Positioning of SBCs in BIM Models Using a Geometric vs Colour Consensus Approach

A. Adán, B. Quintana, S. A. Prieto

3D Visual Computing & Robotic Lab, University of Castilla La Mancha, Spain
E-mail: Antonio.Adan@uclm.es, Blanca.Quintana@uclm.es, Samuel.Prieto@uclm.es

Abstract –

This paper proposes a new approach that recognizes different kinds of small objects that are commonly seen on walls and ceilings of buildings (Figure 1). The general idea supported in this paper is that such objects, called service building components (SBCs), should be inserted into the structure of the standard existing as-is BIM models, as they are automatically generated. But identifying these small building components within the vast dataset provided by the scanner is a difficult issue not solved yet. Our approach first processes a dense coloured point cloud and extracts global geometry and colour features to identify potential SBCs. A novel consensus algorithm between geometry and colour features is the basis to efficiently recognize and calculate the position of the existing small objects in the as-is BIM model of the building. The method has been tested in real and simulated environments providing encouraging results.

Keywords –
Object recognition; Scan-to-BIM; Automatic BIM; 3D data processing.

1 Small building service components: the last semantic level of a BIM model

Many researchers are currently working on the automatic creation of as-is BIM models at several semantic levels. This paper is framed into the methods that automatically obtain some sort of 3D building model from 3D data. Nowadays, and roughly speaking, we can distinguish between four semantic levels which go from a mere point cloud model to a detailed 3D CAD model of the building structure.

The first semantic level covers the set of automatic data acquisition algorithms that provide a rough point cloud of the building. This model usually has a poor-semantic content and most of the research efforts are focused on finding an efficient scan planning algorithm, which provides a complete dataset of the indoors [1], [2] or outdoors [3] of buildings.

Figure 1. The image represents a coloured point cloud and different objects recognized in a wall. Apart from the doors, our recognition algorithm identifies five service building components.

The second level is achieved after processing the initial point cloud of the scene. The data are usually segmented into a set of representative parts, which follows specific geometric patterns (e. g. vertical/horizontal flat regions), and the scene is finally represented by a B-rep model. Essentially, this is a polyhedral model with certain attributes (i.e. vertex, edge and face) and their corresponding relationships. Works at this level can be found in [4], [5].

In the third level the segment extracted in the second level are recognized as essential constructive elements of the building. This is a higher semantic level in which a meaning of the earlier data segments is introduced. At this level, the model contains primarily objects such as “wall”, “ceiling”, “floor” and “column” ([6], [7]).

The fourth level completes the previous level by adding other important elements which lie in the constructive elements, such as windows, doors and frames. Examples of models at this level are that of references [8]–[10]. Other works include pipes or scaffolding in the BIM models of industrial facilities ([11], [12]).

Beyond the fourth level, there are more components of a building that could be introduced in the BIM model as permanent or as-designed components. These small components are related with the habitability of the building, mainly related with power and security issues. As is argued in the abstract, from a constructive point of view, these components might have a relative importance, but are however essential for a safe and reliable life of the inhabitants of the building. Therefore, we propose a fifth level that includes such components which, from here on, we call service building components (SBCs). Previous work in the detection of SBCs is dealt in the next section.

2 Detection of SBCs: previous work.

Very few proposals achieve this level of detail in a 3D semantic building model and only partial solutions that recognise luminaries, sockets or other particular SBCs have been published to date. In addition, most of these works are framed in robot interaction applications.

Specific electrical equipment can be easily detected in thermal point clouds. For example, in [13] hot and cool regions are detected on ceilings. These regions are assumed to be electrical systems, heating, ventilation and air-conditioning components.

In [14], Díaz-Vilariño et al. process 2D coloured images of ceilings and identify two types of light fixtures. It is assumed that the segmented regions correspond to these objects, so that there is no proper recognition algorithm. Sockets and switches are also recognized in 2D images in [15]. Eruhimov et al. ([16]) classify between power holes, ground holes and the background in images acquired by a mobile robot. Meeussen et al. ([17]) recognize doors, door handles, electrical plugs and sockets, also under robotic applications.

Some authors provide more encouraging results. In [18], insulations, electrical outlets, studs and different states for drywall sheets are detected in 2D images. Unfortunately, the recognised objects are not positioned into a 3D model of the facility. The sensorial system presented by Bonanni et al. in [19] identifies - with the help of a human being- a set of usual small components, such as electrical outlets, fire extinguishers, hydrant boxes and printers. This is again a part of a human-robot system which is not related with the extraction of semantic models of buildings. The recognised small components are not therefore integrated into a 3D building model.

As is clear, the aforementioned SBCs detection methods are frequently associated with the recognition and pose estimation of objects in 2D images, which is not connected with an as-is semantically-rich 3D model of the building.

3 Justifying a new SBC recognition method in a BIM framework.

Recognition of SBCs in the BIM context is a difficult problem in which the origin and quality of the data to be processed plays an important role.

As is known, in general the problem of recognizing objects in 2D images has been extensively studied for many years and multitude of efficient solutions - including SIFT, SURF and others - have been proposed. All these algorithms commonly work on high quality images taken from medium/high resolution cameras, which signifies that the objects appear clear enough, with sufficient resolution and without significant superimposed noise. Nevertheless, object recognition in 2D images is restricted to merely identify, but not to estimate the position of the object in the 3D space (i.e. into a 3D indoor model).

Additionally, these techniques could yield frustrating results when applied to the raw scan data (the kind of data used for the construction of as-is 3D models), more precisely to the orthoimages generated from a coloured point cloud. Note that a balance between the resolution of the collected point cloud, the associated memory and the time requirements must be imposed in a building scanning process. On the other hand, in order to avoid occlusions, several scans must be taken (and later aligned) from different scanner positions. All this entails imprecisions on the coordinates of the registered data along with slight variations in the colour assigned to the surface of the potential SBCs (which have been viewed from different angles). Consequently, the orthoimages generated from the accumulated coloured point cloud are frequently, if not always, noisy and of a low resolution.

In practice, our automatic building scanning system generates orthoimages of 5mm/pixel. This resolution is achieved with an angular stepwidth of 0.065º, which yields 10 million points in 83 seconds per 360-scans. Of course, we can force the scanner up to a stepwidth of 0.0024º, but in this case, the system would become impractical.

To recognize a query (small) object in such a poor quality and low-resolution image (in fact, it is an orthoimage), new recognition methods need to be applied. The contributions of our approach lie in two pillars.

First, the geometry and colour data contained in the coloured point cloud are separately processed. Afterwards, the corresponding results are put in common by following an original consensus procedure. This is the most important issue of the paper, which is explained in detail in Section 4.

The second pillar consists of avoiding local features and descriptors in the recognition algorithms. Since the orthoimages might appear blurred and with a poor colour quality, we define a supervised learning algorithm that uses a pattern composed of global descriptors, which are invariant to scale and rotation. In the experimental section, we briefly refer to a particular feature pattern that has provided encouraging recognition results.

Figure 2 illustrates the poor quality and low resolution of the SBCs' images contained in the orthoimage of the frontal wall of Figure 1. Note the poor quality of the fire-alarm switch image with 26x26 pixels in size (13x13 cm).

Figure 2. Images corresponding to BSCs in the scene shown in Figure 1.

4 A consensus framework for SBC recognition

4.1 Assumptions and inputs

The objective of this paper is not to explain specific recognition algorithms, but to propose a new approach that identifies and calculate the position of SBCs by means of a consensus between geometric and colour-based recognition strategies. We therefore present a consensus approach by assuming that a number of 3D processing stages have already been completed.

Let us consider that previous pre-processing stages, such as data collection, registration, colour fusion and initial data segmentation have successfully been carried out. Let us also assume that the accumulated point cloud has been segmented into the essential constructive elements of the building, including openings. According to the earlier semantic building model classification presented in Section 1, we start our SBC recognition approach on the basis that the fourth semantic level is available. At this level, the coloured point cloud associated with an already detected and modelled wall is therefore available. The reader can obtain complete information about our mobile mapping system for digitization (MoPAD) and our last works on extraction of automatic BIM models in references [20]–[22].

The set of coloured data belonging to a wall is structured as a 4D orthoimage, J_{CD}, in which each pixel has colour (RGB) and depth (i.e. an orthonormal distance between the 3D points and the wall plane). The colour and depth components of J_{CD} are decomposed into J_C (colour) and J_D (depth), and two different geometric and colour-based algorithms are afterwards applied on the respective orthoimages J_C and J_D.

Let us assume that, as a result of the earlier processes, for each expected object O_i, $i = 1 \dots N$, two lists of candidates $\{C\}_{O_i}$ and $\{D\}_{O_i}$are identified in both images J_C and J_D .

4.2 The Recognition Coherence Matrix

Since there could be more than one instance of the object O_i in the wall, after the consensus between the lists $\{C\}_{O_i}$ and $\{D\}_{O_i}$, the output could be composed of several regions (RoIs) located on the wall.

In order to evaluate all possible combinations of $\{C\}_{O_i}$ and $\{D\}_{O_i}$, we define a *Recognition Coherence Matrix* Ψ . Each entry in Ψ_{O_i} is the *Recognition Coherence Level* α, which measures the coherence between a pair of RoIs found in images J_C and J_D . This parameter is ranged in the interval [0,1] and will be defined below.

The flowchart in Figure 3 explains how Ψ is built for each query object, N being the number of SBC classes lying on the wall. Symbols n_C and n_D are formally: $n_C = \langle\{C\}_{O_i}\rangle$ and $n_D = \langle\{D\}_{O_i}\rangle$, where $\langle A\rangle$ represents the cardinal of the set *A*.

The *Recognition Coherence Level* α between two candidates is calculated by assessing the overlap between a pair of RoIs, B_C^j and B_D^k (with centroid coordinates c_C^j and c_D^k respectively) found in the respective images J_C and J_D . There are three cases:

1. Partial Intersection. B_C^j and B_D^k overlap. In this case, α measures the relative overlap with respect to the bounding box B_{CD}^{jk} that encloses B_C^j and B_D^k. The expression of α is given in equation (1).

$$\alpha = \frac{\langle B_C^j\rangle \cup \langle B_D^k\rangle}{\langle B_{CD}^{jk}\rangle} \tag{1}$$

2. No intersection. B_C^j and B_D^k does not overlap. In this case, $\alpha = 0$.
3. Exclusive detection. $\nexists B_C^j$ or $\nexists B_D^k$. In this case, O_i is only recognized in J_C or in J_D, and $\alpha = 0.5$.

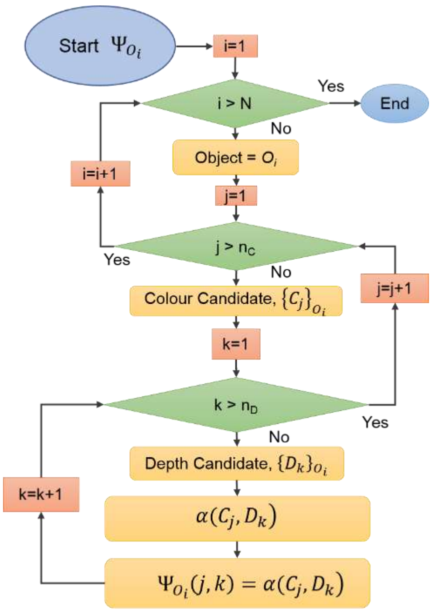

Figure 3. Algorithm for the construction of N *Recognition Coherence Matrices.*

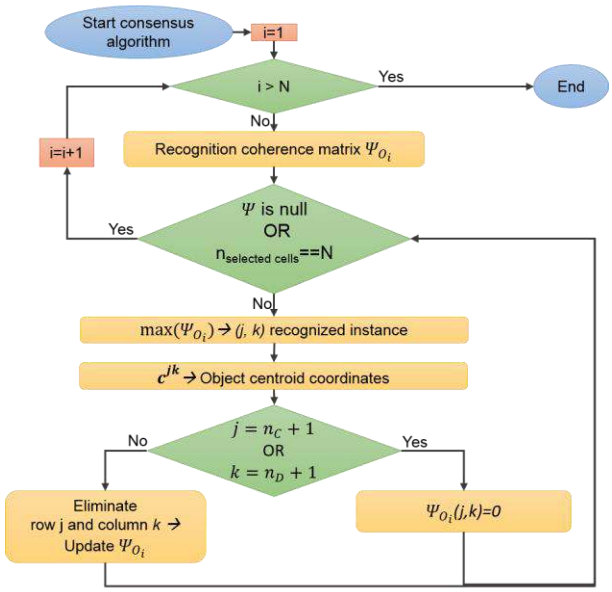

Figure 4. Recognition consensus algorithm.

4.3 Recognizing objects from the Recognition Coherence Matrix

The *Recognition Coherence Matrix* is completed with a new row and column, inserting the value 0.5 on them. The extra row and column are included because, besides the usual assignation of pairs of RoIs candidates, the exclusive detection by colour and depth is always considered in the resolution of the *Recognition Coherence Matrix*. In this way, Ψ_{O_i} is eventually a $(n_C + 1) \times (n_D + 1)$ matrix.

Once Ψ has been filled, the recognition consensus decision is solved iteratively following four steps (see Figure 4 for a better understanding):

4. The highest value of Ψ is selected and considered to be a recognized instance of the query object O_i.
5. The corresponding row and column of Ψ are eliminated, except when the selected cell corresponds to an exclusive detection case. In this case, only the corresponding cell is set to 0.
6. The coordinates of each recognized instance of the object O_i in the orthoimage J_{CD}, are calculated by means of a weighted mean of the corresponding RoIs centroid coordinates, $\boldsymbol{c}_C^j$ and $\boldsymbol{c}_D^k$.
7. Steps 1, 2 and 3 are iterated until Ψ is null or until the number of selected cells is equal to the number of expected instances of the query object in the wall.

Equation (2) shows two weights ρ_C^j and ρ_D^k that are defined depending on the specific geometric and colour based recognition algorithms used when the lists of candidates $\{C\}_{O_i}$ and $\{D\}_{O_i}$are obtained. In our case, we take ρ_D^k as the cross-correlation coefficient, which is obtained when correlating the RoI B_D^k with that of the depth model of object O_i. The weight ρ_C^j is a normalized distance coefficient that evaluates the goodness of the recognition algorithm when comparing B_C^j with the colour model of object O_i. This is a minimum distance classifier algorithm that compares patterns composed of global colour features.

$$c^{jk} = \frac{\rho_C^j \boldsymbol{c}_C^j + \rho_D^k \boldsymbol{c}_D^k}{\rho_C^j + \rho_D^k} \qquad (2)$$

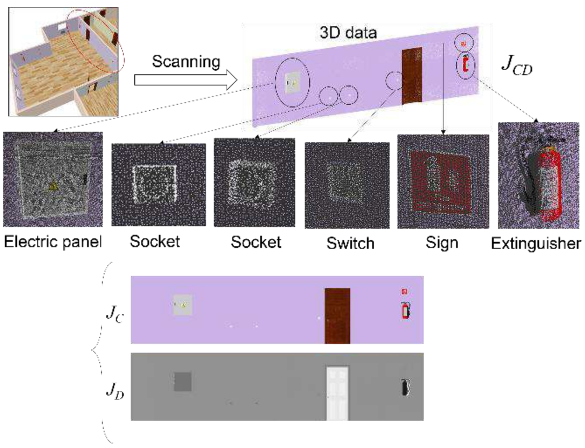
4.4 Showing a case of study

In this section we explain in detail the recognition procedure in a representative case of study. We have simulated the digitization of an indoor floor using the Blensor software [23]. This tool allows us to simulate a scanning process on a 3D building model by using the same scanner we have got in our lab.

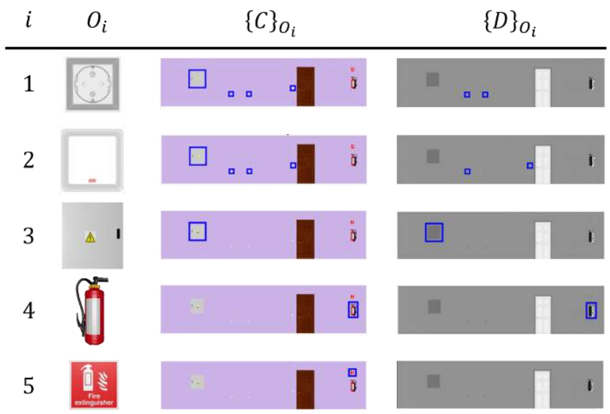
The indoor consists of several rooms with a wide set of SBCs lying on the walls. A representative wall of the room #4 has been taken to run our recognition strategy. This wall contains the following SBCs: an electric panel, two sockets, a switch, a fire extinguisher sign and an extinguisher (Figure 5 a)).

The orthoimage of the wall is decomposed into images J_C and J_D , and then processed separately. The results obtained from the colour and depth-based algorithms yield two lists of candidates $\{C\}_{O_i}$ and $\{D\}_{O_i}$. Figure 5 b) highlights in blue the RoI candidates in images J_C and J_D. Note that the first columns show the colour model of the query objects.

Initially, some surprising candidates are assigned at this stage, particularly in the case of the colour-based recognition. For example, note that the region that contains the electric panel is within the list of candidates of the objects "socket" and "switch". The explanation of this apparently strange result is that we identify the regions in which the query object could be located and, since we use global colour descriptors, the recognition algorithm is invariant to the scale. Obviously, some of the global colour descriptors of the socket could match with that of the regions in which the electric panel lies, and for this very reason, this could be included in the list of candidates $\{C\}_{O_i}$.



a)

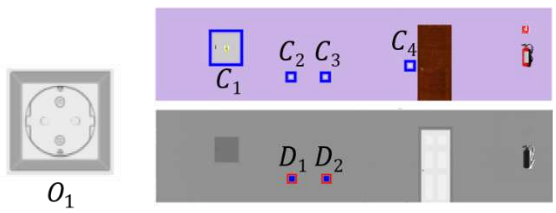


b)

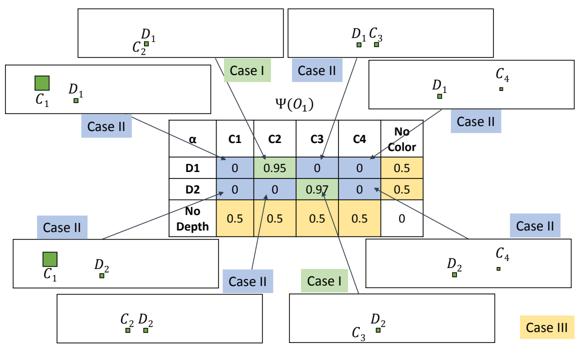
Figure 5. a) up) Representative wall of room #4 and the details of the coloured point clouds of the SBCs obtained from the virtual scanning. Down) Decomposition of the orthoimage J_{CD} into J_C (colour) and J_D (depth). b) The set of candidates $\{C\}_{O_i}$ and $\{D\}_{O_i}$ obtained after applying the recognition algorithms in images J_C and J_D. Candidate regions are highlighted in blue.

Since there are five different objects on the wall, five *Recognition Coherence Matrices* $\Psi_1, \Psi_2, \Psi_3, \Psi_4$ and Ψ_5 must be calculated. Figure 6 illustrates details of the Recognition Coherence Matrix Ψ_1 corresponding to the object "socket". Since $\langle\{C\}_{O_1}\rangle = 4$, $\langle\{D\}_{O_1}\rangle = 2$, Ψ_1 is a 5×3 matrix. The figure shows the positions of the candidates for each assigned pair and, according to the explained in Section 4.2, its corresponding overlapping type. Since we assume two instances of the object "socket" in the wall, the resolution process of Ψ_1 will take two iterations (See Figure 7).

As was explained in Section 4.3, the highest *Recognition Coherence Level* of Ψ_1 is taken as the first recognition result. This happens for the pair (C_3, D_2). The centre of the recognized instance of the object "socket" is then calculated according to equation (2). After deleting the corresponding row and column, the second assignation (C_2, D_1) is established and the same process follows. Since the number of selected cells is equal to the number of expected instances of the query object, the recognition process for the object "socket" comes to an end.



a)



b)

5 Experimental test

This section is devoted to showing the efficiency of the geometric versus colour consensus approach in an experimental test. We simulated an indoor floor composed of 5 rooms containing 116 SBCs of 13 classes (See Figure 8). This scenario was virtually scanned with Blensor [23], which allows us to simulate the same real scanning process as with our Riegl VZ-400 3D laser scanner. In order to make the data acquisition process more realistic, noise to the position and colour of the collected point cloud was added.

The objective of this test is to compare the recognition results using, on one hand, separated colour-based and geometric-based algorithms (algorithm I and II in Table 1) and, on the other hand, the consensus approach (algorithm III in Table 1).

As mentioned in Section 4.3, our geometric-based recognition approach is a simple cross-correlation algorithm that compares the obtained RoIs B_D with that of the depth models of the objects existing on the wall. The colour-based recognition algorithm is a minimum distance classifier algorithm that takes some global colour features, such as the two principal saturation values in the HSV colour-space, the redness versus greenness and the yellowness versus blueness, which are parameters *a* and *b* in the Lab colour-space. Anyway, it is noteworthy to point out that the most important thing here is not in the specific geometric and colour-based algorithm applied, but in the efficiency of the consensus approach.

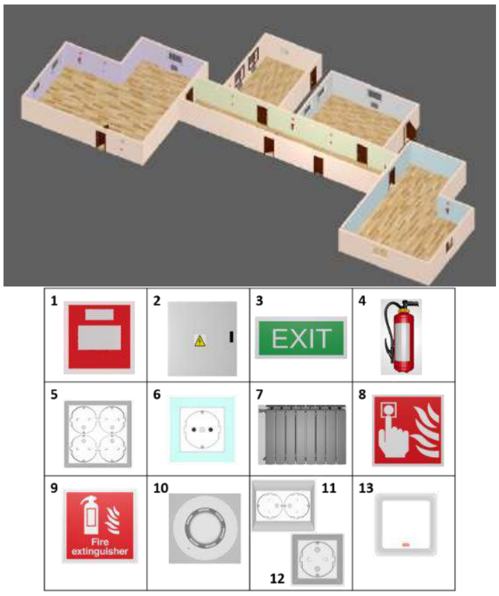

Figure 8. Simulated scenario used in the experimental test and the set of service building components included in the scenario.

Table 1. shows the recognition results after applying the aforementioned algorithms. The table includes the true positive cases (the algorithm recognizes successfully the query object), the false positive cases (the algorithm recognizes an object that is not the query object) and the false negative cases (the algorithm does not recognize the query object). Columns #1 to #5 refer to the five rooms of the scenario, column T is the total count and column Perc. signifies the recognition percentage.

The consensus algorithm achieves the greatest recognition percentages (90,5%) compared with algorithms I (83,6%) and II (41,4%). Although the geometric-based algorithm yields the lowest false positive percentage (5,2%), there is not a significant difference compared to that of the consensus algorithm (8,6%). In addition, the false positive rates are usually considered as the least important numbers in a recognition assessment. However, a more significant improvement can be seen in the figures concerning the false negative percentages. Clearly, the use of our consensus approach reduces the percentages yielded by the colour (16,4%) and the geometric-based (58,4%) approaches.

Figure 9 shows the extracted BIM model and the SBCs recognized after applying our algorithm. In this figure, each red spot represents the centroid of each recognized object.

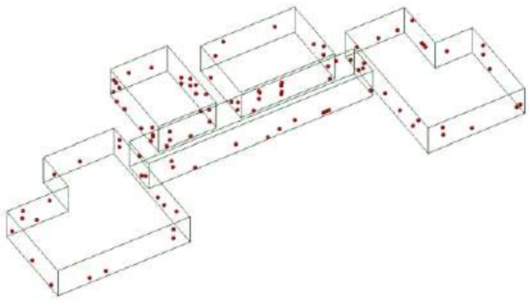

Figure 9. Recognition results superimposed onto the extracted as-is 3D model of the indoor floor. Red spots represent the recognized objects.

Table 2. provides more information about the false negative percentages for each one of the existing SBCs. In general, it can be stated that the objects with low-frequency colour/intensity components in the frequency domain (i. e. flat colour RoIs) are hardly detected by method I. Thus, the fire alarm switch (O_1), the electric panel (O_2) and the smoke detector (O_{10}) are not recognized in half of the cases. In regard to the method II, owing to the lack of depth discontinuity with respect to the wall, the regions with signs (e.g. O_8, O_9) and built-in sockets (e. g. O_6) are not detected as potential RoIs.

Note that the consensus algorithm decreases (or at least it is equal) the false negative percentages in all the cases. Significant improvements appear for the extinguisher (O_4), the socket x4 (O_5) and the smoke detector (O_{10}), in which both algorithms I and II fail. In O_4 and O_5, the false negative cases are eliminated and, in the case of O_{10}, the percentage in reduced up to 20%.

Table 1. SBC recognition results for the colour-based algorithm (I), the geometric-based algorithm (II) and the consensus approach (III). T=Total, Perc.=percentage

Algorithm		#1	#2	#3	#4	#5	T	Perc.
I	TP	20	24	18	21	14	97	83,6
	FP	4	1	5	5	1	16	13,8
	FN	4	3	5	5	2	19	16,4
II	TP	12	6	12	10	8	48	41,4
	FP	1	0	0	3	2	6	5,2
	FN	12	21	11	16	8	68	58,6
III	TP	23	25	21	22	14	105	90,5
	FP	1	1	2	4	2	10	8,6
	FN	1	2	2	4	2	11	9,5

Table 2. False negative percentages obtained per object.

Alg.	O_1	O_2	O_3	O_4	O_5	O_6	O_7
I	50,0	50,0	0	11,1	27,3	16,7	0

III	37,5	25,0	0	0	0	16,7	0
Alg.	O_8	O_9	O_{10}	O_{11}	O_{12}	O_{13}	Total
I	25,0	11,1	50,0	0	0	0	16,4
II	100	100	30,0	0	70,0	25,0	58,6
III	25,0	11,1	20,0	0	0	0	9,5

6 Conclusions

As is known, electric components (e. g. sockets and switches), fire devices (e. g. fire alarms and extinguishers) and a diversity of signs (e. g. exit signs and prohibition signs) are frequently placed inside the buildings, constituting a further but necessary part of the building. These small components, mostly related with the habitability of the building, should be included in the current as-is BIM models of buildings.

In order to recognize and estimate the position of such secondary components, this paper proposes a methodology that takes advantage of the geometric and colour information provided by the current 3D sensors (usually 3D laser scanners). But, owing to the poor quality and resolution of the orthoimages generated from the collected coloured point cloud, the SBC detection and its subsequent integration into the as-is 3D model of the building becomes a difficult problem, which needs to be addressed from new strategies.

The solution presented in this paper separates colour and geometric characteristics and proposes a consensus between the respective separated recognition results. This consensus has been implemented by means of the original concepts *Recognition Coherence Matrix* and the *Recognition Coherence Level*, which allows us to recognize multiple instances of the same object.

The method has successfully been tested on real and simulated data. The results yielded from the experimental work show that SBC recognition rates are greatly improved when our strategy is applied. These improvements signify that the use of the proposed consensus method makes the whole recognition process more robust and effective. In conclusion, our approach recognizes more objects and commits fewer identification failures, thus providing a rich fifth-level semantic 3D model of the building.

Abstract -

In this paper, we propose an approach and workflow in order to detect humans in the environment around a crane with Monocular Images. The considered area is split up into a zone around the crane truck and one around the load. The load will be monitored with an optical zoom camera where we can control the zoom. We discretize the zoom levels and a Convolutional Neural Network for each zoom level is trained. Afterwards a Meta Convolutional Neural Network is trained in order to select the next zoom level. Since there are no public datasets available for this kind of task we propose to generate the needed data with a photorealistic simulation.

1 Introduction

In the construction site environment each human is exposed to many potentially dangerous objects. Common sources for injuries are heavy-duty commercial vehicles. The distribution of accidents in the example of an excavator can be seen in figure 1. As one can see most accidents happen in an area which is not visible to the operator, i.e., behind the vehicle or at the opposite site of the operator.

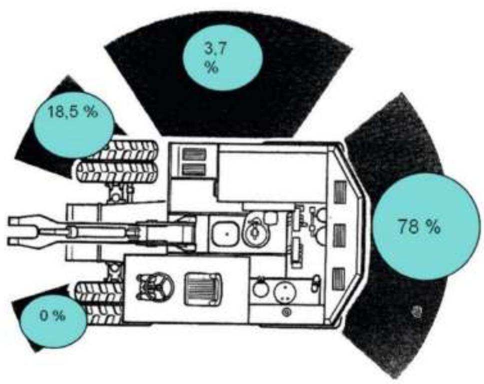

Figure 1. Distribution of fatal and critical accidents with excavators shown in the blue circles[14].

It is, therefore, necessary to support the operator of heavy-duty machines when the area around it is not closed off and humans can appear unexpectedly. Though the problem gets even worse with bigger machines where even bigger areas are occluded by the machine. Therefore there is a need to detect humans in the potential risk areas of a crane, which is definitely one of the biggest machines in a construction site environment. The work presented in this paper is focused on mobile cranes and caterpillar cranes, so specifically tower cranes are not considered. Universal usability for cranes of different manufactures is nonetheless important. We therefore do not make us of the internal crane data. When operating a crane there are two main areas which include a potential threat to humans, one is the crane truck itself and the other is the load of the crane. It is necessary to consider both parts for a reasonable approach.

We therefore propose a methodology which can be used to detect humans around the crane. It mostly relies on already tested *Deep Learning* approaches for object detection. Our methodology does not only detect humans around the crane but also around the load, which is more complicated due to some further restrictions. Additional challenging elements are due to the construction site environment. In road scenarios one can assume that the vehicles are in either a highway, city, urban or metropolitan area, while a construction machinery can operate in a mining field, building site, forest or even rough terrain. The environment effects type and activity of each object that the system is going to encounter during the detection task. One further handicap is that standard approaches for detecting humans around the load are not suitable. Since the shape and material of the load is not known in advance and the load can potentially be moved in a big area, which is also not necessarily planned beforehand. The only remaining possibility is to mount cameras on the crane itself. Because of the sheer size of the crane, off the shelf solutions for detecting humans are not applicable due to unusual perspectives and distances .

In the following sections we describe our approach in detail. The rest of the paper is organized as follows: Section 2 discusses the state-of-the-art of human detection algorithms split it up into the different perspectives which are used in the proposed approach. In section 3 the general structure of the proposed approach is described and again split up in the different zones of interest. Section 4 is considered with the generation of the needed datasets with a simulation tool. Section 5 takes a look at the network architectures chosen in section 3 to solve the detection tasks. Finally in section 6 we recap the proposed methodology.

2 Related work

In construction machines, safety systems mostly conduct without any automatic brake when possibility of a collision occurs. The system simply alarms the operator to brake manually. In some systems, the operator needs to acknowledge the alarm by e.g. touching the monitor screen. Traditionally, safety in construction sites is done by direct manual observation [17]. It mainly uses non vision-based sensors, e.g., RFID tag, ultrasonic or infrared sensors. The sensors can be attached on the workers' helmets or wristbands and inform the crane operator about their position. Due to the characteristics of proximity sensors, these safety systems are unable to predict a person's trajectory and absolute position due to an insufficient detection range. Most vision-based safety systems take advantage of specific cues of a persons appearance. In the construction site environment many such visual features can be used, e.g., hard helmet detection [26], detecting workers from reflective vest [19]. Even though dress code in construction site is strict, some people could unintentionally ignore it or do not realize the risk this poses.

2.1 Crane Truck View

For the detection of humans around the crane most state of the art Convolutional Neural Networks(CNNs) can be used as a basis. The perspectives are quite similar, even though the appearance of most humans is a lot more defined due to the presence of reflective vests and helmets. As a basis we refer for example to [24, 15, 23], which of course does not cover the whole extend of work in the field of human detection.

2.2 Load View

Most Detection algorithms for top view camera systems can be found in surveillance systems. Many different proposed methodologies have been proposed, however, these are not really suited to our needs. These approaches often times make use of the fact that either the camera itself is static [31, 33] or uses distinct features of the background, like a street [3]. Some methodologies use features which are prevalent even in top view images, like the head-shoulder shape [34], which may be different due to helmets or carried objects in an construction site environment. Some also simply try to estimate the number of persons in an image [13, 6]. Most are quite often not build to deal with images from a distance as far as in a crane scenario [22, 6, 30].

Another approach is to use a human detection algorithm which works for the front view case and adapt it in order to deal with different views and scenes [32, 1]. We do not only have to deal with the fact, that there is no fitting approach for our use-case but also no public available dataset. Recent advancements in the usage of simulated data for machine learning have been made in reinforcement learning [18], object detection via CNNs [21], viewpoint estimation via CNNs [20] and segmentation tasks [25]. Hence, there are many possibilities to tackle the introduced task, but additionally to the so far presented state-of-the-art it may be necessary to use domain adaptation techniques in order to improve the results as in [4, 16, 29, 35, 2]

3 Proposed Approach

The application seems to encourage an approach which is separated into the detection around the crane and around the load. In our approach we will follow this idea and deal with both problems in a separate manner. We start with the setup of the sensor system in each case. Afterwards we shortly talk about the used CNNs and how to train them specifically for our application scenario.

3.1 Human Detection Crane Truck

In this subpart of our Application scenario we use a camera setup which roughly looks like presented in figure 2.

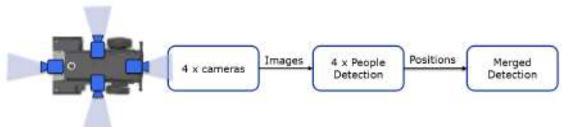

Figure 2. Sketch of camera setup at the crane truck

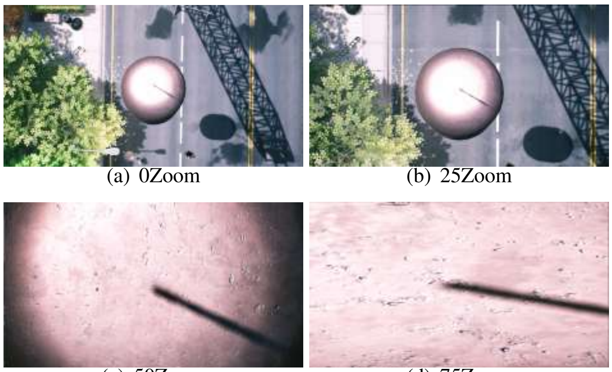
We have a couple of cameras mounted on the crane truck. They look into different directions in order to have the possibility to detect humans in the blind spot of the operator. In the crane scenario the blind spots are not static, due to the revolving superstructure. We are then able to work on each camera image individually and then merge the results. In order to detect humans in each of the images we use a Neural Network. Like already elaborated in section 2, CNNs yield solid performances when dealing with human detection for such frontal views. As for the explicit architecture of the used CNN we refer to [15], since we do not adapt the actual structure to much, still some additional work is needed. Off the shelf trained networks will not yield perfect results since the construction site environment differs from most available training data. Going into a construction site environment and collecting enough labeled data of typical workers to train such a network from scratch is very time consuming. We therefore use a pretrained Network as initialization. Afterwards we apply transfer learning with some examples from construction site environment workers. We also will use simulated data since we will need to generate it anyway, as explained further below. The workflow will be similar to figure 4, but keep in mind that we start with a pretrained network and do not need to train from scratch. With this in hand we have all the necessary parts to combine it into a human detection algorithm around the crane truck.



(a) 0Zoom (b) 25Zoom

(c) 50Zoom (d) 75Zoom

Figure 3. View of different levels of zoom

3.2 Human Detection Load

The detection of humans around the load is more involved. The first problem is how and where to mount the camera system. The possibility of putting, e.g., cameras on tripods on the ground and then merging the images is not feasible due to the fact that the exact trajectory the load will take is often times adapted during the hoisting process. Therefore constant rearrangement of the tripods would be needed, which is not feasible. Another possibility would be to mount a mobile camera below the load, which is only practical with a wireless connection. This is also not feasible due to most loads containing lots of metal parts and therefore greatly interfering with the data transmission. Additionally one needs to consider the fact that a complete hoisting cycle may take up to several hours, which further solidifies the need for a wired connection because of the battery capacity of wireless cameras. So the only possibility which is left is to mount a camera on the crane itself. Of course many cameras could be mounted on the crane boom. We selected the boom top as a first choice, since for other locations at the boom additional need for an alignment with the load is present. This is not the case for the boom top due to the load being approximately perpendicular to the ground.

There are however some other problems arising from mounting the camera on the boom top. A crane can easily reach a height of $100m$, but the boom top may also be close to the ground depending on the hoisting process. So we have to deal with many different perspectives and distances to the ground. This greatly affects the size of the humans in the image. Therefore there is a reasonable necessity for a camera with controllable optical zoom in order to deal with these differing camera heights.

If however one has such a controllable zoom additional effort needs to be made in order to chose the zoom value accordingly. Of course a high zoom value is desirable since then the size of a human in the images is bigger. On the other hand a low zoom value gives us a wider view of the scene. Specifically for the crane scenario an additional limitation is the occlusion due to the position of the load. This occlusion will always be present, so we need to try and optimize the occlusion by adjusting the zoom level accordingly. The optimal zoom level is not only dependent on the pose of the boom but also on the position of the load, see figure 3. We therefore propose the following approach. We split up the zoom levels in discrete parts, for simplicity we here take the zoom levels of $0\%, 25\%, 50\%, 75\%$. For each of the zoom levels we want to individually train a CNN, called $Zoom0$, $Zoom25$, $Zoom50$, $Zoom75$. Each of the networks take images as inputs and we choose the same architecture for each of the networks. Training for each network will be done with its one appropriate dataset. We so to speak need a $DatasetZoom0$, $DatasetZoom25$, $DatasetZoom50$ and $DatasetZoom75$. Since such datasets are not publicly available we follow the workflow proposed in figure 4 for each network individually.

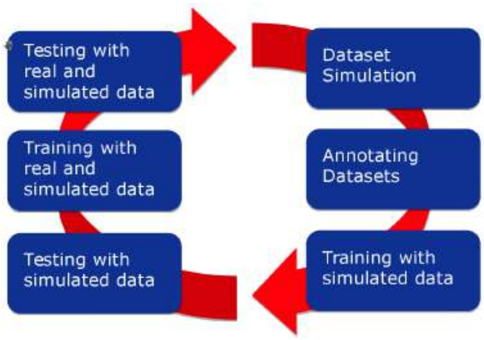


Figure 4. Proposed workflow for each individual network

Assuming this training is finished we take an additional network which we will call MetaNetwork, which differs in its architecture. See section 5 for a closer look at the architecture and the training process. This MetaNetwork will take the current image and the corresponding zoom level as input. Its output is then the proposed number of human each of the four Networks will detect. The idea here is, that the MetaNetwork can, e.g., due to a uniform texture, see figure 3, detect when the zoom level is too high and we have a lot of occlusion. On the other hand the MetaNetwork may notice that only a small amount of occlusion is present, but we are far away from the ground and therefore may say that a bigger zoom level may detect more pedestrians due to bigger humans. Then a deciding algorithm should determine what the appropriate zoom level is and also select the network accordingly. The whole architecture is presented in figure 5.

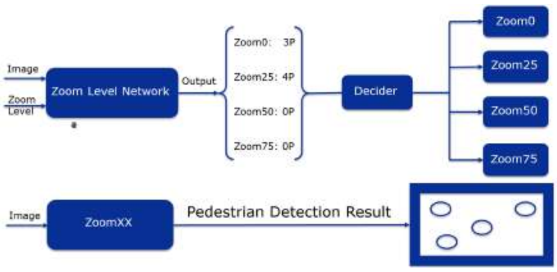

Figure 5. Complete architecture

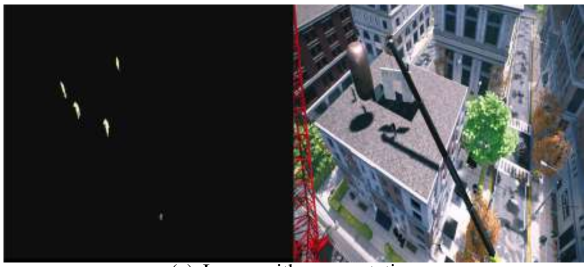
In its easiest form such a Decider could just take the network with the highest proposed number of detected humans. Also more sophisticated versions are possible, e.g., only switch after a certain amount of time has past to prevent constant switching or do not directly switch between *Zoom*0 and *Zoom*75. If all this is put into place we have an algorithm which gives an educated guess which zoom level to choose and then puts a detection network in charge which is specialized to exactly this zoom level.

4 Dataset Generation

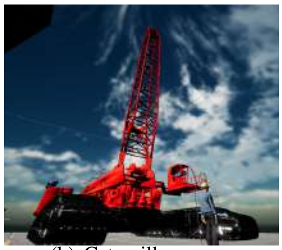
A common problem for Machine Learning in the context of commercial vehicles is the very small number of public datasets. A huge volume of image data is needed. The common datasets and benchmarks which are used in learning process of classification or object detection tasks, e.g., KITTI [12], Daimler [8, 11, 27], Caltech [7], INRIA [5], PASCAL [10], ETHZ [9] are not really applicable to our situation. So in order to generate the needed data we exploit a simulation tool, Unreal Engine 4. The idea of the approach is similar to [28]. Instead of training the human detector using only real-world image data. The Unreal Engine can produce realistic images of a construction site environment e.g different workers, different kinds of weather conditions such as snow, rain, cloud. For such effects see figure 6.

Also different times of day and therefore different lightning conditions are easily simulated. In the case of the construction worker, the tool allows us to create desired character appearance, motion or posture, based on motion capture data. Also different perspectives of the same situation, at the same time are possible. As we will see in section 5 we need to have the exact same situation with different zoom levels in order to get an objective ground truth for training the MetaNetwork. Data gathered in real-life would not be able to fulfill this constraint, since either the timing or the perspective of each zoom level would be slightly off.

The annotation of the synthetic data can be automatically achieved by an object instance mask plugin. In a dataset which is annotated by hand there is always a concern left, that the data may be annotated in a wrong manner. Manual annotation is a tedious task so one can not be sure to, e.g., not miss a human in the image or have slight errors in the localization of an object. All these concerns vanish with the use of automatic annotated data, since the simulation environment knows the ground truth and is therefore inherently objective.



(a) Image with segmentation



(b) Caterpillar crane

(c) Rain and snow

Figure 6. Examples of synthetic data generated from UE4: (a) Hoisting with the appropriate segmentation by the object instance mask, (b) and (c) are scene in construction site.

5 Learning Framework

In the proposed approach a couple of networks are involved. For the detection in each of the zoom levels and around the crane we just use a state of the art object detection network and adjust the trained weights with transfer learning, see [15] for a detailed look on the base architecture. The MetaNetwork needs to be constructed in a different manner. Since it does not only take the image but also the current zoom level as an input we can not simply use a standard architecture but have to adapt to this format. The proposed architecture can be seen in figure 7

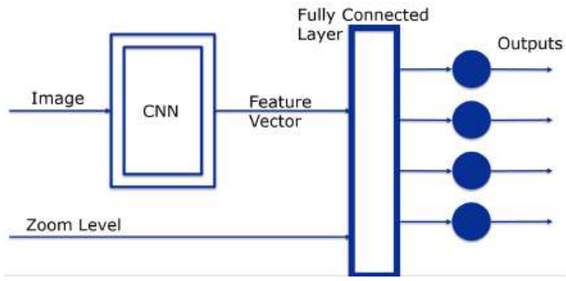


Figure 7. Network architecture of the MetaNetwork

So as we can see we first have a CNN, with nearly the same architecture as in the detection networks for each zoom level. We remove the last layers in order to just pass on the feature vector which is normally evaluated in the last layers of a network. We then connect this feature vector and the zoom level, encoded simply as an integer value, with a fully connected layer. Then the result of this fully connected layer will be given to our four desired outputs. The idea is that this MetaNetwork will deduce similar information as the detection networks but take the current zoom level into account and by that help to chose a suitable network. The training process will differ slightly from a normal CNN. Since the ground truth is the actual number of humans each of the networks detects, the dataset needs to reflect that. Therefore the dataset needs to contain 4 images, one for each zoom level, while the ground truth is the actual evaluation of each image by the corresponding zoom network. Then during training one of the four contained images can be chosen arbitrarily and the zoom level input needs to be passed on accordingly. This means that before we can train the MetaNetwork each of the specialized ZoomNetworks has to be trained sufficiently.

6 Conclusion and Future Work

Let us recap the approach presented in this paper. We defined a sensor setup which is able to detect humans around the crane truck and around the load. This camera setup contains standard monocular cameras and a zoom camera with a controllable zoom. Additionally we presented a CNN structure which is used for each of the mounted cameras individually. Then a meta algorithm, which is itself again a neural network yields a first estimation what an appropriate zoom level would be. According to this estimate the zoom level and the specialized network is chosen. After the proposed approach is evaluated a prototype system which is able to inform the crane operator about humans or other potentially endangered objects entering the working area is being developed

Abstract -

Photovoltaic (PV) solar energy is rapidly growing as an attractive alternative to fossil fuels. PV panels can harvest the solar power and turn it into a clean source of electricity. Traditionally, PV panels are only used on the rooftops of buildings. However, with the emergence of building-integrated solar panels in recent years, other surfaces on the building façade can be considered for the installation of PV panels. Given that different panels have different cost and performance profiles, it is of a cardinal importance to properly design the PV panels on the building facades to ensure a maximum benefit-cost ratio.

Existing simulation and optimization methods do not discriminate between different types of surfaces of the building and treat the building envelope as a set of polygons. This can result in under- or over- design since there is a strong relationship between the type of the surfaces and the type of PV panels that can be attached to them or integrated with them. The advent of Building Information Modeling (BIM) in recent years has provided a rich platform for object-based evaluation and analysis of buildings. Nonetheless, currently, BIM is not used for a detailed and surface-specific simulation of building surfaces.

In this research, a BIM-based method is developed for a detailed simulation of a building envelope using its surface properties. A prototype is developed using Dynamo visual programming platform to demonstrate the feasibility of the proposed method, and a case study is presented for a building in Montreal, Canada. In the light of the result of the case study, it can be concluded that the proposed method is promising in terms of providing the input for a comprehensive planning of the solar panel layout.

BIM; Solar Simulation; Building Façade

1 Introduction

The exacerbating global warming issues, on one hand, and the depleting fossil energy resources, on the other hand, are making the need for sustainable energy resources progressively palpable and vital. As one of the most promising options, photovoltaic (PV) solar energy is gaining growing popularity in recent years [1]. PV energy can be harvested using solar panels, and then transformed into a clean source of electricity that can be used in different industries. According to International Energy Agency (IEA) analysis, solar energy will provide 20-25% of the world electricity supply by 2050 [2].

Buildings account for up to 40% of the total energy use [3]. Therefore, the effective use of solar energy in buildings can tremendously contribute to the reduction of fossil energy. The increasing availability, affordability, and efficacy of PV panels are rendering them an attractive option for use in buildings. Traditionally, PV panels are only used on the rooftops of buildings. However, with the emergence of Building Integrated Photovoltaic (BIPV) in recent years, other surfaces of the building envelop can be considered for the installation of PV panels/films, as shown in Figure 1.

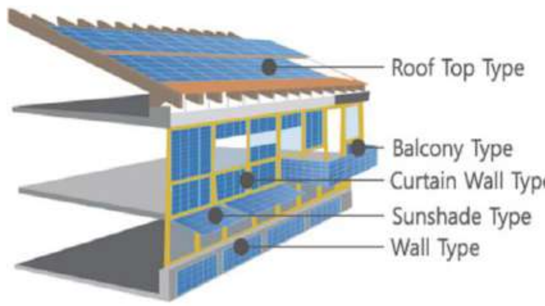

Figure 1. Different types of solar panels that can be used on building envelop

For example, using PV panels on balcony fences, or applying semi-transparent modules for designing glass ceilings or facades can improve the aesthetical aspects [4]. Some PV products such as amorphous silicon tiles can replace the common tiles on roofs. Other PV materials can be applied as shading panels or semi-transparent fenestration films in the design process of new buildings or the renovation of existing buildings. Given that different panels/films have different cost and performance profiles, it is of a cardinal importance to properly design their installation on building surfaces to ensure a maximum benefit-cost ratio.

The ultimate goal of the building solar design is to determine the number, type, location, and orientation of the solar modules on the building exterior surfaces considering the lifecycle cost of the modules. Many researchers have addressed the problem of PV panel layout design and optimization in recent years [5~10]. Nevertheless, the prerequisite to a reliable layout design/optimization is an accurate solar radiation model for estimating the amount of the annual solar energy that each surface on the building envelop can potentially generate [11, 12]. This model should capture the context of a building (i.e., location, orientation, geometry, surrounding buildings and vegetation, season, and weather conditions), to simulate the radiation potential. There are many different approaches for the simulation of the buildings' solar potential [13~17]. However, the majority of the available models work with either (1) 2D footprint of the buildings, or (2) approximated façades generated by the extrusion of 2D footprints. Both of these approaches are suitable for the design of PV panels for the horizontal surfaces (e.g., rooftops), and cannot be used for detailed analysis of vertical surfaces of the building. RADIANCE, Daysim, SORAM, SolarFlux, r.sun, ArcGIS Solar Analyst, and Sky View Factor are some examples of these radiation models [15].

The available methods are not suitable for a detailed planning of PV panels because the accurate 3D representation of the building envelop is not available; and thus, the radiation potential on the actual vertical surfaces cannot be calculated. In recent years, some researchers started to use 3D city models to consider the vertical facades [18, 19]. Nonetheless, while these methods can be used for the 3D simulation of the solar radiation, they are essentially geometric solutions that work with polygons and do not have the specific properties of the building objects. The disadvantage of these methods is that the distinction between different objects on the façade (e.g., balconies, curtain walls, windows, etc.) cannot be made easily. Accordingly, a detailed planning and optimization of PV modules where surface-specific characteristics are considered in a holistic way are not feasible.

On the other hand, the advent of Building Information Modeling (BIM) in recent years has paved the way for the integrated management of building data throughout its lifecycle [20]. Since BIM provides easy access to information of various elements of the building, it can be best used for various types of simulations such as daylight, energy performance, and solar radiation simulations [21~24]. In a recent project, an open BIM-based platform is developed for designing and simulating energy efficient buildings to integrate the simulations in the virtual design office [25]. Also a research project in Germany is trying to integrate the energy active components into the building envelope based on the methodology of the Building Information Modelling [26]. There are several software packages for solar analysis, such as ECOTECT [27] and Insight [28]. However, these packages transform the BIM 3D objects to a polygon mesh. During this process, the semantic information about different objects is lost. As a result, they treat the entire building envelope as a set of polygons with no distinction based on the object types. Consequently, the current tools are not geared toward the surface-specific solar analysis of the building, which is essential for a comprehensive design of PV solar modules.

Accordingly, the main objective of this paper is to develop a method for surface-specific solar simulation of buildings that can later be used for a comprehensive planning and design of PV modules. In this method, BIM and City Geographic Markup Language (CityGML) are integrated to capture both the object properties of a certain building and the surroundings of this building.

The remainder of this paper is structured as follows: first, the proposed method is explained in detail in Section 2. Then, the implementation and case study are presented in Section 3. Finally, the conclusions and future work are presented in Section 4.

2 Proposed Method

Figure 2 presents the overview of the proposed method. The main assumption of this method is that the BIM model of the target building and the CityGML model of the area are available.

This method focuses on the application of off-the-shelf solar simulation software. As a result, the goal is not to develop a new BIM-based simulation tool that can use the object properties and attributes directly in the simulation. Instead, the focus is on creating classes of surfaces that associate with different types of building objects (e.g., exterior walls, roofs, curtain walls, windows, etc.) using BIM capabilities. These classes can be used to run the existing simulation tools on the different classes of surfaces, and thus enable surface-specific simulation of the solar potential.

The BIM model can be available either at the design stage or use as-is modeling. Given that as-is BIM models

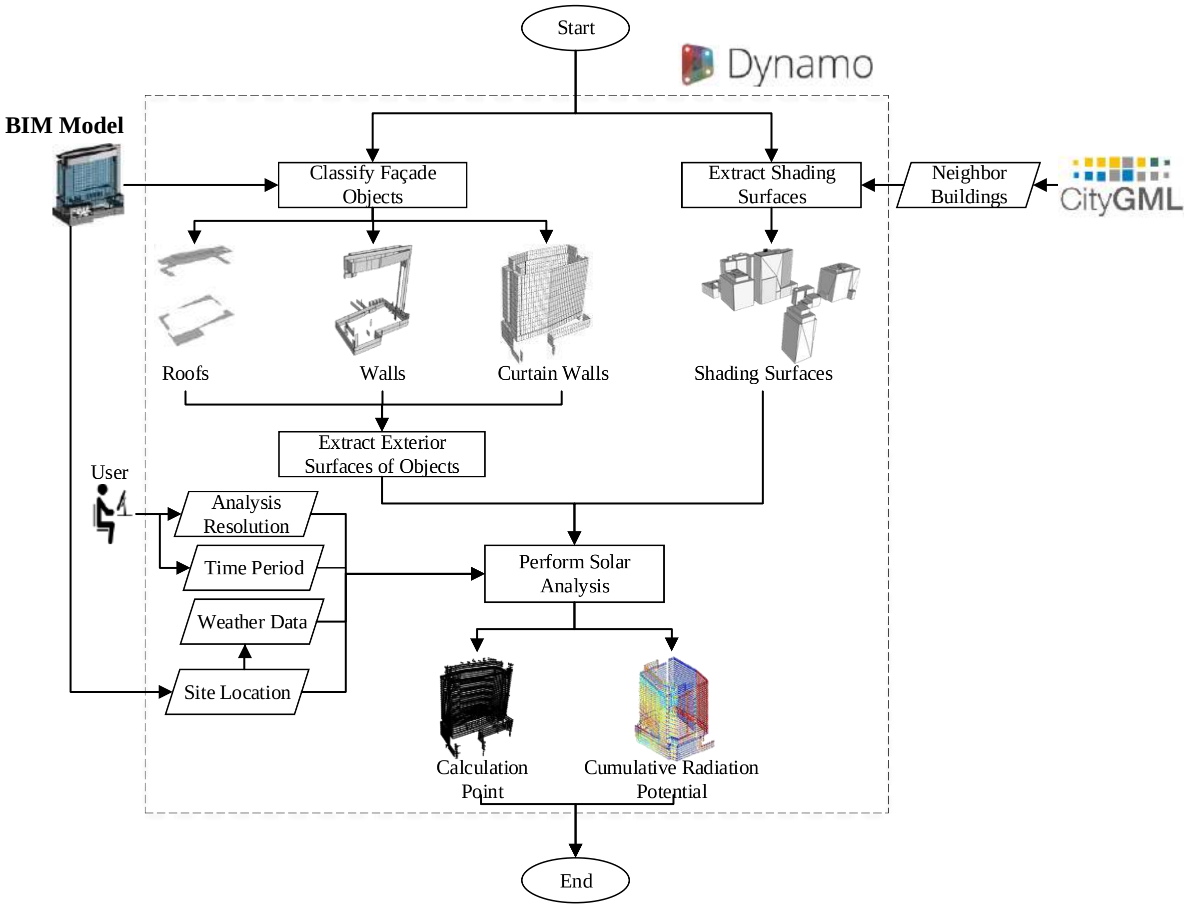

Figure 2. Overview of the proposed method

are not available for many of the existing buildings, as-is modeling is becoming popular in recent years using new technologies such as Light Detection and Ranging (LiDAR). Point cloud data captured by LiDAR can be converted into an object-based model manually or semi-automatically [29]. Although it is possible to scan the entire building (i.e., interior and exterior elements) with LiDAR and generate a complete as-is BIM model, it is -sufficient to generate the 3D model of only the exterior of the building for the purpose of solar potential simulation and PV panel optimization. This can expedite the preparation of the BIM model required for the proposed method. Unmanned Ariel Vehicle (UAV)-mounted LiDAR can be used to further facilitate this process [30].

For the purpose of PV panel planning and design, the Level of Detail (LoD) 200 would be sufficient. At this level of detail, the type and geometry (i.e., size, shape, location, and orientation) of building objects are known [31]. As per this criterion, the basic object detection and classification of the point clouds that can classify different object types (e.g., windows, curtain walls, etc.) and approximate their dimensions can be satisfactory. This allows the use of scan-to-BIM solutions, which reduce the amount of manual efforts required for the generation of BIM models [32, 33].

As shown in Figure 3, the BIM model provides the basis for the classification of different objects of the façade of the building. Depending on the types of the considered PV modules, the classification can be further expanded using the attributes of the elements.

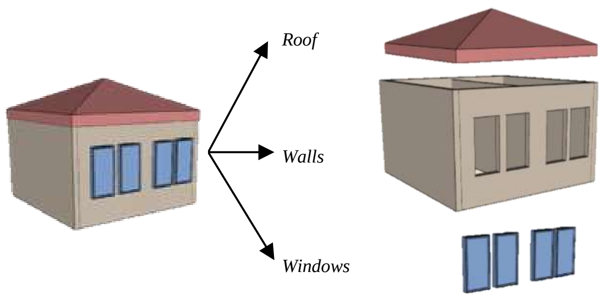

Figure 3. BIM-based classification of façade objects

For instance, the length and width of windows can be used to classify the windows into sub-categories based on their sizes. Such detailed classification helps to select suitable PV modules for the objects based on the materials or sizes of the objects. However, the consideration of detailed attributes in the BIM model (e.g., materials) may necessitate higher LoDs of the BIM model.

After the classification, all the objects in each class are decomposed into the constituent surfaces. For each object, only the exterior surface is kept and the remaining surfaces are filtered out as they are irrelevant for the solar analysis, as shown in Figure 4.

On the other hand, CityGML can be used to capture the surrounding of the building. As shown in Figure 5(a) many cities are already using CityGML to provide high-quality geo-referenced semantic models of their jurisdictions [34, 35]. Therefore, these models are becoming increasingly available for different areas.

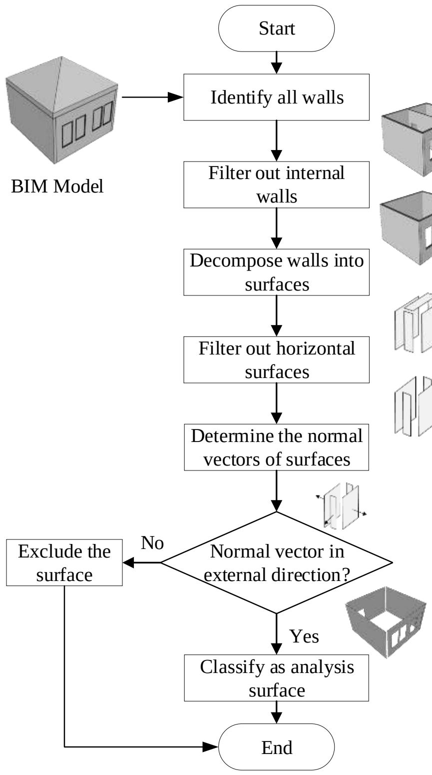

Figure 4. Flowchart for extraction of exterior surfaces from wall objects

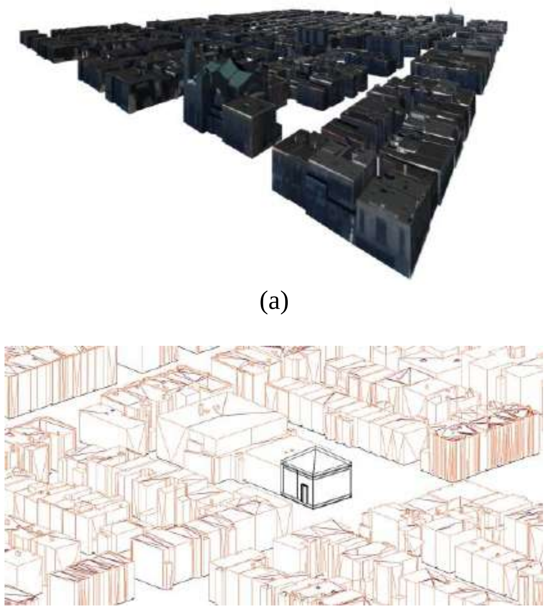
The surrounding buildings are used to represent the objects that have shading effect on the study building. The CityGML model should be trimmed to include only buildings in the effective region of the building under consideration in order to reduce the computational effort of the simulation.



(a)

(b)

Figure 5. (a) An example of CityGML file of Montreal, (b) BIM and CityGML integration

The boundaries of the effective region are marked by the furthest buildings in different directions that can cast a shadow on the building under consideration. Whether or not a building has a shadow effect on the target building is a function of the height ratio of both buildings, the distance between the buildings, in-between obstacles, and their heights, and the orientation of buildings with respect to the true north. This calculation can be done in Geographic Information System (GIS) platforms, but it is outside the scope of the present research. Then, the CityGML model is merged with the BIM model of the building under consideration, as shown in Figure 5(b).

The next step after merging the surfaces of the buildings in one model is to run the solar simulation using off-the-shelf software (e.g., Autodesk Insight). In this step, a series of input from the user is required. Firstly, the resolution of the analysis should be specified, as shown in Figure 6(a). The resolution specifies how many calculation points on each study surface should be considered. The resolution should be selected based on the minimum size of the PV modules that are considered for the analysis and the available computational power.

The user needs to specify the time period of the simulation. While this period can be for any length and from any starting date, since the majority of PV panel optimization and design procedures are based on the annual solar potential, it is recommended to use a whole year for the time period. The site location can be obtained from the coordinates of the BIM model. Based on the location of the building, the weather data can be retrieved from national meteorological databases. Figure 6(b) presents an example of surface-specific simulation of solar potentials.

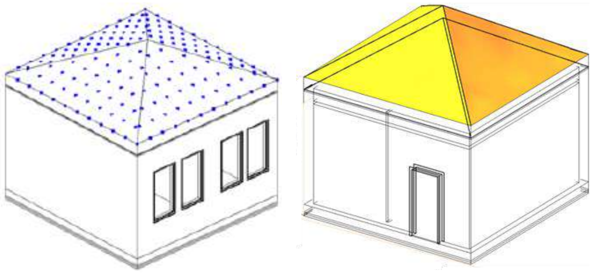


Figure 6. (a) Schematic representation of analysis resolution on the roof, (b) Surface-specific simulation of solar potentials

3 Implementation and Case Study

The proposed method is developed in a prototype implementation. In this implementation, Revit [35] is used as the platform for the BIM model. In order to implement the method in Revit, Dynamo visual programming is used [37]. Dynamo runs within Revit and works as an Application Programming Interface (API). As a result, Dynamo ensures a seamless integration with Revit. Also, it allows rapid coding within Revit and provides a seamless integration between the Revit model and various simulation tools. As an example, Figure 7 shows the implementation of wall object detection and surface extraction shown in Figure 4.

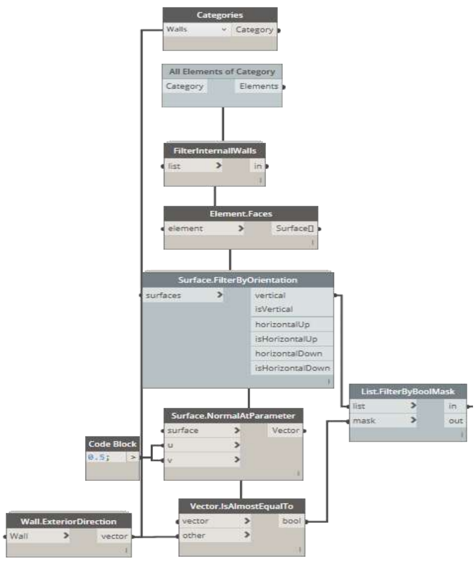

Figure 7. Implementation of wall detection and surface extraction in Dynamo

Similar codes are developed for other parts of the flowchart presented in Figure 2. It is worth noting that some of the nodes, e.g., FilterInternalWalls, are custom nodes that are developed by the authors. To test and validate the developed implementation, a case study is conducted. As shown in Figure 8(a), the case study is performed on Sir George William (SGW) campus of Concordia University in downtown Montreal. The building of John Molson School of Business (JM) is selected for the analysis because of its specific architecture, which includes curtain walls, windows, walls, rooftops, and projected horizontal surfaces at different levels. This complex architecture requires a detailed and surface-specific simulation of the building envelope. The BIM model of JM building is created and imported into Revit. Then, Revit Solar Analyst was used for simulating the solar radiation on the building surfaces. For this purpose, it is necessary to set the geographical location of the study area and define the true north of the buildings.

As shown in Figure 8(b), the city blocks around the JM building is extracted from CityGML model provided by the city of Montreal [32]. CityGML file is converted into a .fbx file and later merged with the BIM model as a unique *site* family in Revit.

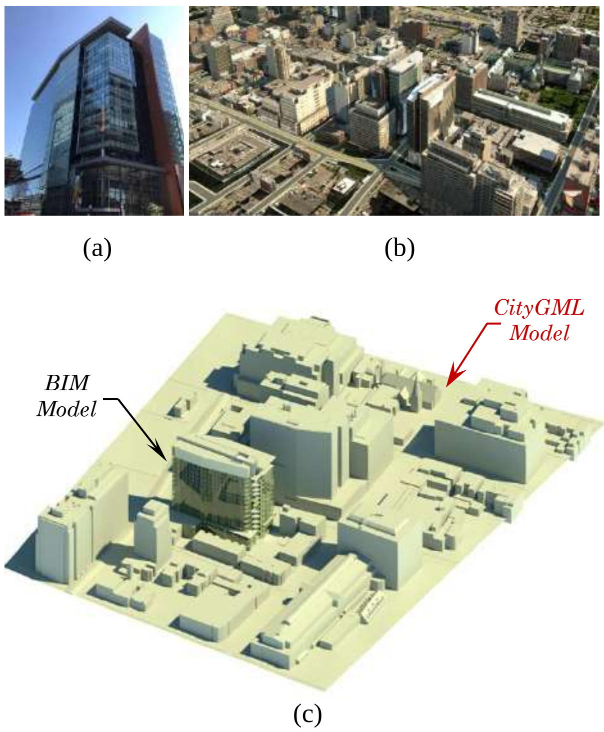

Figure 8. (a) JM building in downtown Montreal, (b) CityGML model of Concordia SGW campus, and (c) integration of the BIM Model and CityGML in Revit

Three classes of objects are considered for this case study, namely, roofs, walls, and curtain walls. Figure 9 shows the external surfaces of these elements. It is important for the implementation that elements are modeled using appropriate families and attributes in the BIM model. For the resolution of the simulation analysis, a grid with the spacing of 1 m is used, as shown in Figure 9(d, e, and f). The weather data is automatically determined based on the site location and the annual solar radiation is calculated for one year.

In the next step, the solar analysis is applied in Dynamo using the predefined node. The radiation value is then calculated for every single point on the grid of the classified surfaces. The corresponding values of the annual solar radiation for each surface type are then stored in a separate Excel sheet. These values are then imported into MATLAB to visualize the simulation results. The results of the simulation for each class of surface are shown in Figure 10. As shown in this figure, in line with the expectations, the higher floors received more radiation. Additionally, the backside of the building which was overshadowed by the surrounding buildings is receiving less radiation than the front side.

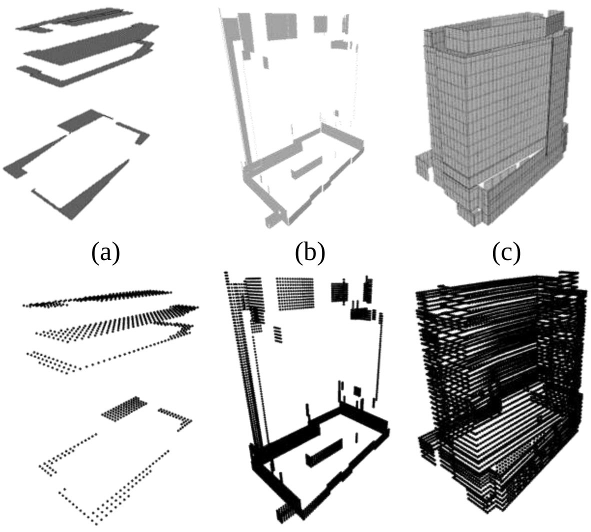

Figure 9. Extraction of external surfaces of (a) roofs, (b) walls, (c) curtain walls, and resolution of simulation analysis for (d) roofs, (e) walls, and (f) curtain walls

4 Discussion

Integration of the simulation results with Matlab to visualize the radiation values will facilitate the next step of the project to optimize the PV panel installation. Although this paper focused on a single building to perform the radiation analysis, analyzing multiple buildings can be done by combining several BIM models. In order to do that it is necessary to index each building based on its address to allow identification of building-specific surfaces.

5 Conclusions and Future work

In this paper, a BIM-based method is developed for a detailed simulation of a building envelope using its surface properties. The BIM model provided the basis for creating different categories of surfaces associated with different types of building objects such as exterior walls, roofs, curtain walls, and windows.

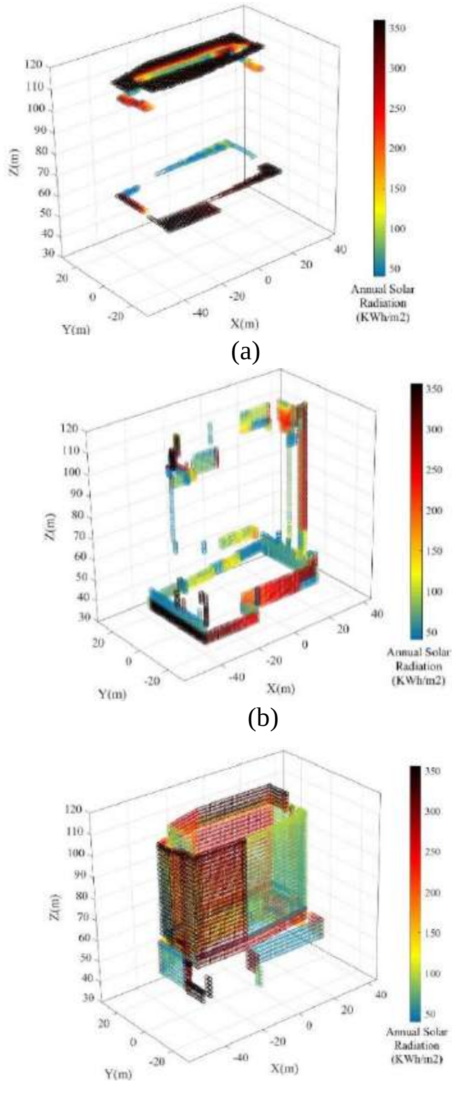

Figure 10. Visualized results of the solar radiation simulation for (a) roofs, (b) walls, and (c) curtain walls

A prototype is developed using Revit and Dynamo visual programming platform, and a case study is presented for a building in Montreal, Canada, to demonstrate the feasibility of the proposed method.

In the light of the result of the case study, it can be concluded that the proposed method is promising in terms of providing the input for a comprehensive planning of the solar panel layout. Future work will aim to optimize the installation of PV modules on building surfaces considering maximum energy generation and minimum life cycle cost of the modules.

Abstract

Information retrieval and automated progress estimation of on-going construction projects have been an area of interest for researchers in the field of civil engineering. It is done using 3D point cloud as-built and as-planned model. Advancements in the field of photogrammetry and computer vision have made 3D reconstruction of buildings easy and affordable. But the high variability of construction sites, in terms of lighting conditions, material appearance, etc. and error-prone data collection techniques tend to make the reconstructed 3D model erroneous and incorrect representation of the actual site. This eventually affects the result of progress estimation step. To overcome these limitations, this paper presents a novel approach for improving the results of 3D reconstruction of a construction site by employing two-step process for the reconstruction as compared to the traditional approach. In the proposed method, the first step is to obtain an as-built 3D model of the construction site using 3D scanning techniques or photogrammetry in the form of point cloud data. In the second step, the model is passed through pre-trained machine learning binary classification model for identifying and removing erroneous data points in the captured point cloud. Erroneous points are removed by identifying the correct building points. This processed as-built model is compared with an as-planned model for progress estimation. Based on the proposed method, experiments are carried out using commercially available stereo vision camera for 3D reconstruction.

Keywords –

3D reconstruction, point cloud, as-built, as-planned, progress estimate

1 Introduction

Traditional monitoring of construction projects has always been manually driven process involving visual inspection and human judgment. This makes these methods slow and inaccurate, reducing the ability of infrastructure managers to monitor project performance indicators, including schedule and cost. These poor monitoring techniques are comprehended as one of the reasons for cost and time overruns in construction projects [1]. Importance of accurate and efficient progress monitoring have been reiterated by several researchers. Research establishes project monitoring as a critical success factor for in-budget completion of a construction project [2]. The time taken for identification of inconsistency between the as-built and as-planned model is proportional to the cost overrun and increased difficulty in implementation of the corrective measures in a project [3].

In the past, several automated methods of progress monitoring have been developed and tested by researchers and practitioners to enable better monitoring. Automated progress monitoring can be divided into four steps: (1) Data acquisition, which is capturing digital representation of as-built scenes, (2) information retrieval, this refers to extraction of useful information from the data collected without loss of any information required for accurate progress estimation, (3) progress estimation, this is a comparison between as-built model and as-planned model in order to determine the state of progress, (4) visualization of the results obtained via previous steps [4].

Recent advancements in the field of reality capture technologies, like, 3D imaging, laser scanning, in-situ sensing equipment, onboard instrumentation and electronic tagging, has made data acquisition possible for automated progress estimation. Moreover, developments in the field of machine learning and computer vision have made analysis of the acquired data efficient. While the impacts of these advancements are compelling, numerous challenges continue to persist. [5][6] These challenges prevent them from maturing into technologies that could be deployed to an on-going construction site for monitoring without human intervention. It can be alleged that there are no practices which offer automated analysis of construction data to estimate progress [4].

Thus, the goal of the study is to improve the result of progress estimate of a construction by generating a correct 3D reconstruction of construction. Considering the high variability in site conditions and data collection techniques, the method should be robust to these variations for any given site.

It should be noted that 3D reconstructed point cloud model is obtained using commercially available stereo vision camera. The process of 3D registration of images to produce point cloud is known to be error-prone, producing erroneous points with no correspondence in actual site [7][8]. Thus, data pre-processing becomes of paramount importance, involving outlier removal and noise filtering. But these methods are preliminary in nature and erroneous points continue to exist in the point cloud data. Therefore, there is need to identify these error points.

In this study, we work to improve the results of progress estimate of construction calculated by comparing as-built model, obtained using a commercially available stereo vision camera, and as-planned model. The research employs machine learning techniques for processing and refining 3D point cloud model before progress estimation is made. The processing involves detection of the masonry followed by its distinction from erroneous points. This is done to obtain a more accurate representation of the captured scene as compared to the output of 3D reconstruction. Subsequently, this processed as-built model is used for progress estimation by comparing it with the as-planned model.

In this paper, a novel method is proposed to classify between normal and erroneous points using machine learning techniques. "Normal" class representing points which correspond to constructed parts in the 3D point cloud model whereas "erroneous" class represents points which have no correspondence or correspond to parts other than constructed elements. In this method, a supervised binary classifier is built by training it over data collected. This trained classifier is used for identifying masonry points and thereby removing erroneous points from a point cloud, eventually producing better progress estimate. The study has been done for masonry construction, but can be extended to other types of construction.

2 Problem Statement

The aim of the paper is to develop an approach to reduce erroneous points generated in 3D reconstruction. Thus, it trains a classifier to reduce false positive in the 3D point cloud model reconstructed. The study also deals with the impact of the different site conditions like lighting, and different data collection parameters, like the speed of capture, yaw of the camera, the pitch of camera, etc. on the 3D reconstruction and progress estimate. The methodology developed needs to be independent of these parameters.

3 Review of the literature

Laser scanning and photogrammetry are two popular techniques for obtaining as-built point cloud of a construction site. Although laser scanning produces dense point clouds capturing tiniest details of the site, it is very costly. On the other hand, though the camera has the drawback of lower geometric accuracy; flexibility to use and cost-effectiveness makes them a favorable choice. Bohn & Teizer have explored advantages and challenges of camera-based progress monitoring [9]. The efficacy of stereo vision cameras to obtain as-built point cloud model using 2D images and depth map has been studied and proved by various researchers. [10]–[12]. Thus, imaging (stereo vision camera) system is used to obtain input for the as-built modeling stage.

The accuracy of reconstruction has a crucial impact on the progress estimate. The reconstructed models are highly corrupted with outliers and missing values because of imperfect conditions in which scanning is done, for instance, the motion of the object, multiple reflections, object occlusion, etc. Therefore, the output of the data acquisition step, that is reconstructed point cloud model, needs to be processed and analyzed before feeding to the next step of information retrieval and progress estimation. The standard tasks involved in pre-processing of point cloud data are (1) Outlier removal, (2) Handling missing value and (3) Reducing noise (or smoothening) of data [13]. For large point clouds, downsampling through voxelization is done, in order to reduce the computational time and cost.

Outlier removal for point cloud is a non-trivial task because of following reasons: geometrical discontinuities, no apriori knowledge of outlier distribution, and varying local point density [14]. Outlier removal methods in literature are mostly based on local properties of points, popularly calculated using density-based approach [15] and distance based approach [16]. Some of the local statistics are local point density, nearest neighbor distance, eigenvalues of the local covariance matrix, etc. [17]. Wang et.al, proposed connectivity-based and clustering approach for detection of outliers [14]. Similarly, the point cloud is processed for noise smoothening, involving noise filtering and point update.

The processed as-built point cloud is to be compared to as-planned BIM model for progress estimate. There are two ways to do the comparison: (1) convert the point cloud model in BIM model (involving semantic segmentation and object recognition) and compare, (2) convert the as-planned model to point cloud format and compare. In this paper, latter is adopted progress estimation.

It is worthy to note that in almost every data pre-processing techniques, no apriori knowledge of error (i.e. outliers) distribution is used. Thus, though these techniques help in cleaning data to an extent, they cannot

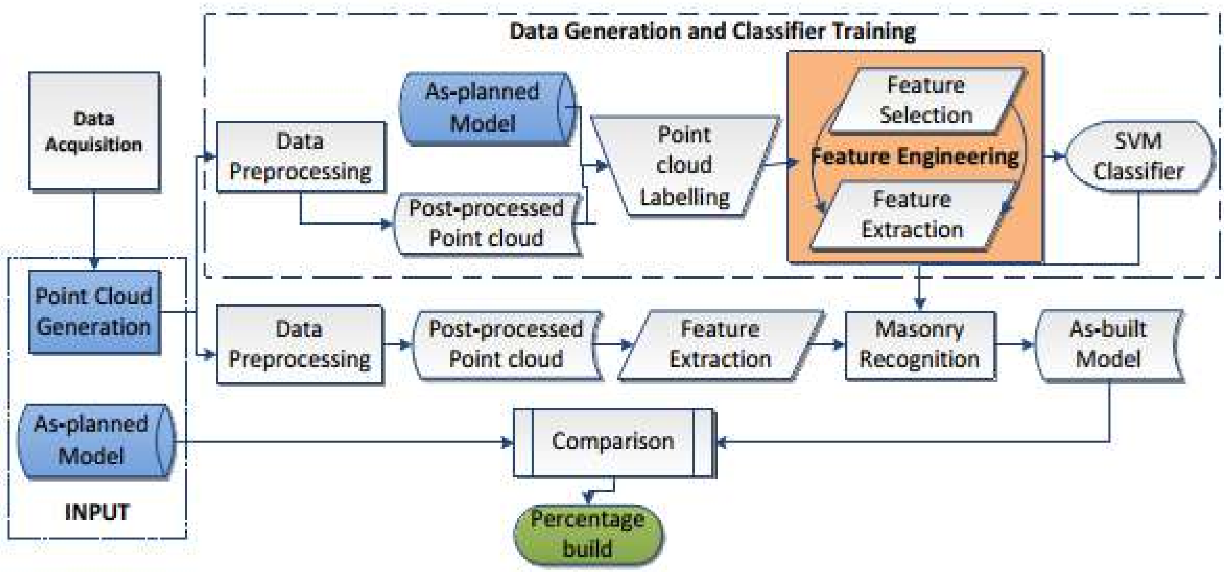

Figure 1. Proposed Methodology

remove incorrectly reconstructed points which are dependent on the methodology followed for reconstruction, data collection technique, and site conditions. In this paper, we propose a method to learn the characteristics of the construction materials and elements and use this knowledge to detect the same, and thereby removing the erroneous points. The erroneous points are detected using machine learning technique. This detection is posed as standard binary classification problem to classify between normal and erroneous points, which is solved by training a classifier based on local and contextual features (which are discussed in detail in later sections).

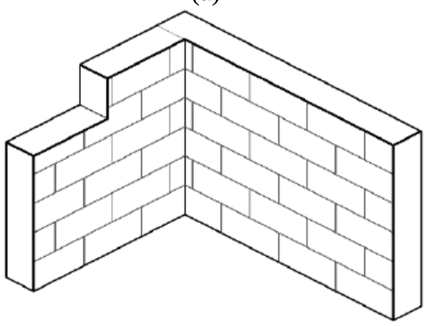
4 Methodology of Research

In this research, we focus to improve the as-built model reconstruction accuracy. In addition to, data pre-processing, the point cloud is subjected to supervised binary classification for construction material detection. This detection method has two-fold advantages – First, it eliminates the need to manually assign threshold values, which requires expertise. Second, it enhances the ability to scale the method, as this can be easily re-implemented after re-training. The proposed methodology excluding data acquisition and pre-processing (outlier removal and noise smoothing), can be divided into four components: (1) Data generation, (2) Feature Engineering, (3) masonry recognition using machine learning based supervised classification, (4) progress estimation and evaluation. Each of the above components are discussed in detail in the following sub-sections:

4.1 Data generation

This is the first step in the proposed framework. The input to this method is point cloud data and corresponding BIM model. The point cloud is annotated

(a)



(b)

Figure 2. A sample of 3D models used for data generation (a) as-built model showing erroneous points marked in yellow (b) as-planned model corresponding to the model in figure 2(a).

using BIM model as ground truth. Instead of following the common strategy for point cloud labeling, which involves over-segmenting the data and then assigning labels to segments. The data is annotated pointwise, considering two-fold advantages – (1) to avoid inheritance of error from segmentation step (2) to prevent classifier from learning hand-crafted rules of segmentation algorithm, when used for training [18].

3D annotation is done by manually comparing the point cloud model with the BIM model. The two models are overlapped and annotation is done view-by-view. A view is fixed and in this view, all the points lying within the boundary of BIM model, with a small tolerance value, are marked as normal while the rest of the points are marked as erroneous. This process is iteratively repeated for different views until all the possible views are covered. The problem with this way of annotation is that, same points appear in different views, appearing erroneous in one view and normal in another. To tackle this problem, a point is marked normal if it appears normal from all possible views and erroneous if it appears as erroneous from any possible view. Eventually, the point cloud is separated and labeled into two classes – “normal” and “erroneous”.

4.2 Feature Engineering

Performance of any machine algorithm is only as good as the ability of the features (or parameters) used to distinctly define the underlying distribution. In this regard, we attempt to learn a list of features which can be used to identify point corresponding to masonry in a point cloud. Rashidi et.al., realized three categories of construction materials depending upon appearance and color features[19]. Thus, discriminating features are learned for masonry data through an iterative process of, feature extraction and feature selection. The types of features learned are spatial and color, which are discussed below:

4.2.1 Spatial Features

These features are used to model the geometrical properties, like angles, distances, and angular variations, of masonry data. In a 3D point cloud, these features for a point in space is calculated by considering the spatial arrangements of data points in the neighborhood. The neighborhood can be assumed to spherical [20] or cylindrical [21] with a fixed radius. The neighborhood can also be selected based on k-nearest neighbor, depending on 3D-distance from the query point, where $k \in N$ [22]. For classification, spatial features were calculated for fixed radius spherical neighborhood. In order to obtain appropriate and uniform features across different data models, features are calculated at a fixed scale.

Neighboring points in a 3D model are known to be correlated and interdependent [23]. And therefore in order to capture this correlation, apart from individual features, some of the features are obtained which take this interdependency into consideration. Some of the features which are used are:

- **Individual**: Normal, local point density
- **Contextual**: Fast point feature histogram (FPFH) descriptor

FPFH descriptor is calculated in two steps: (1) for every point p, relationships are calculated between the neighbor and the query point, this histogram is named as simplified point feature histogram, SPFH. (2) In this step, for each of the query point, its nearest k neighbors are found, and FPFH is calculated using equation (1)

$$\mathrm{FPFH}(p)=\mathrm{SPFH}(p)+\frac{1}{k}\sum_{i=1}^{k}\frac{\mathrm{SPFH}(p_k)}{w_k} \quad (1)$$

where, k represents the number of nearest neighbors to a query point, w_k represents the distance between the query and the neighboring point.

Figure 3 illustrates the influence diagram of a point and highlights the neighborhood of a point which contributes the feature at that point [24]. These features are computed using Point cloud library [25].

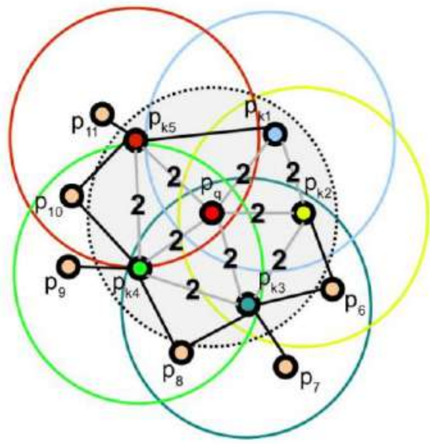


Figure 3. Influence diagram of FPFH to capture the interdependence of the neighboring points in the 3D point cloud [24]

4.2.2 Color Features

For the recognition of masonry, color values are very effective feature given its distinctive bright red color. It serves as an effective indicator for differentiating masonry from rest of the objects found on a construction site. However, it is worthy to note here that though the color value for a given does not vary drastically in a given point cloud, it might vary significantly when the same material is compared from two different point clouds, captured for different site conditions. This is illustrated in figure 4.

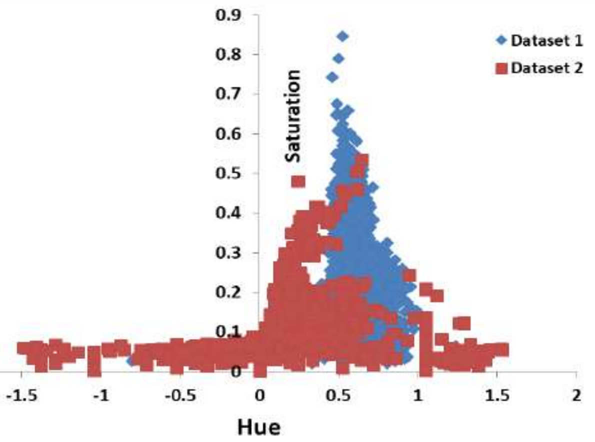

Figure 4. Hue and Saturation plot for two different datasets, collected under different conditions

The color values are obtained in the RGB space. Though these are most widely used color space, these RGB values are susceptible to a high variation on exposure to the same object under different illumination. And since illumination is an uncontrolled construction environment is ought to vary, dealing with these variations is highly important to produce effective results. Therefore, in this study, we have transformed the color space from RGB to HSI. It is compelling to make this transformation because: (1) it is very intuitive as it is similar to the way in which color is perceived by humans, (2) it separates the chrominance (color) and luminance (intensity) information, which has proved to be advantageous in image processing application. Hue (H) and Saturation (S) correspond to the color component of the RGB space, whereas Intensity (I) represents the illuminance-dependent part. Therefore, hue and saturation provide a good parameter for classifying masonry points from the rest. The color is changed from RGB to HSI using following equations:

$$H = \arctan \frac{\sqrt{3}\,(G-B)}{(R-G)+(R-B)} \tag{1}$$

$$S = 1 - 3\frac{\min(R,G,B)}{R+G+B} \tag{2}$$

$$I = \frac{1}{3}(R+G+B) \tag{3}$$

4.3 Masonry recognition

For the recognition of masonry in the point cloud, the pre-trained binary classifier is used. The following sub-sections explain the details of the classification.

4.3.1 Classifier training

An SVM classifier is trained over a training dataset generated using the method explained in data generation step. Instead of using voxel-based approach for training, a point-based approach is used. Despite the computationally costly and time-consuming nature of point-wise training, it is acceptable because: (1) it helps in improving recall values while detecting concrete points, (2) training is a one-time process, to be done during the setting up of the system. Hence, selection of the approach was done based on accuracy rather than computational cost.

Since the classification boundary was non-linear, Radial Basis Function (RBF) kernel was used. The parameters C and γ are to be determined for RBF kernel SVM model. C is regularization parameter and γ is kernel parameter [26]. In order to validate the results obtained using the training set, an independent validation set is used, which was obtained using a method similar to training data.

4.3.2 Masonry detection

The classifier obtained in section 4.3.1 is used for detection of points corresponding to masonry points in the post-processed point cloud. Features are extracted from the input 3D point cloud data (different from the data used for classifier training) depending on which classification is done. The point cloud is separated and classified as in two classes: “normal” and “erroneous".

4.4 Evaluation

For evaluating the performance of the system, two popular measures – Precision and recall are used.

$$\text{Precision} = \frac{TP}{TP + FP} \tag{4}$$

$$\text{Recall} = \frac{TP}{TP + FN} \tag{5}$$

Where, TP represents true positives, a number of points that are correctly predicted, belonging to the normal class, FP represents false positive, points which are predicted as normal but are actually erroneous, FN represents false negative, points which are erroneous but are predicted as normal.

5 Preliminary results

Based on the study, it is observed that colour features are distinctly different for both classes and therefore contribute most to the classification results. This is attributed to rich colour properties of a masonry construction. The erroneous points are observed to have low values of hue and saturation. The performance of the system with only colour features used for the training of the classifier is 69% in precision and 72% in recall. This result of colour acting as dominating feature in masonry detection is in coherence with different studies done in the past [12] [27].

The value of the evaluation metrics obtained in the preliminary study is given in Table 1. These results were obtained using all the features discussed in Section 4.2. The precision and recall values obtained are low in comparison to other studies which were conducted using 2D images as the dataset. These low values are the result of low point density in comparison to a high pixel density of an image. Moreover, training dataset used for training of the classifier was small in number. Therefore, these values need be improved further by using a larger training dataset, which is representative of the entire population of variations causing erroneous points reconstruction.

Table 1. Precision and recall value obtained from the test dataset

Metric	Percentage (%)
Precision	73.1
Recall	77.3

6 Conclusion and Future work

This study has presented an automatic system for information retrieval and progress estimation, with a goal to improve progress estimate by introducing a step of construction elements/material recognition. Masonry brick wall is used as a construction element in the study. The work needs to be extended to other construction materials/elements. A larger dataset needs to developed which can be used produce better results by employing data-intensive machine learning techniques, like tree family algorithms and deep learning algorithms. In future work, apart from geometric and colour features, texture features and other local geometric features needs to be explored in order to obtain better results. Although stereo vision-based imaging was employed for the study, the proposed methodology is expected to perform equally well irrespective of the technique used for data collection, as long as inputs are in the form of 3D point cloud with colour features. Moreover, detection of construction material can help in case of occluded scenes, where the building is to be separated from the rest of surrounding.

Abstract –

Building Information Modeling is the process and the technology transition from a traditional single sequential form to a modern multiple parallel form of data integration. BIM is the process of data sharing and distribution with the ability to employ the data via numerous applications for managing several multidimensional tasks and activities of AEC/OM (Architecture, Engineering, Construction/ Operation and Maintenance) throughout the building lifecycle. Indeed, employing BIM technology not only seems vital for small and medium-sized enterprises (SMEs) who are active in the construction sector of the building industry but also it is unavoidable for the firms who are seeking to increase their competitiveness and even their existence in the future era of the industry. The era of automation, robotics and 3D printing is coming faster due to the extraordinary developments and innovations in the digitalization and automation sectors, absence of desire productivity and efficiency in the building industry where BIM can efficiently provide the required information and accurate data to be used for model simulation and machine control in robotic construction.

However, most of the active SME contractors are not aware of building information modeling, nor are they familiar with the BIM implementation framework and its key factors. Therefore, the main aim of this article is to provide realistic key factors for an initial BIM implementation framework that can help the SMEs, who are working in the construction sector of the building industry such as contractors, to understand BIM as modeling and employ it with less costs and more efficiency.

Keywords –

Building Information Modeling (BIM); Building lifecycle; SMEs; Competitiveness; Building industry; BIM implementation framework; Automation and robotics;

1 Introduction

This research study encompasses a background on building information modeling (BIM), its importance for the building industry, the construction and particularly SME contractors. The importance of BIM in automation and robotics will be discussed too. Next, the problem and the research focus will be explained. Followed by, the research methodology covers the most relevant studies about BIM implementation, published in the last decade. Finally, key factors and an initial BIM implementation framework will be presented.

1.1 Background of BIM

What is BIM? A common question with numerous answers and definitions! BIM as a context is not a new phenomenon. In 1975 a building description system (BDS) was introduced by Eastman [1]. However, after popularity of the term "BIM", several definitions and explanations for building information modeling have been introduced. For instance, Laiserin indicated BIM as a process and not a software [2], while, Woo described BIM as a new methodology for building design and documentation that provides faster and easier construction process for all involved parties [3]. Similarly, Penttilä defined BIM as a methodology but for managing the digital format of design and project data during the building lifecycle [4]. Furthermore, Eastman et al defined BIM as a technology that allows the building digital and virtual models to support design process phases by the accurate geometry and data. This not only will support the fabrication, procurement and construction phases but also will be used for other phases and activities of the building lifecycle. Thus, BIM can facilitate a form of integrated design and process that marks higher quality and reduces costs and time of the project [5]. Furthermore, in 2007 the US National Building Information Modeling Standard (NBIMS) defined BIM as "BIM is a digital representation of physical and functional characteristics of a facility" [6]. Azhar [7] expressed BIM as a pattern within AEC industry that can boost integration of all stakeholders on a project.

Although there is not a common consensus among researchers, software developers and practitioners, it is possible to distinguish an immediate difference between BIM as "modeling" and BIM as "a model". Nevertheless, BIM as a model can be derived a product of building information modeling. BIM as modeling is the process and the technology transition from a traditional single sequential form to a modern multiple parallel form of communication and data integration. In addition, building information modeling is the process of data distribution and data sharing with the ability to employ the data via numerous applications and tools for managing several multidimensional tasks and activities throughout the building lifecycle. A related point to consider is that in practice, current building information modeling and BIM software as well as BIM tools have their own limitations and challenges particularly for existing buildings and renovation that requires more research and development activities [8] [9].

1.2 Importance of BIM

There are familiar questions that the industry practitioners, specially contractors, ask such as "Why should we employ BIM?" or " What are the benefits of BIM?". In this section and through the next paragraphs, the BIM importance and its impacts on the building industry as well as its future use for the automation and robotics will be discussed.

1.2.1 BIM and the Building Industry

It is well known that the building industry is a late majority adopter or even the laggard adopter of new technologies, processes and methods in comparison with, for instance, the aviation industry. This lack of willingness to change, throughout the past decades, have created significant levels of time waste, quality decrease and profit loss as well as duplicating activities and repeating mistakes for the industry [7]. In addition, the construction industry has not been fully employing new innovative opportunities [10]. A very good example of the industry's hesitation to use the latest technologies, which is significant to be addressed, is BIM implementation, particularly, in the SMEs.

However, the building industry in general and the SMEs in particular demand for an effective and more integrated management during the initiation phase to the closing phase of a project. In addition, construction industry should seek for productive time, higher quality and fewer costs as well as try to avoid the parallel and unnecessary activities. Furthermore, eventually, the industry will ask for automation as unique solution to the lack of sufficient efficiency, mass production, labors and professional workers. Finally, the industry should intensely consider reducing waste materials and using recycled products and materials.

Although BIM has been introduced for years, for many the SMEs in the building and construction sectors BIM is yet to be recognized as a modern 3D software. On the other hand, BIM has several direct and indirect impacts on the building industry. Same as any other new technology, BIM brings advantages and disadvantages for its users. However, it has been confirmed that employing BIM will increase a firm's ROI (Return of Investment) which means more profit for the company in a long term [11]. Additionally, Barlish and Sullivan (2012) [12] developed a method for analyzing and quantifying BIM benefits, value, impacts and outcomes. The metrics, investment and cost, were tested against multiple cases on BIM based projects and traditional based projects. The results reveal that actual ROI varies depended on each project but for BIM based projects, there is a high potential of benefits. In addition, according to the NISB report, only in the national level, an estimated cost of inadequate data interoperability in the US capital facilities industry is approximately $15.8 billion dollars annually [13].

Furthermore, in a project level, the lack of interoperability increases costs of projects up to 3,1% of total project costs in the building industry [5] which is shown in Figure 1. Nonetheless, this is likely to be a small portion of the cost showing only the top of the industry's cost "iceberg". Consequently, it is not far from reality that the costs of inadequate and poor data management and interoperability consist billions of dollars of many countries' GDPs per year, globally. Furthermore, the study of using BIM in different stages of a building lifecycle shows that BIM is mostly used just in early stages and the use of BIM decreases while a project is progressing to the next stages. It is also found that BIM collaboration and process create positive impacts on projects. Also, clients as well as facility managers can benefit from BIM [14, 15].

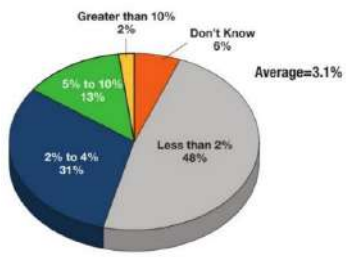

Figure 1. Total AEC/OM cost of non-interoperability, adopted from [5]

Thus, BIM is an essential technology for the future construction processes and the SMEs who have started to employ BIM will experience a higher level of competitiveness and technical improvements. Besides, BIM users will experience faster delivery, enhanced quality and efficiency in the projects [16] [17]. On the other hand, employing BIM requires new investments and some changes of the firms' organizational structure and culture [12, 18]. Possibly, in the long term BIM may change the industry's lifecycle management too. However, the indirect impact of BIM can benefit and help a wide range of other fields such as saving energy, waste materials, CO_2 emission and natural recourses and it can increase sustainability [17] [19].

1.2.2 BIM and Automation

The building industry is seeking potential solutions to the current problems. Problems such as high costs, traditional time consuming tools and methods, low quality, high waste, labor difficulties, high risk, inefficiency, low sustainability and low productivity [20]. Alternatively, the developments and innovations in the ICT, digitalization and automation sectors of the building industry are visible such as automated equipment and methods [21]. Thus, based on that, it is not out of imagination that inevitably the industry will employ more automated processes and automatic machines in the near future for mass production too. However, while BIM and digitalization are booming among the industry practitioners, automation and employing robotic technology as well as 3D printing are scaling. This will gradually motivate and seize attention of more contractors and innovation organizations who are active in the construction section.

On the other hand, dimensional control and identification are required for exploiting automation [22] and BIM can efficiently provide the required information and accurate data to be used for model simulation and machine control in construction automation and robotic construction. Therefore, BIM's importance and effects on the future usage of automation and robotics in the industry not only appear strong but also, in the long run, they are inevitable for the firms who are seeking to increase their competitiveness [20], productivity [23] and even their existence in the future era of the building industry.

1.3 Problem Statement and Aims

Regardless of considerable development of BIM based tools, still AEC/OM firms, particularly the SMEs, hesitate to employ BIM so its technical and financial benefits are not fully employed [16] [24]. On the other hand, according to the EU user guide to the SME definition, about 90% of enterprises and over 67% of jobs are generated by the SMEs. The SMEs include a broad category of companies from micro to small and medium-sized enterprises comprising less than 250 employees and a turnover of less than 50 million Euros annually [25]. Thus, due to the significant number, role and effect of the SMEs on the building industry in general and the construction market in particular, it is essential to address the issues, the BIM technology and its implementation framework to the SMEs.

The problem is that most of the active SME contractors are not aware of building information modeling, nor are they familiar with the BIM implementation framework and its key factors to increase their competitiveness. Thus, the main aim of this article is to provide the realistic key factors for an initial BIM implementation framework that can help the SMEs, who are working in the construction sector of the building industry such as contractors and sub-contractors, to understand BIM as modeling and employ it with less costs and more efficiency.

2 Methodology of the Study

This study is mainly based on a literature review on BIM implementation in the AEC sectors of the building industry with more emphasis on BIM adoption for contractors in the construction sector of the AEC/OM industry. In order to achieve the goal successfully, first the most related factors of a successful BIM implementation will be explored through the literature review from the past decade publications. Then a proposed solution as an implementation framework will be provided in order to increase the practitioners' general knowledge of BIM and the factors related to BIM implementation. This must be mentioned that likewise any other research, the framework is limited to and will focus on SME contractors in the construction section. Figure 2 illustrates the general view of the study structure including the problem statement, the aims, methodology and anticipated output.

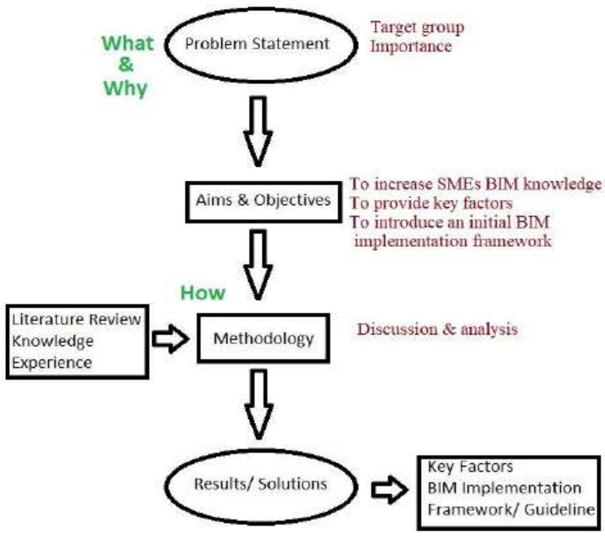

Figure 2. The research structure

2.1 Literature Review

To establish a related context of this study on BIM implementation, a selected literature review of the most relevant publications of the last decade of BIM implementation and adoption studies is provided. Table 1 illustrates a summary of the literature review.

In 2006, Brucker et al [18] offered a strategic BIM implementation plan for USACE (the U.S. Army Corps of Engineers) in order to improve the processes of design, planning and construction. The proposed BIM implementation plan, for the designing phase, is as follows:

- Gather up the current design team including the managers and the designers to define the current process and the responsibilities for the transition
- Assign a BIM team, including the design team and the lead technicians, to create and organize a BIM action plan including tasks, processes, metrics, expectations, BIM vision and team's needs
- Technical and organizational training by workshops based on the staff's role and responsibilities are required

Arayici et al (2009) [26] identified the BIM implementation challenges and factors by surveys in the UK and interviews in Finland with the construction stakeholders and academics. The study indicates that BIM implementation requests considerable changes of organizations and processes. However, in order to decrease resistance to change and build the process of implementation, training of BIM technology and BIM based tools are essential. This also, includes the change of redefining HR (Human Resource) system of the organizations, their responsibilities and the working processes. According to the study, the main challenges and barriers for BIM implementation are as follows:

- Lack of sufficient knowledge of BIM technology and BIM definition
- Unwillingness to employ the new technology and train/ lack of trained staff
- Lack of demand
- High costs of implementing that cannot cover the costs and make benefit
- Low rate of return of investment (ROI) which requires longer time to make BIM beneficial

Nonetheless, a paper published by Succar (2009) [27] describes an ontology of the BIM domain concepts and identifies the conceptual parts of BIM and main BIM activity fields. The main BIM activity fields are introduced as process, technology and policy that partially share deliverables (e.g. regulations, standards, construction products and services, software, hardware and equipment) and players (e.g. designers, engineers, contractors, manufacturers, technology developers, owners, operators, legal bodies, researchers).

In addition, Gu and London (2010) [28] conducted a FGIs (Focus Group Interviews) research study on the focused group of architects, engineers, contractors, BIM consultants, academics and software vendors for BIM adoption in the building industry. They found that besides various implementation levels, based on practical knowledge of BIM, there are mainly two types of issues as technical and non-technical that can affect BIM adoption and technology diffusion among the building industry. The technical issues comprise technical tools and software whereas the non-technical issues are related to work practices, strategies and processes.

Jung and Joo (2011) [29] addressed the variables for a BIM framework consisting of three main dimensions as BIM technology (dividing into four categories including standards, data properties, relation and utilization), BIM perspective (of industry, organization and project) and construction business function (design, contracts, estimation, scheduling, planning, materials, safety, quality, administration, finance, HR, cost control, sales and R&D).

Besides, Khosrowshahi and Arayici (2012) [30] provided a roadmap for BIM implementation in the UK to be used at operational and managerial levels. According to their suggestions, in BIM implementation, firms should consider three factors, including organizational culture, information management and training.

Following, Eadie et al (2013) [14] established an analysis of BIM implementation showing that BIM can be used throughout all stages of a building lifecycle. They found that the stakeholder collaboration aspect is the most effective factor following the process, as it is more important than software besides training. The two barriers are the lack of training and the industry experience of BIM. Takim et al (2013) [31] studied factors of BIM implementation in the AEC industry at two levels, the national level and organizational level in Malaysia. The study revealed several factors can create gaps for the implementation such as product limitation and interoperability, technical support and process change, economic demand and people acceptance, perceived usefulness and ease of use.

An analytical study by Miettinen and Paavola (2014) [32] presented that local experimentation, continued learning, standards and guidelines have a main role in BIM implementation. In addition, for BIM implementation, Morlhon et al (2014) [33] established an interaction model based on some critical factors such as reengineering business process, standardization, external stakeholders involvement, education whether technical and or information management as well as system selection process. Meanwhile, Peter Smith (2014) [34] examined the issues of BIM implementation in the construction industry. The results of the study show that leadership and government support, national and global standards, liability and legal issues, research, education and training as well as business impacts and opportunities have critical role on BIM implementation.

In 2015, Lindblad and Vass [35] investigated the changes, in three areas of product (model), organization (resources) and process (work practices), required for BIM implementation initiating in a large public infrastructure organization in Sweden. Furthermore, Son et al (2015) [36] studied the drivers of BIM adoption in design organizations of AEC industry aiming to examine the factors enabling the adoption process by the architects. What they found show that computer self-efficiency, top management support and subjective norms are the critical factors to make the adoption useful and ease for the architects. Risto Tulenheimo (2015) [37] introduced several key challenges and obstacles of BIM implementation generated by customers/ clients (demand, procurement skills and contracts), companies/managers (vision and strategy, management's will and competence, and ROI), organizational behavior (change resistance, education and training, project organization) and technologies (such as hardware, software) in Finnish construction industry.

Bui et al (2016) [38]			○		○		○
Cao et al (2016) [39]			○		○	○	
Hosseini et al (2016) [40]					○	○	
Ghaffarianhosein et al (2017) [16]	○	○	○		○	○	

Bui et al (2016) [38] studied the issues preventing BIM implementation in developing countries. The factors of current BIM adoption are mentioned as technical, perspective (including lack of standards and professionals, legal issues and governmental support) and construction business function (including unclear benefits of BIM). Cao et al (2016) [39] conducted a research on social and economic motivations for BIM adoption in construction industry projects in mainland China. They suggested that BIM users will experience more economic motivation while BIM is maturing. Also, there is relation between organizational ownership and BIM implementation motivations. Additionally, Hosseini et al (2016) [40] studied that the main obstacles to BIM implementation is the lack of clients' and subcontractors' interests and that the SMEs' key stakeholders recognize higher risk of investment and uncertain ROI. However, it is indicated that in Australia the main barrier is not lack of resources and knowledge.

Finally, in 2017, Ghaffarianhoseini et al [16] studied current BIM adoption, its benefits, risks and challenges. The study revealed that lack of adoption is due to factors such as cost, ROI, demand and interoperability issues (software, skills and experience). They suggest that in order to have a successful BIM implementation, firms need to invest in training, software, hardware, an internal process development and business development based on BIM technology. Table 1 shows a summary of the BIM implementation key factors adopted and or are equivalent from the literature review.

3 Discussion on the Key Factors

In order to understand the challenges and issues, we define fields and factors or equivalent parameters. Each field points a group of factors addressing challenges and essential needs that can affect BIM implementation. Although the BIM implementation studies show various approaches and viewpoints of challenges and factors by the researchers, the most cited factors can be divided into five main fields as people, technology, process, organization and policy. The first four fields are showing inner layer factors of firms and the policy field shows an outer layer field that indicates the influences that other organizations and enterprises can make on firms, such as policy makers and governments covering e.g. legal issues, national standards and guidelines.

Figure 3 shows the BIM implementation key factors distribution cited in the literature review and their frequent citations in percentage. The most cited factors are belonged to the organization field, the people field, the process field, and the technology field followed by policy field including standards, regulations and legal issues with 32%, 25%, 17%, 15% and 9% respectively.

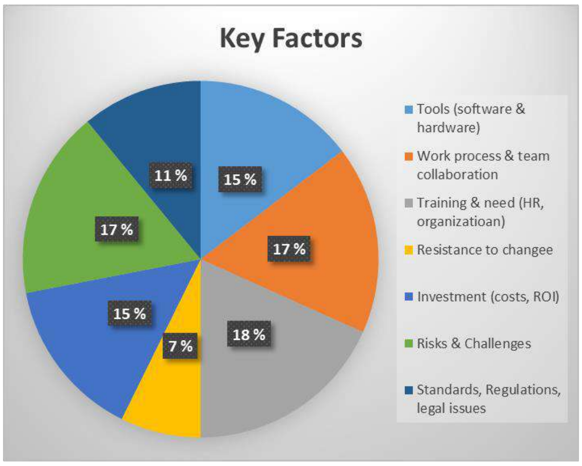

Figure 3. BIM implementation Key factors distribution

The people field includes training human resources (HR), organizational culture and change management issues. The factors of people are challenging parameters that can affect a successful adoption too. The process field is the roadmap of how the technology and people execute the activities and tasks. The technology field indicates the factors including tools, software and hardware. Without appropriate hardware and required software BIM implementation cannot be practically executed. Nonetheless, people, technology and process fields are parts of organizations that decision makers are involved with financial factors such as investments, costs and ROI as well as organizational risks, challenges of business changes and processes.

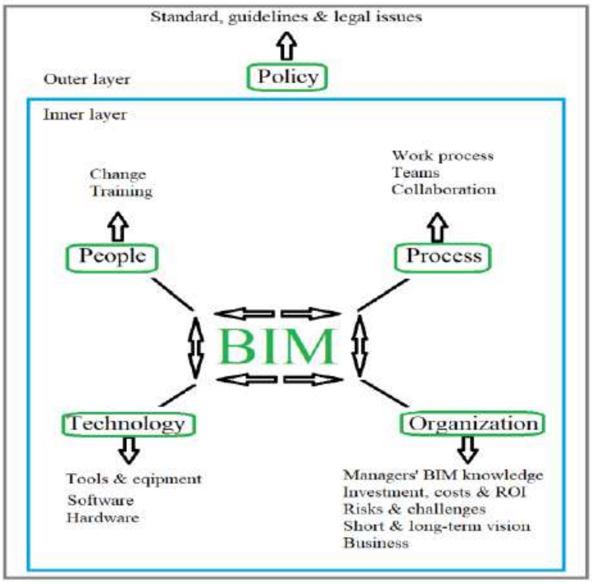

Figure 4. The key factors and BIM fields

Figure 4 illustrates how BIM is centered in the inner layer creating a common source and the outer layer as policy. However, the four internal fields are interconnected and can affect each other.

4 BIM Implementation Framework

BIM implementation is a complex process, due to the mentioned various factors being involved in the implementation process. This article attempts to point out the common aspects applicable to SME contractors. Regarding the similarities and differences between design, construction and service firms, the other firms, with some modifications, can also benefit the presented system to design their own frameworks.

Figure 5 shows an initial BIM implementation framework presented by this study for the SMEs. The framework consists of three main steps and each main step includes some sub-steps addressing challenges, activities, planning, communication, integration and collaboration under the fields of organization, people, process and technology. The first step consist two parts. The first part is targeting that managing directors, boards and shareholders of the SMEs fully understand BIM challenges and impacts. They are ready to change the firms' long-term strategy from the current form to an integrated form, invest in the BIM based business, and work model. The second part is related to the middle level mangers such as directors and managers of technical sectors, ICT sectors, business sectors and financial sectors. They are responsible for change management in their sections, addressing challenges, legal issues, security issues and discovering new business opportunities as well as short-term targets for the firms and assigning BIM teams.

The second step is planning step and the BIM team including current team members should analyze current processes of activities, human resources and tools in order to design new processes based on BIM technology and tools. This is crucial to communicate the progress of this step and send the feedbacks to the organizations for adopting and supporting new decisions aligned with the short and long-term strategies. This step also can benefit current available standards and guidelines for BIM implementation, depends on their availability.

The third step is piloting what has been planned in the second step. The output of second step supports people, process and technology to be employed in real work places. For instance, during bidding phase the teams can prepare quantity takeoff list (QTL) and cost estimation by the 3D parametric models and BIM based software instead of using traditional means. However, constructability and clash detection are feasible and an accurate construction plan can be obtained. In the execution phase, work activities, timetable and scheduling as well as site and risk management are considered more accurate by using BIM based project managing software and other tools like virtual reality (VR) and augmented reality (AR). For the monitoring phase tracking activities, verification and guidance are covered. In order to review and reorganize the involved processes, people and technology for each piloting step the feedback and results as well as challenges should be reported to the BIM team. The circulation of information, feedbacks and knowledge between the three steps supports the system to improve the framework and acquires more advantages from it.

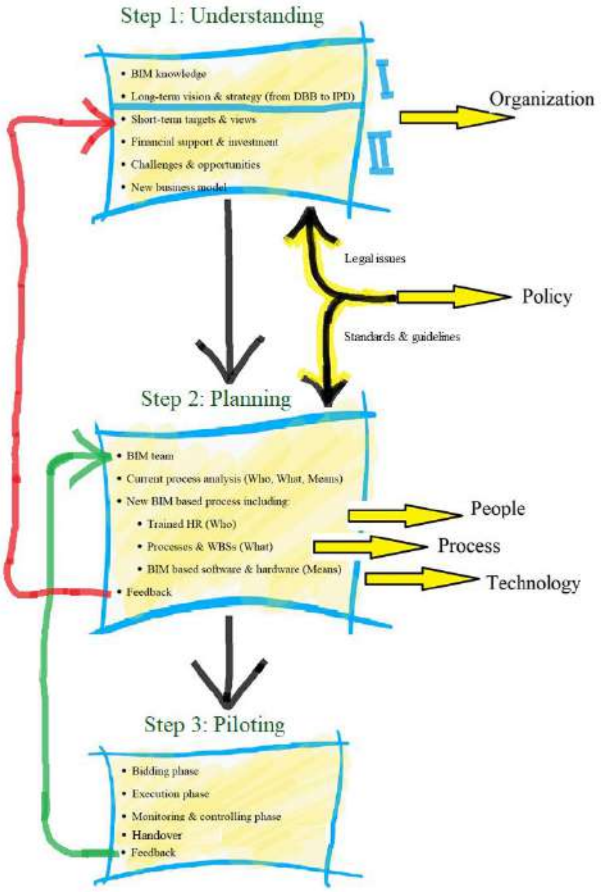

Figure 5. Initial BIM implementation framework

5 Conclusion

In this article, the authors have tried to define and introduce BIM as a modeling system, which can increase ROI and competitiveness of the SMEs and in the near future will be an essential approach and tool in the building industry. Additionally, BIM in the building industry and the current necessity of BIM implementation as well as the future role of BIM in automation and robotic construction were discussed. However, as the main aim of this article, a simplified initial implementation framework for SME contractors was introduced. The authors expect that this article to help the SMEs to understand BIM as modeling and employ BIM with less costs and more efficiency by knowing the key factors of the implementation framework and strengthening their competitiveness.

Finally, this study is limited to an initial BIM implementation framework for SME contractors and has not categorized the SME firms so as a future research proposal a more detailed investigation on the BIM implementation framework for different types of construction firms via real cases can be conducted.

Acknowledgment

The authors would like to express their gratitude to the director of civil engineering school of Oulu University of Applied Sciences (OAMK) Jyrki Röpelinen, the project manager Antti Haapalahti and all other members of the EU funded Interrg Nord project, ICNB (Increasing Competence in Northern Building), from Finland, Sweden and Norway for their general contribution during the meetings and workshops.

Abstract

The development of 3D reconstruction from 2D building images enables cost-effective and accurate acquisition of spatial data. Feature extraction is a fundamental technique for 3D reconstruction method. However, buildings mostly consist of planar surfaces whose entities are feature-less. This study presents 3D building reconstruction using A-KAZE feature extraction algorithm. Because A-KAZE algorithm does not use Gaussian blurring like SIFT and SURF, A-KAZE algorithm has potential to extract correct visual features for feature matching and 3D reconstruction. The proposed method was tested on actual building scenes acquired from a high-resolution camera. The experimental results showed that the A-KAZE algorithm can detect the sufficient number of features with low computation time. It is expected that the proposed method can be implemented in comprehensive 3D reconstruction of civil infrastructures.

Keywords –

3D reconstruction; feature extraction; A-KAZE; binary descriptor; structure from motion; photogrammetry

1 Introduction

The demand for 3-dimensioanl (3D) reconstruction of a building is increased over the last decade in the field of the Architecture, Engineering, Construction and Facilities Management (AEC&FM), with the purpose of collecting as-built spatial data. As-built spatial data can be used for a variety of applications including inspection of defects [1], building performance assessment [2], and document updates [3]. Traditional approaches of collecting spatial data like manual measurement with visual inspection and total station survey are not only labor-intensive and time-consuming, but also inaccurate because such measurements become highly dependent on the skill, experience, and expertise of the workforce. A potential alternative to these conventional approaches, therefore, is a laser scanning technology, which can generate 3D point cloud data of a structure promptly with a high level of accuracy. However, in spite of the distinctive advantage of this remote sensing technology, its use is limited by its expensive cost and requirement of highly skilled operators. To overcome this challenge, image-based 3D reconstruction has drawn attention because of its ease of use, inexpensive cost, and higher accessibility with the development of computer vision-based techniques.

Structure from Motion (SfM) is a photogrammetric method that generate 3D point cloud data using multiple images acquired from different view angles [4], which is an equivalent principle to a human's ability to perceive a 3D structure from 2D projection. To estimate the intrinsic and extrinsic parameters of camera and to reconstruct a 3D geometry, SfM method uses a process of finding corresponding features from the images. So far, numerous feature extraction algorithms have been proposed in the field of computer vision and image processing since extracting and matching such pairwise features among images are the key steps of SfM method [5]. However, using only visual features to reconstruct a 3D scene is a challenging task. Recently, many researchers have used different types of geometric entities as visual features to estimate the parameters of camera. The most commonly used visual feature is the point-based feature, also known as interest-point or keypoint. Since point-based methods have significantly high time complexity, lines and planes are also used as high-level visual features [6]. These visual features can be found on building scenes, whose objects are mostly consisting of planar surfaces. However, high-level visual features are commonly variant to changes in orientation of scenes and illumination information [7].

Recently, retrieval algorithms with localized keypoint are widely used in 3D reconstruction techniques. The keypoint is mostly detected on regions with significant variation in edges and keypoint descriptors are invariant to orientation changes of images acquired through different angle-view. In computer vision, several 3D reconstruction commercial software packages have emerged to gain robustness and enhance efficiency of extracting features from images.

During recent decades, Scale-Invariant Feature Transform (SIFT) [8] algorithm has been perceived as the most common choice for feature detector and descriptor. However, SIFT and Speeded Up Robust Feature (SURF) [9] exploit Gaussian scale space which blurs the details with noises to equivalent extent and does not preserve boundaries of an object [10]. Since buildings have elements with sharp edges like wall and roof, other alternative algorithm is needed rather than SIFT and SURF. Otherwise, manual optimization of miss-matched image pairs is required when using an unreliable feature extraction algorithm. Barazzetti et al [11] presented 3D reconstruction method to obtain accurate point clouds automatically. This study evaluated the performance of SIFT descriptor on different sizes of test images. The evaluation results showed that computation time increased considerably when the size of the image was increased.

This study presents a 3D reconstruction method using A-KAZE feature extraction algorithm for finding pairwise features from building images, to generate an accurate 3D points clouds automatically. A-KAZE is a non-linear scale space-based algorithm that has a great potential of preserving sharp boundaries of buildings' elements. In this study, the comparative analysis among SIFT, SURF, and A-KAZE has served to evaluate each algorithm as a feature detector and descriptor. To achieve a practical implementation, a typical building has set to be a target for 3D reconstruction.

2 Methodology

Accelerated-KAZE (A-KAZE) feature detector and descriptor, which is proposed by Alcantarilla et al. [12], uses nonlinear scale spaces to extract corresponding features of images. This algorithm is developed from KAZE algorithm [13] by embedding mathematical Fast Explicit Diffusion (FED) in pyramidal structure to speed up the nonlinear scale space computation. In comparison to Gaussian scale space of SIFT and SURF, nonlinear scale space can extract corresponding features of images while maintaining details and reducing noises by means of nonlinear diffusion filtering. Moreover, the computational complexity $O(n^2)$ (where n is the number of input images) of A-KAZE is lower than that of SIFT and SURF [14].

A-KAZE is mainly comprised of three steps: a nonlinear scale space building with FED, feature detection, and feature description. The first step is to define a set of evolution times for building the nonlinear scale space. Then A-KAZE detects the feature points that are the local maxima of the determinant of the Hessian matrix using nonlinear scale space. Finally, given feature points are represented by Modified-Local Difference Binary (M-LDB).

In the first step, A-KAZE builds pyramidal structure of nonlinear scale space. The scale space is discretized into a series of octaves (O) and sub-levels (S). The set of octaves and sub-levels are identified by discrete octave (o) and a sub-level (s) and they are mapped to their corresponding scale (σ) as shown in equation (1).

$$\sigma_i(o,s) = 2^{o+s/S},\ o \in [0...O-1],\ s \in [0...S-1],\ i \in [0...M] \quad (1)$$

Where M is the total number of filtered images. Then the set of discrete scale levels in pixel units is transformed into σi time units because nonlinear diffusion filtering is defined in time term as shown in equation (2).

$$t_i = \frac{1}{2}\sigma_i^2,\ i = \{0...M\} \quad (2)$$

Moreover, the input image can be convolved with a Gaussian blurring of standard deviation σ to reduce noise and possible artefacts. From the filtered input image, the contrast factor (λ) is computed in an automatic way as the 70 % of the gradient histogram. To overcome the main drawback of KAZE which is its high computational cost, FED scheme is embedded into the pyramidal structure.

In the second step, feature points which are local maxima are detected from the filtered images (Li), by computing the determinant of the Hessian matrix in the nonlinear scale space. Hessian matrix of the images is computed by a normalized scale factor as shown in equation (3),

$$L^i_{Hessian} = \sigma^2_{i,norm}(L^i_{xx}L^i_{yy} - L^i_{xy}L^i_{xy}) \quad (3)$$

Then the determinant of the given Hessian Matrix is computed to find local maxima points at each evolution level. The pre-defined threshold for potential local maxima points is set to be a window of 3×3 pixels. The computation is implemented efficiently by discarding non-local maxima points. These candidate points are recalculated to determine whether the points are maxima by comparing each point form i+1 and i-1 evolution level. Finally, the given maxima points are assigned to be feature points.

A Modified-Local Difference Binary (M-LDB) is employed as a feature descriptor in A-KAZE. The M-LBD descriptor follows the principle of a LDB descriptor [15] that computes binary strings for image patches using gradient and intensity information from non-linear scale space. In the LDB descriptor, each image patch is divided into various sizes of n×n grid cells and those partitions are efficient to compute average intensity. However, the LDB descriptor is sensitive to rotation of image patches that requires high computational cost. Thus, A-KAZE achieves a scale and rotation invariance by scale-dependent sampling and estimating the main orientation information. The M-LDB uses horizontal and vertical derivatives from detected features to construct the descriptor.

In this study, a brute-force method is employed for efficient feature matching. The brute-force approach finds corresponding features from multiple images in different angle. The process mainly consists of three steps: comparing binary descriptors and testing ratio, using estimators to compute fundamental matrixes, and using epipolar constraint for eliminating outlier matches. Then, only inlier matches are exploited for homography estimation by using random sample consensus (RANSAC) method.

3 Experimental Results

To demonstrate that A-KAZE algorithm is an optimal feature extraction algorithm for building scenes as a feature detector and descriptor, a comparative analysis has presented. OpenCV library is used for implementation of feature extraction and matching algorithms, with the default parameters. The test images of building's wall surface are captured by a Zenmuse Z3 camera equipped in a Quadcopter DJI Matrice 100 (see Figure 1). Resolution of the images are ultra-high-definition of 4000×2250 pixels (4K). Since the size of the building is incompatible to any other objects, 3D reconstruction is needed to be facilitated by using images of high resolution to provide a 3D model with valuable and practical information for building operators.

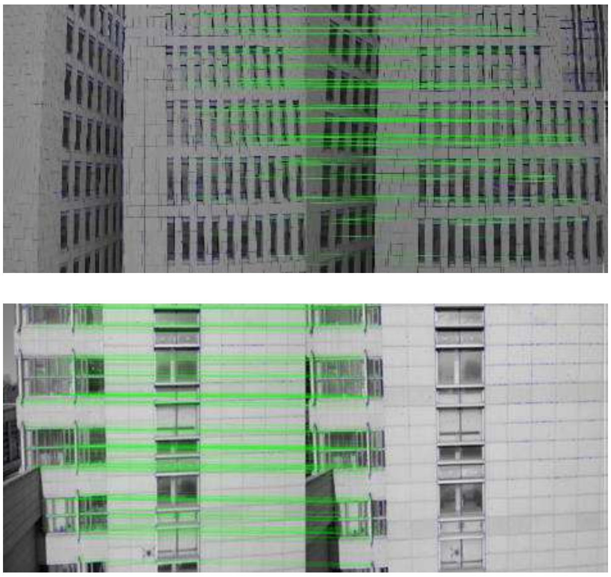

Figure 1. Exemplar images of feature extraction results of building scenes

Table 1. The results of feature extraction and matching of building scenes. The highest values are indicated in bold.

	Detected keypoints	**Matching score**	**Computation time (sec,)**
SIFT	2051	26.09	6.88
SURF	**16603**	16.26	11.06
A-KAZE	3317	**32.47**	**5.91**

As shown in Figure 1, keypoints are sufficiently detected and matched. The results also imply that A-KAZE algorithm reliably extracted corresponding keypoints from building scenes whose objects had poor-textured surface. Table 1 presents the matching results of Figure 1 using SIFT, SURF, and A-KAZE. As presented in Table 1, the matching results indicate that SURF algorithm detected the highest number of keypoints from the images and for the matched features. However, SURF algorithm showed the lowest matching score among algorithms. Although SIFT algorithm showed compatible matching score result, the number of detected keypoints and matched features are relatively lower than other algorithms. A-KAZE algorithm achieved a stable performance in detecting keypoints with the highest matching score.

Since feature extraction and matching are repetitive processes on many multiple images in 3D reconstruction procedure, computation time is a critical determinant. The time complexity for computing A-KAZE algorithm is presented as the lowest among the three algorithms, as shown in Table 1. These results potentially imply that A-KAZE is an optimal algorithm for extracting and matching correct features from building images.

Figure 2 is a result of 3D building reconstruction of which surface is poor-textured. The 3D reconstruction model is generated by 43 sequential images of 4K resolution using A-KAZE algorithm. The result presents a similar scene to its source images. This potentially imply that A-KAZE is an optimal algorithm for extracting and matching correct features from building images.

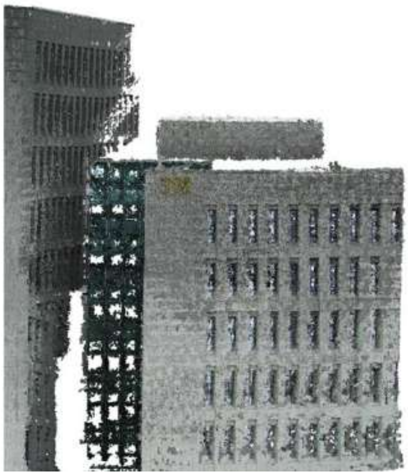

Figure 2. Exemplar images of 3D reconstruction of building

4 Conclusion

This study presented a 3D reconstruction method using A-KAZE feature extraction algorithm to detect correct corresponding keypoints and to reconstruct accurate 3D point clouds of buildings automatically. Because buildings mostly consist of texture-less elements with planar surfaces, conventional feature extraction algorithms encountered challenges. To solve this problem, A-KAZE feature extraction algorithm was employed in this study. To assess the performance of A-KAZE algorithm as feature detector and descriptor, analysis of detecting and matching results has conducted. The results presented that A-KAZE algorithm reliably and efficiently detected corresponding features from high-resolution building images which were acquired in different view angles. This study, thus far, contributes to establishing a comprehensive 3D reconstruction method for buildings.

Abstract –
This paper presents an ongoing work in relation to the development of a parametric design algorithm and an automated system for additive manufacturing that aims to be implemented in 3D clay printing tasks. The purpose of this experimental study is to establish a first insight and provide information as well as guidelines for a comprehensive and robust additive manufacturing methodology that can be implemented in the area of 3D clay printing, aiming to be widely available and open for use in the relevant construction industry. Specifically, this paper emphasizes on the installation of an industrial extruder for 3D clay printing mounted on a robot, on toolpath planning process using a parametric design environment and on robotic execution of selected case studies. Based on existing 3D printing technology principles and on available rapid prototyping mechanisms, this process suggests an algorithm for system's control as well as for robotic toolpath development applied in additive manufacturing of small to medium objects. The algorithm is developed in a parametric associative environment allowing its flexible use and execution in a number of case studies, aiming to tentatively test the effectiveness of the suggested robotic additive manufacturing workflow and their future implementation in large scale examples.

1 Introduction

The term Additive Manufacturing (AM), also commonly known as three-dimensional (3D) printing, is used to describe the process of material deposition in layers, leading to solidified products. The technology of AM has gained considerable attention the last few decades and today has succeeded to be a rapidly growing field worldwide with a number of technologies available for public use. This direction of investigation has been thoroughly explored and various methods have been introduced and discussed [1]. To name a few, these might include Fused Deposition Modeling (FDM), Selective Laser Sintering (SLS), Inkjet Powder Printing, etc. [2, 3]. A number of advantages have led the manufacturing industry to introduce such technologies into daily production, which include the freedom to create any morphology without the application of molds [1], the minimization of material waste, etc.

Today, we have reached a stage where AM technologies are available for industrial and household applications in reasonable prices or even are available for reproduction through open source platforms and mechanisms [4]. Nevertheless, any selection of specific technology and its application contains particular limitations and constrains. These might include limitations in regard to the size of working area, leading to print results in small scales, constrains in regard to the type of material used, the type of mechanisms as well as the methods applied.

When tasks refer to the 3D printing of small to medium scale objects, these can be largely solved with available industrial technology. However, an area that faces limitations in large extend in terms of AM implementation is the construction industry, where the necessity for manufacturing building parts or even complete structures in actual scale, demands more thorough and comprehensive procedures that take into account actual construction parameters. In addition, due to the multiple and complex tasks involved during the construction of a building, including the need for specific technique and materials implementation [1], the introduction of open source and custom platforms for additive manufacturing is more than a necessity in order to allow direct and flexible intervention of automated mechanisms according to the large scale objective under investigation.

Large scale AM and particularly its application in construction industry is an area that is rapidly growing with many examples attempting to introduce techniques derived from 3D printing principles for the production of houses in full scale, for instance the 3D Print Canal House in Netherlands [3]. Towards this direction several attempts to provide such technologies have been conducted, especially in the area of concrete printing. Such works date back to the well-known Contour Crafting (CC) technique [5] and later to the introduction of other techniques, for instance D-Shape [6], Concrete Printing [7], Additive manufacturing of concrete [8], CONPrint3D [9], and so on. Although, similarities can be found in the abovementioned technologies in regard to their objectives, differences can also be observed, mostly it terms of material deposition and control automation processes. The techniques of Concrete Crafting and Concrete Printing as well as similar directions of investigation are based on the layer-by-layer deposition of concrete materials with the application of gantry and mounted nozzles [5, 8, 10], while technics like D-Shape follow principals similar to the Inject Powder Printing [6]. Beyond the obvious opportunities that innovations in large scale AM can bring to the construction industry, numerous advantages might be offered, which include reduction of construction cost and time, minimization of errors during construction, etc. [11]. Also, might allow issues related to the local and ecological aspect of material use to come to the fore [12, 13, 14], an area that lies within the broader field of sustainable construction, currently under consideration. This direction, together with the introduction of digital fabrication, for instance 3D printing in large scale, can reduce the environmental impact of structures [15].

In addition, recent attempts towards the introduction of advanced technology in Architecture, Engineering and Construction (AEC) industry, for instance, the use of digital design and modelling tools including Building Information Modelling (BIM) and parametric associative design or the application of robots and automation mechanisms in fabrication process, open new opportunities for integrating design to production processes. This might allow a more thorough and complete investigation, both in terms of the selected designs to be realized due to the ability of BIM and parametric tools to allow their real time control and modification prior to their actual construction according to a number of criteria (environmental performances, constructability, etc.). Also, this might include a more flexible and customized processes for controlling output data for construction of non-standard morphologies and later on their physical execution using automated and robotic construction systems [16, 17, 18]. In addition, advanced tools and mechanisms allow a more productive and open source approaches [19], which can be applicable to the construction industry, advantages that are necessary to be acquired during an AM process in actual scale.

However, in order to complete a fully operable system for 3D printing, knowledge in regard to the software and hardware installation are necessary, an area that is not always accessible by the majority of architects or constructors. In this paper, an attempt to overcome such limitations is conducted by introducing a robotized method for hardware installation and toolpath planning process that can be easily available and can be adopted by people involved in similar research directions. Further prospects are, by using similar principles, to extend the scale of additive construction, aiming at their implementation in various scales with emphasis on large scale manufacturing, an area that currently is in the forefront of the research conducted in our laboratory for sustainable robotic construction [12].

Within this framework, and by following similar principals [16], this paper presents a methodology for integrating parametric design and robotic additive manufacturing, aiming to be applied in, both small/ medium and large scale 3D clay printing tasks [13, 14]. The process aspires to promote the sustainable aspect of the material evolved but also to stress the advantages carried out in the design and construction industry by integrating parametric tools with automated construction technics.

The structure of the paper is as follows; in the next section the methodological framework is briefly explained; then, analytical descriptions in regard to the installation process of the industrial 3D clay extruder and the robotic calibration are given; afterwards, the toolpath planning development process, the robotic control and finally the robotic execution are demonstrated by testing a number of case studies; and finally, conclusion is drawn.

2 Methodological framework

As it has been mentioned, the aim of this ongoing study is to develop a robust and reliable methodology that will allow the integration of parametric design with robotic additive manufacturing mechanisms for 3D clay printing. This, in combination with the application of clay material, which promotes the ecological aspect of the suggested methodology, aspires to provide a sustainable and custom/open source platform that can be applied in different case studies. Such cases might include printable objects range from small/medium to large ones, using them as individual building elements in the construction industry.

Analytically, the proposed methodological framework considers all necessary actions required to embed the selected automated mechanisms for 3D clay printing in the overall automated construction system. Also, is designed to include all necessary steps required for a complete workflow procedure from design to production with emphasis on toolpath planning process and robotic control.

Initially, the installation of an industrial 3D clay extruder, and specifically the Clay Kit with LDM Wasp Extruder by WASP [20, 21] is embedded in the construction system and particularly is mounded at the end of an industrial robot ABB 600-20/1.65 with IRC5 controller. The industrial extruder consists of two main parts, the clay pump that extrudes the material and the 3D clay extruder that is responsible for the deposition of material in layers. The installation of the mechanisms as well as the robotic system calibration are necessary parts for an accurate and effective 3D clay printing procedure. This, in combination with the need for an inseparable workflow that achieve the parametric development of the objects to be built, the toolpath planning generation and subsequently the robotic control for robotic execution, consists all necessary steps towards a complete and integrated methodology.

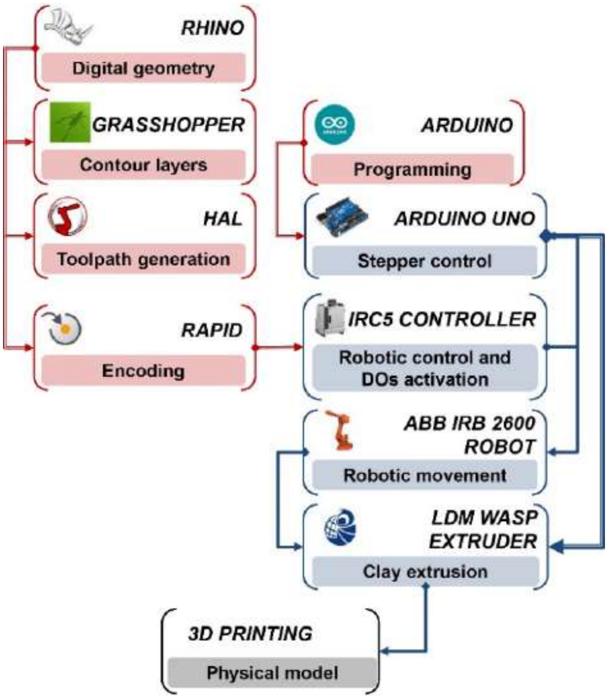

Figure 1. Methodological framework in the form of diagram for the 3D clay extrusion system development

In regard to the installation of the industrial 3D clay extruder, a number of sub-components consisting the overall system are studied and carefully mounted on the robotic arm. These include the clay pump that is responsible for continuous clay material feed to the clay extruder (nozzle) and the 3D clay extruder with nozzle that is responsible for extruding clay material and for layer deposing according to predefined width and height. As regards the toolpath planning process, similarities with other conventional [22] or advanced parametric tools and platforms [23] used for toolpath planning, which are introduced in additive manufacturing can be found. In this case, due to the parametric nature of the customized/open source platform that is introduced, the implementation is achieved in the parametric design environment of Grasshopper software [24] (plug-in for Rhino [25]). This enables the development of various morphologies in digital form that can be easily modified and parametrically control, offering large number of design possibilities. After the digital geometry is developed in the parametric environment, this is sliced based on contour-layer development algorithm, leading to the toolpath generation. Simultaneously, 3D print parameters are embedded to the digital geometry related to the width and height of each contour (filament) and according to the clay material mixture applied. Then, the HAL software [26], a robotic control plug-in for Rhino, is used to produce all necessary data in RAPID code and in turn to be executed by the ABB robotic arm. The following sections describe, in detail, the main steps of the suggested workflow procedure (Figure 1).

3 Installation of 3D extruder and robotic system calibration

3.1 Overview of the automated construction system

The robotic system consists of four main parts, where its synchronization aims at creating a process that will allow 3D clay printing of various complex and non-standard shapes. The system consists of the following parts:

1. The cylindrical tank for clay feed connected with the industrial clay extruder.
2. The industrial clay extruder that consists of one stepper driver that rotates an auger in the form of a rotating helical screw inside a cylindrical chamber, extruding the clay through 1mm nozzle.
3. The on-off switch and flow rate control board for the industrial 3D extruder that is run through an Arduino board, which controls a stepper motor driver.
4. The industrial robotic arm ABB 600-20/1.65 with IRC5 controller.

As it has been mentioned, the automated system is run in the parametric environment of Grasshopper in conjunction with HAL, which allows parallel control of robotic arm movement and activation of the industrial 3D clay extruder. As a result, clay is fed to the extruder at the edge of the robotic arm through the provided clay tank. Important aspect towards a seamless printing process is the accurate/functional design and programming of the automated clay printing control system.

3.2 Design and installation of 3D clay extruder system

Initially, an acrylic base functioning as the supportive system of the industrial 3D extruder is designed, fabricated and finally mounted at the end of the robotic arm. The suggested design solution allows undisturbed ventilation of the stepper motor, easy connection with the industrial clay extruder system, and simple assembly and disassembly of the mechanism for maintenance purposes. The acrylic base is attached to the robotic arm through a supportive steel blade with four screws, which also encloses the industrial 3D extruder fixed with two screws. Figure 2 shows the tool adjusted on the robot.

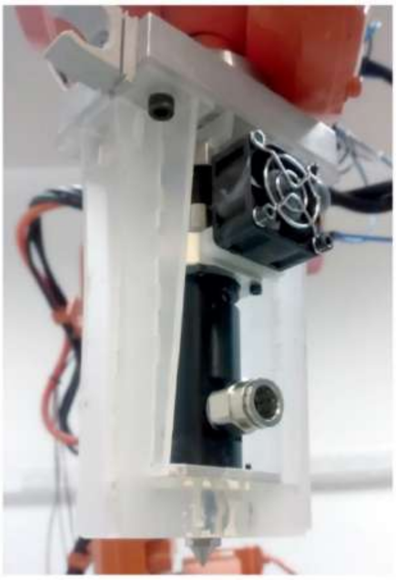

Figure 2. The industrial extruder with the supportive system mounded on the robotic arm

In order to feed with material the extruder at the end of the robotic arm, the cylindrical tank is filled with clay that is provided by the manufacturer [27]. By pushing air pressure into the tank, the piston is activated and pours the clay that is inside. The clay is passed to the cylindrical chamber of the industrial 3D extruder through a plastic pipe. In order to activate the industrial 3D clay extruder through its stepper motor, a stepper controller is used for rotation movement. The programming of stepper controller (CNC Single Axis 4A TB6600 2/4 Phase Hybrid Stepper Motor Drivers Controller) is achieved in Arduino environment using an Arduino UNO board. The programming allows pulse rate control in order to adjust the rotational direction and speed of the stepper motor. For powering the Arduino UNO board and the stepper driver, an external power supply is used. With the use of a Siple Pole Double Throw Toggle Switch (SPDT), it is possible to activate the Arduino UNO directly from the power supply or through a relay connected to the power supply and controlled by the IRC5 robotic controller. The use of switch allows manual preparation of the system for printing and automatic control through the control of robotic arm. Finally, the board for system's control is placed on the robotic arm (Figure 3).

Figure 3. The 3D clay printing control system mounted on the industrial robot

3.3 Robotic system calibration

In order to achieve accurate and automated 3D clay printing process, the control of material flow from the pneumatic piston to the nozzle is important to be examined. The Arduino UNO board is programmed to control the rotation of the stepper motor at a constant and continuous rotational speed, which achieve the movement of clay material into the chamber and then its exit from the nozzle. As it has been mentioned, the Arduino board is powered by an external electrical source that is connected to a relay on the robotic arm controller. By activating the relay, the Arduino operates and controls the flow of clay. When the relay is switched off, the clay funneling stops. The on/off control of relay occurs in real time using the HAL plug-in. The activation or deactivation of nozzle funneling is based on the generated toolpath that is derived according to the digital shape under investigation.

A significant aspect in the printing process is the calibration of the robotic arm movement with the clay extrusion speed. This is done by observing the results derived from initial case studies, where several changes in robotic movement speed occurred. During the case studies execution, the robotic movement is controlled using the Teach Pendant, allowing determination of its right speed. Figure 4 shows results of calibration: under extrusion print (A) using 15 mm/s speed; over extrusion print (B) with TCP velocity of 5mm/s, and calibrated extrusion print (C) with a robotic movement speed of 9 mm/s.

Figure 4. Results of 3D printing speed calibration. A. Under extrusion speed, B. Over extrusion speed, C. Calibrated extrusion speed

Finally, for the correct deposition of material on the base of working area, the height calibration of the nozzle in relation to the base is required. This is done by placing the nozzle perpendicularly to the corner of the base with an approximate distance of 0-0.2mm. For the correct positioning of nozzle, this is repeated three times, as many as the rest of base's corners. Using the HAL plug-in, the point of nozzle placement is recorder, updating the point in the parametric environment and then associating this with the base. In addition, for the right deposition of material, two initial layers of the geometry are added to the base with 5mm offset from the perimeter in accordance with the first layer of the shape. The form is printed on a solid layer, providing results of uniform clay layers.

4 Toolpath planning, robotic control and execution

4.1 Parametric design and control

In a 3D printing process, important parameters determining the end result are the layer height that defines the distance between the sections in the contour process, the line width that is influenced by the filament width of the extruded materials and the wall thickness that determines the number of polylines per layer, calculated based on the width of extruded materials. These parameters are introduced into the Grasshopper parametric environment in order to identify the robotic toolpath.

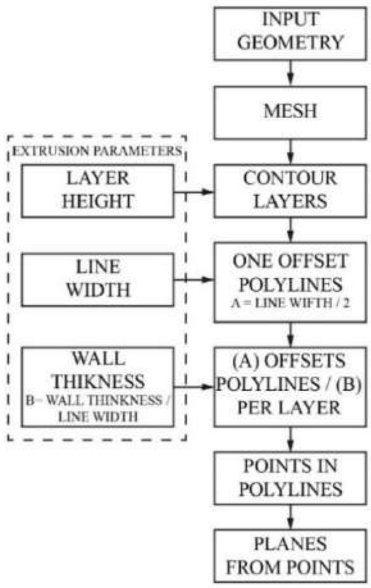

Figure 5. Flowchart of the contour geometrical configuration algorithm

The purpose of the parametric algorithm is to receive and process any digital geometry (BREP), by converting this into mesh object. Then, it generates contour layers in the form of consecutive polylines. The users can determine the print precision by varying the layer height up to 2mm. In this phase of experimentation and for case study purposes, the layers are defined with a height of up to 1mm. Subsequently, the sequential sections of layers are offset with inward direction and with value 0.5mm that is determined by the line width, which represents the filament of the extruder material (in this case 1mm/0.5). Moreover, the wall thickness is defined by the user, by specifying an integer number of required offsets in order for the extruder to print the expected width. The integer number is described by the roundness reduction of the thickness/line width relationship and also it calculates the group of polyline assigned in every layer height. Finally, polylines are divided into successive points, which create the toolpath of the robotic arm (Figure 5).

4.2 Toolpath planning

The development of toolpath for robotic motion behavior is based on the successive points of contour polylines generated in the parametric environment. Also, in the same algorithm the digital output (DO) activation control connected to the relay is used to activate the Arduino board, resulting in the rotation of stepper motor, and hence in the extrusion of clay material.

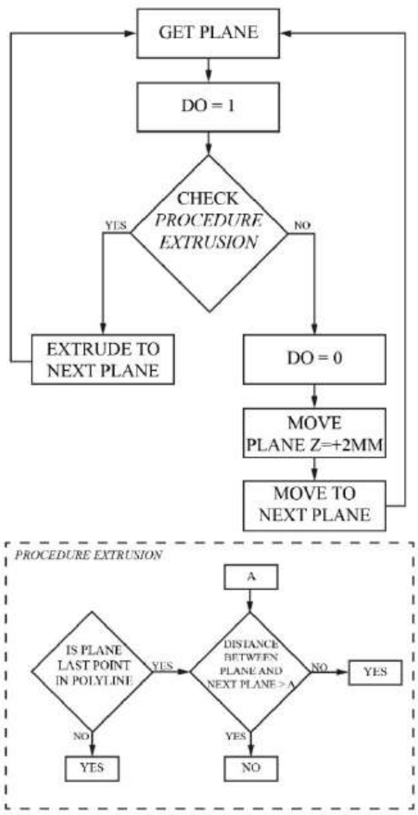

Figure 6 Flowchart of the toolpath development process

The robotic movement commences at the starting point of toolpath that is assigned outside the geometry at the corner of the base, and at the same time the clay extruder is actuated. Then, the deposition of filaments on the two thick layers of material on the base are executed. This process is based on the geometry of the initial contour layer (polyline), whereas the contour is offset 5mm and it is filled with radial lines from the center of the polygon in outwards direction. After the two layers on the base of the object are generated, the process of toolpath development is taken place.

The toolpath development process (for material extrusion) is based on the point-to-point motion driven by each contour layer, geometrically defined as polyline. The algorithm compares the distance between previous polyline's end point and next polyline's start point. If the line being created does not belong to the previous polyline, then the extruder is deactivated. In off state, the nozzle is disabled and is raised 2mm from the printed layer (from previous polyline's end point to the next polyline's start point) at a height of 2mm.

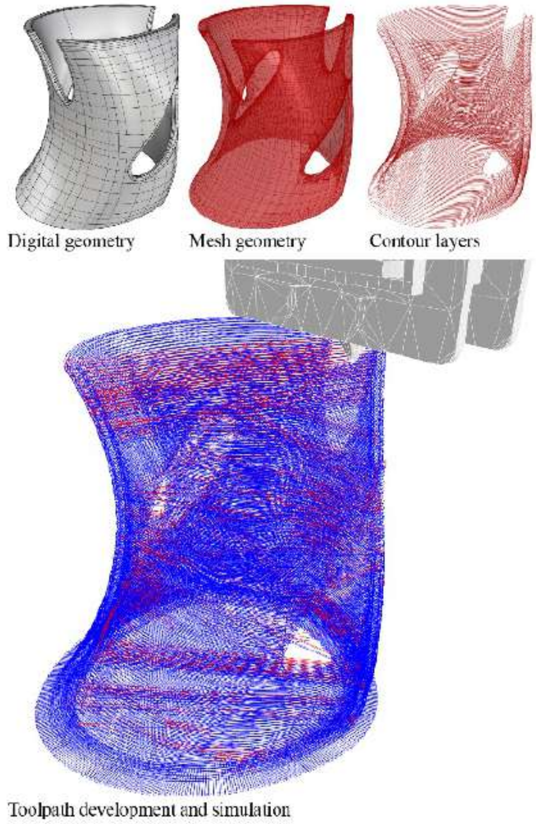

Figure 7. Toolpath development results. Blue colour shows the DO activation and red colour shows the DO deactivation

Subsequently, the nozzle approaches the next polyline's start point and the clay extrusion is activated. By turning off the nozzle at a height of 2mm ensures that the object is properly printed, as the movement of the nozzle does not touch or collide with the printed structure or does not deposit material in undesirable areas of the geometry. Finally, the toolpath development process is repeated in each sequential group of polylines for each contour layer in order to develop the overall toolpath. This is sent to the robotic controller for printing execution. Figure 6 shows the flowchart that describes the toolpath development process and figure 7 the toolpath generation in the parametric environment. Several case studies have been conducted, as shown in figure 8, in order to investigate results and draw useful conclusion for evolving printing process and for improving the functionality of the integrated platform.

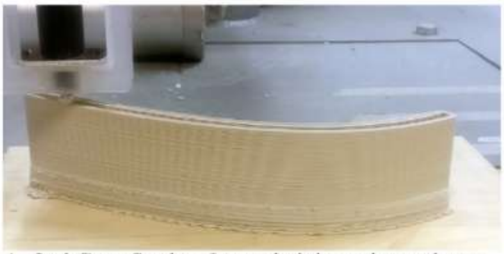
In the first case study, a compact geometry is used to investigate the toolpath for clay extrusion. In this case, clay material waste is observed because there is no interruption and removal as well as deactivation of the extrusion process. Also, the layer height range is investigated, resulting in 1mm being the ideal one. Figure 8 (A) shows the second case study, where the appropriate layer height is defined and the speed of the robotic arm relative to the extrusion speed is investigated. In this case, as mentioned above, the speed of the robotic machine (TCP velocity), relative to the rotation of the stepper motor, is set at 9 mm/s. Finally, in the third case study (Figure 8B) a more complex form that consist of openings is tested, and specifically the ability of the methodology applied to automatically activate/deactivate and remove the nozzle in cases of open hole patterns is explored. Also, results in terms of the quality of printing (smooth surface resolution, etc.) are derived, which are influenced from the layer width and height.

Although, the experimental case studies introduced in this paper are in small scale, our attempt is to apply the suggested methodology in medium scale printing, but most importantly, in large scale tasks that can be revealed in construction industry. An experimentation in all scale levels with the parallel examination of appropriate clay material mixtures [27] will allow thorough and comprehensive results to be derived, evaluating in parallel the feasibility of the suggested platform to be introduced in construction industry in a future stage.

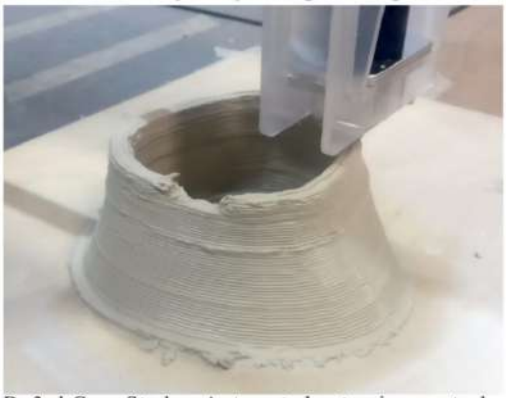
5 Conclusion

Currently, there is a tendency towards parametric design incorporated within platforms for performance evaluation of buildings, offering opportunities for design optimization and selection of the best results that can be realized in actual scale. Also, there is an increased interest among educational establishments towards automated construction processes, mainly by using industrial robotic arms for the manufacturing of complex and non-standard morphologies. However, little work has been observed in regard to the coherent and robust integration of such advanced digital design tools with automated construction processes. In this paper, the methodological framework and the initial results of experimentation in regard to the integration of a parametric design environment with a robotic additive process is presented. The aim is to develop an open source/customized platform that offers an alternative and ease solution for 3D clay printing in robotic construction tasks.

The methodological framework includes all important steps for a complete and effective integration that can achieve a smooth and seamless workflow from digital parametric design investigation to robotic production. The main pillars of this investigation include; the installation of industrial 3D clay extruder and robotic system calibration; the toolpath planning and the robotic control process, incorporated into the parametric environment; and finally the robotic execution, initially through small scale 3D clay printing studies. Within this framework, results in term of automated construction system calibration including extruder's stepper motor and robotic speed are obtained. Also, results in terms of toolpath planning process including layers' width and height of filament are obtained, offering all necessary data required for robotic execution in actual scale.



A. 2nd Case Study - Layer height and speed test



B. 3rd Case Study - Automated extrusion control

Figure 8. Two case study experiments using the 3D cay extruder mounted on the robot

In conclusion, this investigation has demonstrated a first attempt to integrate design and manufacturing tools within an open source platform. This allows an ease and effective development of robotic-driven automated system for 3D clay printing that can be potentially available for further implementation and use. Although, the first results are quite promising, further studies are required in order to test the feasibility of suggested methodology, together with a more thorough examination in regard to the use of clay mixtures and their application in different scales. Simultaneously, further studies in robotic AM need to move beyond experimental stage towards application in real construction scenarios taking into consideration sustainability criteria.

Abstract

One of the difficulties encountered at a plant construction site is frequent changes to design, which causes work overload. This can lead to increased construction costs, delayed progress, inferior work quality and poor productivity due to redundant work among project participants or omission of work.

In this study, we propose a work management system that uses smart devices based on augmented reality technology, which provides real-time information on plant construction so that site workers and managers can reduce wastes and errors, as well as check maintenance information more easily.

Keywords –

Augmented Reality; Smart-Device; Pipe-assembly; DBS(Device Breakdown Structure)

1 Introduction

1.1 Research Background and Purpose

A plant construction project is large in scale than general construction site, and involves complicated planning and processes. At a plant construction site, work data are generated for different stages of work, including architectural work, pipe installation, electricity and other facilities. During construction, massive amounts of data are generated, and management of this data is challenging. Thus, plant construction projects are harder to implement compared to other construction projects.

Various research has been undertaken for efficient management of plant construction, including studies on MIS using QR codes, barcodes, RFID and cloud systems.

However, these technologies entail the problem of redundant work due to delayed processing of real-time data and duplicated systems. As a result, construction time is stretched, and the same work is repeated unnecessarily. Productivity also declines in the maintenance and management stage, as a delay in the resolution of troubled tasks spreads to other related tasks.

In this study, we gather construction site managers' opinions to identify work processes that need improvement and design a plant site information management system accordingly, which can be useful for site workers and managers. At a plant site, a manager often works inefficiently due to poor processing of real-time data and lack of communication between the company and the site office. Moreover, construction workers have difficulty communicating with a manager due to complicated plant design. To address these issues, we apply an AR (augmented reality)-based smart device for pipe installation and construction management, which account for the largest part of a plant project (43%), to identify how to effectively install pipes and manage object data.

1.2 The Scope and Methods of Research

As mentioned above, we propose a management system for plant construction workers and managers that uses an AR-based smart device. At a plant site, workers install pipes based on drawings generated prior to the implementation. However, there is a wide discrepancy between drawings and the actual site, which makes it hard to install pipes. Thus, it is important to establish an information-sharing system between workers and managers to deliver accurate information on the site situation when installing pipes. To this end, we propose using an AR-based smart device.

The method and process of this research is:

(1) Preceding Research Analysis
- Existing review of literature
- Analysis of management characteristic of plant construction and process

(2) Requirement Analysis and Function Derivation
- Figuring out smart device applicability in the

plant field
- Requirement analysis to solve problems

(3) Establishing DBS (Device Breakdown Structure) for optimal plant construction
- Process Analysis at Plant Site
- Analysis of maintenance Work at Plant Site
- DBS Proposal by Different Work Processes

(4) AR Technology at Plant Construction Site

2 Research Trend

2.1 Literature Review

Since the mid-2000s, active research has been undertaken to identify how to use various IT technologies to improve plant construction, specifically, to shorten construction time, reduce costs, ensure flawless construction, engage in accident-proof planning, enhance work predictability, eliminate wastes, improve productivity, and reduce maintenance costs.

Most studies on plant construction and management have been limited to proposing conceptual methodologies or solving logistics issues (e.g. delivery of materials). There are few studies on how to generate and utilize real-time information on pipe work or how to discover errors.

Table 1 Existing research

Area of management	Research subjects
Construction	Ontology-based BIM modeling; AR-based system framework 4D tools for greater efficiency in site management
Site condition	Use of smart phone to improve management process; visualization of project information using real-time data sharing and management, wireless communication; and augmented reality
Safety	New 4D safety management and monitoring system 'C-RTICS2' for more efficient construction and communication among work partners Behavior-based preventive safety system, visualized management with VCS (Virtual Construction Simulation System)
	Note
Construction	Marker-based AR: Research on identification of objects, selection of marker type, marker detection, and marker-less AR technology
Site condition	Wearable device for real-time work coordination Wearable device; Cloud system for massive data management
Safety	Set apart in terms of device and visualization method, while similar in technology for communication between office and construction site Partly applicable to safety management in terms of carrying out preventive safety management in visualized form

2.2 Plant Construction Management

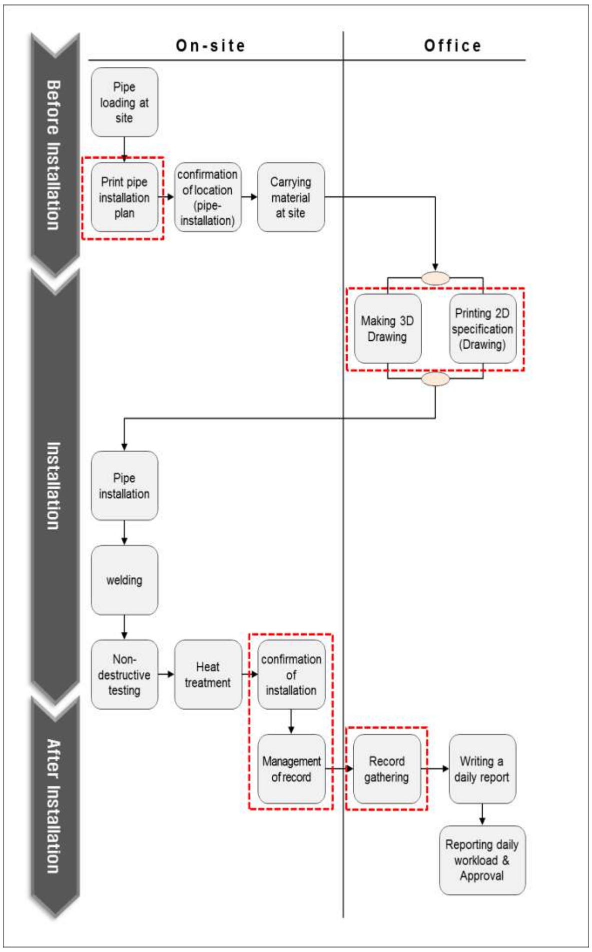

Figure 1. Pipe construction process

At a plant construction site, pipe installation can be divided into three stages: pre-installation, installation and post-installation.

In the first stage, materials are delivered and detailed 2D drawings are produced, based on which the site is surveyed, and 3D drawings are produced.

In the installation stage, workers install pipes based on the drawings. In the after-installation stage, managers and workers carry out maintenance work.

In this process, workers and managers do not fully share information, and it is hard for a manager to accurately explain the installation process to workers based on drawings. To resolve this difficulty, we propose a new process and system.

3 Analysis of plant workers' needs

Moon [16] conducted an interview with and surveyed the project sites of S company, one of the country's leading construction companies, and found out that workers needed smart applications for construction assistance, data confirmation and checks and guidelines, particularly for communication support and progress management (Figure 2.).

He showed that, at plant construction sites, workers need to have a smart device system to share information during the design and implementation processes.

Table 2 Applicable work territories

Direction	Contents
1	Construction Assistance App.
2	Data confirmation and check App.
3	Data input App.
4	Guideline App.
5	Communication support App.
6	Progress management App.

At a plant site, workers need drawings and related data to handle materials and make necessary installations.

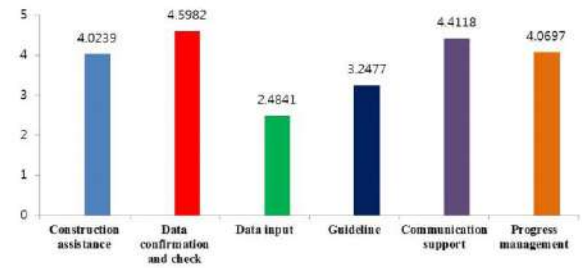

Figure 2. Overall result

These data are generated in different forms and communicated to workers in visualized forms. The alteration of certain data affects other data and generates new information. Using smart devices and applications could support this process

4 Establishing DBS(Device Breakdown Structure) for optimal plant construction

4.1 Process Analysis at Plant Site

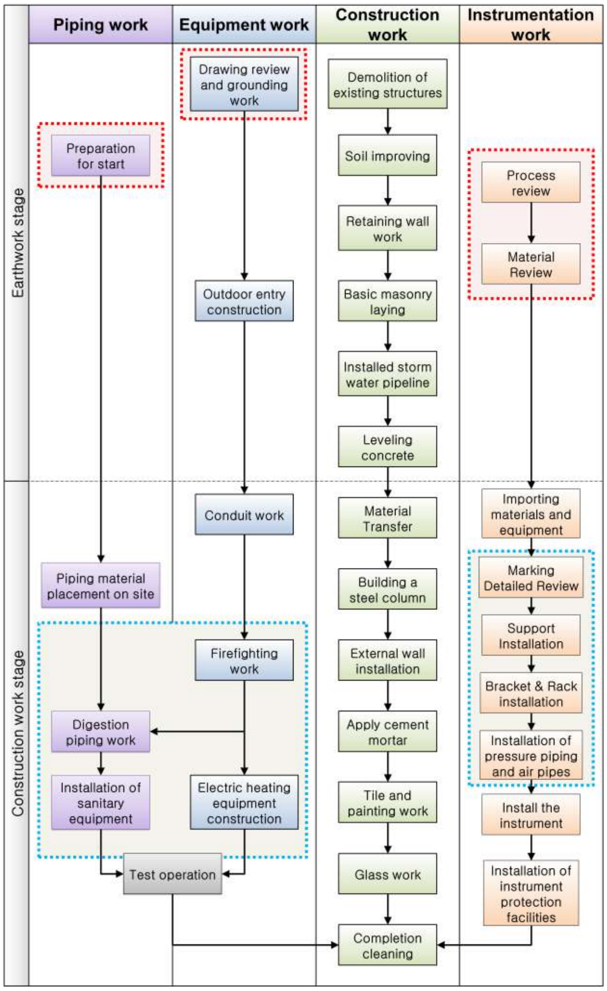

Figure 3. Construction work process of plant site

We analyzed the construction process at a plant site to identify areas of work in which the use of a smart device can be applied. The analysis was done for earth work and architectural work, specifically for processes such as architectural work and electricity, pipe and facility installation.

The analysis results showed that, for earth work, it is important to convert materials data and drawings into a 3D model to help workers' understanding of the process. For architectural work, it is important to produce information on materials and processes that are in progress or completed, and to provide a 3D model based on augmented reality for review.

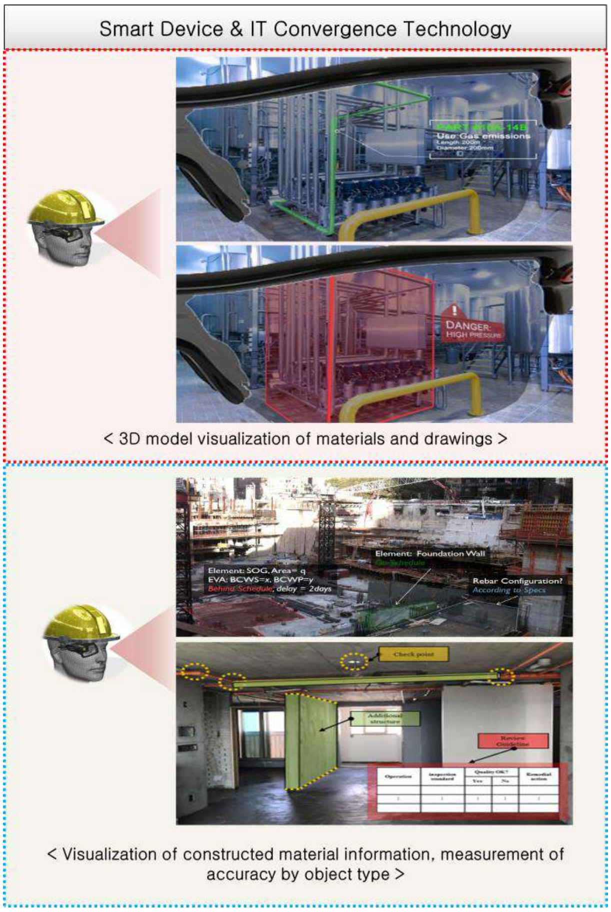

Figure 4. Smart device & IT convergence technology in plant site

4.2 Analysis of maintenance Work at Plant Site

The analysis results showed that facilities management companies, inspectors and facilities managers need a maintenance system that uses an AR-based smart device to inspect, maintain and repair plant facilities.

More specifically, tasks that could use an AR-based smart device included planning and review of facilities maintenance, updating drawings/records for the facilities management company, managing records and site locations confirming maintenance results for inspectors and conducting site check and maintenance work for facilities managers. Smart devices can be used to track records of materials and visualize related information.

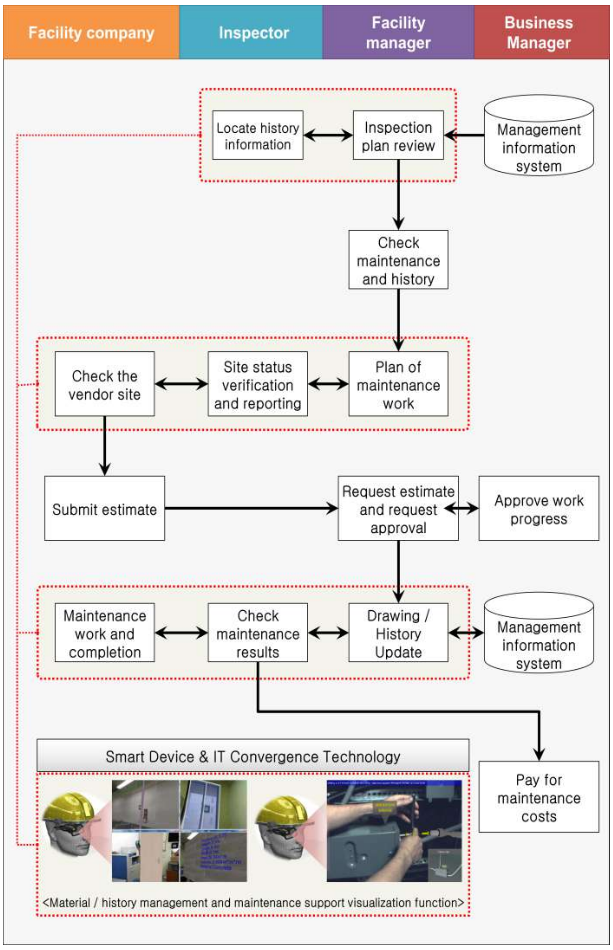

Figure 5. Maintenance process of plant site

4.3 DBS by Different Work Processes

Based on interviews and analysis of plant processes, we identified smart devices suitable for various participants of a plant construction project, that is, plant constructors, architectural workers, facilities supervisors and facilities managers. Then we examined various functions of smart wearable devices that can be used to process data generated by site workers.

Our investigation showed that watch-type, band-type, and glass-type devices are suitable for a plant construction project. As for device sensors, bio information, GPS/NFC, accelerometer, visual information and Bluetooth are applicable to plant construction. We matched site workers' needs with different types and functions of smart devices so that the workers could choose an efficient device.

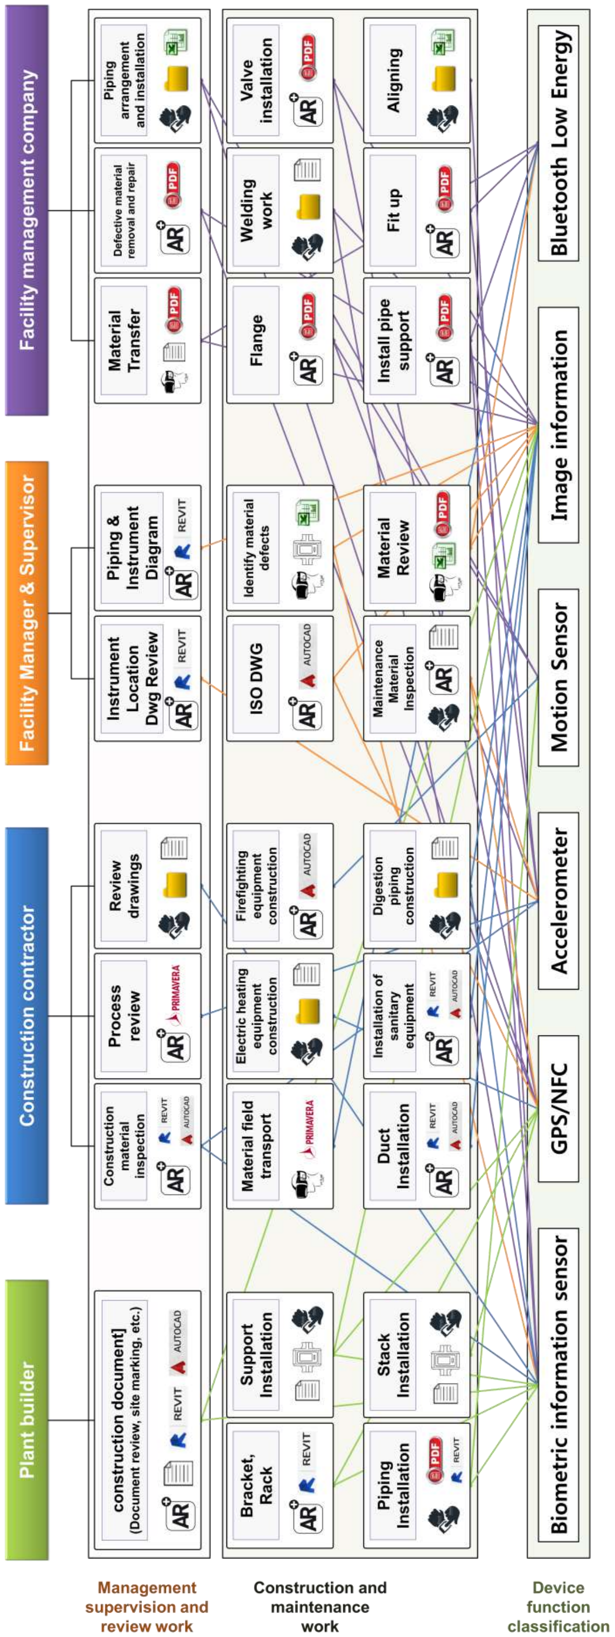

Figure 6. Device breakdown structure

5 AR Technology at Plant Construction Site

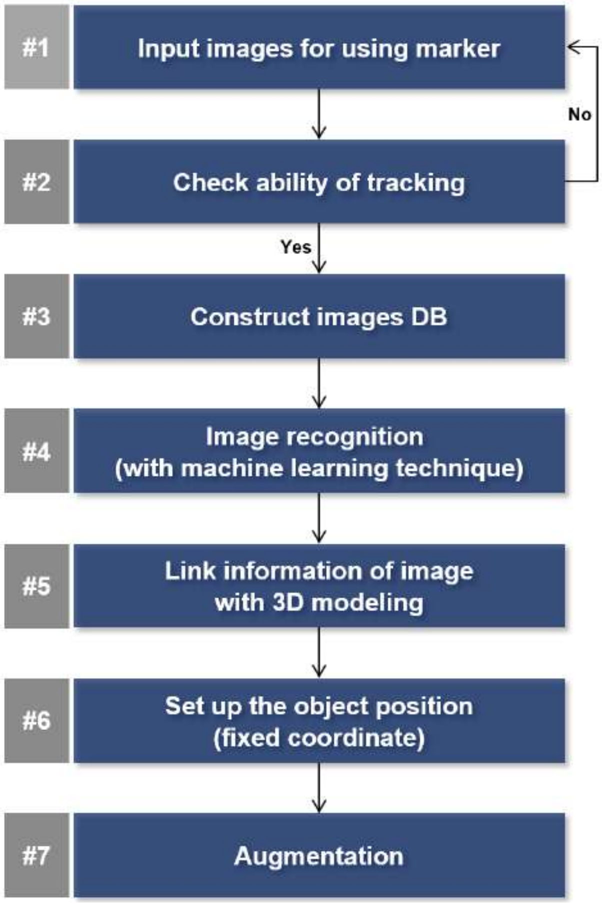

Figure 7. Augmented Reality System Diagram

To apply AR technology at a plant construction site, we conducted an experiment (See Figure 7). First, image input was made to use marker. Second, to check that images were recognized as markers by the smart device. If the image was recognized as a marker, save it in DB. or if not, input the image again. Third, image data of useful information were collected to generate an AR marker file. Fourth, the stored image data is used to improve the object recognition rate through machine learning techniques. Fifth, the marker was linked with 3D modelling/images, and sixth, the position of the object was set on a smart device display. Lastly, AR data were generated accordingly for use at a plant site

Through this process, the worker uses the camera of the smart device at the plant construction site to recognize objects from various angles as markers, and links objects and 3D modeling information.

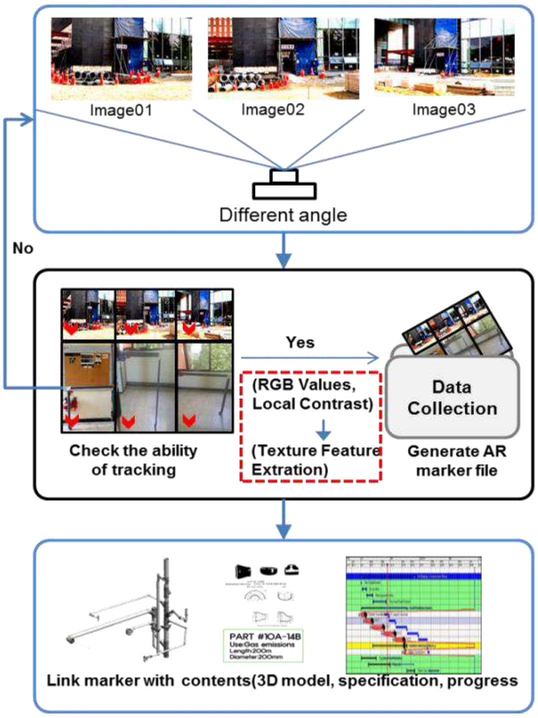

Figure 8. Images for using marker

6 Conclusions

In this study, we analyzed traditional processes of plant construction, conducted interviews to identify difficulties and problems at plant construction sites, and explored the applicability of smart device at plant sites. To this end, we analyzed work processes at plant sites, examined maintenance work, established DBS (Device Breakdown Structure) for various participants of a plant construction project and examined how to apply AR technology.

Regarding work processes at a plant site, we examined different stages of a construction project and identified technological elements that can be applied to earth work and architectural work. For analysis of maintenance work, we identified areas of work that need visualized information. Additionally, we established DBS for site participants and examined how to adopt marker-based AR technology at a plant construction site.

Based on the analysis of plant construction processes and maintenance work, smart devices can be adopted at a plant construction site according to DBS of different work areas, and AR data can be generated through marker-based image links. Using these data, workers can check information and acquire better understanding of the work process. Moreover, a Cloud system may be introduced for real-time information sharing. Based on these findings, we plan to conduct further research on marker-less image tracking using deep-learning technology.

The new tradition - Dialogues on production in architecture

M. Ferrari

Department of Architecture and Arts, Università Iuav di Venezia, Italy

E-mail: margheritaf@iuav.it

Abstract –

Tools of digitalisation and automation are changing the labour market and human's interaction with production material in general. In architectural processes, this change involves the stage of production but also, and more interestingly, the design one. Architecture has a social role, which includes many processes. Each process requires different times, challenges, and tools. Consequently, the impact of innovation is not the same for these processes. Many manufactories require innovative design and advanced researches. These manufactories have different relationships with digitalisation and innovation, and not all factories have advanced technology; the lack of updates is due to financial or cultural reasons.

This paper aims at investigating the production of structural wood components of the architectural process. The analysis of the impact of innovation in the architectural process cannot be limited to robot or other digital tools, but it is necessary to consider the social and cultural context as well (1). The study is divided in two sections: (2) the role of architecture at the margin of numerous processes (between design and production), but also between innovation and tradition. The investigation needs to include many factors in order to best describe how innovation affects the design and the production. (3) The methodology is structured in three dialogues: with research, design, and manufacturing. Each one of these has specific limits and tools. The collected data describes the role of innovation and tradition in the specific sector of structural wood components of the architectural process.

Keywords –
Cultural change; Dialogue; Architecture; Manufacturing.

1 Introduction

Technical evolution has always been considered within its social conditions: the cultural and geographical backgrounds influence technological innovation and its impact on people.

Three important truths emerge from this close relationship: the rapid development of digital tools, the gap between different work sectors, and the 'fear' of machines and automation. These conditions are closely related, and each one determines the others.

The rapid development of digital tools improves day by day: the possibility of working from different countries or of sending digital information to line production are only two of many examples.

These digital tools interact with humans in various ways every day, consequently absorbing innovation in different ways as well: the lack of updates can be a discriminating factor, and it can increase the distance between the different work sectors. This is a dangerous gap because it can compromise the entire process, like the complex one of architecture for instance.

The third emerging reality is that of 'fear', deriving from the gap between those who use digitalisation and those who do not. There is a misunderstanding of digital evolution, as it is not considered in accordance with the context in which it develops. Consequently, this fear fuels the rejection of digital change, of evolution, and of the introduction of new work tools. In the course of history, many technical revolutions have evolved the labour market and human's social condition. However, actual technical evolution is different: it is very fast and it influences many aspects of human life (especially work related), its identity, and its cultural tradition.

Therefore, the three emerging truths – rapidity, work gap, fear - concern every work process, and could compromise its actual quality, even in architecture.

This paper aims at investigating the impact of digital innovation on architecture, how new tools are integrated in its processes, especially in the component production one. Although the paper focuses the research on this specific process, evaluating the development of other architectural processes is also necessary in order to better understand the development of digital and automation tools. Considerations on a single process cannot be made separately from the others.

The paper is organised in two parts: the first one reconstructs the processes of architecture and it describes the impact of innovation on them. These processes are very different, because each one has its own times and tools. For this reason, communication between these different processes is not simple and the involved factors often encounter difficulties. An architect must be capable of coordinating the numerous factors that move along the margins of the various processes. In this scenario, digital tools could simplify this complex communication and could help to solve some difficulties between the many architectural factors. This section focuses on the interaction between design and production because there is a gap between them that is rapidly expanding. One of the reasons for this is the close relationship between manufactories and their local tradition. In order to investigate the relationship between innovation and tradition, we chose one specific productive process: the structural wood components of the architectural process, because it represents one of the best contexts in which tradition meets innovation. In the architectural context, there are numerous digital tools for design processes on the one side, and many manufactories connected to their traditional tools for wood modelling on the other. The evolution in the design and the production processes necessarily have different speeds: each process involves different kinds of factors and materials. This difference can generate the abovementioned work gap and human fear: in architecture, these correspond to solutions that are less and less adaptable to the social needs. Moreover, productive actions today are not only human or mechanic, but also automated and robotic. The actual processes of modelling and assembly can be expanded beyond human capabilities and its traditional tools. These new limits redefine architectural processes and their relationship with tradition, local materials, and cultural context. The aim of the research is to analyse this specific gap.

The second section of the paper describes the methodology used to investigate main architectural processes: design, research, production, and their levels of innovation. This methodology was structured for the PhD research in progress at Università Iuav di Venezia. The research deals with the impact of automation on the design of structural wood components, starting from industrial applications, experiments, and failed attempts, up to discovering the new limits that are created by automation and new intelligences.

This requires different investigation strategies, although the challenge is the same: defining the level of innovation and its impact on the building sector.

The analysis allows reconstructing the role of automation in each architectural process and evaluating their interaction. This last aspect is in fact fundamental in order to develop architectural quality, in accordance with the social and functional needs described by Virginia Gangemi [1]: in this case, automation can contribute to the development of an appropriate technological and architectural design.

To understand the appropriation of technology, it is necessary to investigate on more levels. A specific methodology that uses several research tools, in accordance with the different processes and actors, has been developed precisely for this reason. Final data collection helps to compare the role of innovation in each single process: for example, comparing the advanced university research with the manufacturing production, and the innovative automation with the traditional tools. Thanks to these comparisons, it is possible to evaluate how the architectural production process is changing, and consequently how the architectural design process is as well. This research is structured in three dialogues that deal with some of the most important factors of the architectural process: the researches, the designers, and the manufactories. The final comparison can help describe the appropriateness of automation in architecture and in its cultural context.

Figure 1. The human action in the processing of a wooden component.

2 On the margin

Invisible technology, as Nicola Sinopoli describes it [2], deals with the complexity of the architectural process and the numerous operators who are involved in it. Digital innovation has a specific type of impact on each process, with important consequences on the communication between the factors involved. In fact, digitalisation and automation allow many operators to communicate in shared digital dimensions through shared languages of informatics. On the other side, the tools of digitalisation and information can amplify the gap between the various architectural processes, like between design and production. Therefore, the interaction between these invisible technologies (in accordance with the integration of digitalisation) can either be very efficient and productive, or bring to architectural and social failure.

The architect is the administrator of these invisible processes, although the complexity of the architectural discipline has grown century-by-century in history: today, there are numerous specialisations in the field, and the architect is required to hold and balance most of them. It is like a sort of 'borderline', a common ground where several professions meet, each with its own challenges, times, tools, and approaches to automation and digitalisation. Today's digitalisation and automation are changing every profession and every profession's processes. The capability of these processes to update themselves weighs in on the balance of the architectural production as a whole. Therefore, the misunderstanding of the digital evolution and the lack of updates could compromise the architectural quality and its construction. The proposed analysis aims to understand the main reasons behind this deficiency: these reasons could be financial or even cultural, where tradition holds an important role.

By investigating along the margins of innovative and traditional production, the paper aims to understand the impact of digital tools on architectural quality, in order to explore and redefine the relationship between men and their architectural means [3], both human and robotic. As according to Stephen Kieran and James Timberlake [4], an architect cannot embody all qualities of a master builder, but thanks to digital tools he can integrate the numerous processes that are involved in the construction project and can coordinate the architectural design in every process and detail. This refers to several architectural aspects and on several scales: the design and the manufacture processes are closely linked and cannot be considered separately from one another. The architect, like an artisan, has the capability of transforming ideas into manufactured matter, modelling it through its intrinsic proprieties. Material production and its tools has a long history, one that has revolutionised the architectural process in time. The same is happening today: digitalisation and automation influence architectural design and creativity.

The interaction between idea and material matter through digitalisation can contribute to "rebuild" the figure of the manufacturer. As Guido Nardi says [5]: "The choice of materials and the use of particular techniques […] are strongly conditioned by social, family, and religious traditions, which are the cultural element that is usually internalised, operating in a subconscious dimension. In material civilisations, the manufacturer was the holder of this complex but uniform knowledge. They converge both technical abilities and scientific and social knowing in their manufactured product". Therefore, the architect is a figure that stands on the margin of design and production, but also of tradition and innovation. Today's "contemporary master builder" could resume this care for detail and its production.

The research methodology elaborated for this investigation aims to describe the interaction between architectural processes, as well as how this same interaction can improve the architectural design. The methodology is based on an important definition of innovation and its role. The level of innovation cannot be measured according to one specific technique. Innovation deals with technology, which is the application of a technique in a specific context that holds specific social and cultural needs. Innovation represents a change in a cultural process. Therefore, innovative technology is considered as a cultural process and not as a mere tool. Only a multidisciplinary investigation can make it possible to evaluate how new technologies will be innovative and appropriate for the people, their culture, and their tradition.

3 Investigation methodology and factors

Methodologies deal with an array of operators and factors, which interact with automation in many different ways. Therefore, the proposed methodology is based on several tools in order to investigate in different contexts, some more innovative and others more traditional. As said earlier, the sector of the production of structural wood components represents one of the best cases of interaction between traditional and innovative tools.

The architectural process in wood component design and production involves numerous factors and operators, distinguishing three categories:

- researches (from university and companies);
- designers (architects and engineers);
- manufactories (carpentries and joineries).

These factors are respectively associated to three architectural processes: advanced research, architectural design, and production. The investigation aims at describing the role of automation and digitalisation in each process, outlining three investigation phases:

- the limits of the survey;
- the construction of investigative tools;
- the data collection.

The three investigation categories (Researches, Designers, Manufactories) are described below and are considered as 'Dialogues': dialogue represents one of the first and most important tools of knowledge, like the ancient example of *Platonic Dialogues* (IV-III cen. BC); this research also underlines the importance of dialogue in creating an interaction with several realities, like academic research and manufactories. However, there are some useful considerations that must be made in order to devise proper investigation tools: the expected results will be both theoretical and practical, so their comparison could seem difficult, but it presents many common points. The second consideration is the geographic location of the object of the investigation: the cultural context and the financial status contribute (or not) to the development of automation technology.

3.1 Dialogue 1 - Researches

Advanced research in automation in architectural processes covers an extensive field that is, however, increasing accessible. Many different figures work on architectural automation, therefore a more selective investigation is necessary.

The specific limits of the survey were structured on the following conditions:

- research unit (both universities and companies);
- research unit with at least 5 years of activity;
- research on structural components, both modelling and assembly;
- research unit in Europe.

In this investigation, wood is not a restricting parameter: a general investigation on automation and structure was preferred to a specific investigation on wood structures. It allows to better understand the interaction between different research fields and their developments. 30 research units were identified in Europe, but only 9 units follow the said parameters. These are generally specialised in specific sectors of architecture or tools: for example, robot or additive manufacturing, solid material modelling or component movement.

The research units were analysed on the basis of progressed researches, which contribute to the definition of a profile for each research unit. The bibliography and the interview were the main tools of investigation in this category.

3.2 Dialogue 2 - Designers

The second dialogue is with designers, aiming to form a database of best practices. The selection of architects and engineers began with the identification of case studies. In this category, the limits of the research field refer to buildings (not designers). Each case study had to follow specific parameters:

- it must present an existing building, with environmental and security parameters;
- the building must present a wooden structure;
- it must be localised in Europe;
- its construction must have been completed in the last 10 years;
- the wood component production must have had a significant role in the design process.

The case studies represent the best examples of interaction between design and production. The dialogue between operators is the most important tool that allows the development of the architecture. Digital tools contribute to simplify communication, reducing the margin of error. This communication concerns human and machines, redefining the invisible technology of the architectural processes.

Each case study had to follow specific parameters, with the aim of reconstructing the timeline of the design, production, and assembly processes. Another important parameter was the kind of machine that was used for the wood component production. Thanks to this data, it was possible to identify the most popular machines for architectural production.

3.3 Dialogue 3 - Manufactories

The third dialogue deals with manufactories, presenting several complexities according to their variability and their availability to dialogue with research. Analysing this category is important in order to describe the impact of innovation on local economy. In fact, new digital tools can help develop new architectural design processes, on one side, but also redefine the work processes and the role of human workers on the other. Initially, this dialogue aims to evaluate the innovation in the wood production process through the quantity of the machines and robots that are used. The final goal was to create a "map of innovation"; however, many manufactories would necessarily be excluded from this map because of their lack of machines and automation.

Figure 2. Traditional tools in a Venetian joinery.

As mentioned previously, technological innovation is a process and is not only the result of digital or automated tools: innovation is also conditioned by the social and financial context. Therefore, the geographical location of these manufactories is determinant for their innovation. The investigation became the main tool in discovering the state of the art of manufactories, their variability, and their innovative levels. The analysis was developed in the geographical area of North-East Italy, known as Triveneto, which is composed by three regions: Veneto, Friuli Venezia Giulia, and Trentino Alto Adige. The Triveneto represents one of the most productive areas of Europe and it is characterised by the presences of small and medium businesses with a historical tradition. The parameters for the category were:

- The geographical area (North-East Italy);
- The specific business product, according to the Italian Business Register. Each product was required to have a specific code: *ATECO*; this research used two ATECO: 16.10 *Cutting and planing of wood*, 16.23.2 *Manufacture of other wood carpentry products and carpentry for construction*;
- The manufactory had to be an active business.

Through these parameters, 3.112 businesses were selected, of which 770 carpentries and 2342 joineries. This business database was then ordered according to the specific geography, number of employees, and start year of the business.

A questionnaire was elaborated in order to collect data from the selected businesses, following several levels of investigation. According to the number of participants, thanks to this questionnaire it will be possible to describe the role of automation in wood manufacturing and the role of automation in production.

The questions deal with the presence or absence of digital and automation tools, their use or disuse, and consequently the main reasons behind several production choices. Following this first step, a second step addresses the type of machines and their use for architectural components or material.

In the dialogue with manufactories, the impact of innovation is obviously considered, but the other important common point that is considered is the manufactories' relationship with tradition, their tools, and their materials.

4 Conclusion

The research on automated machines and robots in architectural processes needs to consider many various aspects: the languages of communication, the kind of activity, the level of innovation, the update and upgrade status, and the relation with social context. The paper aims at investigating the impact of digitalisation on architecture, starting with the definition of the methodology of research.

A multidisciplinary approach was necessary to investigate the complex issue, not only for the nature of the processes and their main tools, but also for their integration with innovation and automation.

Starting from the definition of three emerging truths – rapidity, work gap, fear – the investigation on the role of automation in architecture is necessary to describe how innovation can actually contribute to architectural and social quality as a whole. There is a direct connection between architectural design and production: the research aims to identify a strategic point of view on the issue, in order to develop a knowledge and understanding of technological improvement in architecture. It is possible to set up an investigation at the margins of architectural processes, analysing each one and comparing them.

The research focuses on the production of structural wood components, because this sector represents one of the best interactions between tradition and innovation, since it involves advanced design and research in local manufactories. The manufactories that are considered are joineries and carpentries presenting different levels of innovation. The comparison between the architectural factors and the description of their innovative role is the main tool for a better understating of the appropriation of automation and digitalisation in architecture.

The research identifies three process categories: the research, the design, and the manufacturing. Each one of these processes includes factors with which it dialogues. Therefore, the research methodology is structured and adapted in order to investigate different processes with different research limits.

The research methodology is based on three forms of dialogue: Researches, Designers, and Manufactories. The comparison between these processes concerns the impact of innovation in social culture. Innovation is more than a simple technique: it is a process and a cultural change. The interaction between these three sectors represents a cross-disciplinary description, which is useful to understand if an innovative technology can be appropriate. Although this paper investigates a specific context (structural wood components), the research methodology can be applied to several sectors, which can differ in their architectural and geographical qualities. The aim of the research is the dialogue between many aspects of the architectural process: design and production, human and machine, tradition and innovation. Therefore, dialogue becomes the main investigation tool, able to involve and compare many factors. It can contribute to contrast the human fear toward digital innovation and its rapid evolution. It can help define the role of innovation not only in architecture, but also in society and in the labour market. 'Dialogue' holds the capability of comparing the innovation levels between many processes and their contexts. It is where research and designers come into contact and where (and how) man redefines a new tradition. Comparing research and manufactories, designers and production is necessary to understand the role of automation and digitalisation in architecture. Architecture must be capable of answering social needs and offer a better quality of life. Therefore, dialogue is not an answer but a tool for the analysis of the appropriation of innovation in our society. Innovation is not automation but how we use it. Luca De Biase wrote [6]: "Distinguishing between what is important and what is only interesting, and making the umpteenth cultural leap. Everyone, together. Because even if computers go faster, humans can go farther". Human capability is fundamental in developing new tools and in recognising the cultural change to which they contribute. The research on automated machines and robots in architectural process cannot be made separately from the cultural context, the human workforce and its traditions. Man must continue updating his capabilities and his territorial knowledge: thanks to these, he can use innovative tools like automation and digitalisation to increase his potential and his culture. He can redefine tradition: he can build a new tradition, a new relationship with materials through new tools. If not, if technique remains the main point of innovation, man will inevitably become and remain only a spectator.

Abstract –

Unrecognized hazards increase the likelihood of workplace fatalities and injuries substantially. However, recent research has demonstrated that a large proportion of hazards remain unrecognized in dynamic construction environments. Recent studies have suggested a strong correlation between viewing patterns of workers and their hazard recognition performance. Hence, it is important to study and analyze the viewing patterns of workers to gain a better understanding of their hazard recognition performance. The objective of this exploratory research is to explore hazard recognition as a visual search process to identifying various visual search factors that affect the process of hazard recognition. Further, the study also proposes a framework to develop a vision based tool capable of recording and analyzing viewing patterns of construction workers and generate feedback for personalized training and proactive safety management.

Keywords –

Hazard Recognition, Construction Safety, Computer vision, Eye tracking

1 Introduction

Every day about 6.5 million workers work on more than 200,000 construction sites across the United States [1]. However, with 900 fatal and over 200,000 non-fatal injuries a year [1], construction workers are more likely to be injured than their counterparts in other industries. Over the years, researchers have attempted to understand the underlying precursors of accidents in construction [2,3]. Among others, hazard recognition has received significant attention [4–6]. Recognizing hazards is one of the first steps in effective safety management; however, studies across the world have shown that 30% to 50% of hazards remain unrecognized in construction environments [6–10].

To improve hazard recognition skill of workers, several training programs have been developed and implemented within the construction industry. However, research has shown that construction workers fail to recognize a significant portion of hazards despite having received training [11,12]. Research in human factors and visual search [13] has revealed several contributing factors that influence person's detection and recognition performance while they scan their environment for hazards. For example. a recent study [14] argues that one of the reasons for unrecognized hazards is that workers often pay attention to the primary task alone and ignore the surrounding areas. The same study also suggests that workers often selectively pay attention to a particular type of hazards while ignoring others types, which result in poor hazard recognition levels.

To recognize hazards in their workplaces, workers need to first detect the hazardous object or condition and identify it correctly, to associate a level of risk to it. This is essentially a visual search process and the outcome of any such process is affected by the viewing pattern and attention distribution of the person conducting the search [15]. Therefore, it is important to design training interventions that aim to improve workers' visual search and enable them to detect hazard better. The first step towards developing such training interventions is to understand what constitutes a good visual search.

Hence, there is a need to explore hazard recognition from a visual search perspective to identify and evaluate various metrics that define the viewing patterns of workers and affect their hazard recognition performance. In order to gain an intrusive understanding of workers' viewing behavior, it is important to study their viewing patterns while they engage in their regular work in real construction environments. However, examining the viewing patterns of workers manually would not only require a lot of time and repetitive effort but will also be prone to human errors causing inaccurate assessment and inefficient feedback. Therefore, the objective of this study is 1) to identify the visual search metrics that affect hazard recognition and 2) automate the capture and analysis of visual search data collected from workers in real construction sites.

More specifically, the study provides a framework for a computer-vision based system that can be used to generate personalized feedback for workers and safety managers for training purposes and generate data that will potentially assist in proactive safety management.

2 Background

2.1 Visual Search

Visual search is a task of scanning the environment to find particular visual stimuli or features (the targets) among other visual stimuli or features (the distractors) [16]. Hazard recognition can essentially be viewed as a "multiple target visual search process" where hazards are the targets while other objects and features in the environment serve as the distractors.

The visual search is influenced by several factors, such as age differences [17], professional experience [18], the similarity in targets and distractors [19], and the type of search being conducted [16]. Therefore, studying visual search allows us to examine attentional abilities, cognition and perception.

Eye-tracking provides an objective measure of stimuli that received attention during visual search activities by analyzing eye movement data and has found application in aviation, medicine, transportation, and education [20,21]. The Eye tracking device records the corneal reflection of infrared lighting to track pupil position, mapping the subject's focus of attention on his field of view (gaze) [22].

2.2 Computer Vision in Construction

Computer vision seeks to enable computer systems to automate the tasks that the human visual system do [23–28]. Computer vision techniques include image reconstruction, object detection and tracking, feature extraction, pose estimation, image restoration etc. One of the most popular applications is perhaps the face detection in our cell phone cameras.

Computer vision is widely used in robotics[23], medicine [24], surveillance [25], transportation [26] and others. In construction, computer vision is gaining popularity due to its applications in progress monitoring[29–31], productivity analysis[27,32], structural health monitoring, 3D reconstruction [33,34] and automated documentation [35,36]. Although computer vision has not been leveraged to its full potential, it has several applications in replacing or augmenting the conventional field-based safety monitoring tools [37].

3 Objectives

The objectives of this research were:

1) to identify the visual search metrics that affect hazard recognition performance of workers and

2) to provide a framework for developing an automated vision-based system that records the gaze behavior of workers in a construction site and computes the visual search metrics identified above.

Objective 1 helps us understand the process of hazard recognition from a visual search perspective and Objective 2 enables us to collect and analyze that information automatically for a large-scale personalized safety monitoring and training. Achieving these two goals will enable interventions and proactive safety management while maintaining a high manager-to-worker ratio that is economically inevitable.

4 Research Method

The study was completed in two phases (fig 1). Phase 1 consisted of identifying the visual search metrics that affect hazard recognition performance. Phase 2 consisted of developing a computer vision based tool to capture and analyze eye-tracking data in order to compute the identified metrics automatically and on a large scale.'

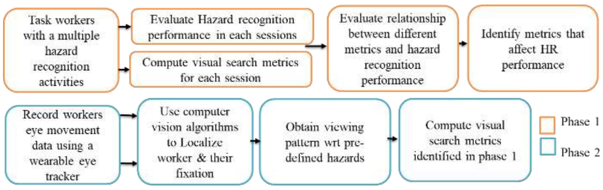

Fig 1. Method Overview

4.1 Phase 1

This phase was completed in two steps as detailed below

4.1.1 Data Collection

Twenty-four construction workers representing diverse speciality trades were selected. The experience of workers varied from 2 years to 28 years (Mean: 10.05) and their ages ranged from 19 years to 51 Years (Mean: 32.5). After gathering worker demographic information, the participants were placed 30 cm from a computer screen with the centre of the screen in line with participant's eyes. An Eye tracking device (Eyetech VT-2) with the sampling rate of 60 Hz placed at the top of the screen was calibrated for each worker.

The workers were then tasked with identifying hazards in 12 pre-selected construction case images that were randomly selected from a set of 24 case images captured from real projects. The images were displayed on a computer screen with a resolution of 1920 X 1080. As the workers identified hazards verbally from each case image, the researchers catalogued the information and their eye movements were captured and recorded by the eye tracker.

The hazards in each case image were pre-identified by an expert panel of three safety professionals with the cumulative experience of 62 years. The hazard recognition performance of workers was measured in terms of hazard recognition index:

$$HRI = \frac{Hazards\ identified\ by\ subject}{Total\ Preidentified\ Hazards\ in\ that\ image}$$

The eye movement data captured during the experiment was used to calculate following visual search metrics:

Search Duration (SD)

Search duration is the time (in seconds) for which the participant views a scene before terminating the search. The search duration consists of fixations (when participants focus on a particular point) and saccades (rapid eye movements between fixations)

Fixation Count (FC)

The fixation count is the number of discrete points in a visual field, where participant fixates or focuses their attention. The number of fixations is indicative of the importance or "noticeability" of objects/ areas to a user [38].

Fixation Time (FT)

Fixation time is the time spent by each participant in fixating on different objects or areas. It is calculated by taking the sum of durations of all fixations. Fixation time reflects the amount of attention paid by the participant to each photograph.

$$T = \sum_{i=1}^{n} (E(f_i) - S(f_i))$$

Where E and S are the end time and start time for i^th fixation (f_i)

Mean Fixation Duration (MFD)

The mean fixation duration (MFD), also known as average fixation duration [39], is the sum of the durations of all fixations divided by the number of fixations[40]. It is computed using equation [37]

$$MFD = \frac{FT}{FC}$$

This metric indicates the time spent by the participants focusing on individual objects. Longer fixation durations indicate that subjects spent more time and effort in evaluating and extracting information from the stimulus [41]. Longer fixations are also indicative of more visual effort and "substantial increase in demand for attentiveness [42]

Ratio of On-Target: All-target Fixation Time (ROAFT)

Each hazard in the case images was defined as the area of Interest (AOI), which is an area that fully encloses the hazard. The Ratio of "On-Target" to "all target" fixation time or ROAFT [43] is the sum of durations of fixation on AOI, divided by the total duration of all fixations for the entire case image (Area of Glance or AOG). It is computed using equation [43]

$$ROAFT = \frac{\sum_{i=1}^{n}\big(E(f_i) - S(f_i)\big) in\ AOI}{\sum_{j=1}^{n}\big(E(f_j) - S(f_j)\big)\ in\ AOG}$$

Where E and S are the end time and start time for i^th fixation (f_i) in AOI and j^th Fixation in AOG in numerator and denominator respectively.

This metric is a good indicator of the amount of visual attention devoted to hazards relative to the total time spent on the case image.

Fixation Rate (FR)

Fixation rate is the ratio of the number of fixation in AOI to the total number of fixation in the entire case image (that is Area of Glance or AOG).

$$FR = \frac{f_n}{f_N}$$

Where f_n = the number of fixations in AOI

f_N= Total number of fixations in AOG

The fixation rate is indicative of search efficiency, with smaller ratio suggesting that participants spend more effort in finding the pertinent objects, thereby indicating lower search efficiency [38].

4.1.2 Data analysis

After collecting the data, the correlation analysis was carried out for each worker to measure the correlation between each of the metrics listed above and hazard recognition performance.

For each worker, average HRI index was calculated using equation:

$$AV\_HRI_j = \frac{\sum_{i=1}^{n} HRI_{ji}}{n}$$

Where AV_HRI_j =average hazard recognition performance for j^th worker

HRI_{ji} = Hazard recognition index for jth worker in ith photograph

n=number of photographs = 12

Similarly, for each visual search metric described above, the average value was computed for each worker. Finally, Pearson's correlation coefficients were calculated for each metrics to obtain each of degree of correlation with hazard recognition performance.

4.2 Phase 2

Once relevant metrics are identified in phase 1, this phase focused on developing the framework for an automated vision based system that captures eye-tracking data from workers while they engage in their regular work and compute these identified metrics.

The framework of the system can be demonstrated in two sub phases- Pre-processing phase and test phase as shown in the figure 2 below.

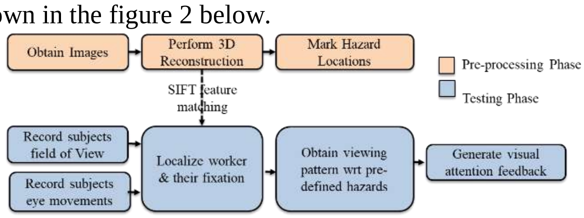

Figure 2. Method overview for Phase 2

4.2.1 Pre-processing phase

This phase focuses on building the pre-processing data. It is completed in two steps as detailed below

4.2.1.1 Obtaining initial reference images

Multiple images of a construction site are obtained using a monocular camera. The easiest way to obtain such images is to record a walkthrough video of construction site while following different trajectories. This ensures that objects are captured from different angles and distances. The frames are then extracted from this video, which serve as reference images to be used in subsequent steps.

4.2.1.2 Annotating AOIs

In this step, a panel of safety experts pre-identifies the hazards in the work site by watching the walkthrough video and conducting open discussions. The locations of these AOIs are marked on an initial set of images as AOIs. This can be semi-automated using homography matrices and affine transformation (discussed later in the case study). The hazards are annotated on preprocessing images as rectangular bounding boxes. The bounding boxes are defined by Xmin, Ymin & Xmax, Ymax, which correspond to the upper left corner and lower right corner of the bounding box respectively.

4.2.2 Testing Phase

This phase focuses on computing various visual search metrics for individual workers as they move in a real world construction site. This involves localizing the participant and their gaze positions at regular time intervals. This helps in defining participants' attention distribution and in turn compute various visual search metrics. The steps involved in testing phase are as follows:

4.2.2.1 Obtain test images

As participants move around the construction site, a wearable eye tracker equipped with an HD video camera can simultaneously record their gaze position & direction, and their field of view as first-person view (FPV). The image frames are then extracted from the recorded video, which serve as test images to be used in subsequent sections.

4.2.2.2 Localizing workers

In this step, the position of a worker at different intervals is obtained. The test images are appended to the point cloud, developed in pre-processing phase, and each test image is feature matched with the pre-processing images, to find the best match for each test image. Scale Invariant Feature Transform (SIFT) algorithm [44] is used to conduct pairwise matching. These matches (or correspondences) are stored in an array for future use discussed in step 2.4). The best match for a particular test image is the pre-processing image that has maximum matched features with it. The known camera location of the preprocessing image gives us the location of the participant for its best-matched test image. This enables us to track the trajectory of worker throughout the construction site.

4.2.2.3 Obtain gaze location for each frame

The goal of this step is to obtain the fixation point (gaze location) of the subject in each testing image. The wearable eye tracker records, the data stream that contains gaze position of the subject at every 1/100th second. Using the timestamps, the data is synced with the frame rate of the FPV to extract a gaze positions such that they represent each frame of the FPV. Since each frame represents a test image, we have a gaze position for every test image.

4.2.2.4 Transforming gaze positions using Homography matrices

After the 4.2.2.3, we now have a fixation point (gaze position) for each test image and from step 4.2.2.2; we have a corresponding preprocessing image for each test image. Hence, the objective of this step is to transform the fixation point location from test images to the matched preprocessing image. After this, the system checks whether the gaze location is within any of the AOIs or not. If it is, we count the fixation for that AOI and measure the duration of fixation using the timestamps.

To transform the location of fixation point from testing image to its corresponding pre-processing image, we compute the homography matrix for each match [45] using the correspondences obtained in step 4.2.2.2. The homography (H) matrix is calculated using the following equation 1 [45]

$$\boldsymbol{x_i'} = \boldsymbol{H x_i} \qquad \textit{Eq. (1)}$$

Where $x_i = [x_i\ y_i\ w_i]^T$ and $x'_i = [x'_i\ y'_i\ w'_i]^T$ are the point correspondences that are obtained through pairwise SIFT feature matching.

4.2.2.5 Obtaining viewing pattern with respect to pre-identified hazards

The following condition is checked for test image with x' y' being the transformed gaze position calculated above

$$X` > X_{min}\ \boldsymbol{AND}\ x` < X_{max}\ \boldsymbol{AND}\ y` > Y_{min}\ \boldsymbol{AND}\ y` < Y_{max}$$

Where X_{min}, Y_{min} and X_{max}, Y_{max} are the lower left and upper right corners of bounding box defining the particular AOI.

If the condition is met, it indicates that the fixation point is within the AOI. In this case, the fixation is counted for the particular AOI, if the condition remains true for at least 240ms (average fixation duration in a visual search process). The duration of fixation is obtained by calculating the difference between the timestamp when the condition was met and the last timestamp before the check fails.

4.2.2.6 Analyzing the data and computing metrics

Finally, the visual attention distribution for each subject is generated. Specifically, the output provides information about the areas subjects paid attention to and areas they did not. This information is used to calculate various visual search metrics identified in phase 1.

5 Results

5.1 Phase 1

The results of correlation analysis are shown below.

Table 1. Results of Phase 1

Metric	Pearson's Correlation Coef	p-value	N
SD	0.563**	0.005	23
FT	0.635**	0.001	23
FC	0.649**	0.001	23
MFD	0.393*	0.064	23
ROAFT	-0.093	0.673	23
FR	-0.132	0.548	23

** Significant at $\alpha = 0.05$, * Significant at $\alpha = 0.07$.

The results indicate that hazard recognition performance is strongly and positively correlated with search duration, fixation counts, and fixation time. MFD shows a weak correlation, which is also significant at $\alpha = 0.07$. This implies that searching for longer durations, focusing visual attention on more number of objects and areas, and fixating for longer durations can improve hazard recognition performance.

The results do not provide enough evidence to suggest that a relationship between hazard recognition and remaining two visual search metrics exist (at $\alpha<0.05$).

5.2 Phase 2

5.2.1 Case study Set up

The framework for automated capture and analysis of eye tracking data presented in this study was validated in a live construction site in Raleigh, North Carolina. The objective was to automatically record and analyze attention distribution of a subject while they move around the construction site wearing a wearable eye-tracking device and validate the accuracy of output by comparing it with manually computed results. Five hazards were pre-identified by a panel of safety experts in the portion of the construction site that was to be used for this case study. These hazards are shown in figure 3

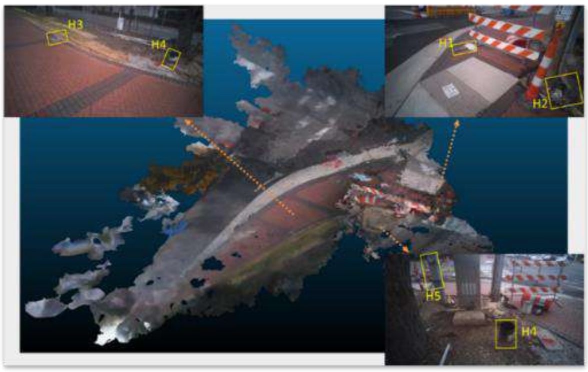

Figure 3. Predefined Hazards. H1: Trip Hazard; H2= Live Electrical Wires; H3: Protruding Rod; H4: Chemical Hazard; H5: Electric Junction Box

The methodology described in 4.2 was followed as explained below.

5.2.1.1 Pre-processing Phase

A walk through video of the selected portion of the site was recorded using Tobii glasses 2 front mounted HD camera with the 10p resolution. A one-minute and 42-second video captured the test area from multiple angles and 2512 frames were extracted that served as pre-processing images.

The features were extracted from these images using SIFT algorithm and these features were used to perform 3D reconstruction of the test area using Structure for Motion or SFM [46]. After this, the pre-identified hazards were annotated on the pre-processing images as AOIs. The AOIs were manually annotated in few images and using the homography between the images, the locations of AOIs were computed automatically on other images using homography matrices.

5.2.1.2 Test Phase:

The subject was tasked to move in the test area while his eye movement data and his field of view were recorded using Tobii glasses 2. It recorded the gaze position and gaze direction, which was used to compute the fixation point location (gaze location) of the subject. This data was recorded at 100Hz and the video was recorded at 25 FPS that captured subject's field of view.

The video recorded by Tobii glasses was exported and 362 frames were extracted from it, which served as test images. The eye tracking data was also exported and the data rows containing the gaze position were extracted. The localization of subject and his gaze position was carried out as explained in the method section (4.2.2.2). Finally, the number of fixations on each AOI and fixation durations were computed as described in step 4.2.2.5. The process was repeated for all test images to obtain the visual attention distribution for the subject while he was in the test area and compute all metrics described in 2.1

5.2.2 Case Study Results

The visual attention distribution for the subject was computed in terms of distribution of dwell times (total fixation duration on an AOI) among five pre-identified AOIs. The other visual search metrics were computed as described in section 4.1. Table 2 & 3 shows the results obtained from the proposed system.

Table 2. Visual Attention distribution of subject

DT_1 (ms)	**DT_2 (ms)**	**DT_3 (ms)**	**DT_4 (ms)**	**DT_5 (ms)**
900	235	257	1148	1270

Table 3. Visual search metrics computed by system

SD (ms)	**FC**	**FT (ms)**	**MFD**
18250	33	8212.5	248.86

As shown in Table 2, participant spent 18 seconds in the test area and fixated on 33 different objects/areas. The Dwell times are shown in table 1 DT1 to DT5 give the distribution of attention over different AOS, which indicate that the participant focused mainly on hazard 4 and 5 paid little attention to hazards 2 and 3. The total fixation time (FT) was 8.21 sec, meaning subject spent only 45% of the time in obtaining information from the scene; remaining 7.52 sec or 55% of the time was spent in searching with no acquisition of visual information.

6 Validation of Accuracy of Localization

To validate the accuracy of localization of fixation points, the dwell times obtained from the system were compared with the swell times computed manually using fixation overlay video obtained from Tobii's recording software. The fixation count for each AOI was obtained by manually counting the number of sets where fixation was within AOI for six consecutive frames. This was multiplied by the mean fixation duration to get the dwell time for each AOI. The results of validation show an accuracy is 88% on average.

Table 4. Validation Results

AOI	**H1**	**H2**	**H3**	**H4**	**H5**
DT1 System	900	235	257	1148	1270
DT2 Manual	744	248	248	992	992
Variation (ms)	156	13	9	156	278
Accuracy %	**83%**	**94%**	**96%**	**86%**	**78%**

7 Discussion & Conclusions

The results of this study advance the theoretical knowledge in the area of construction safety and assist researchers and practitioners develop effective training programs and hazard control strategies. This study represents one of the first research efforts towards understanding hazard recognition from a visual search perspective and evaluating the key parameters that impact hazard search. The contributions and the implications of this study are discussed below.

First, the study identifies and examines various visual search metrics that are closely related to hazard recognition performance. This paves the way for further studies aimed at identifying and studying the effects of various factors that influence workers ability to detect and recognize hazards in construction environments.

Second, the results suggest a strong correlation between the duration of search and the number of hazards recognized by a worker. The current practice does not require workers to spend a specific amount of time in searching for hazards. Instead, workers arbitrarily (or based on experience) examine the work environment, hoping to detect all hazards. Hence, sessions that involve hazard recognition in the field (such as Job Hazard Analysis) should be designed as such to require workers spend a set minimum amount of time to search for hazards in their work environment. Similarly, the training programs can focus on the importance of spending sufficient time in searching hazards as well.

Third, the second phase of the study demonstrates the use of computer vision techniques to automate the process of analyzing eye movement data. It presents a novel framework for developing a system that is capable of analyzing eye-tracking data with dynamic subjects in real environments, which is an active problem in eye tracking research. It helps in automated analyses of viewing behavior and visual attention distribution of construction workers on a large scale. This data can be used to provide focused and personalized process feedback to workers, which will help subject understand their viewing behavior and identify specific deficiencies in their hazard search.

Moreover, the system enables us to collect and analyze visual attention data on a much larger scale. This large data will help researchers better understand the relationship between viewing patterns and hazard recognition performance. The data can also provide insights about common viewing patterns among workers and help safety managers identify hazards that are more likely to remain unrecognized in construction sites.

Finally, the framework would be beneficial to eye tracking researchers in other areas as well, that require analysis of eye tracking data when subjects are moving in real-world environments.

Abstract

Building automation is becoming increasingly popular due to the growing use of the Internet of Things (IoT) framework in the built environment. While there has been a spurt of mobile applications that control electronics in buildings, most of these utilize complex user-interfaces that require multiple interactions to realize user-intent which negatively impacts their adoption. In this paper, we present a framework that provides an intuitive and effective user interface to control electrical devices and fixtures in the connected home of the future. The framework utilizes a handheld point-and-click device that can be used to turn appliances on and off by pointing at them. This functionality is enabled by tracking the location of the device in real time within a virtual building model to determine the user's context and intent.

The position and orientation of the device is used to project a ray in the virtual world to determine the appliance of interest to the user, which is then controlled through the IoT infrastructure. The system is proposed to be implemented using ultra-wideband (UWB) and inertial measurement units (IMU). This research proposes a novel and necessary interface between users and "things" in the IoT paradigm for the built environment that does not require extensive modifications to the appliances itself. Future research will be performed to determine means of incorporating our framework into existing automation efforts such as motion-controlled devices and for defining presets for multiple devices through an extension of the presented framework. Additionally the virtual model also provides a means for tracking and accounting for the electricity usage of the home per device. This utility of the prototype enables sustainable maintenance and operations to optimize the energy-usage of buildings.

Keywords –

Smart homes, Internet of things, Appliance Control, Real-time tracking

1 Introduction

Over the past two decades, significant improvements in sensing and telecommunications has led to the emergence of smart environments [1]. This trend has resulted in the idea of smart homes take root in society, and we are starting to see isolated implementations of increasingly sophisticated tools, devices and systems for home automation. Examples of these innovations include automatic systems for temperature regulation, illumination control, and waste disposal.

The definition of what constitutes a smart/automated home has changed over time due to the rapid development of networking frameworks. Specifically, the growth of Internet of Things (IoT) applications in built environments has led to the increase of inter-connected platforms within the smart home.

According to Mendes et al. [2], a smart home is "A concentrator and disseminator of information and services to cover the totality of a home's functional areas in order to improve the levels of comfort and quality but also to provide a gateway or interface to the exterior by the means of an interaction with other paradigms". De Silva et al. [3] describes the smart home as a "home-like environment that possesses ambient intelligence and automatic control capable of reaction to the behavior of residents and to offer various accommodations (to them)".

It is observed that true home automation is only achieved when an established intelligent space improves overall user experience by simplifying and expediting the process of indoor environmental interaction. Creating an efficiently working intelligent area requires novel ways for humans to be able to communicate with it. An example of such an innovation is the context-aware system infrastructure for indoor location tracking. These technologies improve current smart house frameworks by providing an automated area in which the human location, orientation and gestures can be used to regulate and control appliances in the home.

Current methods of appliance control have improved the ability to exploit the functionality and utility of smart houses. However, these control devices are often expensive, with extensive hardware infrastructure, and inefficient interface operation. Given all of the above, it is the goal of this paper to present an appliance control prototype that fills in efficiency gaps discovered in others by providing an intuitive interface, cost-effective overall design and aesthetically pleasing architecture.

2 Literature Review

Research efforts in the creation of appliance control systems have culminated in mobile and fixed applications that utilize complex procedures that require multiple interactions and the recollection of numerous commands to realize user-intent. Moreover, many current state-of-the art automation systems have the disadvantage of being expensive due to the need for large amounts of physical components for these systems to work for both wired and wireless systems. This section highlights some of the issues with currently available solutions for home automation control.

2.1 Inefficient Interface Design

Based on literature review conducted by the authors, there are three main interface designs used for smart home control devices. These include graphical user interfaces, gesture driven interface, and command line interface. Identified products and prototypes have adequately been able to achieve some level of effective home automation. However certain limitations of these systems have been recognized. Details of these findings are provided in this section.

2.1.1 Graphical User Interface (GUI)

This interface type allows the user to interact with target appliances through graphical icons displayed on a control device. One method used to create GUI interfaces for controllers is with a top-down layout. The design works by providing echelonically arranged icons that allow specific actions to be reached the when the user progresses through the necessary hierarchical levels. When used for home-automation, top-down interfaced controllers typically have display screens that show the different areas of the building which contains all of the appliances or implements that the user could possibly interact with. These zones are made up of several tiers or layers that the user has to go through in order to locate the specific item they would like to communicate with. There are several examples of researchers employing this interface layout to successfully create remote controllers to communicate with appliances.

Vikram et al. [4] in 2017 designed a Wi-Fi based, low-cost automation system that had a similar GUI arrangement. The interface utilized an Android application and allowed the individual to exercise desired control over the lighting, air regulation and other electronics systems within their vicinity. Prototypes like the one created by Kumar and Sharma [5] also used a top-down interface design when creating a smart home platform that was controlled with both a computer and smartphone. The framework was fabricated to allow a remote user, control and monitor the on/off status of connected appliances within an interior intelligent space.

Despite the adequate functionality of the systems discussed above, their GUI top-down layout has an innate problem. Specifically, these kinds of interfaces excessively prolong actualization of an action in a target by requiring the refining of a user`s intentions before producing results. This procedure ends up defeating the entire purpose of home automation by making it more cumbersome than some traditional manual methods of appliance control. For example, an individual using a home automation device with a top-down interface in a small-sized room may have to go through several menu-screens just to turn off a light fixture. In this situation, flicking a wall switch (which is supposed to be the slower manual method) ends up being the faster way of realizing the user’s desires. Additionally, using top-down design approach creates difficulties when the interface has to be programmatically constructed. When a change has to be made to a menu screen, it is difficult making sure that the alteration is in the right hierarchal position in the top-down arrangement [6]. As a result, moving items across different graphical layers becomes overly convoluted.

To resolve the issues related to top-down interface layouts, different methods to GUI design have been proposed by different entities. One of these approaches suggested by Gamba et al. [6] utilized a reverse approach to the top-down methodology. They suggested a bottom-up strategy to create a different and more simplistic procedure of executing home automation. The goal of the researchers was to start from the thought of the user to affect a target in a zone.

Ultimately they ended up with a three-tier interface layout for reaching target areas. Even though the bottom-up approach is an improvement, it still requires multiple steps before a target appliance can be turned on or off. Moreover, for more complex appliance systems, the categorization of labels is required before the correct device can be chosen. This labeling process further complicates the construction of the system. Also developers have to always worry about arranging labels on a functionality basis. If this is done incorrectly, the system will revert to a top-down platform thereby defeating the overall goal of the proposed three tiered approach.

2.1.2 Gesture and Voice Driven Interfaces (GDI)

Gesture driven interfaces have also been increasing used for indoor intelligent spaces. The interface relies on specific physical gestures done by the user to create an automated response. Devices like the gesture pendant allow the wearer to control elements in the house via hand gestures [7]. Within the home, the pendant was used to regulate entertainment systems and room lighting with movement of the pendant wearers arm. Similar to this device, a smart class room was created by Shi et al. [8].The goal was to improve teaching within a school setting by utilizing video to recognize specific motions that can be used to display information and visuals needed to aid in student learning. Within workplace settings, systems like the Monica project employ gestural identifiers to retrieve and present needed information to employees within an office [9]. Ultimately, this helped streamline work processes by speeding up information recovery. More recently, electronic home-assistants such as Google Echo and Amazon Alexa are enabled with the functionality of control devices in the home using voice commands.

All of the examples listed above work well enough within their respective indoor smart environments. However, there is a fundamental issue with reliability when it comes to gesture and voice-driven systems. Most dependability problems stem from accidental activations. A user may be performing day to day tasks and set-off an automated response by unknowingly gesturing a signal. Contrastingly, in some situations, the user may actually intend to issue a specific command and the system may not respond due to the slightest inaccuracies in the individual's gesture or accent. Since there are not any templates in most of these systems to provide real-time direction on gesture accuracy, the user might have to try (without guidance) slightly changing their input multiple times before performing the right command. Consequently, this situation leads to frustration when the system is in use.

Additionally, a frequent user of the system may experience fatigue when using gesture driven interfaces. Particularly for hand-based gesture driven interfaces, having to do different motions constantly becomes an exhaustive process. This is especially true since most of these motions are not ergonomic, thereby causing muscle fatigue and user discomfort when done for a period. In the case of voice-based interface, the user is expected to verbally describe their intent, which would require them to suitably label each appliance in their home and recollect that label while issue verbal command.

2.1.3 Command Line Interface (CLI)

Even though considered dated, command line interfaces are still being used by some home automation developers. These interface frameworks work by allowing the user to provide commands in the form of lines of text. These texts then activate a response in target devices. Some mobile telephony technologies utilize command line interfaces to allow human interaction with a smart environment. By definition, mobile telephony refers to the connecting telephones to provide communication over distances. In 2008, Shahriya et al, [10] developed a procedure that utilized mobile telephony to communicate with appliances. This prototype used Short Message Service (SMS) capable mobile phones to provide attention commands that allowed communication with certain appliances within a home. One unique feature of the system is that it only supports Java enabled phones. This may prove to be a problem over the course of the decade due to the decline of manufactured Java enabled phones [11].

A similar telephone based design was proposed by Baig et al. [12] .Their prototype was created to help regulate appliances remotely by using a mobile application that required voice commands. The commands were then converted to line texts that were then transferred to a GSM network. Command line interfaces like the examples listed above have been tested and proven to work. However the major downside of these interface platforms is that they require the recollection of several different commands. Memorizing multiple different commands might prove difficult and overall negatively impacts user experience.

2.2 Extensive Hardware Infrastructure

The hardware requirements for extant home automation systems can pose to be hindrances to their adoptions. This section describes the components necessary for wired and wireless home automation frameworks.

2.2.1 Wired Frameworks

The history of home automation efforts begun first with the development of wired networking protocols. Power line communication frameworks were mostly used to achieve this end. These systems require the alteration of already existing communication lines to transfer both data and electrical power [13]. X10 technology is one of the older innovations that led the way in main stream use of powerline technology for home automation. The system allowed control device interact with target electrical units within the home. Even with this advantage, the inherent wired design of X10 created problems with distance restriction, power phase limitations and overall poor performance due to its unreliability. To resolve these issues, technology like A10 have been created to improve upon X-10 signals while other manufacturers have developed their own unique power line protocols (i.e. Universal Powerline Bus).

Despite these improvements in the utility and functionality of powerline frameworks, the fundamental issue of the system (i.e. requiring extensive hardware infrastructure) remains. This issue presents a problem since it leads to the increase in energy expenditure. Additionally, the need for large amounts of hardware limits the ability to scale the system since the implementation of changes will be difficult.

2.2.2 Wireless Frameworks

Wireless frameworks have recently been gaining popularity in the home automation industry as a more permanent solution to the limitations of current wired systems. Platforms like Z-wave help set the standards for wire-free home automation. Zigbee, which is similar to Z-wave, is another technology that provides great home automation service with great network reliability.

However, these wireless systems (and others similar to them) require receivers attached to their target appliances in order to be controlled by the user. The cost of installing individual receivers on each item increases home automation expenditure.

2.3 Goals of Proposed Prototype

After completing literature review and identifying gaps in the current state of the art, the authors present an alternative methodology that aims to accomplish the following goals:

1. Improved User-Device Interaction

Device aims to simplify user interaction with the smart indoor environment to allow a more straightforward means of communicating with target appliances. Utilizing a simple point-and-click device, the system should prevent users from having to navigate through several different graphical displays before being able to trigger a real-world action. This design should also allow minimal back-end modeling when there is a change in the layout of electrical appliances in a room.

2. Lack of Appliance Modification

Another goal set by the researchers is to create a system that does not require any additional modifications to the functionality of the electrical appliances themselves. The only alteration done will be to the power source of each target appliance. Wireless relay switch systems will be employed to this end.

3. Reduced Infrastructure/Cost

The system utilized ultra wide band wireless technology instead of a wired solution. Doing this should reduce the overall cost of the hardware infrastructure thereby curtailing the need for excessive wiring. Moreover, the proposed framework does not require target appliances to have receivers in order to work; further lowering installation costs. The reduction in infrastructure should also allow for a more aesthetically pleasing design without cables and wires strewn about the home.

4. Scalability

The research aims to create a dynamic prototype that is also scalable. The wireless nature of the prototype allows for the easy implementation of changes when the extension or reduction of the network is required. This is in contrast to wired installations, in which cable extensions are a tiresome affair [14].

3 Methodology

This section details the conceptual design of the proposed framework. The appliance control system is comprised of different components that are that are connected by wireless communication technology. The wireless set-up allows interaction between these device components and enables automation based on commands issued by the user.

To actualize these commands, the user requires input hardware. A microcontroller equipped with a position sensor was used to achieve this end. This data is then fed to a created virtual environment that is a model of the real-world indoor location. The virtual environment determines the user's desires through spatial analysis and communicates with a relay to enable or pre-vent the flow of power to the electrical device.

Discussed in the next few sections are details about the major components of the system and specifics on how they work. Figure 1 further highlights the processes involved to enable the prototype operate.

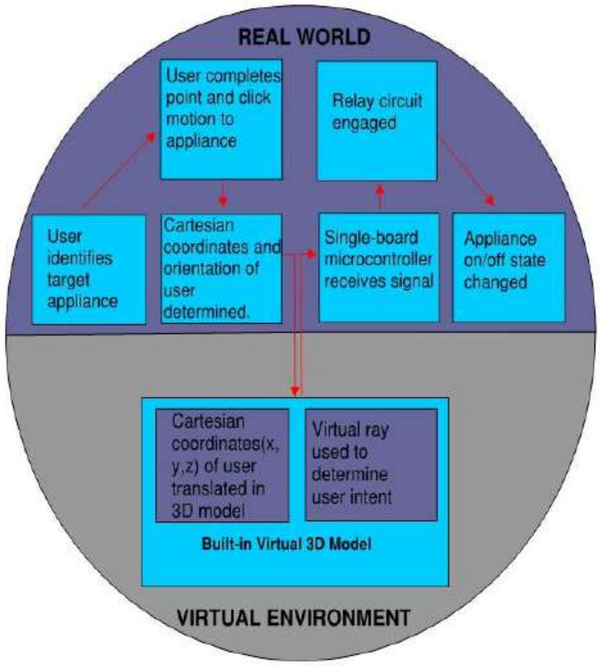

Figure 1. Process Model of Prototype

Figure 2 provides an overview of the components of the entire appliance control system. All physical components of the prototype are displayed with arrows indicating how each of them interacts to produce desired results during use.

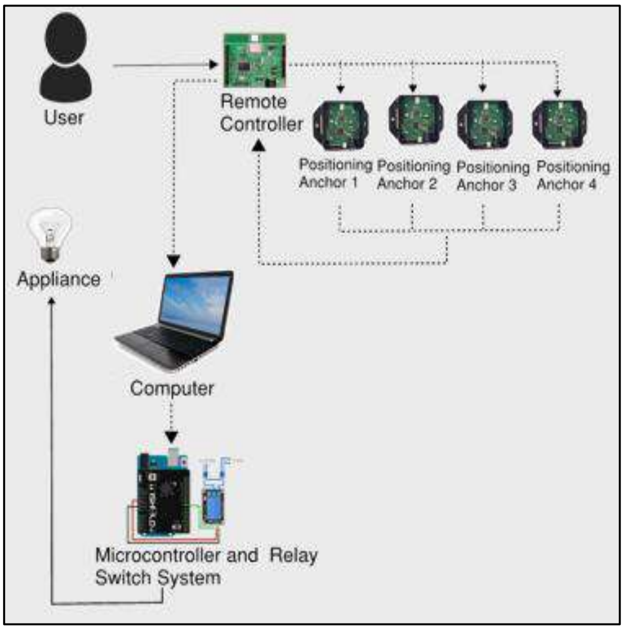

Figure 2. Overview of System Prototype

The systems consists of the following major components:

1. Position and Orientation Tracker

The system uses a position and orientation to provide information of an object or a user within a spatial area. This information is require to determine the user's intent as it will be used to select the appropriate appliance for control.

2. Handheld Remote

The remote device is the medium through the user directly interacts with the electrical appliance control system. The proposed handheld device will be a portable microcontroller with a singular button. This design concept allows for a user-friendly, easy-to-use gadget. This set-up is makes it easier and faster for the individuals to see their desires actualized.

3. Electrical Control System

This hardware component comprises of a microcontroller circuit board with wireless communication capabilities and a relay switch. The relay is necessary to separate the electric current required to power the appliance from that necessary for operating the microcontroller. This component is shown in Figure 4.

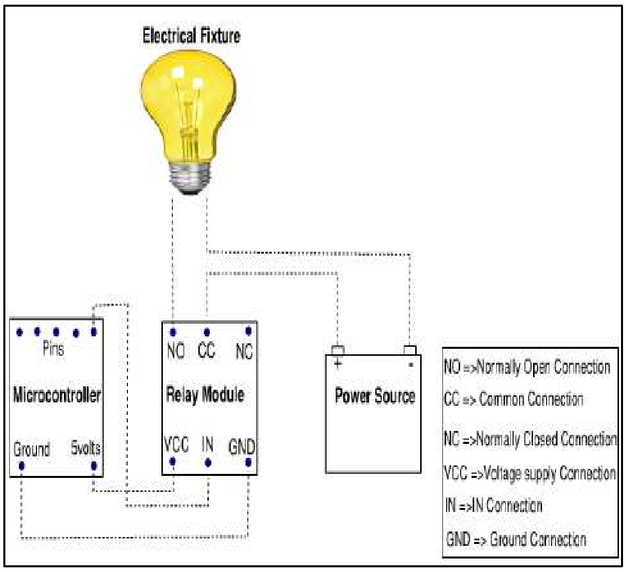

Figure 4. Circuit Diagram of relay/electrical control system.

1. Virtual Environment

A virtual environment was created as part of the main component of the of the appliance control prototype. The virtual environment will act as the medium that translates the user's intentions. The position and orientation of the handheld device is used to project a ray in the 3D environment to determine the appliance of interest to the user, which is then controlled through the IoT infrastructure. The pre-built virtual environment has the benefit of serving as a virtual reflection of the real-world location.

4 Case Study

A case study was performed to test a prototype of the system proposed for appliance selection. This involved selecting a suitable room with multiple electronic fixtures and performing the following steps as described in this section.

4.1 Virtual Environment Creation

After a room was selection, its geometric and spatial dimensions were obtained using a laser measurer. Care was taken to ensure that all measurements were highly accurate and were precise representations of the structural design of the room. Additionally, the spatial location of the light fixtures were determined and recorded. This spatial information was used to create a virtual model of the room.

To create the virtual environment, the research goals demanded a dynamic platform that allowed easy replication of any layout changes that might occur in the real word. Typically for architectural design work, building information modeling tools like Revit are used to graphically depict as-planned and as-built models of building structures. However for the purpose of this research, employing Revit for three dimensional design work would have proved limiting due to the software's long rendering time and lack of interactivity during walkthroughs [15]. To prevent this issue, a game engine, was used to create the virtual environment. Specifically, Unity 3D was the gaming tool utilized. Its programmable interface and cross platform ability made it the ideal tool required for the project [16]. Additionally the ability of the game engine to allow easy alteration to virtual elements means that unexpected changes in the real-world location can readily be replicated in the virtual environment to maintain a high degree of accuracy.

4.2 Positioning Tracking Technology Installation

Monitoring the location of the user required the installation of ultra wideband (UWB) tracking technology and motion sensors. To this end, UWB anchors were utilized to help determine the user's context within the confines of the testing location. This hardware is comprised of four anchor/sensors and a remote device.

To begin the installation procedure the four anchors were placed across the room at exact locations on walls.

To ensure the anchors positioned optimally they were placed at elevated points within the line-of-sight of the user. Care was also taken to ensure that all sensor hardware was spread around the user at different heights per anchor to improve coordination between anchors and boost their ability to deter-mine the 3D spatial location of the user. Additionally, anchors were placed far away from metallic objects to prevent diminished performance of the anchor's antenna.

Next, a tag was configured to enable communication with the anchors. The tag works by determining its location relative to the installed anchors in the room. This location dictating feature is facilitated through the creation of a coordinate system based on the spatial relationships between each anchor. One anchor is selected to be the origin point of the coordinate system. Going off this origin point, two other anchors are then set as the y-axis and x-axis. Once all the axes have been substantiated, manual measurements using a laser was conducted to determine for each anchor, their heights from the ground and their relative location on the created coordinate plane. Results obtained from these measurements represented the x, y and z coordinates of each sensor. Since all of these devices were distributed in a non-linear form around the location, the newly created coordinate system conformed to the rooms shape and orientation.

With the coordinate points set, the microcontroller is initialized by uploading it with code written in C language. The previously measured x, y and z points of each anchor is put into this code and algorithm uses this information to find the relative location and orientation of the handheld remote device.

This relative positioning algorithm works by treating the anchors as reference frames in a three-dimensional space and used these set points to determine the real time coordinates of the user as they move around the room. To read the orientation of the users pointing motion, the code was further expanded to communicate with an embedded gyroscopic and accelerometer sensors in the remote controller. Given the tri-axis nature of these sensors the absolute orientation or rotation of the device can be extracted. To do this, quaternions are utilized. The Quarternions which are represented by 4 parameters provide mathematical notation to represent rotation state of an object. Next, all of this data is communicated to the game engine software thereby allowing the real-world orientation and spatial location of the remote device to be visually replicated in the created 3D environment.

4.3 Relay Installation

For this step in the set-up process, a relay was installed to provide the means of controlling the appliance by leveraging electromagnetic fields to open and close the switches. The researchers performed following procedures to complete the relay-microcontroller framework:

4. Required components were identified and gathered for use. These components included a micro-controller circuit board and a 5V relay module.
5. Next, the connections between the controller circuit board and the relays were set-up. Using wiring, the board is connected to an inlet pin of the relay. Next the power supply pin (5V) and ground pin of the board is linked to the relay module.
6. The third step involves the relay connections to the ac current power source and the chosen light fixtures. The relevant relay terminals required to achieve this end are as follows:
    - Common connection: The central terminal of the relay. It was connected to the power source of the ac current.
    - Normally open: This connection is a switch for the circuit. Like the name suggest it stays open in its initial state. Closing it however allows current to flow to the light bulb, thereby turning it on.
    - Normally Closed: This connection is opposite to the normally open. When opened its interrupting the current flowing through the light bulb thereby turning it off.

Ultimately, the microcontroller was programmed to regulate the on/off state of the relay based on a received wireless signal.

4.4 Prototype Testing

Once all of the requisite components of the prototype had been set up, testing began. The test location was a simple rectangular shaped room in an office building.

A user was then given the point and click device to regulate the on/off state of each light fixture. To ensure that the prototype worked to maximum efficiency, the area of room was divided into 10 equal sized rectangular sectors. Then the tester was placed in each rectangular sector in the room and allowed to press the button that controlled the electrical appliance at different angles. Doing this helped the researchers ascertain the accuracy of the motions sensors in determining the user's context in the chosen location. Additionally selecting different areas of the room to activate the light fixtures, helped in calibrating the orientation-determining feature of the system to maximum efficiency. A distribution schema of 10 was selected to make it easier to obtain a percentage of accuracy for the prototype.

Figure 4 and 5 respectively show the real world use of the hand held controller and its replication in the virtual world.

Figure 4. Real-world testing of handheld point and click device.

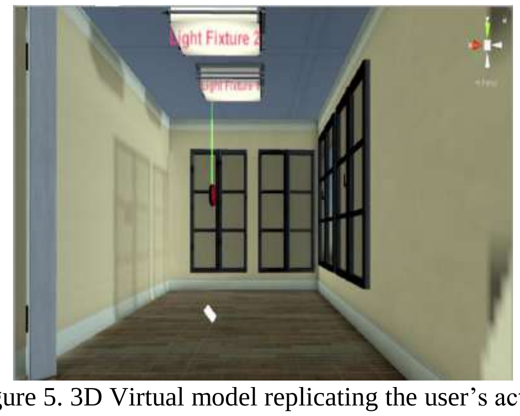

Figure 5. 3D Virtual model replicating the user's action

5 Results and Discussion

As expected, the completed prototype was fully functional for each sector throughout the room. The single button feature of the device created a direct method for the individual to interact with the test area. Also utilizing a simple design provided a shallow learning curve for the user to understand how to operate the device and expedited the process of target appliance response.

The system was created using ultra-wideband technology as the basis for wireless communication therefore curtailing the need for excessive components. This setup makes the prototype less physically extensive than wired systems for home appliance control.

Moreover using multi-connected electricity relay systems and a virtual environment for target identification further reduced the need for additional hardware components traditionally used in popular wireless platforms (i.e. receivers). Consequently this design allows for a more affordable, easily scalable and easily changeable prototype. All of these results and features of the final product meet the goals set by the authors and show the overall benefits of utilizing the proposed system for appliance control.

The concept of indoor-positioning innovations and context aware systems was introduced earlier in the paper to set up a simple positionally aware appliance control device. The proposed prototype was successfully created by integrating microcontroller circuitry, wireless communication, electrical relay switches, and virtual environments. Testing the limits of the created platform revealed its suitability in reaching all performance and design goals set in this research paper.

This research can enables applications within the field of home automation. The use of the prototype can be expanded by integrating an electricity usage monitor to track the power consumption of individual electronic appliances within the home. Doing this will encourage the user to adopt environmentally friendly behavior and aid them in managing their home by providing a means to regulate energy consumption (and thereby utility expenses) of the home.

Abstract –

Earthmoving operations are complex system where many resources collaborate to carry out tasks. Although considerable efforts have been made in the development of efficient methods and systems for recommending appropriate fleets of equipment, in practice, average production rate method still prevails in favour of its simplicity at the cost of possible inaccuracy in planning and estimating at construction stage. In this paper, a simulation-based fleet selection methodology was introduced. Then, Simulation-based Earthmoving Fleet Optimization Platform (SEFOP), as an intuitive and efficient tool for equipment selection optimization in earthmoving operations, was presented. The proposed methodology and tool were applied on a real-world rough grading project and the outputted results proved that the SEFOP tool is able to provide a decision maker with insightful fleet selection strategy and accurate cost and duration estimates.

Earthmoving; Fleet Selection; Simulation; Optimization

1 Introduction

Due to the lack of specific information such as equipment models, the temporary haul road layout design, and earthworks volume assignment plans, it is unrealistic to come out with resource allocation plans by examining the detailed earthmoving operations at bidding stage. As a result, the industry often applies general deterministic approaches by applying “four to six passes” rule based on average production rates [1]. In particular, the average production rates are derived from RS Means [2] or other company-specific or industry-wide benchmarking database by considering basic factors such as fixed truck and excavator type, bucket size, hauling distance, soil properties, average cycle time, efficiency factor, and etc. This kind of average production rates based deterministic method for fleet selection [3] is widely taught at post-secondary institutions and is the primarily applied method in construction industry. However, once being processed to the construction stage when specific field information become available, average production rates methods may fall short in resource planning and productivity estimating as it only accounts for particular categories of equipment and work conditions. As proofed by Yi and Lu in [4], the method based on average production rates tends to underestimate crew productivity by an average of 30%, compared to detailed operation analysis method, resulting in poorly selected fleet and reduced chances to the successful earthmoving operation.

In order to help obtain the optimum resource allocation in earthmoving operations, a substantial number of researches have been conducted by modelling the earthmoving operations [5][6][7]. Gransberg [8] used a deterministic method of dividing the cycle time by the loading time of the trucks in order to determine the required number of haulers. Shi [9] used neural networks in order to determine the number of haulers required for a particular excavator. Later, heuristic algorithmic innovations have been integrated with simulation modelling to optimize earthmoving operations. Marzouk and Moselhi [10] successfully established an automated system named Earth Moving Simulation Program (EMSP). It will integrate heuristic algorithms into the simulation model to select a near-optimum fleet configuration. Cheng et al. [11] proposed simulation optimization by combining GA with CYCLONE or other simulation techniques. Zhang et al. [12] further proposed an integration of particle swarm optimization (PSO) and a construction simulation so as to determine efficiently the optimal resource combination for a heavy construction operation. Integrating genetic algorithm, linear programming, and geographic information systems (GIS). The simulation model for large-scale earthmoving operations are developed and successfully applied to two numerical examples [13]. Morley et al. [1] applied simulation to optimize truck numbers by allowing for a multiple truck and excavator types to be considered.

Nevertheless, field planners still use average production rates together with their experience by default for fleet selection at construction stage even though specific field information become available, due to the lack of professional simulation modelling and optimization training, and haste planning under time constraint. Based on author's personal research and working experience in construction industry in Alberta, field supervisors/managers are interested in simulation tools, but hesitate to apply due to prohibitive time consumption compared to average production rates method in the fast-paced and profit-chasing construction industry. In this context, it is necessary to devise a scientifically reliable yet easy-to-use tool to tap all the information at construction stage to result in a refined resource plan in guiding workface executions to the purpose of maximizing profit.

2 Haul Job Definition

In site grading project, haul job is the fundamental unit for earthmoving planning, resource allocation, and production estimating. In this paper, a complete haul job is defined by seven attributes: source, destination, earth volume, haul path, resource, duration and cost. Varying by the earth volumes and hauling route between source and destination, the resource allocation (i.e. truck number), cost and duration for completing haul jobs could differ considerably. Generally, a source is defined by a cut area where a destination is defined by a fill area. A haul route corresponds to a pair of source and destination with a pre-planned haul path, through which the trucks pass to haul the material from cut to fill. In this thesis, haul job is further classified into two categories: cut-dominated haul job and fill-dominated haul job.

Mathematically, a haul job is defined as $H_{ij} = \{v_{\mathrm{ij}}, P_{ij}, Res_{ij}, C_{ij}, T_{ij}\}$. v_{i} is the calculated soil volume in bank measure to be excavated in cut area i; v_{j} is the calculated soil volume in bank measure to be dumped in fill area i; v_{ij} is the soil volume to be hauled in current haul job. If $v_{\mathrm{i}} < v_{\mathrm{j}}$, H_{ij} is defined as a cut-dominated haul job; otherwise, if $v_{\mathrm{i}} > v_{\mathrm{j}}$, H_{ij} is defined as a fill-dominated haul job. P_{ij} is the haul path between cut area i and fill area j; Res_{ij} is an integer number starting from 1 to indicate truck numbers allocate to current haul job; C_{ij} *and* T_{ij} are total cost and total duration of current haul job respectively.

In practice, the earthmoving tasks are decomposed to haul jobs to guide workface operation executions. Similarly, in this paper, haul job serves as the fundamental unit in earthmoving fleet optimization.

3 Optimize Truck Number and Excavator/Truck Type

The number of trucks is determined in order to match up with the production rate of the excavator, which is generally assumed to be the governing resource in earthworks estimating. The number of trucks is dependent on the specific excavator being used, the specific truck type being considered, temporary haul road design, and the truck hauling cycle time. The truck selection starts with one truck. The average total haul job duration with one truck being employed will be recorded and corresponding total haul job cost will be calculated, according to Eq.(1):

$$C_{ij} = \frac{T_{avg}}{f}(U_t N_t + U_{ex} + U_{oh}) \quad (1)$$

Where T_{avg} is the average haul job duration from simulation; f is the operations efficiency factor; U_t is unit cost of truck in \$/hour; U_{ex} is unit cost of excavator in \$/hour; U_{oh} is unit cost of field overhead in \$/hour; C_{ij} is the total cost of haul job H_{ij}.

With same method, total haul job cost of employing multiple trucks can be calculated. The truck number selection strategy is illustrated in Figure 1. It is noted that the termination criterion "Cost N+1 > Cost N" means that employing one more truck will lead to total direct cost increase.

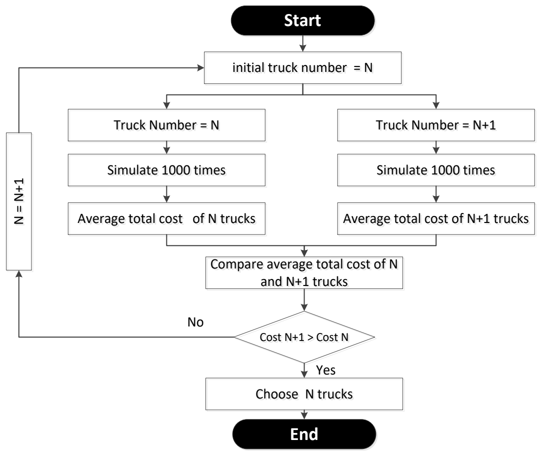

Figure 1. Simulation-based truck number optimization methodology

Having the basis of truck number optimization, truck/excavator type optimization can be made possible by adding one more loop by iterating all the possible truck/excavator combination, as shown in Figure 2. The total project cost (consist of multiple haul jobs) under different truck/excavator combinations will be calculated and compared to result in the optimal truck/excavator selection in terms of minimum total project cost.

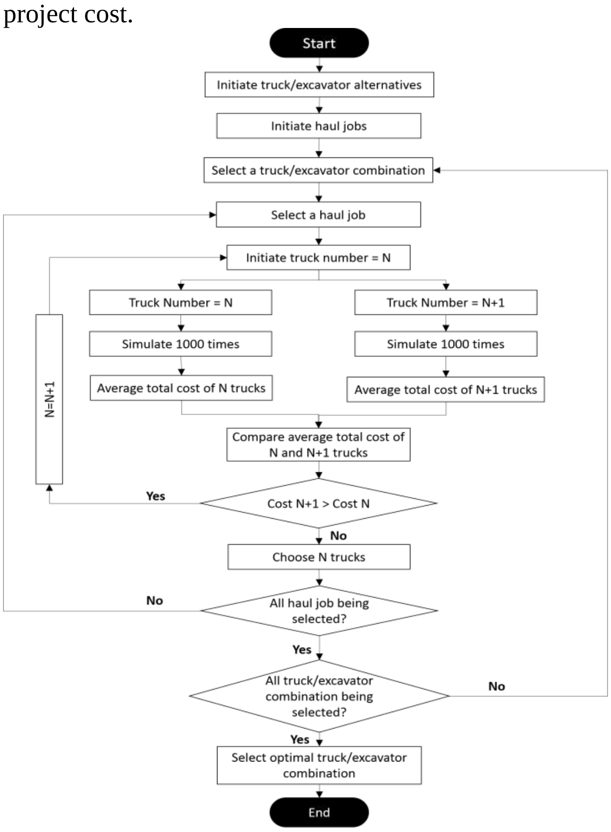

Figure 2. Simulation-based truck/excavator type optimization methodology

4 Simulation-based Earthmoving Fleet Optimization Platform (SEFOP)

For current fleet optimization problem in earthmoving operation, the whole operation process was simulated with discrete event simulation functions in SimPy, providing the foundation for the proposed Simulation-based Earthmoving Fleet Optimization Platform (SEFOP). The excavator was defined as resource in the simulation environment with a default number of 1. Truck loading, hauling, dumping and waiting was encoded with SimPy functions. When loading, the truck needs to call the excavator from resource in the simulation environment. The excavator was simulated to load the truck bucket by bucket when there is no other loading work occupied. When all the earthworks tasks done for current haul job, the program automatically outputs duration and cost, in order to identify optimal truck numbers.

Firstly, to optimize truck numbers, SEFOP will automatically simulate haul job cost and duration under different truck numbers to identify the optimal truck numbers in terms of minimum total haul job cost. Secondly, for equipment type optimizations, SEFOP will automatically simulate different truck/excavator combinations on the basis of truck number optimization program, outputting optimal truck/excavator types together with optimal truck numbers for haul jobs. In addition, SEFOP was programmed to allow optimization for multiple haul jobs.

4.1 SEFOP Main UI Screen

By running the SEFOP application, the below User Interface (UI) will pop up for users to (1) input haul job(s) parameters, and (2) select optimization mode.

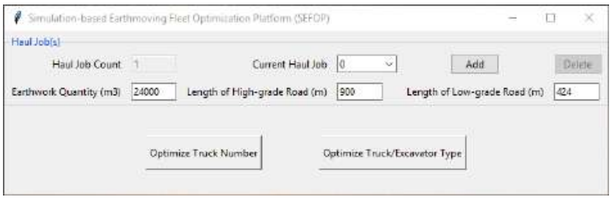

Figure 3. SEFOP User Interface (main)

For each haul job, users need to input "Earthwork Quantity (m3)", "Length of High-grade Road (m)" and "Length of Low-grade Road (m)". The program allows users to input multiple haul jobs by inputting haul job parameters and clicking "Add". Users are also allowed to check each haul job being inputted by choose haul job from a dropdown menu in "Current Haul Job", or delete any haul job by clicking "Delete".

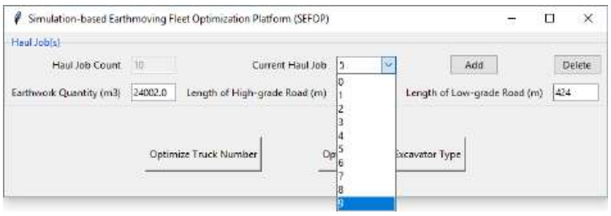

Figure 4. Add Multiple Haul jobs

Once haul job(s) information has been inputted, users can choose either to optimize truck number (when truck and excavator type being selected by field planner or no alternatives exist), or to optimize truck/excavator type (when truck and excavator types not determined and multiple alternatives available), by clicking either "Optimize Truck Number" button or "Optimize Truck/Excavator Type" button on the UI screen.

4.2 Optimize Haul Job Truck Numbers Function

If users choose to optimize truck numbers, the below

UI window will pop up.

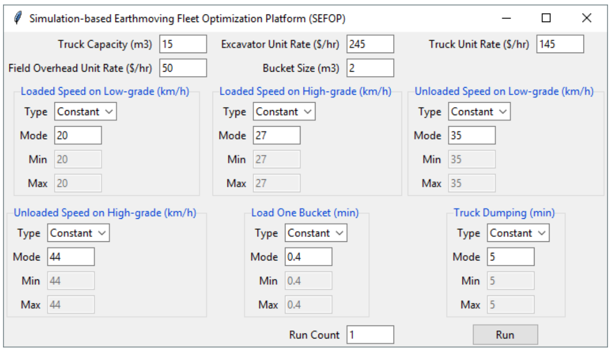

Figure 5. SEFOP User Interface (truck number optimization)

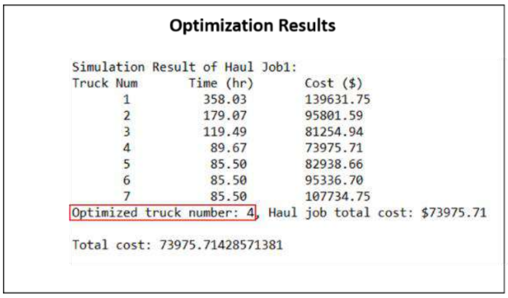
Users need to input "Truck Capacity (m3)", "Bucket Size (m3)", "Excavator Unit Rate ($/hr)", "Truck Unit Rate ($/hr)", "Field Overhead Unit Rate ($/hr)", "Loaded Speed on Low-grade (km/h)", "Loaded Speed on High-grade (km/h)" , "Unloaded Speed on Low-grade (km/h)", "Unloaded Speed on High-grade (km/h)", "Load One Bucket (min)", and "Truck Dumping (min)".

For truck speed and time inputs, users are allowed to input either deterministic value or distributive values by selecting "Constant" or "Distributed" from dropdown menu "Type". For distributive inputs, users are requested to input three values as "Mode", "Min", and "Max". The distribution used in SEFOP is triangular distribution.

The last input requested is "Run Count", to specify how many simulation runs the users expect for the program to iterate. Theoretically, the more run counts, the more accurate the final averaged results are. Once all the requested fields have been inputted, users can click "Run" to obtain the optimized truck numbers for each haul job. A sample output from SEFOP is shown in Figure 6 with optimal truck numbers marked with red box.



Optimization Results

```
Simulation Result of Haul Job1:
Truck Num        Time (hr)        Cost ($)
    1             358.03          139631.75
    2             179.07          95801.59
    3             119.49          81254.94
    4              89.67          73975.71
    5              85.50          82938.66
    6              85.50          95336.70
    7              85.50          107734.75
Optimized truck number: 4, Haul job total cost: $73975.71

Total cost: 73975.71428571381
```

Figure 6. Optimal Truck Numbers Output

4.3 Optimize Truck/Excavator Type Function

SEFOP is also able to optimize truck/excavator types together with optimal truck numbers for each haul job by considering the entire project. In SEFOP, if users choose to optimize truck/excavator type, the below UI window will pop up.

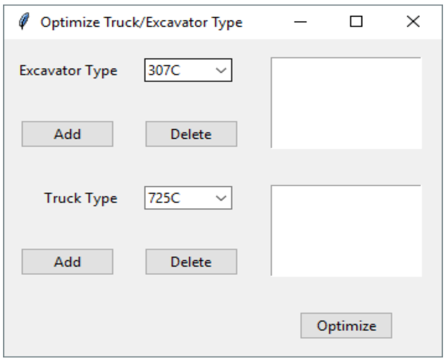


Figure 7. Optimal Truck Numbers Output

The program allows users to input multiple excavator and truck alternatives. Users are also allowed to select excavator type by a dropdown menu including all the common excavator types. Note the SEFOP application only include truck and excavator types from Caterpillar with truck and excavator performance parameters built in the program; the truck and excavator performance parameters can be easily accessed by Caterpillar Handbook [14]. Once excavator type is selected, user need to click "Add" to add the selected excavator type to the excavator pool. Users can delete excavator in the pool by selecting an excavator type in the pool then clicking "Delete". The truck type input functionalities are the same as excavator. Once alternative trucks and excavators are selected and added to the pools, users click "Optimize" to result in optimal excavator/truck type, together with truck numbers of each haul job and project total cost. A sample output from SEFOP is shown in Figure 8 with optimal truck and excavator types marked with red box.

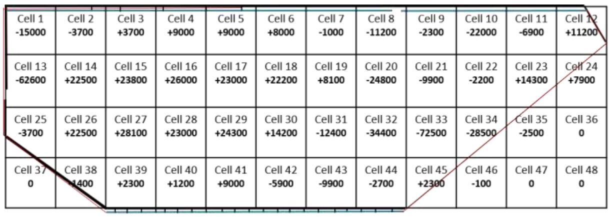
5 Case Study

A rough grading project was utilized for evaluating the proposed method. The rough grading project was the preliminary work package of a camp site construction in Fort McMurray, AB. The field was around 120 hectares, divided into 48 cells each being 150 m by 150 m, as shown in Figure 9.



Cell 1 -15000	Cell 2 -3700	Cell 3 +3700	Cell 4 +9000	Cell 5 +9000	Cell 6 +8000	Cell 7 -1000	Cell 8 -11200	Cell 9 -2300	Cell 10 -22000	Cell 11 -6900	Cell 12 +11200

Figure 9. Cut and fill cells with earth volumes

A total of 43 earthmoving haul jobs together with temporary haul road designs were obtained by employing the analytical method proposed by Li and Lu (2016) on the current case study project, as shown in Table 1. One fleet will be used to perform the earthworks job with one excavator being the lead resource that governs the production capacity. CAT 320D and CAT 336D excavators are available to this project. CAT 735C and 730C articulated trucks are considered for hauling the earth.

To apply SEFOP tool to optimize equipment selection, the 43 haul jobs in Table 1 were inputted into SEFOP, as shown in Figure 10. Alternative trucks and excavators were inputted as shown in Figure 11.

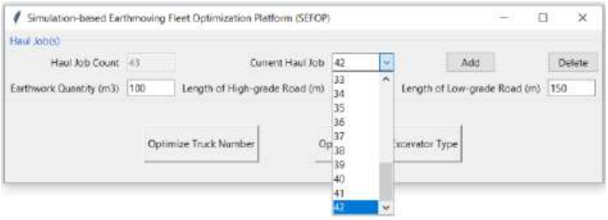

Figure 10. Haul job inputs in SEFOP (start from 0)

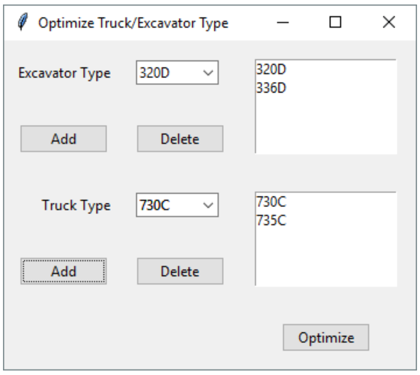

Figure 11. Equipment performance inputs in SEFOP

The simulation run count is set as 1000. By clicking "Run", the cost, duration, and optimal resource for each haul job of each excavator/truck combination were outputted. In this paper, only the results of the optimal excavator/truck combination were shown, in Table 1.

Table1. Optimal excavator/truck combination and cost, duration, and resource for each haul job

42	900	0	362	3	3.66	2103.2
43	2800	0	150	2	11.08	6368.2
		Excavator Type				336 D
		Truck Type				730C

As shown in Table 1, resource allocation, duration, and cost for each given haul job was optimized in terms of minimal operational cost as per methodology in Figure 1. By summing up costs for 43 haul jobs, total earthmoving cost can be obtained. Then, by comparing total earthmoving cost among four fleet combos (320D and 730C, 320D and 735C, 336D and 730C, 336D and 735C), 336D and 730C were selected as optimal solution.

6 Conclusion

A well-designed equipment selection and allocation plan is crucial to the success of earthmoving operations of rough grading projects. In order to help decision makers to select and allocate critical resources, this paper proposed a Simulation-based Earthmoving Fleet Optimization Platform (SEFOP) to automate the fleet selection and allocation process in earthmoving operations in an efficient and user-friendly manner. In specific, this tool provided planner a platform to do "what-if" analysis, providing insight for contractors to select optimal fleet for earthmoving operations. The proposed methodology and SEFOP tool were applied and tested dependent on a real world rough grading projects. It was shown that SEFOP could not only automatically optimize equipment selection and allocate trucks to each haul job consisting of the entire earthmoving job, this intuitive tool could potential improve the business efficiency in resource planning with maximization of profit. Future research will focus on integrating more practical features, such as the nature of soil, the amount of work, the type of earthworks, hydrogeological and other conditions in the simulation process to result in more accurate truck and excavator selection strategy.

Abstract –

Temporary haul road layout design is a main factor influencing the cost and safety of haulage in heavy civil construction, especially on large site grading projects which entail mass earthworks. The ideal design of temporary haul road layout is to deliver the project in the lowest construction budget while guaranteeing haulage safety. Previous research endeavours have focused on achieving the lowest earthmoving cost in designing temporary haul road layout but failed to incorporate the equally important safety factors, thus rendering the optimized design to be possibly associated with high safety risks. This paper proposes a framework that aims to quantify haul road design related safety factors in a large site grading project. The feasibility and effectiveness of the proposed methodology is further evaluated by a real world case study. A comparative table with information on safety performance index values and safety indicator values of four alternative layout designs is given to visualize the quantification outcome. In conclusion, the proposed methodology enables construction planners to quantitatively evaluate haul road related safety impact, leading to significant improvements in the safety performance of temporary haul road layout.

Site Grading; Temporary Haul Road; Layout Design; Safety; Evaluation

1 Introduction

Haul roads are most commonly built in mining projects to improve hauling efficiency and ensure hauling safety on mine haul jobs. In the Guidelines for Mine Haul Road Design [1], haul roads are categorized into temporary, semi-permanent and permanent haul road. Unlike the mining project, for site grading and earthmoving operations over a large area, it is not realistic to link a loading area (cut) and a dumpsite area (fill) by permanent or semi-permanent haul roads since the project generally lasts several months. For improving hauling efficiency and safety in large site grading projects, the common practice is to build a limited length of temporary haul roads (e.g. gravel surfaced) along critical truck hauling paths on site. Due to its temporary nature, temporary haul roads are typically built with pit run, limestone or gravel with minimum thickness or even directly laid on rough ground. Generally, the temporary haul road can be simply classified as high grade vs. low grade where high grade haul road can be gravel surfaced while low grade haul road remains rough ground requiring frequent maintenance (by grader) [2].

While haul road design guidelines are available to regulate on various aspects of the haul road on mining projects (e.g. alignment, curvature, surface, and etc.) [1][3], there lacks insightful design specifications for temporary haul roads for heavy civil projects. In trying to establish the guideline, several research endeavors were made recently. Liu [4] proposed a multi-generation compete genetic algorithm (MCGA) to search for the least-cost temporary haul road layout design. Based on Liu's work, Yi and Lu [2] further proposed a more sophisticated mixed-integer linear programming (MILP) method to analytically identify the least-cost design by considering accessibility and connectivity constraints. Though cost-efficiency has been satisfied in the resulting design, the previously proposed methods failed to consider safety factors, thus making the optimized design possibly exposed to potential safety hazards.

As operations safety is highly dependent on well-designed, well-constructed and well-maintained haul roads, insufficient haul road design will have an immediate negative impact on operations safety. Due to the size and weight of earthmoving equipment, when accidents occur, consequences are often severe. According to electronic educational material published by Occupational Safety and Health Administration (OSHA), approximately 75% of struck-by fatalities involve heavy equipment. Also, in the same source it mentioned that one in four "struck-by vehicle" accidents resulting in a fatality involves construction workers, more than any other occupation [5]. The most common causes of heavy construction equipment accidents resulting in fatalities and injuries are categorized by OSHA (2003) [6], namely: (1) being caught in/between; (2) being struck-by equipment/falling objects; (3) falling from vehicle; and (4) equipment rollover. In a typical earthmoving site where large amounts of heavy equipment exist, a well-designed and maintained haul road network will considerably reduce the possibility of encountering safety hazards.

In order to incorporate safety as a design factor in designing temporary haul road layout, the quantification for the underlying safety hazards in a unified measurement is required. Given that there are no safety quantification methods for the earthmoving operations in existing literatures, the objective of this paper is to propose a conceptual framework that can support the quantification of safety by (1) introducing a grid model to represent the earthmoving site and temporary haul road layout design; (2) identifying haul road related safety impact factors in earthmoving operations; and (3) proposing formulating schema for each identified safety impact factor in a consistent unit of measure based on the presented model. The following sections provide a detailed description of how to fulfil the objective step by step with a practical case study.

2 Grid Model, Graph, And Traffic Flows

The grid model of a possible haul road layout design on a rough-grading site was proposed by Liu and Lu, (2015) [4], as demonstrated in Figure 1. For each cell, the centroid is simplified to be the cell's geometric centre; thus, the potential road layout design can be denoted by road links, each connecting the centroids of two adjacent cells with straight-line sections. The road type of each link can be distinguished by a dot line for "rough ground" by default and by a solid line for "gravel surfaced". It should be noted that the "road links" are segments between the centroids of any two adjacent cells, instead of between any two cell centroids; two cells are deemed adjacent only if they are 'immediately adjacent' or 'diagonally adjacent'.

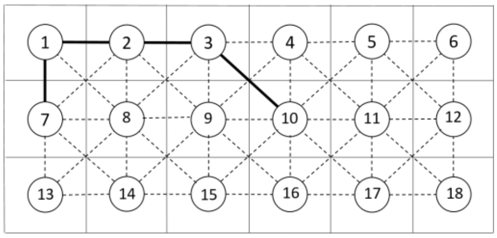

Figure 1. Site partitioning strategy and road links to represent haul road design

Based Graph Theory, an undirected graph is written as $G = (V, E)$, meaning that G consists of node-set V and edge-set E. We use v to represent a node (centroid of a cell) and (i,j) to represent an edge (road link) in the haul road network. Note $\forall$ v $\in$ V, and all $\forall$ (i,j) $\in$ E where i and j are end nodes of edge (i,j). The type of haul road is denoted by a Boolean parameter $x_{(i,j)}$, which equals to "0" given "rough ground" haul road; equals to "1" given "gravel surfaced" haul road (e.g. in Figure 1. $x_{(1,2)} = 0$; $x_{(6,7)} = 1$).

Validated by previous research [4][7], when cut and fill volume data of each cell is given, the optimally allocated traffic volumes on each road link (i.e. traffic flows, in m^3) can be determined by applying linear programming techniques, as shown in Figure 2. The previous research achievements for determining traffic flows on each road link lay a firm foundation for proposing safety index formulating schema described in the subsequent chapter.

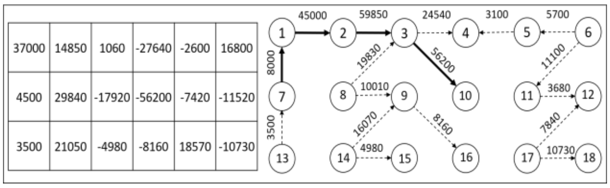

Figure 2. Cell based cut and fill design and optimal earthwork flows

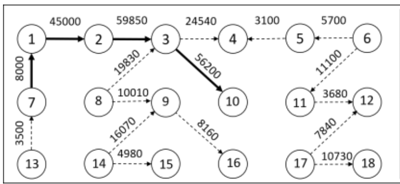
3 Safety Quantification Framework

In trying to quantify hauling safety in earthmoving based on the presented model, a comprehensive literature review [1][3][8] and several field studies were conducted in order to define practical measures that can be taken during the temporary haul road layout design process in evaluation of construction safety. This investigation led to the identification of three major safety measures: (1) proper design of temporary haul road (both geometrically and structurally) to improve the safety at curves and minimize the hazards (e.g. collision, out of control) caused by blocking line of sight; (2) reducing surface hazards such as potholes, rutting, settlement, wash-boarding, and heaving caused by heavy traffic volume; and (3) control of hazardous equipment near labour-intensive onsite facilities.

3.1 Curve Safety Index (CSI)

In current model, a curve is denoted by (i,j,k), which stands for truck hauling from node i to node k, passing node j; i is curve starting node, j is curve centre node; k is curve ending node; note i and k are interchangeable since trucks haul in round trip. In this study, three curve angles are considered, as 45°, 90° and 135° in alignment with the grid model, as illustrated in Figure 3. The dot circles indicate curve centre nodes. Different curves could share the same curve centre node, forming an intersection (e.g. node 3). All the curves are identified based on earthwork flows and cut and fill design, as summarized in Figure 3.



Curve ID	Curve nodes	Curve Degree
1	7_1_2	90°
2	14_9_16	90°
3	2_3_10	45°
4	8_3_4	45°
5	6_11_12	135°

Figure 3. Horizontal curves

From a safety standpoint, haul road must be designed to accommodate the braking capabilities of those vehicles having the least braking potential which will most likely to transverse or directly hit on obstacles (such as wild animals, breakdown trucks, and falling rocks) due to inability to stop in time. This situation is especially severe at horizontal curves. At curves, driver's line of sight is blocked by a hill crest, trees, or an obstacle on the inside of the curve. Insufficient stopping distance can adversely affect the truck hauling safety at a curved section. According to published design regulations [1][3], truck's stopping distance is related to road grades, friction coefficients, rolling resistance, climate condition, and truck sizes. In order to guarantee the safety of truck hauling at curves, contractors are responsible to properly design the temporary haul road layout. To this end, a minimum stopping distance is required to guarantee the hauling safety at curves.

In this paper, the degree of safety at curves is quantified by a performance metric named Curve Safety Index (CSI), scaled from 0% to 100%. This index is formulated in Equation (1):

$$\text{CSI}\ (\%) = \text{Function}\ (\text{R}, \text{SD}, \text{L}, SD_{ijk}^{z}) \qquad (1)$$

R is the minimum allowable radius of a horizontal curve which can be found in AASHTO Green Book, (2001) [9]. In this study, it is assumed that the minimum allowable radius criteria are used by the contractors to design the curve's geometry at the preliminary design phase in that a lot of detailed information on site conditions and crew selections are generally unavailable. With R known, the minimum stopping distance (SD) can be derived from equation in [10]. According to the equation in Department of Labor (1999)[8], the actual stopping distance (L) can be estimated.

With L and SD known at each horizontal curve, a percentile-based measurement indicating the degree of risk in accordance with the SD-L relationship is proposed, namely stopping distance safety indicator (SD_{ijk}). This indicator (SD_{ijk}) classifies the SD-L relationship into four different categories, as (1) L ≥ SD, which represents the occurrence of accidents with SD_{ijk} valued at 100%; (2) 3/4 SD ≤ L < SD, which represents the high risk due to high probability of haulage-related accidents - any minor misbehaviour would cause accidents, SD_{ijk} is valued at 75%; (3) 1/2 SD ≤ L ≤ 3/4 SD, which represents an intermediate level of risk due to low probability of haulage accidents such as driver's absent mindedness and brake failure, SD_{ijk} is valued at 50%; and (4) L ≤ 1/2 SD, and therefore haulage safety is unaffected with SD_{ijk} valued at 0%.

3.2 Surface Hazard Safety Index (SHSI)

According to Thompson and Visser [11], haul road surface condition is related to traffic volume, wearing courses, maintenance management and weather. Failure to establish a good haul road surface will result in increased possibility of encountering surface hazard. Poor haulage surfaces (e.g. potholes rutting, settlement, wash-boarding, frost heaving, and etc.) caused by poor compaction, precipitation/runoff, heavy traffic volume, and inadequate maintenance will severely compromise the ability of a vehicle to safely negotiate the route; or in many instances, drivers may attempt to avoid a certain situation, which could cause serious accidents [12]. According to Mine Safety and Health Administration (MSHA) [8], the surface haulage accidents include: (1) haulage trucks going out-of-control; (2) vehicles/persons being run over by large trucks; and (3) trucks going over dump points. These hazardous situations need to be properly addressed so as to minimize the risk of haulage accidents.

In order to improve safety on construction sites, planners need to comply with MSHA standards and design proper haul road surface condition onsite. The haul road grades should be selected according to truck type, traffic volumes, and maintenance frequency. In the present model, a newly developed performance metric named Surface Hazard Safety Index (SHSI) is proposed to accommodate the quantification of haul road surface hazard. As shown in Equation (2):

$$\text{SHSC}(\%) = \text{Function}\ (f_{ij}^{1}, f_{ij}^{2}, QM_1, QM_2, \text{N}) \qquad (2)$$

f_{ij}^1 is the allocated traffic flows on rough ground haul road while f_{ij}^2 is the allocated traffic flows on gravel-surfaced haul road; N is the total quantity of haul road segments onsite; QM_1 and QM_2 are the "need maintenance" threshold volume of earth being transported on rough ground haul road and on gravel-surfaced haul road, respectively; which means once QM_1 m3 of earth have been transported on rough ground and QM_2 m3 of earth transported on gravel-surfaced haul road, the haul road surface deteriorates to the need - maintenance level. The maintenance frequency, denoted as f_{ij}^1/ QM_1 and f_{ij}^2/ QM_2, will help classify the degree of risk in the present methodology. The higher maintenance frequency, the more likely trucks will encounter surface hazard. The degree of risk can be expressed as 10%*(f_{ij}/QM), subject to $f_{ij}/QM \leq 10$.

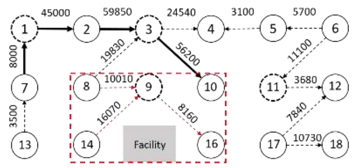
3.3 Travel Routes Safety Index (TRSI)

On site construction facilities such as parking lot and temporary office, where the density of workers peaks among the entire site, is the most sensitive area to safety issues. Frequent truck hauls near the facilities will not only expose the workers to high safety risks (e.g. hit by out-of-control trucks), other harmful effects such as noise, air pollution by dust, and etc., will be produced, potentially influencing workers' health. Therefore, the haul roads need to be properly designed to minimize the safety impact near these facilities. OSHA recommends possible hazards (e.g. fire, explosions, pollution, heavy traffic) shall be located far away from onsite facilities [6].

The present model incorporates a newly developed performance metric named Travel Routes Safety Index (TRSI), as shown in Equation (3). In calculating TRSI, the model allows the user to specify whether a haul road segment within safety impact area (1) has a high level of traffic and close distance to facility, giving rise to high safety risks; or (2) has a low level of traffic and far distance to facility, therefore does not create a significant risk.

$$TRSI(\%) = Function\ (d_{ij-f}, TR_{ij}) \qquad (3)$$

Where d_{ij-f} is the shortest distance between the geometric centre of the facility and the haul road segment; TR_{ij} is a percentile-based measurement indicating the degree of risk in accordance with traffic volume and haul road grade (as shown in Figure 4). In the present model, a safety impact area is defined as a rectangular area within site boundaries that contains the facility area, with 100 meters side-to-side distance (assume all facility areas can be represented by a rectangle). A detailed illustration is given in Figure 4. The red dot line encompassing the onsite facility denotes the safety impact area. The red dot haul road links denote the haul road segments presenting significant safety risks to the facility.



Haul Road Grade	Level of Traffic	Hazard Degree	TR_{ij}
Rough Ground	High	Very High	100%
Gravel-surfaced	High	High	75%
Rough Ground	Low	Medium	50%
Gravel-surfaced	Low	Low	25%
No Road	N/A	No Hazard	0%

Figure 4. Measuring the near-facility hazard on site

3.4 Haul Road Safety Indicator (HRSI)

Therefore, the temporary haul road layout safety is quantified by introducing a safety indicator named Haul Road Safety Indicator (HRSI), which aggregates the three indexes by relative weights, as shown in Equation (4):

$$\mathrm{HRSI} = \mathrm{w1} * \mathrm{CSI} + \mathrm{w2} * \mathrm{TRSI} + \mathrm{w3} * \mathrm{SHCI} \qquad (4)$$

In this formula, the relative weights (w1 to w3) of the three safety indexes can be best obtained from historical safety records of previous projects that classify fatalities and/or injuries into these three major categories. In the absence of such company data, the planner can provide his/her best judgment on their relative weighting by referencing national average figures such as the occupational injuries statistical report published by Bureau of Labor Statistics [13].

4 Case Study

A practical rough grading project is utilized for evaluating the proposed method. The rough grading project was the preliminary work package of a camp site construction in Fort McMurray, AB. The field is divided into 48 cells each being 150 m by 150 m. The project had a total amount of 335,600 m3 of banked earth to be handled from cut and fill. The material considered has no appreciable swell. The cut (-) or fill (+) volume of each cell along with the cell identification number is shown in Figure 5.

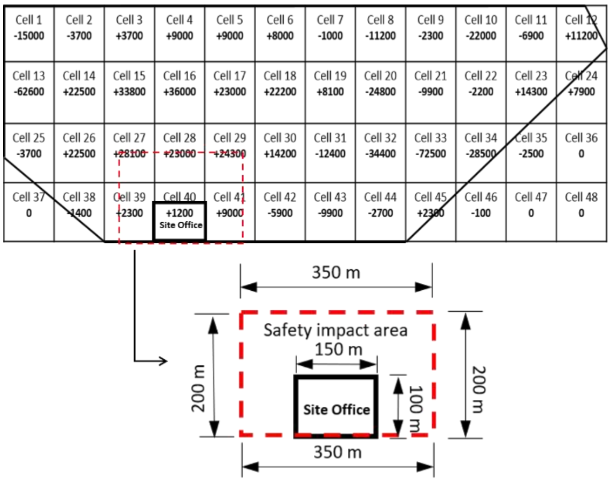


Figure 5. Haul road within safety impact area of onsite facility

The relative weights denoting the three safety indexes were chosen as w1: w2: w3 = 0.4:0.4:0.2. The four layout design options in [4] are selected for evaluation purposes, as shown in Figure 6-9. The proposed approach is coded in Python Version 3.5 [14]. The safety evaluation results of the four layout options are summarized in Table 1.

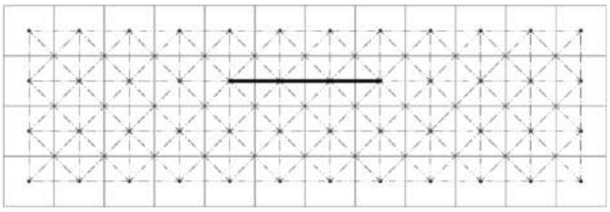

Figure 6. Haul road layout option 1

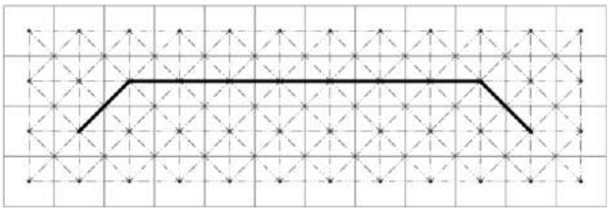

Figure 7. Haul road layout option 2

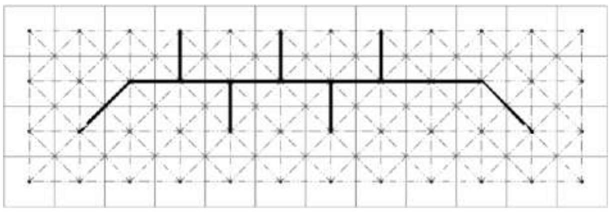

Figure 8. Haul road layout option 3

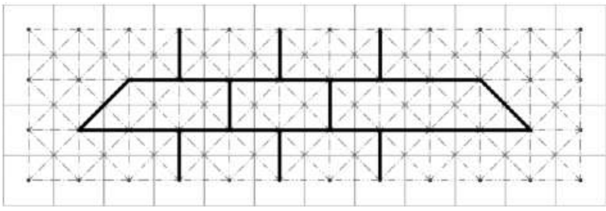

Figure 9. Haul road layout option 4

Table1. Safety evaluations and comparison between the layouts

Layout Option	Road Length (m)	CSI (%)	SHSI (%)	TRSI (%)	HRSI (%)
1	450	65.8	75.3	50.0	66.44
2	1,474	58.5	64.5	57.1	60.62
3	2,224	46.0	55.3	57.1	51.94
4	4,024	34.6	25.7	71.4	38.40

Layout 1 is the riskiest design alternative (HRSI = 66.44) while layout 4 has the least safety risk (HRSI = 38.40). The proposed methodology can lend effective assistance for designers or project manager to evaluate hauling safety, providing insight in designing safer temporary haul road layout.

5 Conclusion

This paper proposes a framework for the quantification of temporary haul road related safety to aid in designing a safer temporary haul road layout in large site grading projects. The quantification approach is developed in four major steps that focus on (1) modelling the earthmoving site and temporary haul road network; (2) identifying potential safety hazards in earthmoving operations in connection with haul road designs; (3) proposing formulating schema for each identified safety hazard in unit measure (0%-100%); and (4) integrating them into a unified safety indicator. A case study with four alternative temporary haul road layout designs is given as a test-bed to evaluate and validate the proposed methodology. The safety evaluating results for respective design alternatives are summarized in a comparative table to intuitively visualize the quantification outcome. In summary, the proposed methodology can be readily implemented in the real world in order to materialize safety impact on temporary haul road layout design. In addition to safety evaluation, the research deliverables could lay a solid basis for immediate future research in developing a robust model that supports multi-objective optimization of temporary haul road layout design in order to realize maximization of safety and minimization of total earthmoving cost simultaneously.

Exploring Virtual Reality in Construction, Visualization and Building Performance Analysis

M. Al-Adhami[a], L. Ma[a] and S. Wu[a]

[a]School of Art, Design and Architecture, University of Huddersfield, UK
E-mail: Mus.Adhami@hud.ac.uk, L.Ma@hud.ac.uk, S.Wu@hud.ac.uk

Abstract

In the past two decades, the Architecture, Engineering and Construction (AEC) industry has investigated different approaches to improve communication among project parties, including Virtual reality (VR) however these approaches have not been widely adopted by the industry.

Today, the tremendous advancements in technologies and computer hardware have potentially improved the current approaches and enabled a significant enhancement of user experience of Virtual reality (VR) devices. Based on that the researchers have conducted a review to investigate the global VR applications research in (AEC) community in 2015-2017 to understand the status and the trend of immersive virtual reality (IVR) research in the world using these affordable devices.

This paper also presents a result of an experiment to integrate three different types of AEC digital modeling data and proposed workflows for IVR applications in construction, visualization and building performance analysis. The experiment deals with construction simulation, rapid generation of the VR scene for existing building and airflow visualization. Several workflows investigated game engine and VR tools have been used.

1 Introduction

The Virtual reality (VR) technology has emerged in various domains in the past two decades. It enables the users to immerse themselves in a computer-generated environment which simulates complex, real situations and contexts[1]. The experience of wearing the VR headset has been significantly enhanced due to the tremendous development of computer hardware, central processing unit (CPU), graphics processing units (GPU), data storage et al. Also, these devices have become more affordable. In fact, any business considers computer graphics and 3d modeling will be affected by this technology[2]. The Architecture, Engineering, and Construction (AEC) industry heavily rely on digital modeling, visual communication and simulation[3]. This has attracted the research interests to investigate and applying VR technology to AEC applications.

This paper presented a review of the development of VR technology and their uses in AEC industry through literature review, and conduct an experiment to implement immersive virtual reality (IVR).

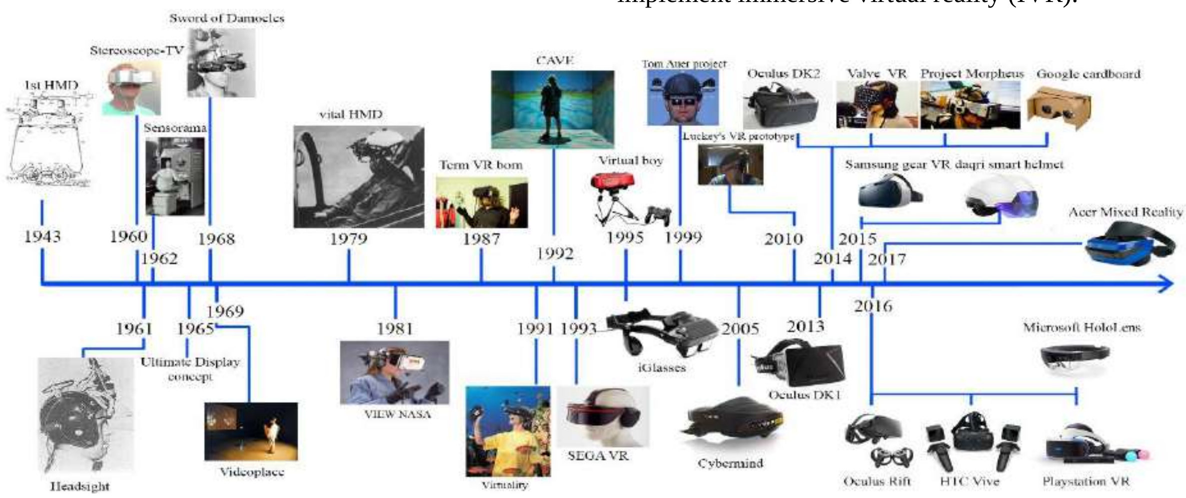

Figure 1. Development of VR headset

2 A review of VR applications in AEC industry

The research compiled the timeline below that demonstrates the development of VR devices Figure 1. The first head mounted display (HMD) was created by McCollum in 1940s. His idea was to display noninteractive films supporting visual display without tracking motion, but there was no integration of computer and image generation. In the late1980s, the term VR was coined by Jaron Lanier. It combines the devices with video imaging and computer graphics[4]. Now, many headsets have been devised which enable human interaction with computers using motion controllers, depth-sensing camera and natural user interfaces.

This review analyzed all articles related to VR applications since 2015 in the Web of Science core collection database. The review centred on architectural design, construction and building technology. A total of 2,790 paper was found. Figure 2 shows the number of research articles published by authors from different regions. Only the regions that have at least 27 publications are listed here. The researchers from the USA (756), England (286), China (224) and Germany (224) have made the most significant contributions in these areas. Also, researchers for the USA have widely collaborated with researchers from other countries (presented as the thickness of the links between the nodes).

Based on an analysis of the keywords of the 2,790 bibliographic, only 89 articles have been identified that are most related to VR applications in the AEC industry. The keywords used in these articles are shown Figure 3.

The keywords were clustered into five groups (shown in different colours in the figure). They are also listed in Table 1.

Table 1 Clusters of keywords used in publications related to VR applications in AEC industry

Group	Keywords
1	Architectural design BIM Design Environment GIS System Visual geographic environment Visualisation
2	Augmented reality Construction Dwelling Education Mixed reality Safety Technology Unity
3	Architecture Cultural heritage Perception Space perception Virtual reality
4	Evacuation Games
5	Construction safety Management

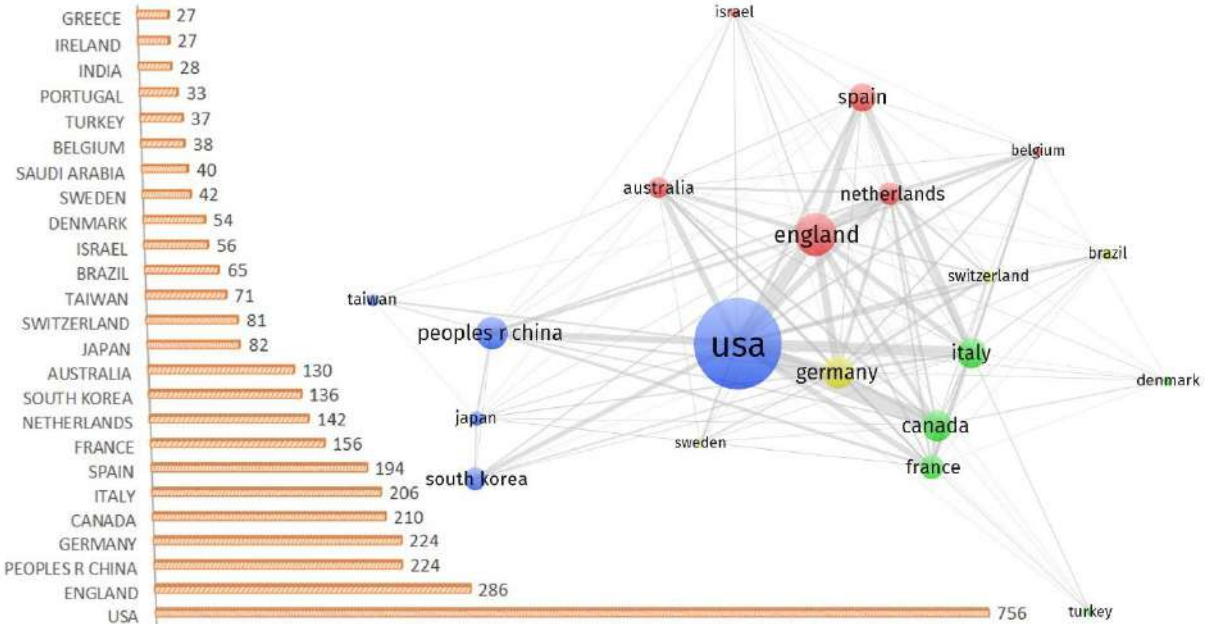

Figure 2 Number of related publications by researchers from different regions

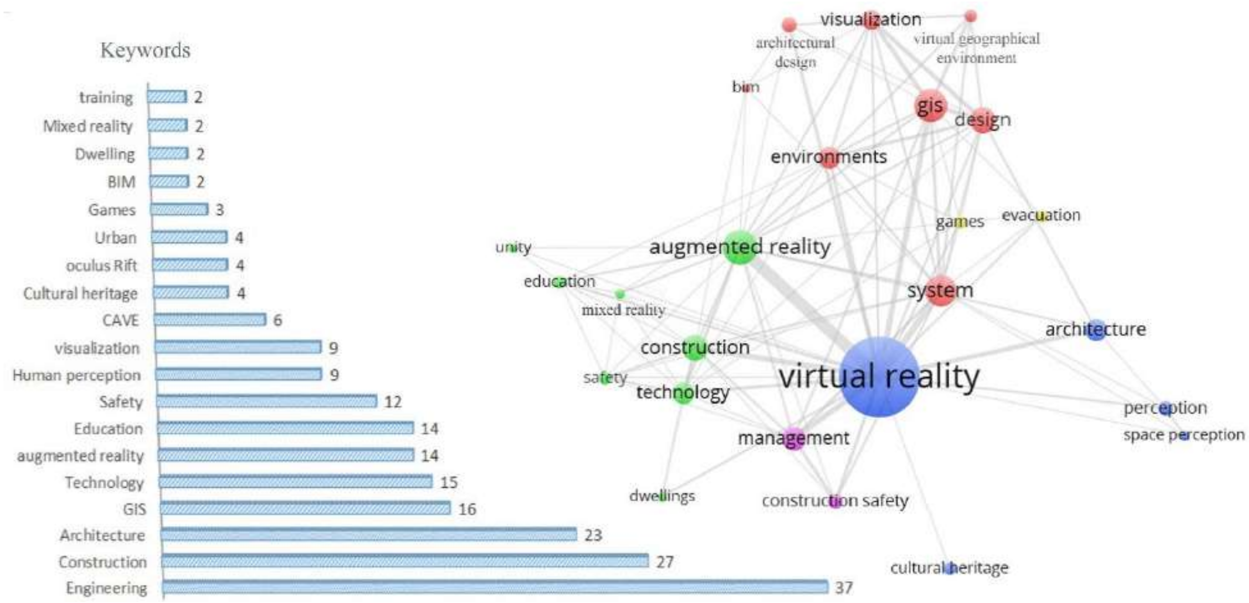

Figure 3. Keywords used in applications of VR in AEC industry

The group 1 shows that BIM-enabled VR has been widely used in architectural design and urban planning (GIS system) for visualization purpose; the group 2 shows that VR together with augmented reality and mixed reality technologies have been widely used for construction safety education; group 3 shows that VR has been used for investigation of space perception in cultural heritage; group 4 shows that VR has been used for education through games; group 5 shows that VR has also been implemented in construction safety management.

Most of the researchers mainly utilised the non-immersive VR devices in their work. These devices mainly provide visualisation capability, while the immersive VR devices enable more advanced human interaction with the computer. Nine research papers [3, 5-12] using immersive VR are shown in Table 2.

3 Experiment for establishing a workflow of IVR applications

The experiment based on three types of data:

1. 4D construction simulation in VR
2. Rapid generation of the VR scene
3. Airflow visualization in VR

3.1 Construction simulation

We prepared the BIM model of the Queen Street Studio (QSS) at the University of Huddersfield using Revit; convert the model data from RVT to FBX file format; then import the FBX file in Unity (a game engine). It was found that the texture of the BIM model was missing in Unity, so the modeller needed to add the texture layers in Unity again.

For the 4D simulation, we used Autodesk navisworks manager to divide the BIM model into parts that represent the construction batches. Then, we defined the construction schedules using timelines, as is shown in Figure 4. The TimeLiner data was exported from naviswork to 3ds max and then the animation data with geometries was exported to Unity. Finally, the immersive VR application was generated from Unity, as is shown in Figure 5.

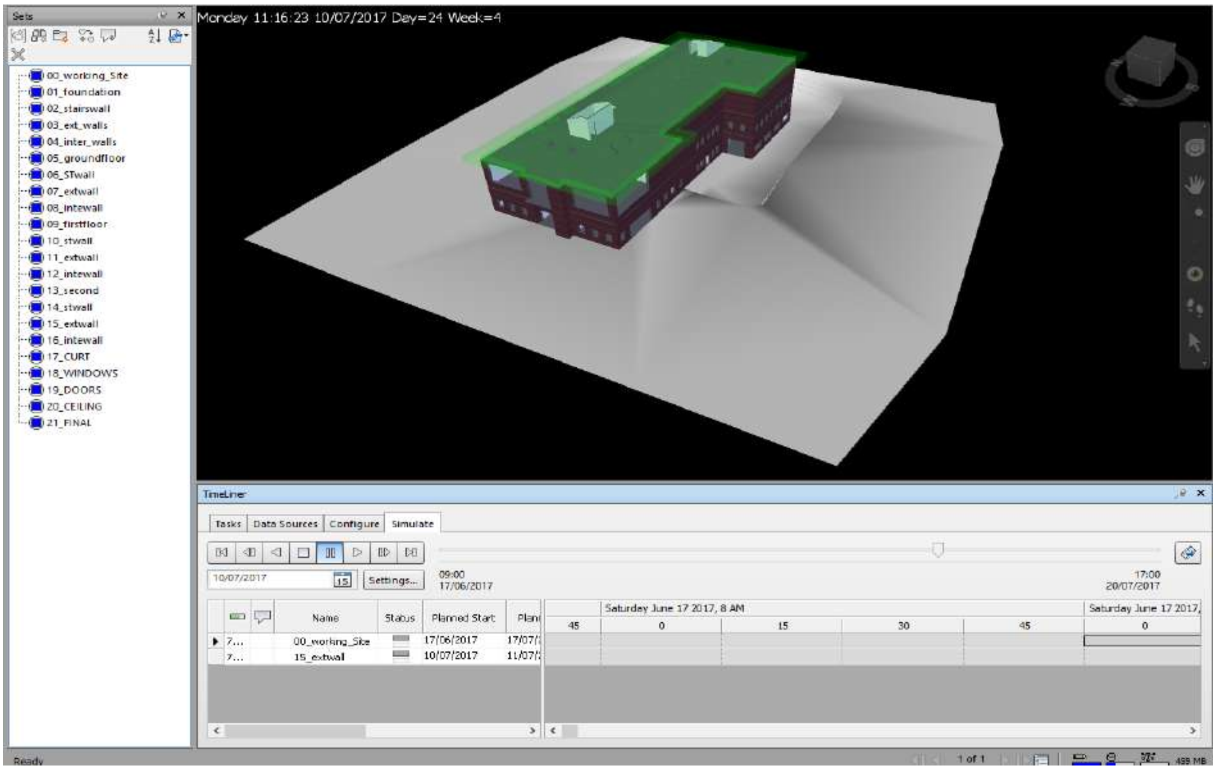

Figure 4. The BIM model and construction sequence of the Queen Street Studio

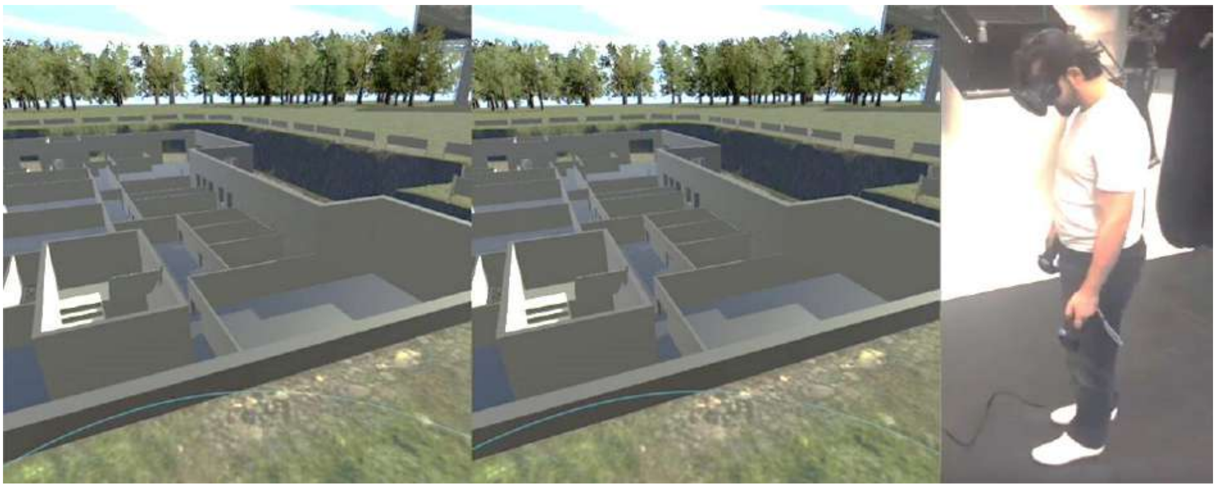

Figure 5. Construction simulation in immersive VR

3.2 Rapid generation of VR scenes

The Terrestrial Laser Scanner is a state-of-the-art survey technology. We used the FARO Focus scanner to capture the 'as-is' state of four rooms in the QSS building, as is shown in Figure 6. The rooms were chosen according to the space area, type of lighting, and the function (shown in Table 3).

Then, we generated the mesh model of the room using the collected point cloud data and then import it to Unity and built the VR application, as is shown in Figure 7. We also import the point cloud directly to Unity and built the VR application as is shown in Figure 8. The mesh model has a better visualization while it requires more process time.

Space Name	Floor	Type	Area(m2)	Lighting / windows Orientation	Scan stations
Café Area	Ground Floor	Public	62	Daylighting - SE	Three
Design Centre	Ground Floor	Semi public	188	Artificial - S	Four
PC Lab	Basement	Private	58	Artificial - none	Two
Design Studio	First Floor	Private	88	Mixed – SW	Three

Figure 7. Mesh object in Unity

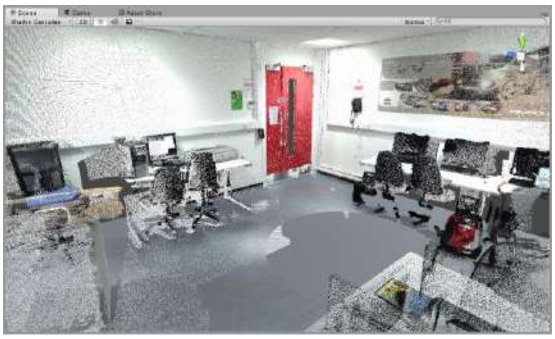

Figure 8. Point cloud data in Unity

3.3 Rapid generation of VR scenes

We used Autodesk CFD to perform CFD simulation of the PC lab at the QSS building. Simulation parameters include: Air Changes per hour is (15) and Supply temperature is (20°C). The results were exported as CSV files which contain the information of velocity, temperature, pressure and density in the simulated space, as is shown in Figure 9.

CFD data was then imported to 3ds Max to generate geometries for visualizing the velocity, temperature, and pressure. There are several representations of CFD data such as splines, planes, arrows, etc.

We set airflow data as splines with temperature colour. The data was then exported as FBX file and imported as a new asset in Unity. Finally, the VR application was built and visualised in the headset, as is shown in Figure 10.

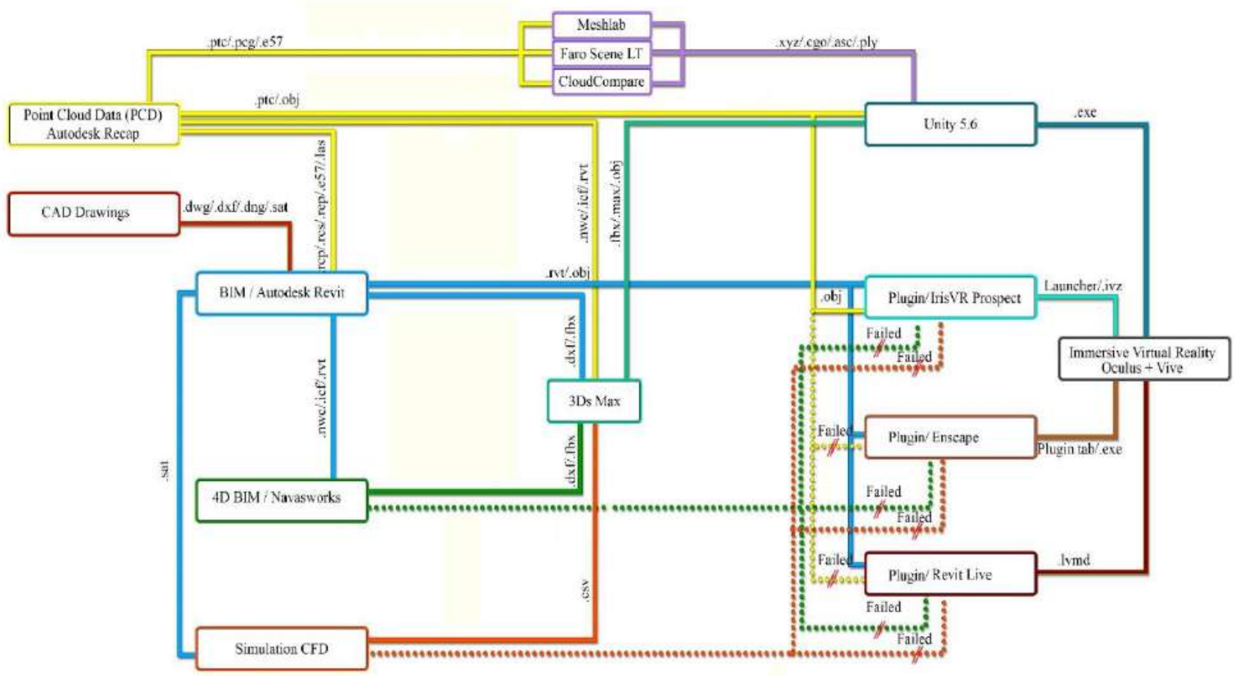

Figure 11. The interoperability of VR applications

4 Summary

This paper reviewed the development of VR devices and literature of VR applications for AEC industry. It also demonstrated three workflows for construction simulation, VR scene generation, and building performance analysis. The literature has shown VR technology was successfully applied in many fields, however, the use of immersive virtual reality (IVR) still not adopted widely, AEC industry is facing many challenges starting from concept design, construction and operation, today VR technology can be a valuable tool to solve some of these challenges.

There are many tools can be used to create VR applications and it is important to understand their usages, functions and interoperability. Figure 11 shows how to exchange data between different tools. This can help others to select the right tools for using VR in their business processes. However, there are few things we need to consider to develop a sophisticated VR experience, 1) knowing the user, the problem, outline the expectation, and the final goal, 2) VR platform (desktop or mobile) and identify the content of creation in reference to VR experience. 3) Integration method and developing time. In addition, the model needs to be created with fewer polygons so that the model will not be too heavy to be loaded into the VR platform and also get rid of unwanted geometries to avoid overload objects. It is highly recommended to give a unique name to each object in the model and group some of them; this helps organize the work through getting the information faster especially in big projects, and make things less complicated if there is a need to change, edit or replace some object.

Abstract – Infrastructure systems are very essential to every aspect of life on Earth. Existing Infrastructure is subjected to degradation while the demands are growing for a better infrastructure system in response to the high standards of safety, health, population growth, and environmental protection. Bridges play a crucial role in urban transportation networks. In addition to that, they are vulnerable to several deterioration agents such as the variable traffic loading, extreme weather conditions, deferred maintenance, etc. The development of Bridge Management Systems (BMSs) has become a fundamental imperative nowadays especially in the large transportation networks due to the huge variance between the need for maintenance actions, and the available funds to perform such actions. Condition assessment is regarded as one of the most critical and vital components of BMSs. Ground Penetrating Radar (GPR) is one of the non-destructive techniques (NDTs) that are used to evaluate the condition of bridge decks which are subjected to the rebar corrosion. This paper presents a corrosiveness index that is capable of evaluating the extent of severity of corrosion in concrete bridge decks. Different clustering algorithms are compared in order to select the most feasible clustering algorithm. A probabilistic deterioration model is constructed in order to model the future condition rating of bridge decks. Anderson darling test is used to select the most feasible probability density function, and the parameters of the probability density functions are obtained using maximum likelihood estimation. Finally, two case studies are presented to illustrate the capabilities of the proposed model.

Bridge Management System; ground Penetrating Radar; bridge decks; corrosion; deterioration model; maximum likelihood estimation

1 Introduction

Bridges are vital links in transportation networks that should be safe, functional and serviceable during their service life to facilitate the mobility of people and transportation of goods which causes sustainable economic development. Concrete bridges are prone to high level of deterioration because of the variable traffic loading, extreme weather conditions, cycles of freeze and thaw, deferred maintenance, etc. More than 40% (700 bridges) of Egyptian bridge inventory out of 1,700 bridges have exceeded their maintenance limit and are at risk of failure.

American Association of State Highway and Transportation Officials (AASHTO) defined Bridge Management System (BMS) as “a system designed to optimize the use of available resources for inspection, maintenance, rehabilitation and replacement of bridges” [1]. AASHTO and Intermodal Surface Transportation Efficiency Act (ISTEA) defined five main components for BMS which are as follows [2]: 1) database for data storage, 2) condition rating model, 3) deterioration model, 4) cost model, and 5) optimization model for running system. The structure of BMS is shown in Figure 1 [2].

The database is the most essential component of the BMS where it is used to store information that is related to every bridge in the network. Bridge condition rating is based on field inspections to evaluate the condition of bridges. Deterioration model is used to predict the condition rating of different bridge elements over time. The cost model is divided into two main types which are: 1) agency costs, and 2) user costs. The agency costs ae based on the expenditure of maintenance, repair and rehabilitation activities (MR&R) to improve the condition rating of the bridges. The user costs are based on the impact of deterioration on road users as a function of the bridge condition [3]. The optimization model is implemented to determine the optimum maintenance, repair and rehabilitation activities for different bridge components. The proposed model focuses on two bridge management components which are: 1) the condition assessment model, and 2) the deterioration model. A corrosion index is developed based on the ground penetrating radar. Also, the weibull distribution is used to model the deterioration of bridge decks. Accurate condition rating and reliable deterioration models help in minimizing the risk of failure of aging infrastructures.

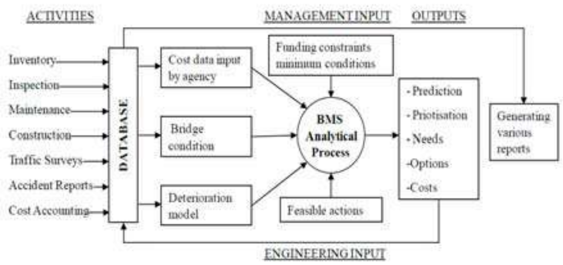

Figure 1: Typical structure of BMS [2]

2 Destructive and Non-Destructive Techniques

The condition assessment model heavily depends on the inspection type. The process of monitoring bridges should be cost effective, efficient, and fit for the purpose [4]. Thus, bridge inspectors should use techniques to assess accurately and effectively the corrosion of the bridge decks. Bridge inspection can be defined as “a process in which the defects on a bridge are identified, recorded to be used for assessing bridge condition”. Inspection techniques are divided into two main categories which are: 1) destructive techniques (DT), and 2) non-destructive techniques (NDT). Destructive Techniques (DT) provide accurate and direct results, but they cause damage to the element under investigation, and they are expensive and time-consuming. Non-Destructive Techniques (NDT) are inexpensive and quick, but they do not provide direct information about the element under inspection. NDTs gain popularity due to their various advantages including; providing a high level of safety for the labor staff, time saving, providing high rates of production in comparison to traditional methods.

Ground penetrating radar (GPR) is one of the non-destructive techniques that are used for field investigation in structural engineering. Ground Penetrating radar can determine the subsurface structure easily and accurately. Moreover, it has the capability of locating metallic and non-metallic objects. GPR transmits pulsed electromagnetic waves from the transmitting antenna which is located on the ground surface and signals are then received by the receiving antenna [5]. The proposed model utilizes GPR in order to evaluate the corrosion of the reinforcement rebars in the concrete bridge decks.

3 Model Development

The utilized GPR system incorporates two ground-coupled antennas which are: 2000 MHZ and 400 MHZ. The 2000 MHZ antenna is utilized because of its high-resolution capability. Thermal drift, electronic instability, cable length differences and variations in antenna airgap can cause ‘jumps’ in the air/ground wavelet first arrival time (usually referred to as the time-zero point). Therefore, traces require the adjusting to a common time-zero position before applying processing methods. This is usually achieved using some particular criteria (e.g., the air wave first break point or first negative peak of the trace) and is often done automatically by the processing software [6, 7, 8].

Several precautions are considered during the operation and processing processes. For the thermal drift, the scanning process was performed at night 2:00 am to overcome the internal heating of the equipment during the operation process. The antenna air gap is removed by moving the profile start time to the asphalt layer. For the dielectric constant of the material (concrete in our case), the wave length of the electromagnetic waves decreases as they encounter higher dielectric material. The utilized GPR is equipped with two antennas. The utilized GPR is equipped with two antennas which are: 2000 and 400 MHZ. Thus, in case the electromagnetic waves fail to reach the desired penetration depth, the lower frequency (400 MHZ) is utilized. The GRED HD software is used to extract the amplitudes of the top reinforcement rebars.

There are two main methods for GPR data analysis which are: 1) numerical amplitude method, and 2) image-based method. Numerical amplitude method depends on the value of amplitude of the reflected waves from the top layer of reinforcement. The higher the amplitude, the better the condition of the bars. This method main limitation is its lack of a clear value for the thresholds that define the different categories of corrosion. For example, the profiles of one bridge deck may have amplitude values from 10 dB to -5 dB, where 10 dB represents the best condition and -5 dB represents the worst for that bridge. Meanwhile, another of Bridges’ profiles may have amplitude values that range from -5 dB to -40 dB, where -5 dB represents the best condition and -40 dB represents the worst condition.

Therefore, a comparison between the clustering algorithms should be performed in order to select the most feasible clustering algorithm. After the selection of the most appropriate clustering algorithm, a corrosion map is developed and consequently a corrosion index is calculated. The second step is to construct a deterioration model. A stochastic model is constructed in order to overcome the vagueness and uncertainties associated with the deterministic models. The most suitable probability density function is defined based on the Anderson Darling statistic. The parameters of the probability density function are defined based on the maximum likelihood estimation algorithm.

3.1 Clustering Algorithms

The proposed model develops a corrosion map that is extensively based on the clustering algorithms. Clustering is the process of partitioning the dataset into a homogenous set of clusters without having any prior information about the clusters where the points within the same cluster share similar features. The selected clustering algorithms incorporate a combination of soft and hard clustering techniques. Hard clustering is the process of the assignment of data points to only one cluster such as K-means. On the other hand, soft clustering is the process of the assignment of data points to the clusters with different membership degrees such as Fuzzy C-means clustering (FCM).

RapidMiner 7.5 and KNIME 3.3.1 softwares [9, 10] are used as platforms to perform the clustering algorithms. The proposed methodology compares between five clustering algorithms which are: K-means, K-medoids, fuzzy C-means, expectation maximization, and X-means. K-means and k-medoids are two similar clustering algorithms. The proposed model assumes that the there are four categories for the condition of the bridge deck which are: "very severe", "severe", "medium", and "good". i.e., three thresholds

3.1.1 K-means algorithm

K-means clustering algorithm is based on minimizing the distance between the average squared Euclidean distance and the clusters' centroids. The output of the clusters' centroids is greatly influenced by the initial selection of the clusters' centroids. The number of clusters in the K-means clustering algorithm must be defined initially. The clusters' centroid is the mean of the data points within the cluster [11]. The output of the K-means is that the similarity between the data points within the same cluster is higher than the similarity between the data points in the different clusters [12]. The main distinct feature between K-means and k-medoids clustering algorithms is that one of the data points represents the centroid of the cluster in the case of k-medoids. K-means algorithm utilizes the mean of the data points.

The steps of K-means clustering are as follows [13]:

1- Select number of desired clusters K.
2- Select K starting points randomly to be used as initial candidates for clusters' centroids.
3- Calculate the distance between data points and cluster centroids.
4- Assign the data point to the cluster centroid which has the minimum distance between the data point and cluster centroids. The distance is simply the Euclidean distance.

$$d(x_i, C_j) = \sqrt{\sum_{d=1}^{n} (x_{id} - c_{id_i})^2} \quad (1)$$

5- Re-compute the new cluster centroids (centroid is the mean point of the cluster).
6- Repeat steps 3, 4, and 5 until convergence (centroid and data points no longer move).

X-means clustering algorithm is introduced in order to overcome a major drawback of the K-means clustering algorithm which is the necessity of knowing the number of clusters (K) before processing. The X-means clustering algorithm tends to search the space to compute the clusters' centroids based on the Bayesian Information Criterion (BIC) or the Akaike Information Criterion (AIC). The expectation maximization clustering algorithm calculates the probabilities of cluster memberships based on one or more probability distribution. The number of the clusters is predetermined in the expectation maximization algorithm. Expectation maximization algorithm is based on maximizing the probability that the data point belongs to the clusters of the model.

3.1.2 Fuzzy C-means Algorithm

Fuzzy C-means (FCM) is an iterative clustering algorithm where each data point is assigned to one cluster or more based on the membership degrees. FCM was developed by Dunn in 1973 and improved by Bezdek in 1981. FCM is based on minimizing the following objective function [14].

$$J_w = \sum_{i=1}^{N} \sum_{j=1}^{C} u_{ij}^m \left\| (X_i - C_j)^2 \right\| \quad (2)$$

Where;
m is a fuzzifier constant that is greater than one. u_{ij} denotes the degree of membership of the X_i in the cluster j and it is between zero and one. X_i is a $i-th$ data point in a d-dimensional space. C_j represents the centroid of the $j-th$ cluster. $||*||$ is a norm distance that represents the similarity between the data point and the centroid of the cluster.

FCM starts by randomly initiating the cluster centroid. The second step is to construct the membership matrix. A membership matrix ($U_{(N\times C)}$) is composed of a group of membership degrees. The degree of membership (u_{ij}) can be calculated using Equation 3. The cluster centroids are then updated and can be calculated using Equation 4. The cluster centroids and the membership degrees are iteratively updated until the convergence criteria are satisfied. The convergence criteria is shown in Equation 5. The de-fuzzification process is performed using Equation 6 where the data point is assigned to the cluster that has the maximum degree of membership.

$$u_{ij} = \frac{1}{\sum_{k=1}^{C}\left(\frac{\|(x_i - c_j)\|}{\|(x_i - c_k)\|}\right)^{\frac{2}{m-1}}} \tag{3}$$

$$C_j = \frac{\sum_{i=1}^{N} u_{ij}^{m} \times x_i}{\sum_{i=1}^{N} u_{ij}^{m}} \tag{4}$$

$$\max_{ij}\{|u_{ij}^{it+1} - u_{ij}^{it}|\} < \zeta \tag{5}$$

$$C_j = \arg_i\{max(u_{ij})\} \tag{6}$$

$$\sum_{j=1}^{c} u_{ij} = 1 \tag{7}$$

Where;

ζ is the termination constant between zero and one. it refers to the number of iteration steps.

3.2 Clustering Validity Indices

Clustering is an un-supervised algorithm. Therefore, evaluating the output of the clustering algorithms is a matter of great importance. Assessing the clustering algorithms is much more difficult than the supervised algorithms because there is no “ground truth”, i.e., there are no-predefined classes for the domain problem. Moreover, it is very difficult to find the appropriate metrics to evaluate the quality of the generated clusters.

The proposed model utilizes two clustering validity approaches to assess the quality of the generated clusters and to identify the optimal partition of clusters which are: 1) Davies-Bouldin index, and 2) Dunn index. The objective of the clustering validity approaches is to select the most feasible thresholds that ensure that the clusters are compact and well-separated, i.e., maximize the inter-cluster distance (distance between the clusters), and minimize the intra-cluster distance (distance between data points within the same cluster) (see Figure 2).

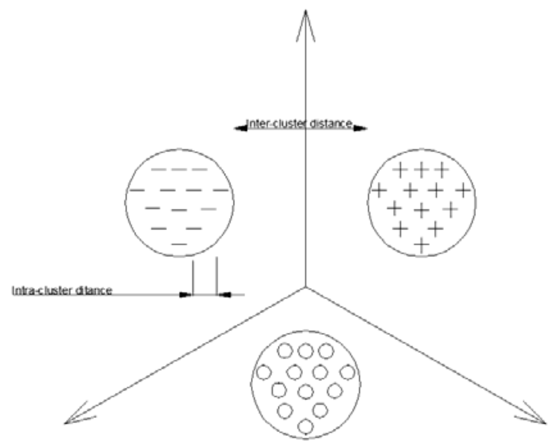

Figure 2: Overview of the clustering process

3.2.1 Davies-Bouldin Index

Davies-Bouldin index is a ratio between the sum of intra-cluster scatter to the inter-cluster separation. The Davies-Bouldin index can be calculated using the following Equation [15].

$$DBI = (\frac{1}{k}\sum_{w,v=1}^{k} \max_{v\neq w}(\frac{D_w + D_v}{d(c_w, c_v)}) \tag{8}$$

Where;

D represents the intra-cluster distance. d represents the inter-cluster distance.

The intra-cluster distance (D), and the inter-cluster distance (d) can be calculated using Equations 9, and 10, respectively based on the Euclidean distance principle. The intra-cluster distance is the average distance between the data points and the cluster centroid. The inter-cluster distance is the distance between the centroid of the two clusters.

$$D = \left(\frac{\sum_{h=1}^{t} ||X_a - C_w||}{N_w}\right) \tag{9}$$

$$d = dist(C_w, C_v) = \sqrt{(C_{w1} - C_{v1})^2 + (C_{w2} - C_{v2})^2 \ldots \left(C_{wq} - C_{vq}\right)^2} \tag{10}$$

Where;

X_a is an arbitrary data point that belongs to a cluster w. C_w, and C_v represent the centroid of clusters w, and v, respectively. N_w represents number of data points in the cluster w. The smaller Davies-Bouldin index denotes that the clusters are compact, and the centers of the clusters are far away from each other (Sahani and Bhuyan 2014). t is the number of the data points in the cluster. q is the number of the dimensions of the model.

3.2.2 Dunn Index

The Dunn index is used to assess the quality of the clusters and it can be calculated using Equation 11 [16].

$$\mathrm{DUI} = \max_{1\le w\le k}\left(\min_{1\le v<K, v\neq w}\left(\min_{i\le K\le K}\left(\frac{\mathrm{d}(x_w,x_v)}{\max(\mathrm{D}(x_k))}\right)\right)\right) \quad (11)$$

Where;

D, and d are defined as above. The larger the Dunn index indicates that the clusters are compact and well-separated.

The clustering index is performed in order to compare between the five clustering algorithms. The clustering index can be calculated using the following equation.

$$CLU = \frac{\mathrm{DUI} - DBI}{2} \quad (12)$$

Where;

DUI represents the Dunn index while DBI represents the Davies-Bouldin index. CLU denotes the clustering index.

Surfer 12 is a plotting and mapping software that is utilized to develop the corrosion map for the concrete bridge decks. Finally, a Corrosion Index (CI) can be calculated as follows.

$$CI = \frac{\sum_{i=1}^{4} Q_i \times W_i}{\sum_{i=1}^{4} Q_i} \quad (13)$$

Where; Q_i represents the quantity of a bridge element in category i. W_i represents the weighting factor for a bridge element in category i. The weighting factors for the "good", "medium", "severe", and "very severe" categories are assumed 100%, 70%, 50%, and 20%, respectively.

4 Deteriroation Models

Deterioration model is the most crucial component of the BMS because it enables the transportation authorities to predict the future bridge condition ratings. Planning of maintenance, repair and rehabilitation activities (MR&R) of bridges is based on calculating accurate future bridge condition ratings. A high-quality deterioration model enables infrastructure managers to optimize MR&R activities and minimize un-planned maintenance activities. The deterioration model constructs a relationship between the facility condition rating and group of explanatory variables such as age, traffic volume, weather conditions, percentage of commercial vehicles, etc.

Goodness of fit is a statistical measure that is used to determine the compatibility of fitting set of data to probability distributions. Goodness of fit is a means to evaluate different probability density functions and to determine discrepancies between observed values and expected values in a certain statistical model. There are several goodness o fit tests such as Kolmogorov-Smirnov test, Anderson Darling and chi-squared test. The proposed model utilizes Anderson Darling statistic.

Anderson Darling test (A^2) is used to compare the fit of an observed cumulative distribution function to an expected cumulative distribution function. Anderson darling provides more weight to the distributions' tail than the Kolmogorov-Smirnov test. Anderson Darling Statistic can be calculated as follows [17].

$$A^2 = -n - \frac{1}{n}\sum_{i=1}^{n}(2\mathrm{i}-1) \times (\ln \mathrm{F}(\mathrm{x_i}) + \ln(1 - \mathrm{F}(\mathrm{X}_{n-i+1}))) \quad (14)$$

There are different methods for parameter estimation of probability density function such as maximum likelihood estimation and least squares, method of moments estimation (MME), and median rank regression (MRR). The proposed model utilizes maximum likelihood estimation (MLE) algorithm as a parameter estimation method. MLE is based on finding the parameters that maximizes the likelihood function where the observations are assumed to be independent. The MLE is characterized by being is asymptotically efficient where larger the sample size the more likely the parameters converge to precise values.

MLE is based on finding the unknown parameter θ that maximizes the $\log \mathrm{L}(\theta/y)$ because it is often easier to maximize the log-likelihood function than the likelihood function itself [18].

$$\log \mathrm{L}(\theta/y) = \sum_{i=1}^{n} \log(f(y_i|\theta)) \quad (15)$$

Where;

$\mathrm{Y_i}$ represents a set of independent variables. $f(y_i|\theta)$ denotes the probability density function of the random variable y_i

5 Model Implementation

There are two case studies to validate the proposed model. The length and the width of the scanned bridge deck of El-Kobba bridge are 20 meters, and 3 meters, respectively. The length and the width of the scanned bridge deck of Torra bridge are 21 meters, and 6 meters. The data collection of El-Kobba bridge deck is shown in Figure 3.

Figure 3: GPR data collection for El-Kobba bridge deck

The grids spacing in both the longitudinal and transversal directions were taken to be 1.0 m. Consequently, the number of scans in the longitudinal and transversal directions in El-Kobba bridge are 3, and 21, respectively. The number of scans in the longitudinal and transversal directions in Torra bridge are 6, and 20, respectively. A plan of the scans of El-Koba bridge deck is shown in Figure 4.

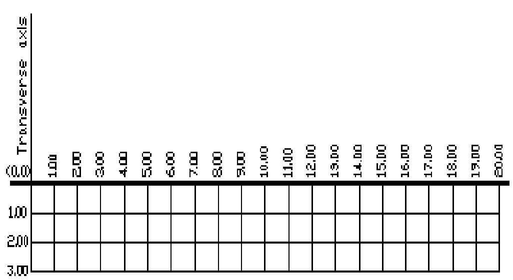

Figure 4: A plan of the scanned paths in El-Kobba bridge deck

After the data collection process, the GPR data profiles are transferred to a PC for processing. The software IDS GRED HD is used to process the B-scans. IDS GRED HD is used to compute the travel time, and the amplitude of each reinforcing rebar. The profile obtained from the GPR is depicted in Figure 5.

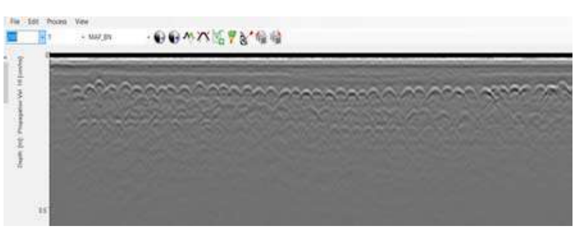

Figure 5: GPR profile of Torra bridge deck

Rebar locations were clear in the raw data as well as obvious areas of deterioration where rebar reflections were weak. Areas of the bridge deck having weak reflection amplitude values are typically indicative of the deterioration. These weaker reflections can be due to several factors, including high chloride content, concrete deterioration or corrosion of the embedded steel rebar, which all attenuate the radar signal.

The RapidMiner software is used in order to perform the K-means clustering, expectation maximization cluster, X-means, and K-medoids. KNIME platform is used in order to perform the fuzzy C-means clustering. The developed clustering model using the RapidMiner platform is shown in Figure 6. The developed clustering model using the KNIME platform is shown in Figure 7.

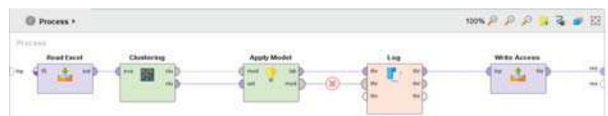

Figure 6: Interface of the RapidMiner platform

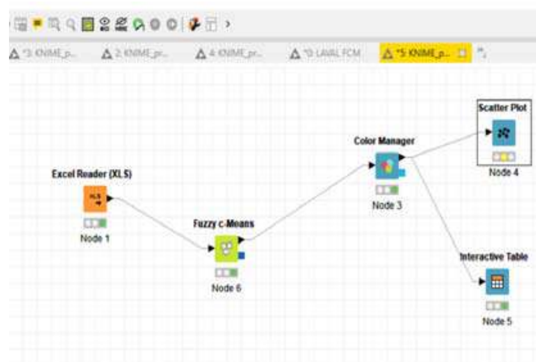

Figure 7: Interface of the KNIME platform

The clustering indices of the five clustering algorithms in Tora and El-Kobba bridges are shown in Table 1. As shown in Table 1, K-medoids has the largest clustering index and therefore K-medoids is the most feasible clustering algorithm. Moreover, K-medoids has the largest clustering algorithm in El-Kobba bridge which means that K-medoids is the most feasible clustering algorithm

Table 1: Clustering indices of the two bridges

Clustering algorithm	Clustering index (EL-Kobba)	Clustering index (Torra)
K-means	1.4118	1.1566
K-medoids	1.8954	2.8291

X-means	1.3948	1.2322
Expectation maximization	1.5585	1.3896
Fuzzy C-means	1.5118	2.3124

The corrosion map for El-Kobba bridge is depicted in Figure 8 where 18.67% of the bridge is a “very severe” condition, 43.98% of the bridge is in a “severe” condition, 30.71% is in a “medium” condition, and 6.64% is in a “good” condition. Based on Equation (13), the Corrosion Index is 70.76% which means that the bridge deck is in the “medium” category. The amplitude thresholds are expressed in volts. The amplitude thresholds are 0.106, 0.202, and 0.325. The corrosion map for Torra bridge is depicted in Figure 9 where 14.8% of the bridge is a “very severe” condition, 22.37% of the bridge is in a “severe” condition, 26.64 is in a “medium” condition, and 36.18% is in a “good” condition. The Corrosion Index is 68.98% which means that the bridge deck is in the “medium” category. The amplitude thresholds are -0.477, -0.3605, and -0.1999.

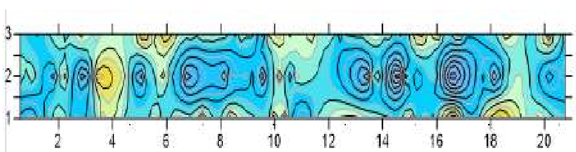

Figure 8: Corrosion map of El-Kobba bridge

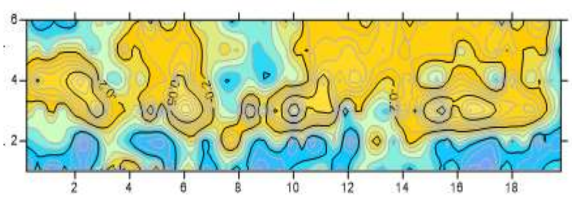

Figure 9: Corrosion map of Torra bridge

The attributes of the bridges are stored in shapefile format for documentation purposes as shown in Figure 10. The shapefile format is a well-known geospatial vector data format for geographic information system (GIS) softwares.

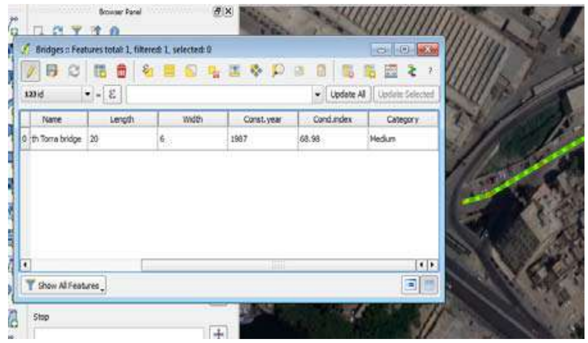

Figure 10: Storing of the bridges’ attributes

Based on the Anderson Darling test, weibull distribution is the best-fit distribution followed by the lognormal distribution, and finally the exponential distribution, whereas the Anderson Darling statistics of the previous distributions are 0.٤٤٨٨, 0.٤٧٠٥, and 0.٦٥٣٩, respectively. The parameters of the weibull distributions are obtained based on the maximum likelihood estimation, whereas the shape factor and scale factor are ١,٩١٧٤, and ٥٠,٩٣٥٤, respectively. The deterioration model based on the weibull distribution is shown in Figure 11.

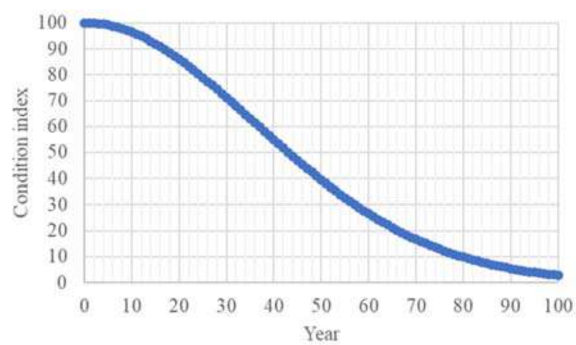

Figure 11: Deterioration model based on weibull distribution

Abstract –

The increasing complexity of buildings has brought some difficulties for emergency response. When fires occur in a building, limited perception regarding the disaster area and occupants can increase the probability of injuries and damages. Thus, the availability of comprehensive and timely information may help understand the existing conditions and plan an efficient evacuation. For this purpose, Building Information Modeling (BIM) should be integrated with three sets of information: (1) occupancy that defines the type of space usage; (2) occupants' information; and (3) sensory data. The Industry Foundation Classes (IFC), as a standard of BIM, has the definitions for all areas, volumes, and elements of a building. IFC also has the basic definitions of sensor and occupant entities. However, these entities do not provide enough dynamic and accurate information for supporting emergency management systems. This paper aims to extend IFC for fire emergency real-time management using sensors and occupants' information. The specific objectives of this paper are: (1) extending IfcSensor entity for occupant's sensors; (2) adding new attributes to IfcOccupant to support emergency response operations and defining a new entity for occupancy; and (3) defining the relationships between sensors, occupants, occupancy, time series, and building components in the context of building evacuation. The feasibility of the proposed method is discussed using a case study.

BIM, IFC, Sensory Data, Sensor, Occupant, Occupancy, Fire.

1 Introduction

Statistics show 1,345,500 fires reported in the United States in 2015; out of which, 37.27% are structure fire that have caused 2,685 civilian deaths, 13,000 civilian injuries, and $10.3 billion in property damage [1]. During a fire evacuation, the lack of comprehensive information affects the success and efficiency of emergency management and results in increasing the number of casualties [2].

Wei-Guo et al. [3] stated that the availability of core information about buildings and infrastructure systems improves the effectiveness of managing disasters. Moreover, Tsai et al. [4] emphasized the need of critical building information, such as building evacuation plans and electrical and mechanical equipment. Walder and Bernoulli [5] emphasized the need for critical spatial information and semantic information related to the structure and equipment, as well as the disaster. An approach to enable rapid and safe evacuation in building emergencies requires accessing the dynamic information about the buildings, occupants and fire propagation. Building facilities' information includes building's structure; floor plans; location of stairs, ramps, exits, doors and windows; facility's materials; and fire protective equipment. On the other hand, the attributes of occupants are presence, number, location, age, mobility condition, ID, etc. In addition, the required information regarding fire propagation includes sensory data about smoke, heat, and toxic gases.

Building Information Modeling (BIM) is emerging as a digital representation of a building with the geometric/topological and semantic entities that describe the elements, materials, and relationships between them. Also, highly accurate and detailed data about the current state of building elements can be provided by BIM [6]. Industry Foundation Classes (IFC) as a platform-independent standard for BIM, is an object-based file format that has been developed by Building SMART Alliance (BSA). IFC is based on a taxonomy standard that describes building ontology [7]. Besides, IFC can facilitate interoperability in the Architecture, Engineering, Construction, and Facilities Management (AEC/FM) industry [8]. Although IFC is an object-oriented building model, modeling all objects related to the building is complicated. Thus, BSA presents an extensible architecture for extending IFC [9].

Integration of BIM and sensor networks for increasing the accuracy and effectiveness of disaster-response decision-making has been discussed extensively in building disaster management [10, 11]. With the spread of Internet of Things (IoT) technologies and intelligent buildings, the need for integrating sensors and sensory data with BIM has also increased. Advanced sensors can collect real-time information about occupants, occupancy, surrounding environment and incidents. Among other applications, such sensory data can provide accurate and useful information to support building evacuation planning and emergency response [12].

For BIM-based fire evacuation planning, several relevant elements along with their common attributes have already been introduced in IFC (e.g., actuators, sensors and occupants). However, creating smart disaster-response decision-making applications requires enhancement of the current standard in at least two major directions. Firstly, to migrate from a static (stateless) to a dynamic (state-full) BIM by adding the sensory data history and associating it with the elements of BIM. Secondly, since having access to comprehensive and accurate data is critical in disaster management, the attributes of some entities (such as IfcSensor and IfcOccupant) need to be enriched and also relationships among such entities must be established.

The objectives of this paper are: (1) extending IfcSensor entity for occupant’s sensors; (2) adding new attributes to IfcOccupant to support emergency response operations and defining a new entity for occupancy; and (3) defining the relationships between sensors, occupants, occupancy, time series, and building components in the context of building evacuation.

2 Review of Related Works

2.1 Building Fire and Evacuation Planning

In disaster management applications, time is one of the most critical factors to decrease casualties and properties' damages. Furthermore, precise information about an incident, structure [13] and human’s behavior [14] can decrease the risk of life threats and asset damages [15]. Dilo and Zlatanova [16] showed that the success of emergency response is related to the perception of environmental elements and events. This awareness is directly linked to the dynamic information in the emergency event. Situational awareness about changes in building components’ conditions can minimize the uncertainty in finding directions and improve safety [17]. Many studies have focused on network modeling, indoor navigation and route finding [18] based on the shortest path [19]. In addition, some studies have used dynamic data about people, to find less congested paths [14].

In the context of indoor emergency response, Tashakkori et al. [15] argued that indoor situational awareness helps in effective emergency management. They used a set of required information for route finding to develop a 3D spatial indoor-outdoor model. However, their solution did not include dynamic information. Tangs and Ren [20] provided a simulation spatial indoor model for fire. This model includes static and dynamic information, such as occupants, fire field, and building geometry.

To summarize, a safe fire evacuation depends on an awareness of the static and dynamic features, especially geometric obstacles, smoke spread and occupants’ behavior. These features have a critical effect on individuals’ decisions and the evacuation process [20]. Therefore, the provision of a dynamic indoor emergency spatial model that supports situational awareness for building evacuation is vital. Such a model will cover both static and dynamic information including both occupants’ behavior and indoor spatial information (e.g., building's structural layout, and fire propagation).

2.2 BIM and IFC

BIM allows to visualize construction processes through 4D simulation and gives an opportunity to manage cost and time effectively [21]. Recently, BIM has been used to improve building disaster management by understanding physical and functional characteristics of objects and visualizing building spatial information in three dimensions [22]. However, effective fire emergency methods should rely on the real-time and dynamic information [10].

BIM, as the base model of a building, can integrate with sensory data to have real-time information about the disaster and occupants. Consequently, occupants can be guided to safe exits rapidly form risky locations. Kensek [23] investigated the feasibility of integrating BIM and sensors such as light, CO_2 and heat. She used Arduino as a single board computer, Revit Architecture as a BIM software, and Dynamo as a visual programming environment to demonstrate how sensory data could change the 3D model. Also, the changes in the 3D model could be actuated on the physical model.

One of the primary goals of BIM is to provide interoperability between different platforms for data exchange, which is currently achieved by the IFC as a common open standard. This standard is used to share physical and functional features of buildings among stakeholders [24].

IFC is a data standard of BIM that has a hierarchical and modular framework consisting different entities. These entities represent tangible components (e.g. walls, doors and windows), as well as conceptual components (e.g. schedules, activities, and spaces). Each entity has common properties (including ID, name, geometry, etc.) as well as relationships to other components [25].

Currently, although IFC is a complex data standard, it can only support a limited number of use cases in the AEC/FM industry. Nevertheless, being an extendible standard, it can be extended to be used for new use cases [9, 25].

2.3 Occupant and Occupancy Information

In disaster management, in order to have occupancy-based control, different sensors are used to accurately determine the occupancy of building spaces and the parameters concerning occupants in real time, such as number of occupants in the spaces of the building. Melfi et al. [26] proposed occupancy resolutions at four levels (occupancy, count, identity, and activity) in three aspects (spatial resolution, temporal resolution, and occupancy resolution). A fifth level was suggested by Labeodan et al. [27] for tracking occupants' movement in different zones. The higher level of accuracy in occupancy detection will lead to better decisions improving safety [12].

2.4 Integrating Real-Time Information in BIM

An intelligent building is a building with smart technologies installation. In such buildings, there is usually a network of sensors and actuators with access to Internet, which can automatically control building components using knowledge-based algorithms and environmental data. For instance, intelligent buildings can monitor occupant's behavior and control building response to decrease energy consumption [28].

The first step towards modelling and managing an intelligent building is adding real-time information to BIM because the current BIM uses static information only. A dynamic BIM, which integrates real-time information and BIM, provides the opportunity of reacting to emergencies in real time by visualizing and monitoring the current situation in the building [29].

Currently, there are several kinds of BIM software (e.g., Autodesk Revit, ArchiCAD, Bentley Building, Solibri, and Vectorworks among other most commonly used tools). Revit is a widely used BIM software for visual analysis, documentation, and design, which also supports IFC. However, these tools can not store and visualize sensory data. To achieve a dynamic BIM with the ability to store and manage real-time information, some add-ins should be developed [29].

2.5 Extending IFC

There are three mechanisms to extend IFC if the current release does not support a specific need: (1) defining new entities, (2) using proxy elements; and (3) using the property sets [28]. Among the three alternatives, defining new entities can be the best method to extend the IFC standard because the newly defined entities can be used in the same way as the existing ones [9]. However, adding new entities to an IFC release can only happen after availability of some "proof of concept", followed by long discussions within the Model Support Group of the BSA; hence, does not really fit the aim of research projects [28]. The other two alternative mechanisms can extend the scope of IFC without changing the schema, although they require additional implementation agreements about the definition of property sets and proxies when they are used to share data with other software. Therefore, the other two alternatives are more practical to meet specific local requirements [9, 25, 28].

Several research projects proposed new objects, entities, and relationships for extending the IFC standard [9, 28, 30]. However, there is limited research about an extension for occupants. Also, IFC still has challenges to represent the live sensor readings.

3 Proposed extension for IFC

To have a real-time fire emergency management, related information can be classified into two main classes (indoor and outdoor). In both classes, the information can be divided into static and dynamic information. To provide the classes with comprehensive data, they should be connected to external databases. For example, occupants' ID can extract more detailed information from the external database, such as age, mobility and health condition. Furthermore, indoor static information can be modeled in BIM as well as dynamic information collected through various sensors, as shown in Figure 1. Then, sensory data should be fused with the spatial and semantic information in the BIM platform.

Figure 2 shows how the BIM model can be overlaid by the real-time information and how datasets can be related to each other. Occupants and fire sensory data can be enriched by connecting to long-term static data. The static data are rarely changed, such as ID, mobility condition, and heath condition. Thus, a comprehensive and real-time dataset containing sensory data and static data can be added to BIM.

After checking the availble information in IFC4 EXPRESS diagrams, an extended data model, including the required attributes and the relations, is prepared using the Unified Modeling Language (UML) format.

3.1 Occupant and Occupancy Data

Basic occupants' information, such as name and type of actor are availble in IfcOccupant. However, the following detailed occupants' information should be added to IfcOccupant: (1) ID; (2) age; (3) location; (4) mobility condition (e.g., wheelchair users); and (5) health condition (e.g., occupants with heart and breathing problems need special help). In addition, the occupancy of a space can be defiend at a lower spatial resolution. For this purpose, a new entity, IfcOccupancy, is defiend with the following attributes: presence of occupant and number of occupant. Figure 3 shows the relationships between existing and new entites.

3.2 Sensors and Sensory Data

Using sensors helps to have awareness about the surrounding conditions. The following relationships should be captured and modeled: (1) the relationship between sensors and building physical/conceptual elements, (2) the relationship between sensors and sensory data expressed by time series, and (3) the relationship between sensory data and occupants' information.

In the current version of IFC, the geometry and definition of all types of spaces (e.g., room spaces) are described by IfcSpace entity. IfcSpace represents a bounded area or volume that provides a certain function within a building. Also, definitions of building elements, such as walls and ceilings, are described by IfcWall and IfcCovering. Furthermore, some mechanical and electrical devices, such as sensors and actuators are available. The sensor is defined as IfcSensor and the sensor type is defined by IfcSensorType, such as gas sensors, temperature sensors, and fire sensors. The static properties relating to the IfcSensorType are defined by the IfcPropertySet. Each property set includes common attributes, such as name, usage, materials, ports, composition, assignments, and representations [7, 31].

To define the dynamic information for the sensors, sensory data should be measured in real-time. IfcMeasureValue is defined to keep different types of measured values, such as volume, time, ratio, mass, count, and area. Also, in order to collect real-time data, IfcTimeSeries entity can be used. This entity describes a set of time-stamped data entries and allows a natural association of data collected over intervals of time [31]. Creating a relationship between IfcSensor and IfcTimeSeries provides a dynamic BIM.

Various types of sensors are defined in IfcSensorType. However, sensors for counting the number of occupants (OccupantCountingSensor) and sensors for determining occupants' location (OccupantTrackingSensor) are proposed to be added in this research. Adding these sensors to IFC and defining a relationship between sensors and time series can help to have dynamic occupants' information in the context of disaster management. Figure 3 shows the proposed model for new types of occupants' sensors and relationships.

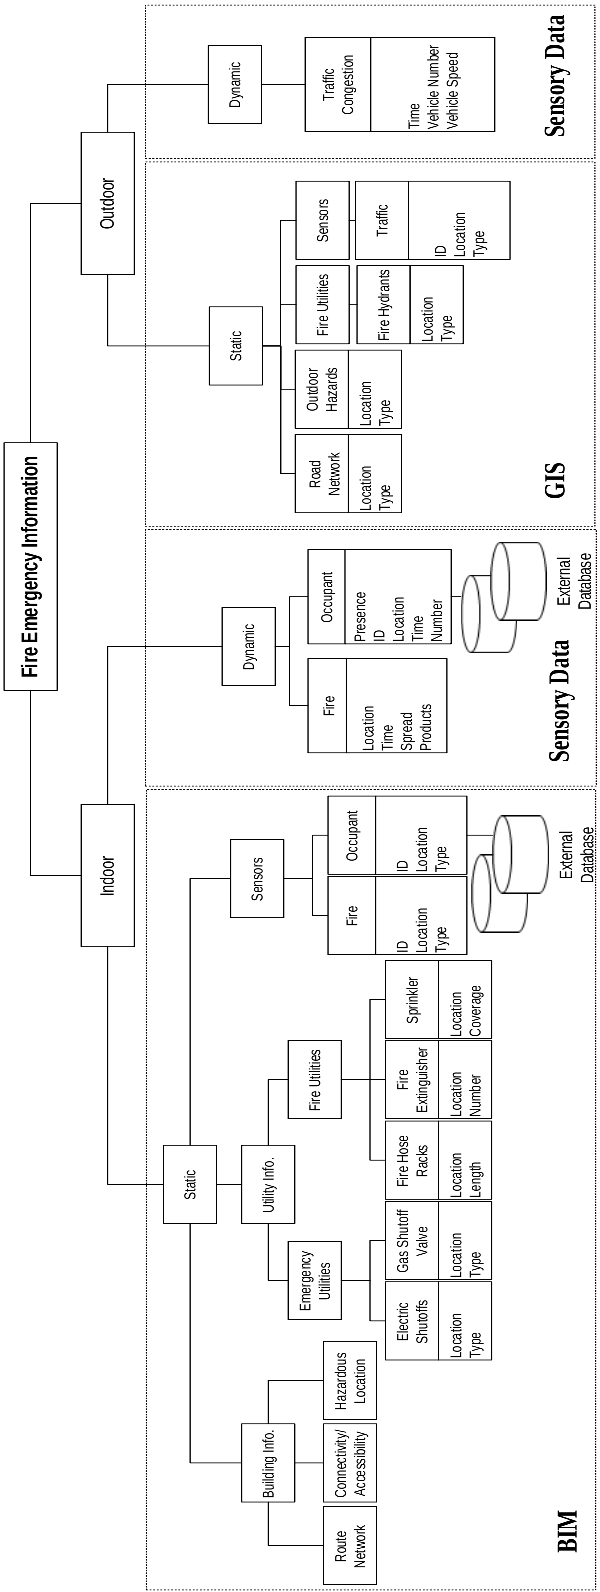

Figure 1. Information classification in fire emergency

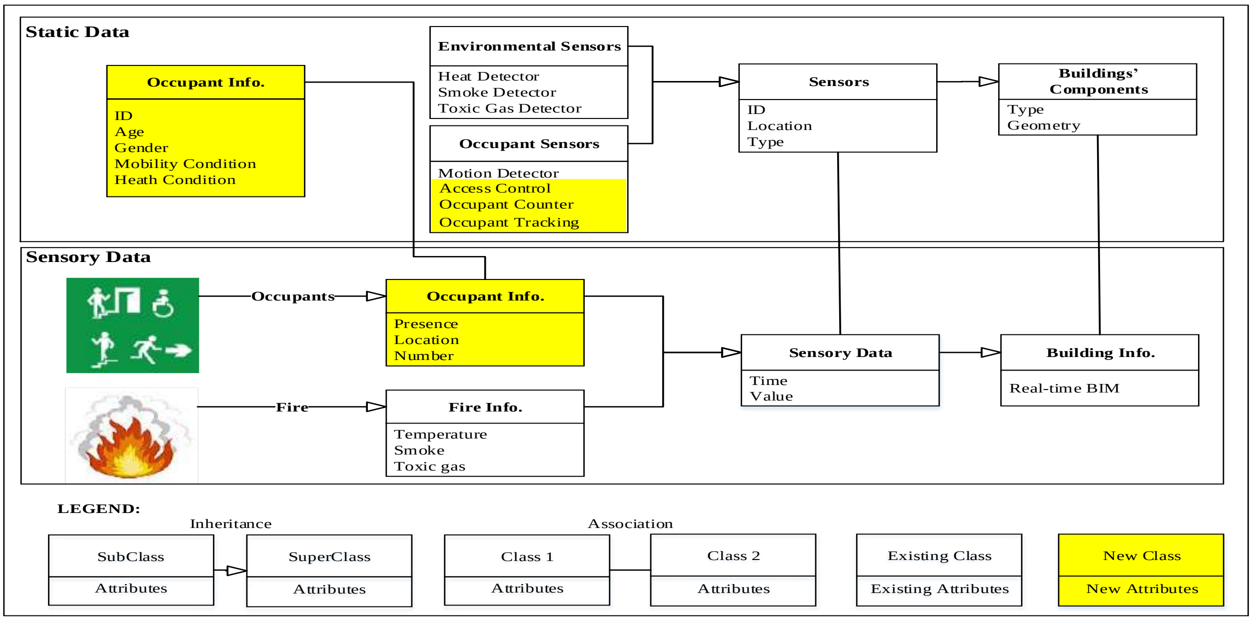

Figure 2. Relationship between sensory data and static data

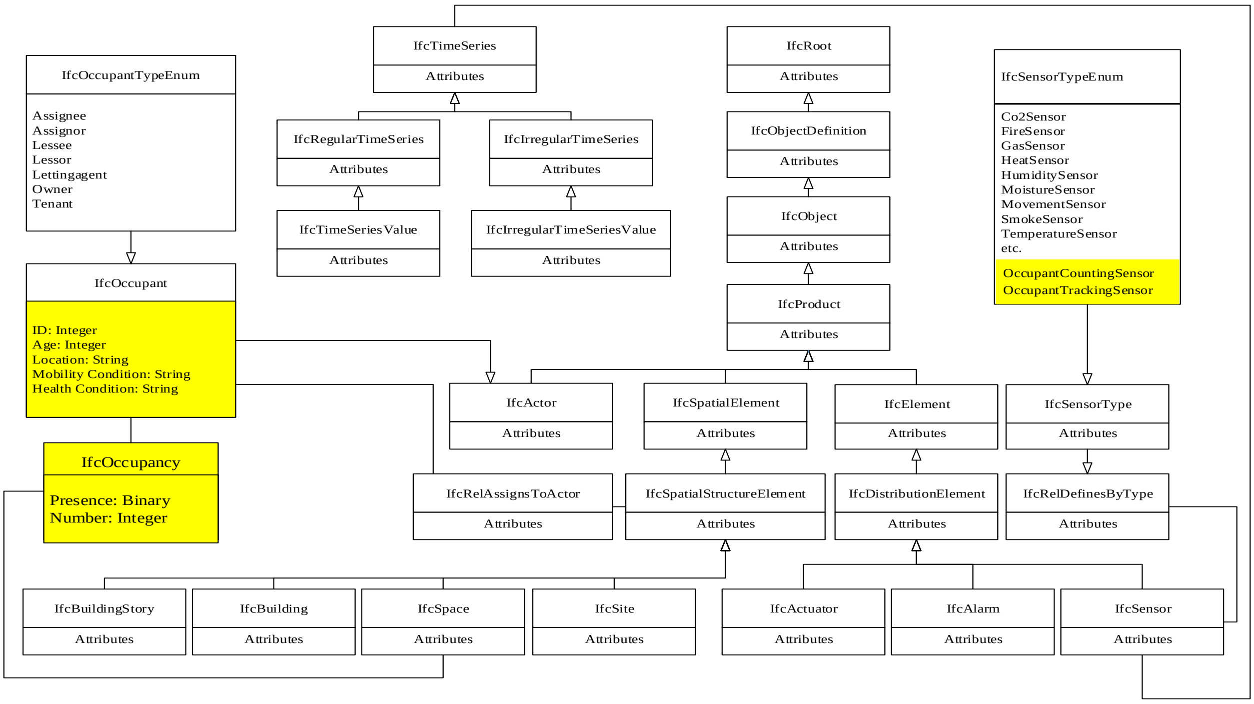

Figure 3. Data model for sensor types and building occupants' information

4 Case Study

In order to validate the proposed method, the 9th floor of the EV (Engineering & Visual Arts) building at Concordia University was chosen as experimentation area. Different types of sensors, including smoke detectors, temperature sensors, heat detectors and occupant's sensors, installed in the facility were used to collect sensory data of fire and occupants.

Collected sensory data from Siemens-Room Temperature Sensor, and Quuppa Intelligent Locating System (which enable real-time occupants tracking), were used to test the proposed method for extending IFC. Then, a fire in the floor was simulated and the temperature data were visualized in BIM.

4.1 Data Acquisition and Integration with BIM

The floor was modeled in Autodesk Revit Architecture 2018. Sensors were added to Revit under the electrical category (as shown in Figure 4). Then, the model (geometry and spaces) was exported to IFC format.

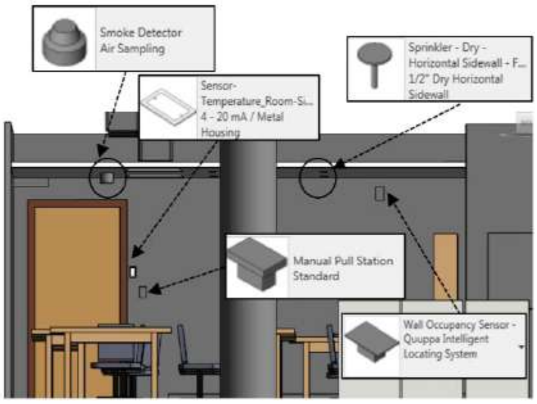

Figure 4. Revit model of a students' lab

Temperature measurement based on date and time were collected by temperature sensors installed in each room and the corridor. Also, Quuppa system gathered information (ID, date/time and X-Y coordinates) of five occupants through wearable tags. The two sets of information were initially recorded as .csv files. In order to avoid overpopulating the IFC file, the procedure of assigning sensory data to BIM can be divided into three major phases: 1. Pre-disaster phase: In the normal condition, the system is in the "monitoring" mode; i.e. sensing the environmental and occupational information, but not storing the results in the IFC. The sensor elements (both heat sensors and the Quuppa sensor system) were modelled as IfcSensor entities (i.e., Heatsensor and OccupantTrackingSensor types respectively). General properties such as the coverage area and the set point temperature were modelled for the heat sensors. Moreover, the hazard threshold was defined for this sensor type as an IfcPropertySingleValue, representing rate of temperature rise, to be sensed as being hazardous. 2. Disaster detection phase-gate: Once the reading in the sensor reaches the set-point threshold, the system starts storing in the IFC, the data collected by the two sensor types. This may update the state of the IfcSpace form "safe" to "hazardous" and will associate the environmental as well as occupation sensory data into it. 3. Disaster/evacuation phase: temperature data collected every second is modelled as an IfcRegularTimeSeries. Storing the occupant information is more complex. For one, the data must be associated with the IfcOccupant, as well as the IfcSpace. Moreover, the data read (by Quuppa e.g.) has more attributes than the heat sensor. Each data-point in this dataset has the ID of the occupant, date, time, and the X-Y location of the occupant. The data is collected and stored every second; hence IfcRegularTimeSeries was used for storing occupant information during the hazard. The IfcTimeSeries was associated with the IfcOccupant (from whom the data were collected).

The values of the IfcTimeSeries are in fact ordered pairs (representing X and Y location of the occupant at the given time). In our study, however, we used two separate time series for the two coordinates. Table 1 shows the attributes of the IfcTimeSeries used for storing the occupants' locational information (X coordinate as an example) during the disaster.

Table 1. IfcRegularTimeSeries attributes for the Quuppa intelligent locating system data

#	Attribute	Type
1	Name	XCoord
2	Description	X Coordinate of the occupant
3&4	StartTime EndTime	IfcDateTime YYYY-MM-DD Thh:mm:ss
5	TimeSeriesDataType	Continuous
6	DataOrigin	Measured
7	UserDefinedData-Origin	N.A.
8	Unit	LengthExponent
9	TimeStep	1 sec
10	Values	An array of X location (in m) for the occupant, with 1 sec interval time updates

4.2 Data Visualization

In the IFC format, new attributes and relationships for sensors and occupants were added to the EXPRESS file, based on the IFC4 standard. Then, the modified IFC model was viewed by BIM Vision as a freeware IFC model viewer that enables users to work on the file in the format IFC4.

In order to visualize sensory data (environmental and occupants) in BIM, as well as linking sensory data back to the Revit model, the visual programming tool Dynamo was used. Firstly, for visualization of the temperature data the following steps were taken: (1) modelling the 9th floor of the EV building, (2) assigning a number to each space; (3) defining parameters of the model, such as temperature and spaces for visual programing; (4) classifying the space temperature as shown in Table 2; (5) assigning a certain color to each class of temperature; and (6) visualizing the temperature classification of the space automatically on the Revit model using the colors as shown in Figure 5.

Table 2. Space classification based on temperature

Temperature (°C)	Zone Color	Condition
T < 23	Green	Very safe
23 ≤ T ≤ 30	Yellow	Safe
31 ≤ T ≤ 50	Orange	Near dangerous
T > 50	Red	Fire/ dangerous

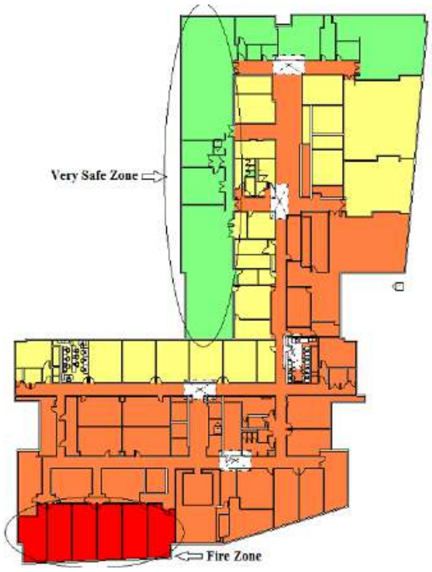

Figure 5. Space classification based on temperature in Revit

Secondly, the locations of occupants in one shared office for graduate students on the same floor (collected through Quuppa system and stored as time series) were visualized through the following steps: (1) modelling the office, (2) changing the coordinate system of the model to match with the local coordinate system used by Quuppa; (3) reading the data related to each occupant for each time step; (4) assigning a certain color to each occupant; and (5) visualizing the locations of the occupants automatically based on the time in the model as shown in Figure 6. This figure shows the locations of two occupants that were present in the office.

5 Conclusion and Future Work

This paper elaborated on the motivations and needs of new types of occupants' sensors and new occupants' attributes to have comprehensive real-time awareness in the case of a fire in a building. An extended IFC model was suggested to identify the entities, attributes, and relationships between sensors, occupants, occupancy, time series, and building components. The proposed model was tested in a hypothetical case study, temperature data and occupant location were added to BIM for visualizing the space conditions under a fire.

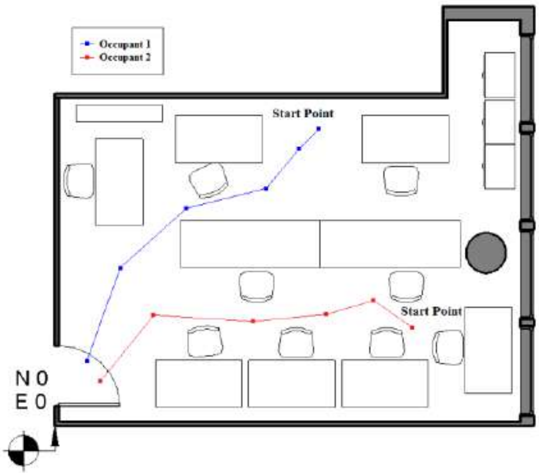

Figure 6. Visualizing the occupants' locations in Revit for the duration of 6 seconds

The proposed method was useful in providing real-time information for effective fire emergency management. Moreover, this work can be used to enhance the emergency first responders' perception by using 3D visualization of the dynamic conditions of the building under fire and occupants' condition.

Our future work will include the following: (1) Further implementation and testing of the proposed method, including the interaction between the occupants and the simulated fire propagation during building evacuation; (2) Extending the proposed model based on the first responders' view of indoor/outdoor fire emergency management; and (3) Developing a platform for the next generation of intelligent building emergency management that can integrate with BIM and IoT.

Signature-based matching of IFC Models

Muhammad Tariq Shafiq[a] and Stephen R Lockley[b]

Abstract –
This paper presents the problem of model comparison in platform-neutral collaboration of Building Information Models. The paper describes that model matching and comparison strategies for platform-neutral models (i.e. IFC models) are the keys to solve the problem of iterative change management during BIM collaboration workflows. It is highlighted that the current model comparison strategies are centric towards using GUIDS which may not lead to accurate results due to the complexity of modelling operations and internal data structures of modelling tools. The paper proposes a signature-based model matching approach for IFC models that use model object characteristics to define object signatures for object recognition and comparison. Examples of creating signatures from IFC object characteristics are presented. The proposed methodologies for creating IFC object signatures are implemented in a custom-built tool, XBIM Signatures exporter, which then demonstrates a successful export of object signatures on a test case. The paper concludes that the proposed object signatures can be useful to establish accurate candidates for comparison and can reduce the workload of the overall model comparison process. However, a robust solution for IFC model comparison would require a weighting formula for various object characteristics to formulate an object recognition and comparison strategy.

Keywords –
BIM, IFC, Model Server, Model Comparison

1 Introduction

Building Information Modelling (BIM) has presented effective solutions to resolved information collaboration problems in the AEC industry. The technology to create efficient Building Information Models is now mature and can support the development of discipline-specific (i.e. Architecture, MEP, Structural) Building Information Models. As the information in a BIM grows during an iterative design and production process and even beyond into maintenance, a critical issue is how to manage the iterative changes because of the collaboration operations and workflows that involve various project participants and heterogeneous applications. The problem of interoperable information exchanges using heterogeneous BIM application has been well researched and has led the development and implementation of Industry Foundation Classes (IFC) over the last 20 years. IFC has now become a widely accepted open and neutral data format specification to facilitate interoperable information exchanges using Building Information Models in the AEC industry.

Today, a platform-neutral BIM enabled collaboration relies on effective management of IFC models using a Model Collaboration System or a Model Server. A model server is a type of database system that allows upload, download, sharing and coordination (e.g., model comparison, and model checking) of models or components by multiple users [1].

An IFC enabled model server is expected to facilitate the exchange of information between the applications used throughout a building project lifecycle (e.g., design tools, analysis tools, document management systems, facility management tools) used throughout a project's lifecycle [2]. The workflow of such a collaboration is built around the concept of finding changes in two versions or variants of IFC model instances and merging them together with the shared data repository. Thus, the issue of IFC model comparison becomes critical to keep track of the changes during the information exchange workflows. The purpose of IFC comparison process is to identify similarities and differences between two IFC models. A fundamental requirement of an effective IFC comparison process is identifying comparable objects or identifying candidates for comparison in the two matching IFC files. Existing IFC Comparisons mechanisms are usually based on using Globally Unique Identifiers (GUIDS) to establish candidates for comparison, in a shallow or a deep tree comparison procedure. GUIDS are a reliable base if these are properly maintained during the IFC roundtripping and the involving editing operations using BIM software applications. However, GUIDS exports are not always consistent due to the complexity of modelling operations, application imprints and different internal data structures of BIM tools, which leads to costly calculations, quality compromises and inaccuracies due to inconsistent GUIDs in IFC model comparison processes.

To address these issues, this paper presents a signature-matching approach that advocates using dynamic object identities, calculated from the value of its properties and attributes using hash keys that can create a unique signature for an object. In BIM collaboration operations, a change can be in (1) an object's position, (2) its shape and its (3) properties. Therefore, an object's position, shape and properties can be used to formulate partial, default or complete signature for an object, which would be useful in establishing candidates for IFC comparison process, independently from GUIDs, and would reduce the overall workload of the IFC compression process. Signature matching is useful even if a complete solution is not feasible, as signature matching can be used to eliminate a significant proportion of elements to downsize the comparison criteria for any further comparison.

2 The Problem of IFC Model Comparison

A critical issue in managing collaboration operations on a model server is the management of iterative changes during BIM collaboration operations. The shared data repository on the server must be updated with any changes because of modifications made in a check in/check out the operation, such as new data instances added, deleted or changed. The information in the shared repository (i.e. Model server) is defined in terms of a moment in time and associated versions in other moments in time, resulting in several versions and variants of a shared repository instance and discipline-specific information models. Thus, the issue of IFC model comparison becomes critical to keep track of the changes during the information exchange workflows.

Typically, the IFC model comparison is a post-rationalisation activity in a collaboration operation where the data management system (i.e. model server or another comparison tool) must deal with what has already happened on a set of data with no or limited knowledge of prerequisites about the incoming data. The comprising IFC files may include changes, application imprints and other data instances due to IFC round-tripping. The process of IFC comparison will require establishing right candidates for comparison before a comparison algorithm can be applied to determine similarities and differences. In post rationalization situations, establishing the right candidates (corresponding objects in comparing versions) for comparisons becomes difficult, for which Globally Unique Identifiers (GUIDs) are typically used in a shallow or deep tree comparison of IFC models [3]. The use of GUIDs in IFC model comparison has been heavily criticised in the literature [[4][5][5][7] as it leads to costly calculations, quality compromises and inaccuracies due to inconsistent GUIDs in IFC data round-tripping. Moreover, different BIM authoring tools may have different semantic representation for a same physical object which triggers another concern that is how to compare models which are constructed independently using different tools because the tools internal representation differs from the IFC exchanged representation

Furthermore, support is required from the client-side application when submitting changes to the model server, for example, to maintain object owner history and the consistent preservation of GUIDs. However, the internal data storage structures of client-side BIM applications tend to be different from each other, with limited support for database level change management within proprietary BIM applications for server enabled collaboration. For example, if a structural engineer decides to change the position of 4 columns, there is no predefined standard workflow for executing this change. The engineer may change each column individually, leading to four changes in the model; or may decide to change one, delete the other three and then copy and paste the first one three times (Figure 1). This will result in one change, three deletions and three new columns in a model, but ultimately the design change would be the same in both cases.

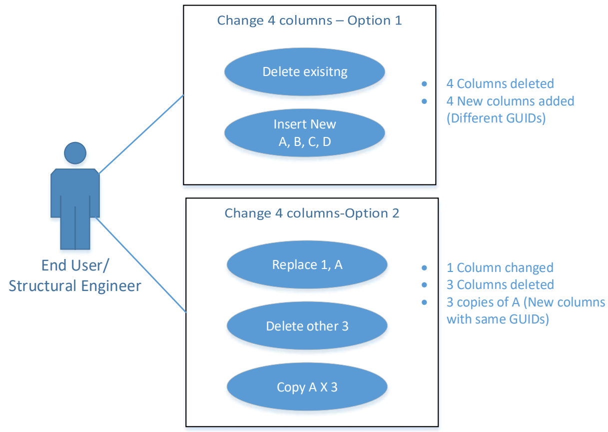

Figure1: Use case of a structural engineer modifying columns in a shared model

In such design modifications, when exporting the latest version of an IFC model, the IFC versioning can be different, as the two editing operations could result in different GUIDs for the same model elements. If the objects' GUIDs are identical, there is clearly a match for comparison (as GUIDs are designed to be unique).

However, two objects can still constitute a comparable pair even if their GUIDs are different. Most model comparison applications (e.g. Solibri, BIMServices, or proprietary applications etc) use GUIDs to establish candidates for comparison and therefore fail if these are different for two comparable objects. Tracking comparable objects across versions is a fundamental task in managing the workflows of model server enabled collaboration on BIMs. In summary, GUIDs are helpful when tracking such changes, but there is a need to consider other characteristics, such as location (same bounding box), containment (same address), name, specification, in addition to using GUIDs for object recognition and identification in a comparison process.

3 Previous Work

Several authors and research projects have addressed the general issue of change management in IFC models [7]**Error! Reference source not found.Error! Reference source not found.** and only a few studies have focused on IFC model comparison strategies [11]**Error! Reference source not found.**[13][14].

Traditional plain text-based comparison tools do not consider specific data organization and representation of comparable files and therefore are not suitable for IFC Comparison. Alternatively, GUID-based comparison strategies were presented to compare IFC models [15] [13]. GUID-based strategies consider two instances in two comparing files as same if their GUIDS are matching and vice versa. [13] developed EVASYS (EXPRESS Evaluation System), one of the first tools that can calculate a number of identical instances in two comparing IFC models under EXPRESS schema. The comparison algorithm proposed in EVASYS was based on using GUIDs (Globally Unique Identifiers) to identify matching object pairs and then used a sequence of steps to filter out matching and different objects by comparing object types<instances<attribute value. GUID (globally unique identifier) is a unique identifier for object instances that follow the universally unique identifier standard (UUID) that provides a way of uniquely identifying an object. **Error! Reference source not found.** reported four weaknesses of EVASYS: (1) it ignores redundant instances; (2) it does not provide any mechanism to analyses IFC owner history; (3) it does not consider if GUIDs are changed but that the property values are maintained; and (4) it is limited to counting structural instances in comparison, ignoring semantics. In IFC models, only entities inherited from IFCRoot will have GUIDs, while many other entities (e.g. IfcPropertySingleValue) not inherited from IfcRoot have GUID **Error! Reference source not found.**. In addition, the GUIDs of instances are often changed during the data exchange between different systems even without a modification to the model itself [14]. Although GUID-based comparison approach is simple and can provide fast results but is error-prone and therefore cannot be relied on.

A graph-based approach is presented by [16] which compares two oriented graphs generated by two IFC files. Similarly, [13] proposed converting IFC file into RFD-RDF graph-based signature algorithms for computing differences of IFC models. However, the matching process in graph-based comparisons still complies with GUIDs comparison.

Error! Reference source not found. proposed a flattening-based comparison approach, which suggests replacing all referencing with actual values in two IFC files and then compares the flattened data instances instead of original files. The comparison process becomes simplified to a string comparison as it overcomes the differences of reference numbers included in attribute values. However, the proposed flattening process can result in quite long strings of data due to complex inheritance and reference of IFC instances. Therefore, the flattening-based approach is time-consuming and not suitable to compare large IFC files [14].

Another IFC comparison approach uses a tree-based comparison of two IFC models using the hierarchal structure of IFC to map instances of two comparing files. This approach was presented by [11] and implemented in an IFC comparison tool “BIMServices”. This approach uses IFC spatial and containment hierarchies to base model comparison as the path along model hierarchy tree will typically have incremental changes, starting from IfcProject, across different versions of the same IFC model. Also, the IFC spatial hierarchy (geometry) is a relatively reliable base across BIM authoring tools and end users, which can help better understanding of the comparison results. The bimServices tool provided a better way of comparing IFC models through a sequential pass to calculate differences and similarities by using a tree comparison. However, the identification of comparable pairs still relies on the assumption that GUIDs of two instances will match in the comparing models. More recently, [16] presented a similar tree comparison approach which uses data instances, instead of GUIDS, to establish candidates for comparison to initiate the comparison process. Their approach extracts three basic terms (i.e. instance name, entity name and attribute values from each data instances) and their referencing relationships to construct IFC file hierarchy to perform the further comparison. This approach can reduce the number of redundant instances and can provide fast comparison results without relying on the matching GUIDS. However, various BIM tools use the different naming structure for instances and can export two different names for the same object in an IFC Import/Export operation. Therefore, constructing the IFC tree comparison using instance or entity names may not lead to accurate candidates for comparison to support the rest of the comparison process.

Previous authors have recognised that in order to get a more meaningful result for IFC model comparisons an extended set of metrics need to be considered that is not solely based on GUIDs but also consider other physical, structural and semantic properties of the IFC models [6], [8]. Preservation of GUIDs is unanimously stressed by previous researchers, as accurate GUIDs can provide quick and useful comparison results. If BIM authoring tools can preserve GUID in the round trip IFC exchange, then it will simplify the IFC comparison problem to a significant degree, however, GUIDs are often lost or changed during a data exchange due to BIM authoring tool imprints or end-user modelling preferences. A fundamental problem with inaccurate GUIDs is an inaccurate selection of candidates for comparison that can lead to completely wrong results. Therefore, a more sophisticated approach is needed to establish candidates for model comparison using different model matching strategies in addition to GUIDs.

4 A Signature Matching Approach for IFC Models

This paper proposes a signature-matching approach to establish object identities in model matching and comparison processes. In a signature-matching approach, the identity of an object is not static but calculated dynamically from the value of its properties and attributes creating a unique signature for an object[17].

[18] defined that "the signature is the collection of values assigned to a subset of syntactic properties in the model elements". The set of values that can be used to determine a signature for an object is called "signature type" [17]. Furthermore, [18] divided signature types into three categories, which are (1) a complete signature that covers all the syntactic properties associated with a model element; (2) a partial signature that covers a certain range of element properties; and (3) a default signature that is only composed of name properties. The selection of a signature type for an object requires user configuration which can be defined using a query language. A signature can be calculated using any number of properties associated with an object that can provide a distinguisher for the object. For example, a signature for an object can be its name, type and location or a combination of these characteristics (e.g. wall, wall type, position coordinates).

A signature does not rely on precedent identity (e.g. GUIDs); therefore, it can also be applied to the models which are created independently of each other using different tools (i.e. as in the case of IFC models populated from Revit or AECOsim). However, the creation of unique object signatures needs to define a series of functions to calculate accurate signatures for model objects based on their signature types. Using the pre-defined signature types, a hash value can be computed for the relevant properties sets which are used to establish a match during the comparison process. A hash function is used to map digital data of arbitrary size to digital data of fixed size, the values returned by hash functions are called hash values or hash codes or hash keys or simply hashes. Signature matching is useful even if a complete solution is not feasible, as signature matching can be used to eliminate a significant proportion of elements to downsize the comparison criteria for any further comparison.

4.1 Signature Matching Application in IFC Models

This paper proposes that characteristics of IFC objects can be used to create signatures for IFC objects, which then can be used in addition to GUIDs, to effectively compare corresponding objects an IFC model comparison process. This leads to a new research question: "What should constitute an effective signature for IFC objects?". It is suggested that this can be answered by considering the structural and semantic characteristics of an IFC model and the type of changes an IFC object can undergo. Fundamentally, a change can be in (1) *an object's position,* (2) *its shape* and its (3) *properties.* Position and shape are absolute as if two objects, in a comparing process, are at the same position and contains the same geometrical shape, then these are likely to be a similar object and thus, are candidates for comparison. Therefore, the characteristics of an object related to its position and shape can be used to create a signature for object recognition. For example, in an 'IfcDoor', the 'IfcLocalPlacement' defines the local coordinate system that is referenced by all geometric representations. The three-dimensional (3D) shape of 'IfcDoor' is represented using 'SweptSolid', 'SurfaceModel', or 'Brep' to define the door geometry. Most BIM authoring tools exchange arbitrary shape extrusions in IFC, which can be used to create a unique object signature.

On the other hand, creating a signature from element properties is complex as it involves a degree of change in object properties. For example, in versions A & B of the same IFC model, change in properties can have following scenarios

Properties of object A (version 1 of a dataset) = P [A]
Properties of object B (version 2 of a dataset) = P [B]
P [A] = P [B] = No change in properties
P [A] > P [B] = some properties have been deleted
P [A] < P [B] = some properties have been added
P [A] ~ P [B] = Properties have been updated/edited

Therefore, it is important to determine what properties are important and if we can determine the degree of importance in IFC properties, then it can be used to create a signature based on the key properties. Several signatures can be created from object properties, such as (1) The total number of property count can be used as a signature; (2) A name key for all the property sets names attached to an object can be used as a signature; (3) A name key of property names can be used as a signature and (4) A property value key can be used as a signature etc. These signatures can be used as passes to determine the degree of change in a potentially matching pair in a model comparison process.

Moreover, the position and shape are a way of reflecting an object on a drawing and in a 3D presentation. Therefore, these two components are compelling candidates to create a unique object signature. However, the case with object properties is different as it involves the degree of change that needs to be incorporated into creating the signature. The following examples demonstrate the development of IFC object signatures from shape and position characteristics.

Example 1: creating a signature from geometric representations (Shape)

The geometry of an IFC element is defined by a shape definition (i.e. 2D, 3D body and 3D path), the IfcProductDefinitionShape & IfcLocalPlacement allowing multiple geometric representations. For example, an IfcDoor may have a profile, footprint, bounding box and several 3D body definitions at different levels of detail. There is an unlimited number of shapes within the IFC schema, but it is schema requirement that it must have at least one 3D body. Therefore, the 3D shape of an element can be a signature type as it is populated every time for an IFC element. Another aspect is bounding box representation, as an IfcBuildingElement may be represented as a bounding box, which shows the maximum extent of the body within the coordinate system established by the IfcLocalPlacement. The bounding box representation is the simplest geometric representation available. The same element shape should always be contained in a same bounding box representation. Therefore, bounding box representation & 3D shape definitions can be used as strong signature types. In simple words, if two objects occupy a similar 3D space then they are candidates for similarity checking. For example, if in two comparing datasets, DS1 = IFC model version A; and DS2 = IFC model version B

RadiusBoundingSphere signature matching

Signature Type: Partial signature
Description: A hash code signature can be calculated by the radius from the middle point that contains all the points in the *shepheId* that contains the shape of an element. MatchElement RadiusBoundingSphere. (DS1, DS2)

>Element. RadiusBoundingSphere.hashcode.DS1 = Element. RadiusBoundingSphere.hashcode.DS2 = Filter for further analysis as potentially matching pairs

>>Element. RadiusBoundingSphere.hashcode.DS1 ≠ Element. RadiusBoundingSphere.hashcode.DS2 = Filter as changed object or new object

See Figure 2 for graphical representation

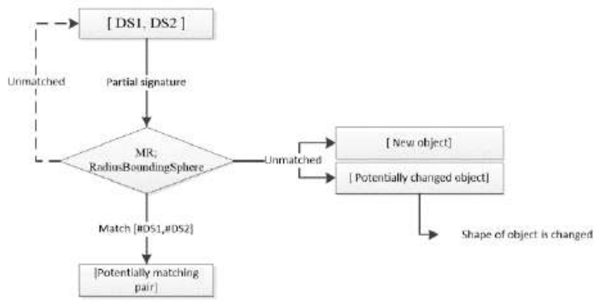

Figure 2. Matching rule for RadiusBoundingSphere signatures

A key aspect in defining shape signature type is to determine how 3D shapes are being generated from BIM authoring tools, as different BIM authoring tool may populate same 3D shape using different profile definitions, due to their internal structural differences and end-user domain applications. For example, Autodesk Revit uses arbitrary profile definitions to generate 3D shapes, whereas Tekla Structures uses parameterized profile definitions (IfcIShapeProfileDef, IfcEllipseProfileDef etc) as these profiles can create more efficient shapes related to structural elements (e.g. beam, columns etc). Therefore, shape signature is not a compound or complete signature, but it can have its contribution to reducing the size of the datasets for comparison. A shape-based partial signature is particularly important in determining the changes, rather identifying the candidates for comparison.

Example 2: Creating signature from Local placement

The geometry of an IFC element is defined by a shape definition and a local placement (i.e. IfcLocalPlacement). The IfcLocalPlacement defines the relative placement of a product in relation to the placement of another product or the absolute placement of a product within the geometric representation context of the project (BuildingSMART, 2014). A signature for local placement can be calculated by the X, Y & Z positions from the middle of an element (Centroid x, Centroid y & Centroid z). A matching centroid value will indicate an equivalent element with no change, whereas an unlatching centroid value will identify a change in the position of the object. For example, if in two comparing datasets, DS1 = IFC model version A & DS2 = IFC model version B

Position (Centroid) signature matching
Signature type: Partial signature
Description: A hash code that represents position signature of an element calculated from its local placement; Centroid for x, y & z

>ElementIfcLocalPlacement.Centroid. hashcode.DS1 = ElementIfcLocalPlacement.Centroid. hashcode.DS2 = Potentially matching pair, filter for further analysis, no change in position

>>ElementIfcLocalPlacement.Centroid. hashcode.DS1 ≠ ElementIfcLocalPlacement.Centroid. hashcode.DS2 = Filter as changed object; Position of the object changed

See Figure 3 for graphical representation

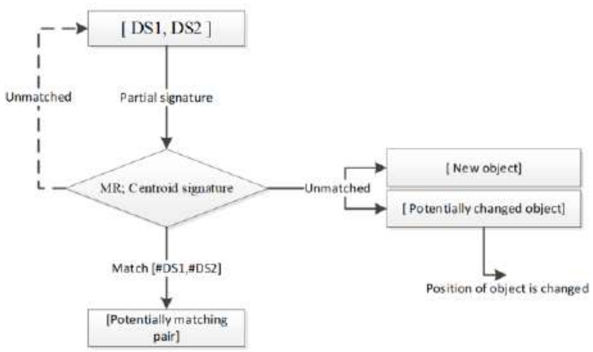

Figure 3. Matching rule for position (centroid) signatures

Likewise, the shape signature, the local placement signature cannot decide on its own for identification of corresponding element pairs in the comparison process, but it can be used in combination with other signature types, to detect potentially matching pairs or also to reduce the amount of work in calculating and identifying potential changes. If two elements have same local placement and shape, it is quite strong to say that it is a potentially equivalent pair, and can be a candidate for comparison. If the local placement coordinates are different for an element, in relation to its corresponding element in a comparable dataset, then it indicates that the element is "moved" in the updated version of the dataset, thus helps to identify the changes undergone. Similarly, signatures can be created from other IFC object characteristics (e.g. Schema type, Object Type, Name, Property Count- see Table 1) and can be used to support establish similar candidates for comparison. It is to be noted that GUID itself can be used as a signatures type as matching GUIDs would constitute a match but different GUIDs can be ignored (i.e. same objects can have different GUIDS).

4.2 Implementation: XBIM Signature Exporter

The proposed signature matching approach is implemented in a custom-built software tool, xBIM signature exporter, a tool that can create a unique signature using various characteristics of IFC building elements according to the proposed methodologies in this research. The xBIM signature exporter is developed on the platform of the xBIM toolkit, the eXtensible Building Information Modelling (xBIM) Toolkit, which is an open source, software development tool that supports IFC schema. The xBIM toolkit supports IFC models for geometric, topological operations and visualisation that can be used to create bespoke BIM middleware for IFC-based applications. The XBIM signature exporter was developed in a commercially funded research project; Therefore, the source code of the tool is not discussed.

The XBIM signature exporter has extracted serval signatures from the test model; however, only a few signatures are useful in IFC model comparison process. The xBIM signature exporter tool is implemented to calculate signatures for "Standard classroom" model using IGC 2.0 coordination view specifications. The test model contained an IfcDoor (1), IfcSlab (2), IfcWallStandardCase (5), IfcWindow (6) and an IfcOpeningElement . The XBIM signature exporter has extracted serval signatures from the test model using the signature types defined in Table 1. Examples of extracted signatures for "Door" and "Slab" are also presented in Table 1.

The limitations of this paper do not allow to present the test case and demonstrate the comparison results obtained using the extracted signatures. Therefore, only examples of extracted signatures are presented in Table 1 to follow the discussion.

Table 1: IFC object signatures definitions in XBIM signature exporter

Signature Type	Description	Example of a "Door" Signature	Example of "Slab"
Model ID	A number that represents the internal ID of an element inside the model. E.g. 2552 for an IfcDoor.	2552	249
SchemaType	A name for a type of building element. E.g. IfcDoor for a door.	IfcDoor	IfcSlab
DefinedTypeId	A total number of defined types attached to an element. E.g. the value for the defined type of IfcDoor is calculated as 2539, in the test model.	2539	0
GUID	A fixed 22-character length string, which is associated with each element and is exchanged with the IFC exchange file structure.	3A3Tihl61FQRUYE_9VB72L	3A3Tihl61FQRUYE_9VB75i
Name	The name of an IFC element is a label in the term by which something may be referred to, i.e. IfcLabel = String (Max.255 characteristics).	IntSgl (1):1010 x 2110mm:1010 x 2110mm:195846	Floor:Ground Bearing Concrete:195839
ObjectType	The type of object of an element.	1010 x 2110mm	Floor: Ground Bearing Concrete
PropertyCount	A number representing the count of total properties given to an element by the author in addition to what it would have by default (i.e. Extension properties in Revit)	56	29
PropertySetNamesKey	These are single value property sets that can be used to generate a signature, considering that the complex property sets are hardly ever used in real examples of IFC models	-863509959	1452519724
PropertyNamesKey	Similarly, a hash key is created from "Names" of the properties (e.g. level, the height of offset from level etc) by sorting out names of the properties in an alphabetical order and creating a hash code signature.	1703689443	1976711505
PropertyValuesKey	Similarly, a signature is calculated for the values of the properties.	570000713	1589767974
MaterialId	This is the name of the material attached to an IFC building element.	(empty, no material assigned)	Floor: Ground Bearing Concrete
Centroid X	This is the position signature calculated by a x,y,z positions of the middle of an object.	-3908.871582	-1556.871582
Centroid Y	Thus, centroid determines the local placement of the object that can be used as a unique	4958.726563	828.9765625
Centroid Z	identification signature for the object recognition and also detect if there is any change in the object's position.	1072.5	-250
RadiusBoundingSphere	This is a number that represents radius from a middle point that will contain all the point in the shepherd that contains the shape of an element. In simple words, it is the radius of the bounding box of the shape of an element. If the shape of an element is changed, it will change the bounding box and vice versa. Thus, it can be used as a unique signature for the shape of an object.	1205.268555	6259.641113
ShapeId	This is the shape ID that defines the shape of an object	-914375451	-444593825

The results suggest that the schema type, GUID, position and bounding box signatures are strong signature types. Considering the volatile nature of GUIDs, schema type, position and centroid signatures provide enough evidence to establish candidates for comparison in the first pass, even if the GUIDs are not matched. After establishing matching pairs for a comparison analysis, signature matching can also help to reduce the size data for detecting fine grain changes if there are any. For example, if a matching pair has a different PropertyCount or PropertySetNamesKey, it means some properties have been added or deleted, and it should be checked for more detailed analysis. Thus, the signature types, such as NAME, Object Type, properties, can reduce the amount of workload to precisely detect changes in further analysis. It is not a brilliant way of calculating differences, but it reduces the amount of work required for further analysis.

5 Conclusions and Future Work

This paper describes that model matching and comparison strategies for platform-neutral models (i.e. IFC models) are the keys to solve the problem of iterative change management. A critical issue IFC model comparison is establishing right candidates for comparison, regardless of what comparison mechanical is being used. Typically, GUIDs are being used to identify corresponding objects in IFC model comparison methodologies, which is criticised for their accuracy and efficiency. This paper proposes that the characteristics of an IFC object can be used to create unique signatures for IFC elements, in addition to GUIDs, to effectively compare corresponding objects in a model comparison process. An object's position, shape and properties can be used to formulate partial, default or complete signature for an object, which can be used as passes to establish candidates for comparison and to highlight changes in a comparable object pair. This approach is useful in establishing accurate candidates for comparison without GUID dependence and can reduce the workload of the overall model comparison process.

In terms of creating an element's signature, there are several issues that need to be considered in the broader perspective of change management in a model server environment. This research has only developed signatures for IfcBuildingElements as it has the highest importance for an end-user from a change management prospectus. Even for IfcBuildingElement, the research has defined signatures for IFC object characteristics which are largely optional and may have different population if models are created using heterogeneous applications. In the context of creating unique signatures from these optional attributes, such questions need to be answered that what level of utilisation these optional properties are in the IFC models? And how likely these are to be found in real-world examples? Potentially, a subset of data can be derived, with the statistical reasoning that some characteristics, relationships and properties of IFC objects can be neglected or be focused on in creating object signatures, depending upon the usability proof from a wider and real-world dataset. This abstraction would require further empirical evidence from the analysis of real-world IFC models, reflecting a cross-sectional view of different BIM authoring tools that are used in creating IFC models. A critical issue is to consider associated weighting of different signature-type attributes of IFC objects to constitute an effective signature for IFC objects.

This study is limited to using optional object properties to create a property-based signature (such as PropertyCount, PropertyValuesKey), however, these optional properties can be referring to the same object but on a different Level of Detail (LOD). Therefore, Future research is needed to explore property signatures in more details, considering associated Level of Details and degree of change in an object's properties. Future research will explore the application of the proposed signature-based matching strategy on IFC models with different level of details and complexity within a model server enabled collaboration environment.

Abstract –

Analyzing urban districts to promote energy efficiency and smart cities control could be very complex as big data have to be analyzed filtered to discover unpredictable patterns. Using clustering method, specifically K-means algorithm, allows to create an energy profiling characterization of urban district models with multiple advantages: as first, large quantity of data can be managed and synthesized, easing the creation of algorithm patterns that could be replicable. Thus, it is possible to operate in a large scale and in a small scale in the same time, choosing the level of detail that is more appropriate for the specific analysis. In the large scale, the disadvantages are the dependence from data, i.e. if there are missing input values, it is hard to rebuild them because of the quantity of data. Missing values can confuse the analysis because scripts cannot identify the entire row missing it. Working with clustering analysis it is thus useful when large amount of data should be organized and interpreted and the technique can help the planner to make faster the analyses process. The research aims at demonstrate the efficiency of clustering methods when adopted for energy consumption issues at city level. In the paper, the clustering process concerning building energy profiles of a European city for the identification of building models is described. This means that an energy template on urban scale is used and clusters are applied on energy profiles based on architectural and energy similarity in order to find representative models. In particular, the study is focused on the relationships between building characteristics and actual building energy profiles.

Keywords –

Clusterization, behavioural modelling, smart city data mining, energy profiling

1 Introduction

In the last years, energy analysis has been progressively boosted to reach high efficiency in buildings, increasing savings and reducing CO_2 emissions according with EU objectives. EU government has set three targets to be achieved by the 2020: 20% reduction of greenhouse gas emissions (starting from 1990 value), 20% increase of EU energy from renewables, 20% improvement in energy efficiency [1].

The building sector is responsible of 40% of European Union's total energy consumption.

The population growth and the strong urbanization process showed in 2014 that the 54% of the world's population is living in urban areas. This proportion is expected to rise to 66% by 2050. Moreover, an increase of 90% is expected to be concentrated in Asia and Africa, according UN report [2]; this situation requires a more consistent energy management in order to reduce wastages and to increase comfort. This goal could be reached by the use of energy monitoring devices that can help to optimize energy consumption. Several studies show that is essential to analyze building energy profiles in order to understand how the occupancy variation affects the energy behavior [3][4] and data gathered are the key factor to understand the consumption distribution and thus to manage the smart city [5][6].

Nowadays, data mining is a powerful framework to promote consciousness and thus achieve strategies efficiency. Cooperation between different clusters of consumers, prosumers and energy production spots and plants [7], methods to analyze big and giant data are crucial to develop models [8] to represent, predict and renovate the cities through IoTed solutions and digital based technologies [9][10]. Digitalization is changing the way we approach the concerns in many fields however the smart city and the energy management is one of the first and exploited sectors in which digital models and predictive as well simulators are adopted extensively since many years. The digital revolution requires a high level of specialization in many fields such as data analysis and coding, computing, data engineering, machine learning, artificial intelligence (AI).

Digitalization is basically dependent on data and for that reason, IoT is increasing and data are gathered in every system up to redundancy. Nonetheless, the amount of data is not a guarantee of amount of information because of unstructured data or data organized in different ways compared to readable ones is leading to a big amount of unused data (90%). The initial vision of the final use and meaning and the correct plan of data collection should drive the "thirst" of data to make them useful. In AEC sector, the adoption of computers is increasingly fundamental as more and more data have to be analyzed and knowledge extracted to outline the predictive models and promote a robust analytical assessment.

2 Methodology

The methodology adopted is based on mathematical methods that are used to operate a data mining process and clusterization of big data. In the following subsections, the specific methods considered together with advantages and weaknesses are described before to go in deep with the methodology and application to the case study of the present research.

2.1 Clustering methods

With the grown quantity of data, clustering methods have been developed to make easier the data mining procedure using many clustering methods such as Hierarchical, K-means, K-medoid, etc. Clustering is an unsupervised learning task that aims at decomposing a given set of objects into subgroups or clusters based on similarity. The goal is to divide the data set in such a way that objects belonging to the same cluster are as similar as possible, whereas objects belonging to different clusters are as dissimilar as possible. Cluster analysis is primarily a tool for discovering previously hidden structure in a set of unordered objects [11].

Clusters are useful for creating and analyzing building energy profiles in order to organize data collected into groups easing to analyze and evaluate them also increasing the relevance of measures and indicators. For example, data could concern the energy consumption related to the use of kitchen and laundry appliances, electronic devices such as TVs or computers. Clusters can be prepared based on the different kind of appliances or based on the different users' behavior in the analyzed buildings [12] and collected through smart meters [13]. Based on specific induction principle many algorithms have been developed for clusterization and the main approaches are hierarchical methods and partitioning methods.

2.1.1 Hierarchical methods

These methods could be called top-down or bottom-up methods since they identify clusters following these two main directions. There are two main types of hierarchical methods and the difference sets in the starting point of the analysis:

- *Agglomerative hierarchical clustering* starts with single objects and each object represents a cluster. Then clusters are merged until a default structure is obtained.
- *Divisive hierarchical clustering* begins with one single cluster that contains all the objects and the subdivision in more clusters occurs successively.

The result of the analysis is a dendrogram representing all different considered groups, which are subdivided into levels (Figure 1).

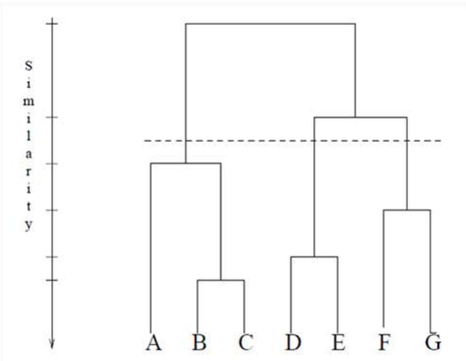

Figure 1. Dendogram: example of hierarchical results representation.

Checking the desired level of similarity, the clustering of objects could be obtained.

In the hierarchical method, more subdivisions that are possible come from the way of the similarity measure of clusters:

- *Single-link clustering* considers the distance between two clusters to be equal to the shortest distance from any member of one cluster to any member of the other cluster. If it is based on similarities, the similarity between couples of clusters is considered equal to the greatest similarity from any member of one cluster to any member of the other cluster.
- *Complete-link clustering* considers the distance between two clusters to be equal to the longest distance from any member of one cluster to any member of the other cluster.

- *Average-link clustering* considers the distance between two clusters to be equal to the average distance from any member of one cluster to any member of the other cluster.

The hierarchical method has the disadvantage of the inability to scale because of the time complexity that is non-linear with the number of objects. The method also has a high degree of rigidity.

2.1.2 Partitioning methods

Partitioning methods consist in move instances from one cluster to another, starting from an initial partitioning. The characteristic of this method is that the number of clusters has to be pre-set. To grasp the optimization an exhaustive enumeration process of all possible partitions is required [14]. There are different types of partitioned-based clustering. The most frequently used are the error minimization algorithms, which works perfectly with compact and isolated clusters.

When the distance of each instance to its representative value is measured, a certain error occurs. These algorithms try to minimize that error. The Sum of Squared Error (SSE) is the most known method and it measures the squared Euclidean distance of instances to their representative values. The most used error minimization algorithm is the K-means algorithm, which divides objects into K clusters, chosen randomly and each cluster is represented by a center or mean. The center is calculated as the mean of all the instances belonging to that cluster:

$$\mu_k = \frac{1}{N_k}\sum_{q=1}^{N_k} x_q$$

Where N_k is the number of instances belonging to cluster k and μk is the mean of the cluster k.

The linearity of K-means method is the key of its success over other clustering methods and even if the number of objects is huge, this algorithm is computationally attractive (Figure 2).

The weakness of this method is the choice of the initial number of clusters: the process of clustering is based on this number and the initial choice can change the entire result since there can be differences between global and local minimum.

Another partitioning algorithm that is part of the error minimization algorithms is the K-medoid or PAM (Partition Around Medoids); this algorithm is very similar to the K-means but it differs from the latter since the representation of the different clusters is dissimilar.

The principle is the same: each cluster has a center that, in this case, is the medoid; a medoid is the most centric object in the cluster and it is not influenced by extreme values and for this reason is more solid than the K-means method. Throughout evaluation methods, clustering criteria compute the optimal number of groups for a dataset calculating the index for each case. They measure the compactness of clusters and the homogeneity of them and choose the cluster for each element.

Graph-Theoretic clustering is a method that provides clusters via graphs. Instances are represented as nodes and this method connect all nodes. There is a connection between hierarchical method and the graph theoretic clustering since there is similarity between the hierarchical representation and the Minimal Spanning Tree (MST).

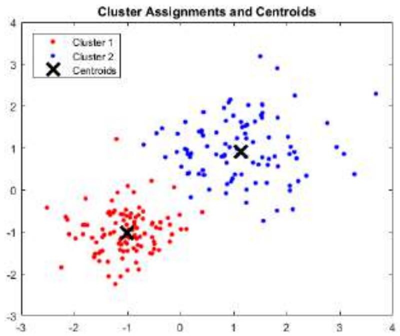

Figure 2. Example of K-means results representation.

2.2 Application in the research

The research consists into analyzing data about energy behavior of a big quantity of buildings gathered by means of smart meters used to register energy consumption during the all year with a step of 15 minutes. Thus, every quarter of hour, smart meters sent the registered data to the central system for monitoring. The analysis is used to identify the specific consumption patterns related to uses and building models. The smart meters have an identification number and for this reason, every smart meter represents the ID (Identification Code/Document) of a specific flat or activity set in a certain building. The research methodology is based on collecting data, sorting data and analyzing them following the scheme (Figure 3).

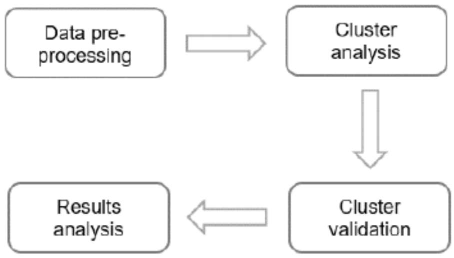

Figure 3. Methodological workflow.

2.3 Data analysis

The methodology start from a first analysis on data metered, after that, the different trends about electrical consumptions have been represent. The representative plots are performed using the ggplot2 R package.

In order to have a clear knowledge about the general trend of data, the smart meters' profiles of the entire year were plotted and compared in order to visualize. the data to be organized to allow the clustering analysis.

With the intention of creating a resume table with mean, median, maximum, minimum and the standard deviation, the main database has been partitioned selecting the unique ID of the smart meters. A table composed by 659 observations (i.e. 659 unique Smart meter IDs in the original database) and n. 6 variables has been created. After the creation of clusters, analysts are able to start the process of clustering validation that is the measure of distances of each data from the center of cluster (centroid) to understand the dissimilarity within each group [15]. This process helps to get a clearer vision about the objects giving a summarizing plot and data tables, which allow comparing results in an efficient way. Than the filtering data procedure started to divide into smaller packages to be handle. Data analyses and cluster methods permits to collect the different information in an easier way than in the past and these methods are suitable for smart cities analysis and strategies [16].

2.4 Cluster analysis

Data analysis allowed collecting various information about thousands of buildings including the geometry, the energy consumptions and the location; hence, it was possible to have insight on the composition of the analysed built environment. The information were about the typology of the analysed buildings such as the use, the year of construction and if changes occurred during the years. Throughout the data, it was possible to perform the analysis on the energy consumption that is strongly influenced by the use of the buildings.

After the data analysis, clusters were organized and the method adopted was the partitioning method with the help of the K-means algorithm.

This process is composed by two steps:

1. A first evaluation by using NbClust R package has been performed. This package provides n. 30 indices for determining the number of clusters and proposes to users the best clustering scheme.
2. The second step was to put the number of clusters that has been identified by the evaluation into the K-means function of R in order to create the subdivision following the similarities of the smart meters' profiles.

As described in section 2, clustering is the partitioning of a set of objects into groups in order to obtain groups with similar objects grouped in the same cluster. Most of the clustering algorithms depend on assumptions with the intention to define the subgroups present in a dataset.

The evaluation process had to tackle difficult problems such as

- the quality of clusters;
- the degree with which a clustering scheme fits a specific data set;
- the optimal number of clusters in a partitioning.

The evaluation was performed with NbClust. All these clustering validity indices combine information about intra-cluster compactness and inter-cluster isolation, as well as other factors, such as geometrical or statistical properties. There are n. 30 index but in the present research, two main indexes has been considered:

- D-index;
- Hubert-index.

2.4.1 D-index

The D-index is based on clustering gain on intra-cluster inertia that measures the degree of homogeneity between the data associated with a cluster. It calculates their distances compared to the reference point representing the profile of cluster that is the cluster centroid in general. The equation [17] representing this index is:

$$w(P^q) = \frac{1}{q}\sum_{k=1}^{q}\frac{1}{n_k}\sum_{x_i \in C_k} d(x_i, C_k)$$

The D index is a graphical method of determining the number of clusters. In the plot of D-index, we seek a significant knee (the significant peak in D-index second differences plot) that corresponds to a significant increase of the value of the measure.

2.4.2 Hubert-index

The Hubert-index r statistics is the point serial correlation coefficient between any two matrices. When the two matrices are symmetric, r can be written in its raw form as the equation:

$$\mathrm{r(P, Q)} = \frac{1}{N_t}\sum_{\substack{i=1\\ i<j}}^{n-1} P_{ij}Q_{ij}$$

Where:

- P is the proximity matrix of the data set;
- Q is an n x n matrix whose (i, j) element is equal to the distance between the representative points (vc_i,

vc_j) of the clusters where the objects x_i and x_j belong.

High values of normalized *r* statistics indicate the existence of compact clusters. The Hubert index is a graphical method of determining the number of clusters. In the plot of Hubert index, we seek a significant knee that corresponds to a significant increase of the value of the measure i.e. the significant peak in Hubert-index second differences plot [18].

After the evaluation, for the application in the case study (section 4) the NbClust function suggested a number of clusters k=5 plotting two graphs: the first one indicates the D-index values and it is possible to understand the number of cluster from the graph seeing the knee of the trend (Figure 4). The second graphs indicates the second differences D-index values and it suggests that the n. 5 is the ideal number of clusters throughout a peak [19]. With the intention of operating the clustering algorithm, the K-means function has been used setting n. 5 different clusters and using the Hartigan-Wong algorithm [20]. This kind of clustering algorithm determines a cluster assignment of a point peaking it repeatedly. It is based on the sum of squares of errors (SSE) and it searches the optimal within-cluster SSE for assigning an object to the proper cluster.

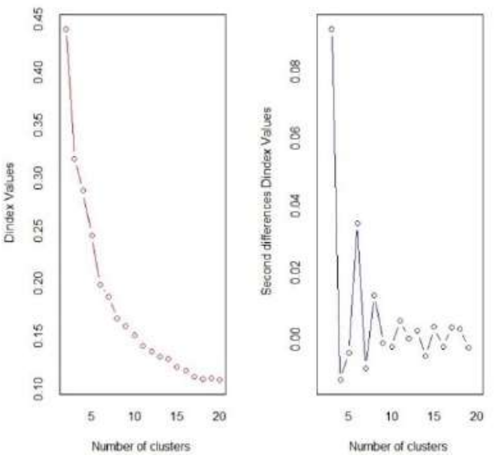

Figure 4. Indications by Hubert and D-index indices for the case studies.

3 Case study

The case study has been a district with 10.000 buildings of a European city where a smart metering strategy has been applied and data collected.

The organization of the buildings' data was based on the ID used in the data processing. After having sorted data, the next stage has been to analyze them trying to find out a significant clustering algorithm. To achieve that, an analysis on the buildings' use has been performed in order to collect Smart Meters with energy values within a correctly sized wide range. Then, a classification of the most frequent destinations of buildings was operated. The most frequent uses in the case study are listed below:

- Banks;
- Coffee shops and restaurants;
- Retirement Homes;
- Municipal Houses
- Residences,
- Private properties and Residential buildings;
- Administration buildings
- Industries and factories.

It is possible to define the type of buildings and the most frequent typology analyzing the residential use: the most recurring was the multifamily houses, followed by the single-family houses. Therefore, the analysis of the multifamily houses was developed since this category had the largest number of samples (Figure 5). Data processing delivers a list collecting the energy consumption value during the entire year identifying day by day, hour by hour, the effective energy usage.

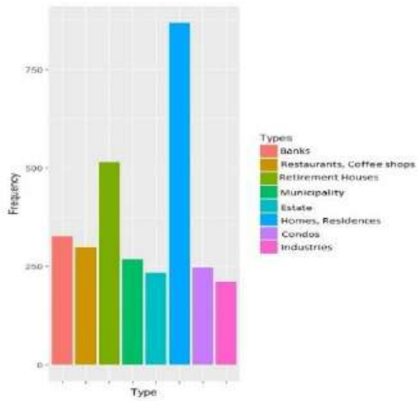

Figure 5. Buildings' use frequency diagram.

The research allowed getting a database composed by 22'994'372 observations with 659 unique Smart Meters IDs. This means that for each ID there are *n* rows indicating day, month, year, hour, and minute for the entire year. The variables of this data frame are n. 9.

This database is significant in order to design energy profiles for each smart meter, to get many other databases analyzing as an example data into workdays or festive days, analyzing month by month the energy use, visualizing systematic trends of these profiles.

4 Results

In order to understanding the results of the clustering analysis, a series of plots have been performed. The first representation of this study consists of plotting singles clusters in order to understand the differences between the groups. In Figure 6 the data for each cluster for one working day are plotted with the representative elements.

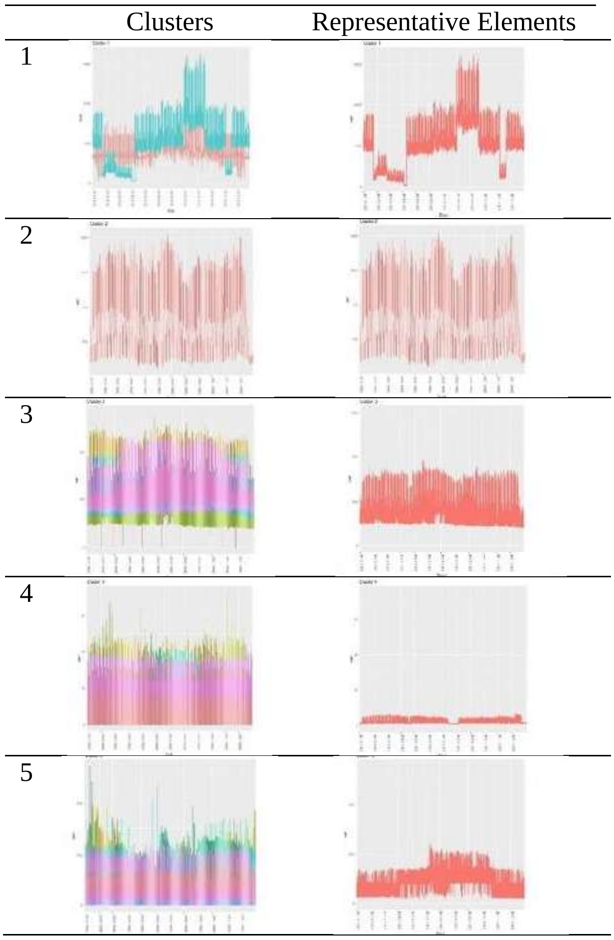

Figure 6 Working January One day profile.

The energy consumed during a year (2014) is thus plotted for each cluster considering the data time step of 15 minutes. In the following, the clusters are listed and data discusses:

- Cluster 1 is characterized by kWh values ranging between 0 and 1600 kWh. This cluster contains two cases and it has the highest range of kWh values.
- Cluster 2 is the smallest one and it gathers one observation that ranges between about 400 kWh and 1260 kWh with a value of around 860 kWh per year.
- Cluster 3 is composed by 8 objects and it has a range that goes from 0 kWh to almost 300 kWh.
- Cluster 4 contains 618 profiles and it is the largest one. The energy values ranges between 0 and 75 kWh and it is the cluster with the lowest range of values.
- Cluster 5 gathers 30 smart meter's profiles and it has an average value of almost 300 kWh with data ranging between 0 and 280 kWh.

In Table 1 the characteristics values of the clusters are reported. It easy to understand that cluster 4 is the cluster in which residential buildings are gathered and which is the most populated cluster. Cluster 1 could be the industrial buildings one and the municipal house could be cluster 2. The idea is that analyzing the data is not needed to go in deep into the identity of the building (with eventually privacy problems) but is possible to define the values trend and to suggest possible implementation strategies through the analysis of the archetypes, also calculating measure to redefine peaks and trends.

Table 1 Clusters Characteristic values

Characteristics	Clusters 1	2	3	4	5
Size	2	1	8	618	30
Mean	12.03	16.47	2.63	-0.13	0.73
Median	11.27	17.93	2.42	-0.13	0.60
Max	13.22	13.52	2.02	-0.14	0.95
Min	0.91	23.38	2.61	-0.08	0.22
SD	12.75	13.85	1.68	-0.13	0.89

In Figure 7, the whole profiles are shown to the left side, a working day (Monday) data are plotted to the right side.

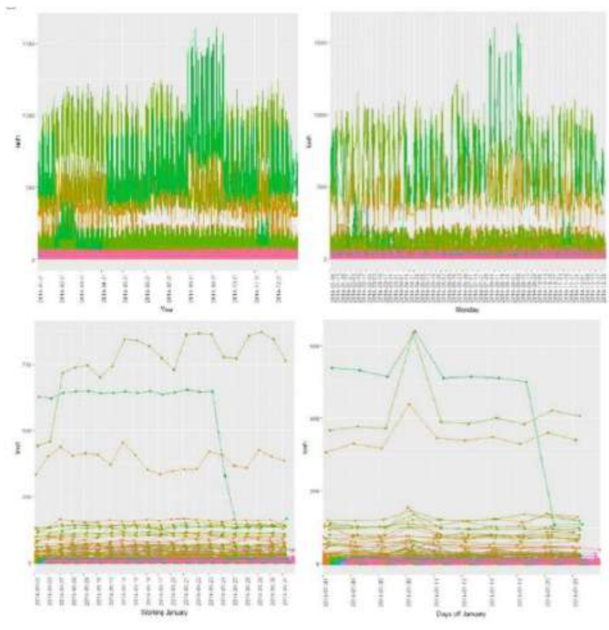

Figure 7 (above) One year smart meters profile and Monday profile and (below) week working day (January) and weekend daily profile.

It is possible to check that the different profiles are defining the city uses and buildings in which the energy consumption is concentrated.

There are the big consumers (Cluster 1 and 2) and all the other profiles with less consumption each but with a great number of units and variability due to occupancy distribution and different behaviors.

Cluster 4 is thus the largest with 618 profiles and this represents the housing stock in the sample used as a case study. For the main cluster 4 is thus shown in Figure 8 for the working day in January and the week end day in the same month.

In the left side diagrams, the yearly-recorded data are plotted and to the right side the daily profile are shown.

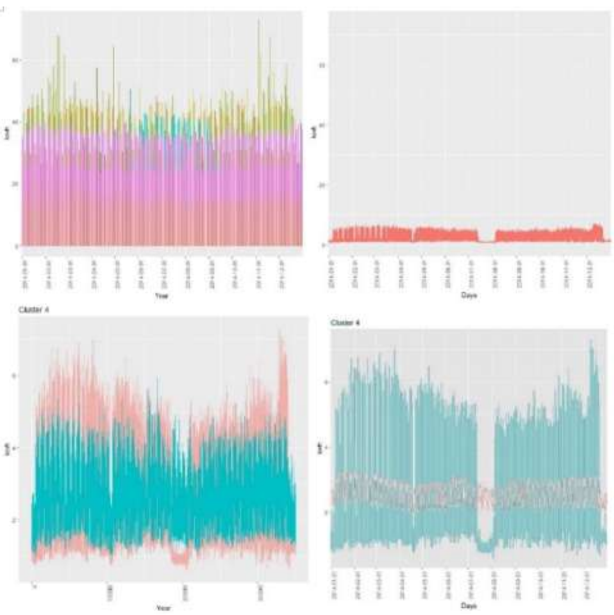

Figure 8 Week working day profile (January) and weekend daily profile.

The representative element of the Cluster represents the profile of a building and an ideal element that has been created through the average and the weighted average of the cluster.

The research showed that the weighted average is most suitable to define this representative profile because as multiple elements are used in the weighted average, the ideal centroid moves away from the representative element.

5 Conclusion

Hence, the digitalization has brought a strong advantage that is the possibility of managing a larger database that can make the pre-analysis process and that can analyse itself faster with a very significant improvement for the time management. A less time expensive but detailed analysis allows to the reduce costs which is one of the main aspects considered by the clients. Europe and the entire world is getting effort in order to achieve important results regarding the reduction of GHG emissions to decrease the global warming effect. The environmental benefits that energy savings through technology advancement are bringing and the way digital revolution is helping the management of energy sources are very important to achieve these goals.

There is a transition from old business models to the new ones that means that private sector and utilities companies are investing on renewable energy and new technologies, for example through smart meters. Smart meters (SM) are very helpful in order to collect a very large quantity of data and since the IoT (Internet of Things) is emerged, massive amounts of data are available and they are easier to manage. SM are bringing many benefits for consumers and for utilities: customers can be constantly informed about their consumptions and the way of communication can be remotely controlled with historical data and locally the consumers are informed by real-time data with a significant improvement of customers' knowledge about their energy costs and carbon emission. These devices allow the electrical appliances to be automatically controlled and this feature is very interesting since consumers can easily manage the electrical system selecting days off where the consumptions can be reduced and, oppositely, the days when users request more power to the system.

In this way, waste of energy can be reduced. For utilities, the advantages are that they can influence the energy profiles of their users; they can have a reduction in 'costs to serve' rationalizing their services and they are able to sensitize customers about global warming issue.

Smart Meters and IoT bring a large quantity of data, as we said, and clustering methods have been and will be critical in order to manage in a better way this data [21]. Clustering method has many advantages: first, it increase productivity through specialized inputs, access to information, synergies [22]. The data management through clustering methods allows creating an energy profiling characterization of urban building models suitable to study and define balance strategies and flatting peaks procedures coupled with policies on energy sources to be adopt considering IoT and Smart Management of the city. The advantages of using clustering methods, specifically K-means algorithm, are that it eases to manage a large quantity of data, synthesized them and create an algorithm pattern that could work for further different cases and thus could be transposed. Therefore, it is possible to operate in a large scale and in a small scale in the same time, choosing the level of details which is more appropriate for the analysis and the calculation useful for energy planning and to support and explain future development.

Abstract –

Three-dimensional (3D) models are increasingly becoming an important tool in project management. At the same time, the 3D data of construction industry is more and more large, whether it is caused by large model scene or the requirement of model accuracy. In order to meet the requirements of the model application, the 3D model needs to be simplified. Mesh models are one of the most common ways to display 3D models, which provide well-defined object boundaries. The simplified algorithm of the existing mesh model cannot keep the important detail features of the original model once the data volume of the model is further reduced. Combined with Quadric Error Metrics (QEM) algorithm, this paper improves the edge collapse algorithm to solve the problem of undetected model structure and over-simplified model details. The proposed algorithm can preserve the integrity of the model while maintaining a high compression efficiency. Experiments show that the proposed method works well for the compression of large-scale scene models, which includes the compression ratio and the structural preservation in the model. This compression method is well suited for the model with huge amounts of data generated by large scene objects in the construction field.

Keywords –

Mesh model; Simplification; Structure-preserving; Edge collapse

1 Introduction

Three-dimensional (3D) models are increasingly becoming an important tool in project management. 3D model can reproduce building scenes and display building structures, which plays a significant role in construction quality, construction progress, construction site safety [1] [2], such as dimensional measurements of structures [3], remote management of the construction site [4].

At present, in the field of architecture, engineering and construction (AEC), polygon mesh models are one of the most common ways to display 3D models. They provide well-defined object boundaries that are suitable for clearly presenting the structure of 3D objects, which greatly improve the visualization of the construction site. These models have been able to achieve centimeter-level display of the details of the object [5]. In general, a polygon mesh model usually consists of complex triangular mesh, which may contain tens or even millions of vertices and polygons [6]. In particular, there are more vertices and polygons for some models of large scenes. There are higher requirements for grid model applications, including adequate storage capacity, high computational power, and to access over bandwidth-limited links [7]. This is often difficult to achieve. Therefore, to compress 3D model effectively is urgent.

The research on 3D model compression started with Deering, who proposed to reduce the amount of data by quantizing all the components of the input mesh into a certain number of bits [8]. Later, the compression of the mesh model evolved. For the current research, the simplified algorithm still deserves further study in the relatively large 3D model, no matter in the compression effect or in the compression time [9].

Combined with Quadric Error Metrics (QEM) algorithm, this paper improves the edge collapse algorithm to solve the problem of undetected model structure and over-simplified model details [10]. The contents of the article are as follows: the second part is the existing model compression method. The third part presents the proposed algorithm. The fourth part and the fifth part are the verification of the algorithm and the conclusion respectively.

2 Related Work

Generally, two different 3D models are available after collecting construction data. One is point cloud model consisting of a large number of points containing the characteristics of the target surface, the other is mesh model in which objects and the entire environment are drawn by polygons. 3D models have a huge amount of

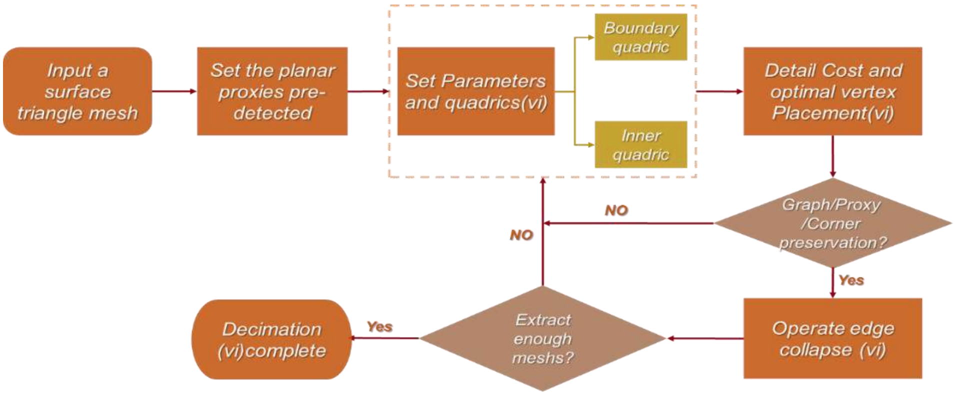

Figure 1 Triangular mesh model simplification process

data. For example, the Faro Focus 3D delivers more than 976,000 3D points per second [11]. The state-of-the-art, light-based 3D camera produces 30 frames per second, roughly 300 MB of raw data [12]. Therefore, to store and manage three-dimensional data while preserving useful information as much as possible, it is important to improve the compression technique of the 3D model.

According to the decompression method after model compression, the 3D model compression algorithm is divided into single-rate compression [13] and progressive compression [14]. Single-rate compression technology compresses an entire model and then sequentially decodes the recovery model, focusing on saving bandwidth between the CPU and the graphics card [15-17]. With the increasing volume of 3D geometric data, this technology takes too long to receive the complete model, which cannot meet the real-time rendering requirements [18]. The advent of progressive compression algorithm has provided the possibility of real-time rendering of model compression. This algorithm first compresses the general framework of the model and then gradually supplements the remaining geometric details of the model. Therefore, the 3D model can be continuously reconstructed by the decoder from coarse to fine Levels of Detail (LOD) when receiving the bit stream [19].

The study of 3D point cloud compression algorithm is mainly divided into tree structure method and height map method. Height map-based method is to compress the 3D point cloud information into a two-dimensional matrix. This method was first proposed by Pauly [20]. Later, there have been some improved algorithms, such as adding geometry [21] [22], or preprocessing the data for compression [23]. The core of the tree-based method is to partition the point cloud space. The common tree structure methods include kd-tree [24] [25] and octree [26] [27]. The 3D point cloud can represent a geometric model of arbitrary shape with a simple structure and its compression technology has been relatively mature [28].

Compared with the point cloud model, the surface structure of the 3D mesh model is slightly complicated. However, the polygon structure can improve the visual effect of the model, which is especially suitable for visual inspection of large scene objects in the field of architecture. The study of model simplification includes vertex clustering [29], vertex deletion [30], wavelet transform algorithm [31] [32], edge collapse [33] [34]. These method is under development. How to compress mesh models well with increasing data volume is still a problem worth exploring.

3 Methodology

The proposed algorithm takes a surface triangle mesh of the model as input, since arbitrary polygons can be easily triangulated. Then preprocess the model to detect a set of the planar proxies. By performing a limited number of edge collapse operations on the above model, a simplified model that retains the structural features of the original model is output. The specific process shown in Figure 1. Edge collapse is one of the most common algorithms in model simplification. However, previous edge-collapse algorithms often caused over-simplification of the model.

In this paper, on the basis of the quadric error metric method (Abbreviated as GH) [10] and the volume-preserving approach (Abbreviated as LT) [35], the concept of planar proxies is introduced to ensure that important features of the model after input can be detected. To prevent the model from being oversimplified, inner quadric and boundary quadric is introduced to measure the error and the rule of model structure preservation is formulated.

3.1 Planar proxies

Before the implementation of the algorithm, the 3D model should be initialized to realize the storage format of the triangular mesh data structure and the vertex data structure. Set the planar proxies pre-detected

Suppose a triangle is selected on a plane, so the plane equation and normal vector of this triangle can be calculated. Center around this triangle and spread to the surrounding area of the triangle. Calculate whether the normal vector of the surrounding area is close to the normal vector of this triangle, and if so, it means that the triangle has high planarity. By analogy, calculate the planarity of different triangles, the triangle from which the best planarity is chosen represents the local area. As a result, the region has been expanding. This process is called planar proxies.

It is assumed that the input mesh presents a near-flat portion that can be detected by common shape detection methods. These near-plane parts are represented by planar proxies. More specifically, a plane proxy consists of a set of vertices and a plane ax+by+cz+d=0, denoted as [a b c d], where n = [a b c] is a flat unit normal vector. As shown in Figure 2, a processed 3D model, in which different colors represent different plane proxies.

Figure 2 the model of the plane proxies detected

3.2 Edge collapse operator

All text must use the Times New Roman font. Edge Collapse $e=v_0v_1 \rightarrow v$ is a mesh operation that merges two vertices v_0 and v_1 into a unique vertex v. The grid extraction algorithm based on the edge collapse is usually as follows: (1) For each edge fold $v_0v_1 \rightarrow v$, the cost associated with the error metric and its corresponding placement strategy are defined to design the local optimal point location for finding v. (2) Calculate the initial priority heap of the edge folding operator at a cost increase. (3) Iteratively extract the lowest cost operator from the heap and calculate its best location. Collapses the relevant edges and updates the priority heap on the edge of the local neighborhood. Based on the quadric error metric for each defined operator, details of the cost and optimal location are determined.

3.2.1 Title Page Error Quadrics

In the early years, GH associated each vertex with a quadratic matrix, which represented an approximation of the error between the current and initial grids. The quadratic plane is designed as a 4*4 matrix, represented by (1), and then the square sum of the distances to these quadratic planes can be further calculated.

$$Q_P=PP^T=\begin{pmatrix} a^2 & ab & ac & ad \\ ab & b^2 & bc & bd \\ ac & bc & c^2 & cd \\ ad & bd & cd & d^2 \end{pmatrix} \quad (1)$$

The sum of the square of the distance from point v to the plane list (Pi) is represented in (2). The advantage of this quadratic form is that it can be encoded with only 10 coefficients, and this formula can calculate the distance from one point to any plane.

$$\sum d(v,P_i)^2=\sum v^T P_i P_i^T v=v^T\left(\sum Q_{P_i}\right)v \quad (2)$$

Based on the previous matrix method by GH, this article optimizes the square sum of the distance from point to point from the following three aspects: (a) to reduce the square sum of the distance from the vertex to the plane of the triangle mesh adjacent to it; (b) to reduce the sum of the squares of the distances from the vertex to the plane where it is adjacent to the plane proxy set; (c) to reduce the boundaries of agents and grids.

Inner quadric The proposed method adjusts the inner matrix of the structure and optimizes Q_p proposed by GH. For a triangle $t\in T_K$, plane P_t where t is located, we denote as Q_{Pt} the quadric of P_t. For the plane proxy φ, we denote as Q_φ the quadric where proxy is located. The set of proxies that contain t is represented by Proxies (t). The quadric Q_t for each triangle t of T(e) is given by (3).

$$Q_t=\begin{cases} Q_{P_t} & \text{if Proxies(t)}=\emptyset \\ (1\text{-}\lambda)Q_{P_t}+\lambda\sum_{\varphi\in \text{Proxies(t)}} Q_\varphi & \text{otherwise} \end{cases} \quad (3)$$

Then, the quadric form of the edge e is defined in (4)

$$Q_{inner}(e)=\sum_{t\in T(e)}|t|Q_t \quad (4)$$

Here, λ is called an abstraction parameter and provides a way to fidelity conversion between mesh and proxy. For example, when parameter λ = 1, that is, both proxies go through edge e, vertices are selected at the intersection of plane proxies. When the parameter λ=0 or no plane proxies passes edge e, the quadric only approximates to the local error measure of the mesh. A larger value for λ means faster removal of proxy details during decimation and faster abstraction. The higher value for λ results in a lower proxy error, but the approximation error is larger compared to the original mesh.

Boundary quadric For any edge e'∈R, a plane e'∈R, define $Q_{e'\varphi}$ as the quadric of the plane that passes through edge e' and is orthogonal to plane R. $E_{\partial K}$ represents a set of edges in K|φ that is only contained by one triangle. For model boundaries $e'\in E_{\partial K}$, t_e' is the only triangle in K|φ that goes through e'. The boundary quadric of an edge e is then defined in (5).

$$Q_{bdry}(e)=\sum_{e'\in E_{\partial K}}|t_e'|Q_{e',t_e'}+\sum_{E_{\partial K|\varphi}}|t_e'|Q_{e',\varphi} \quad (5)$$

In (5), the first part avoids overly simplifying the mesh boundaries to prevent the flat mesh from collapsing to a single point at any cost. The second part preserves the structural characteristics of the proxies. The proxy φ accommodates more information by restrictive triangulation than just an infinite plane. This process increases the sensitivity of the mesh to a simplified structure.

3.2.2 Cost and Placement

The GH algorithm consists of calculating the initial quadric Qv for each vertex v and then summing the distances from each edge collapse operator to the plane. More specifically, for the collapse operator $e=v_0v_1 \rightarrow v$, the quadric of e (Qe) is calculated by adding quadrics of its two vertices v_0, v_1 so that the optimal vertex position v is obtained via the minimized cost V^TQ_VV. Compared with the GH, we recalculate Qe from the current mesh before each collapse operator in terms of improving the efficiency of approximation error.

The process of our method is as follows.

The decomposition quadric matrix Qe is given by (6).

$$Q_e=\begin{pmatrix} A & -f \\ -f^T & g \end{pmatrix} \tag{6}$$

Among (6), A is a 3*3 matrix, f is a vector. Minimizing V^TQ_VV involves solving linear problems Ax = f. When all vertices adjacent to e are distributed in only one or two planes, the determinant of A is 0.

Compute the singular value decomposition *A* in (7).

$$A=U\Sigma V^T \tag{7}$$

where U and V are 3*3 matrixes, whose column vectors are mutually orthogonal. Σ is a 3*3 diagonal matrix whose diagonal values, called singular values, decrease from the upper left corner to the lower right corner.

The diagonal value in Σ is defined in (8), λ_i is the eigenvalue of A.

$$\Sigma_{ii}=\sqrt{\lambda_i} \tag{8}$$

The diagonal value Σ_{ii} decreases in descending order, then truncate the small eigenvalues of Σ and store the result in Σ^+, as shown in (9).

$$\Sigma_{ii}^+=\begin{cases} 1/\Sigma_{ii}, & \text{if } \Sigma_{ii}/\Sigma_{11}>\varepsilon \\ 0, & \text{otherwise} \end{cases} \tag{9}$$

where Σ_{11} denotes the largest singular value, and the parameter ε is set to 10^{-3}.

$\hat{x}$ denotes the center of gravity of the vertices of v_0 and v_1, the singular value decomposition of Qe is shown in (10).

$$x=\hat{x}+V\Sigma+U^T(f-A\hat{x}) \tag{10}$$

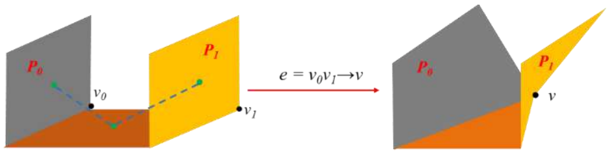
Calculate the optimal position of the vertex v after the collapse operation $e=v_0v_1 \rightarrow v$. Proxies(v) set is determined by Proxies(v_0) $\cup$ Proxies(v_1) when collapsing the edge e, and the quadric of e is defined in (11).

$$Q_e=(1-\mu)Q_{inner}(e)+\mu Q_{bdry}(e) \tag{11}$$

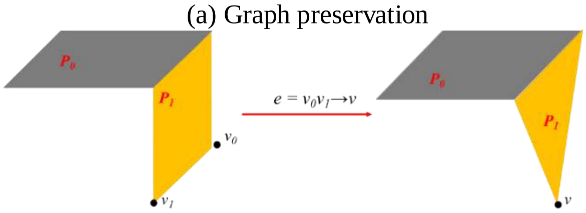
Where $\mu\in(0,1)$ is a parameter used for internally simplifying transaction boundaries. The optimal position for *v* is obtained by the solution of Qe and the cost V^TQ_VV of folding edge *e* is decided.

3.3 Structure-preserving

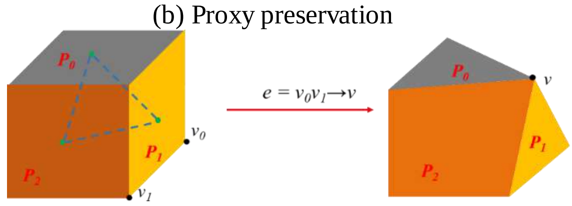
During model simplification, the best graph of the proxy coincides with the corresponding adjacency graph, such that a cube is represented by a double octahedron. In practice, however, it is not possible to have all the proxies correctly detected, and all the vertices are arranged on the same plane as the one to which they belong. Using the sufficient information about the adjacency graph in terms of the arrangement of the structure, three model structure preservation rules are formulated to prevent the structure of the model from being destroyed. These three rules are graph preservation, proxy preservation and corner preservation, Figure 3 is the rule diagram.



(a) Graph preservation



(b) Proxy preservation



(c) Corner preservation

Figure 3 Three types of edge collapsing prohibited

Graph preservation The two parts that are not connected in the graph should not be connected during the simplification. Only when all the proxy pairs in $Pv = Pv_0 \cup Pv_1$ are edges in the original set of G, do we perform edge collapse $e=v_0v_1 \rightarrow v$. Like Figure 3(a), the original two planes P_0P_1, which do not intersect, cannot intersect.

Proxy preservation A planar proxy may degenerate into a vertex or an edge during model simplification. To prevent this situation, as shown in Figure 3(b), the improved QEM algorithm refuses to perform this edge folding operation when the number of vertices forming this proxy is below the user-specified parameters after the edge-folding operation.

Corner preservation To prevent losing corners or migrating vertices away from corners, like Figure 3(c), we need to accurately detect and protect these corners during simplification. The vertices intersected by every three proxies are generally different, so we need to find the best vertex position for the intersecting proxy, taking advantage of the scale-space traversal.

4 Results and Discussions

The focus of this paper is to study mesh model compression techniques to enable the construction industry to conveniently apply 3D models. Therefore, this paper selects two 3D models, an industrial building and a residential building, respectively, for model compression experiments. Table 1 shows the specific information of the two models before and after compression. Figure 4 and Figure 5 show the factory model and the resident building model, respectively.

It can be seen from Table 1, Figure 4 and Figure 5 that the simplified model still retains certain details when the simplified multiples reach high levels. In particular, some of the more complex structures, such as trees, etc., are less simplified than the rest of the model. For large complex models such as factories and residential buildings, the proposed algorithm can maintain the approximate shape of the model and reduce the loss of structural details of the model, while achieving a large simplification multiple.

This algorithm is further compared with GH and LT methods, taking the resident building model as an example. The effect is shown in Figure 6.

Both methods show the approximate shape of the simplified model. However, the proposed method is highly simplified in the planar area, and the meshes in the highly complex details are basically preserved, and the reduction effect is better. The flat part of the model, such as the roof part, etc., because of its simple structure, can be relatively more streamlined to save more space. This method flattens the roof plane into several large triangles, saving space for characterizing the undulating models. Non-planar parts, such as trees, cars, etc. in the model, are less simplified to better illustrate these details, which reduces the loss of structural details. In contrast, the proposed algorithm simplifies the various parts of the model in different degrees according to the complexity of the structure. The proposed algorithm can preserve the integrity of the model while maintaining a high compression efficiency, whose compression method is feasible for models with a large amount of data.

Figure 6 Compression of the two methods for residential building models

5 Conclusion

In this paper, an improved method for simplifying complex models of large scenes in architecture is proposed, which can better preserve the details of the model compared with the classical algorithms. Experiments show that the proposed algorithm simplifies the various parts of the model in different degrees according to the complexity of the structure. This preserves the details of the model as much as possible. With the same simplify multiple, the proposed method has a greater advantage in displaying the details of the model. The proposed algorithm greatly improves the accuracy of the simplified model under the premise of ensuring the compression ratio. However, this paper uses the region growing algorithm to detect plane proxies. This process is complicated and takes some time, which increases the compression time of the model. Future directions will be to refine algorithms to reduce the time required for model compression.

Abstract –

Using multiskilled manpower refers to the ability of dynamically reallocate labour from one stage of production process to another one in response to bottlenecks configuration. This paper investigates improvements in tangible performance measures which can be achieved by incorporating multiskilled workforce in off-site construction. To this end, scheduling in off-site construction analysed in flowshop environment with multiskilled human resource in which operations processing time depends on the amount of human resource allocated to it. The objective of this optimisation problem is to minimise production makespan taking into account labour costs associated with different flexibility strategies. To this end, a mathematical framework incorporating flowshop principles developed, formulations coded in an open source programming interface and solved with a commercial solver providing free license to academic usage. Production data from a prefabrication factory based in Melbourne, Australia fed to the model providing a basis for comparison based on different indicators of productivity. The findings of this study are insightful for human resource development in off-site construction by providing cost and productivity corresponding to different multiskilling strategies.

1 Introduction

Several factors including increasing workforce wages [1], shortage of skilled workforce [2] and a general boost in construction completion time [3] contribute to decrease productivity in the construction industry. Using prefabricated construction is one of managerial and technological innovations to compensate aforementioned pitfalls [1]. Precast construction enhance productivity in different manners including but not limited to reducing costs of site supervision [4], reduction in delay [5] and better construction quality [6]. However, disintegrated processes is a fundamental consequence of prefabricated construction [7]. Crosstraining of workforce is an appropriate way of dealing with task heterogeneity [8].

Crosstraining of workforce simply means learning multiple skills to workers so they can be assigned when and where they are needed [9]. Crosstraining of workforce is beneficial for the employer by enhancing productivity and quality [10] and advantageous for employees by increasing employability, safety and job satisfaction [11,12]. The drawback of incorporating crosstraining is outlined as decreasing efficiency with increasing the number of skills [13] learning and forgetting effects [14], switching costs [15], training cost [16], and extra salary [17].

Despite, body of literature investigating crosstraining in on-site construction is considerable [3,10,13,18,19], off-site construction literature mainly focused on single skilled crew [20]. Considering high potential of enhancing productivity with incorporating multiskilling in manufacturing [9] and semi-manufacturing environment like prefabricated construction [7] enhancing productivity by using crosstrained workers in off-site construction is a significant area of research.

The novelty of this research originates from employing and modifying operational research techniques to evaluate the effect of construction related human resource strategies on performance measures of prefabricated construction with a reasonable solution time. Presented method has the capacity to incorporate a wide range of human resource policies and can be calibrated to deliver different objective functions.

To this end, this study identifies principles of flowshop applicable to off-site construction [21] and presents a mathematical modelling approach to optimise makespan of production as the most famous productivity measure in shop environment [22], incorporating multiskilled workforce taking into account crosstrained manpower cost.

2 Literature Review

Crosstrained labour allocation problem is a subset of human resource allocation problem in which all or some of workers should be multiskilled. Human resource allocation problem is to optimise the use and allocation of human resource with an aim to maximise or minimise certain functions [23].

Despite, there are several techniques in operations research and management science literature for resource allocation problems [24] no one is directly applicable to the construction industry and modifications should be applied on them [19]. Therefore in the following section, selection process of an appropriate framework to solve multiskilled human resource problem in off-site construction argued.

Since, the critical path method does not properly works in precast production [20] considering general production layout, repetitive routines, precedence and dependency of different products, it is suggested to implement principles of flowshop scheduling in precast production [5]. Additionally, optimisation of production performance such as makespan and flow time in prefabricated construction shifts the problem formulation toward shop scheduling in general and flowshop scheduling specifically [20].

A classical flowshop problem defined as a problem which consists of two main elements: a group of M machines and a set of N jobs which should be processed in these machines [22]. There are four basic assumptions for a classic flowshop problem: the jobs should be processed in all of the machines, job splitting is not allowed, operations are non-preemptive and set up times are included in the processing time [22]. There is a wide range of assumptions for different settings of a flow shop problem however, flowshop problem with and without permutation are the best fit to optimise off-site construction scheduling [21].

Considering applicability of flowshop principles to off-site construction with single skilled human resource policy few studies investigated performance of makespan pertaining to specialist manpower [1,20,25,26]. To the best of our knowledge so far there is no study which investigates enhancing productivity in precast construction implementing crosstraining techniques using flowshop fundamentals.

Referring to management science and operations research literature few studies investigated productivity enhancement within flowshop framework via full crosstraining of workforce [27,28] and partial crosstraining of crews [29]. Considering our research follows same objective in off-site construction context, on one hand, and taking into account similarity of off-site construction and manufacturing [21], on the other hand, reviewing this literature exposed same principles with some modifications can be used in our study.

3 Problem Description

Notation (n,m) is an indication of processing product n in workstation m when $\mathrm{N} = \{1,2,\ldots,\mathrm{N}\}$ is set of products and $\mathrm{M} = \{1,2,\ldots,\mathrm{M}\}$ is set of workstations. $\mathrm{W} = \{1,2,\ldots,\mathrm{w}\}$ is set of workers and $\mathrm{K} = \{1,2,\ldots,\mathrm{K}\}$ is set of status meaning the number of workers which can be allocated to a specific operation. $\mathrm{T} = \{1,2,\ldots,\mathrm{T}\}$ is set of time periods where T is upper bound on makespan. Equation (1) requires each procedure to have a unique status and corresponding specific completion time.

$$\sum_{k=1}^{K}\sum_{t=1}^{T}\theta_{nmkt} = 1\,, \qquad n \in \mathrm{N}, m \in \mathrm{M} \qquad (1)$$

Equation (2) presents behaviour of binary variable θ_{nmkt}.

$$\theta_{nmkt} = \begin{cases} 1 \; if\ operation\ (n,m)\ with\ k\ labour\ finished\ at\ t \\ 0 \; otherwise \end{cases} \qquad (2)$$

Given d_{nmk} is duration of procedure (n,m) when k workers are assigned to it, actual duration of procedure (n,m) indicated by D_{nm} is computable according to the equation (3).

$$D_{nm} = \sum_{k=1}^{K}\sum_{t=1}^{T} d_{nmk}\,\theta_{nmkt}\,, \qquad n \in \mathrm{N}, m \in \mathrm{M} \qquad (3)$$

Completion time of procedure (n,m) indicated by C_{nm} can be calculated as formula (4).

$$C_{nm} = t\sum_{k=1}^{K}\sum_{t=1}^{T}\theta_{nmkt}\,, \qquad n \in \mathrm{N}, m \in \mathrm{M} \qquad (4)$$

Constraints (5) and (6) satisfy the requirement for flowshop problem with permutation.

$$C_{nm} \geq C_{n(m-1)} + D_{nm}, \qquad n \in \mathrm{N}, m \in \mathrm{M} \qquad (5)$$

$$C_{nm} \geq C_{(n-1)m} + D_{nm}, \qquad n \in \mathrm{N}, m \in \mathrm{M} \qquad (6)$$

Let a_{wmt} and s_{wm} be binary variable and binary parameter behaving as equations (7) and (8), respectively.

$$a_{wmt} = \begin{cases} 1 \; if\ worker\ w\ is\ allocated\ to\ station\ m\ during\ [t-1,t) \\ 0 \; otherwise \end{cases} \qquad (7)$$

$$s_{wm} = \begin{cases} 1 \; if\ worker\ w\ is\ trained\ to\ be\ staffed\ in\ station\ m \\ 0 \; otherwise \end{cases} \qquad (8)$$

Inequality (9) denotes that workers can just be allocated to workstations for which they are crosstrained.

$$s_{wm} \geq a_{wmt}\ , \qquad w \in \text{Ẁ}, t \in \text{Ţ} \tag{9}$$

Total labour cost, denoted by Q, can be computed as equation (10) considering q_w be daily cost of labour a_{wmt}.

$$\sum_{m=1}^{M}\sum_{t=1}^{T}\sum_{w=1}^{W} q_w a_{wmt} = Q \tag{10}$$

Constraint (11) insures that in each interval of time each worker can just be allocated to one workstation.

$$\sum_{m=1}^{M} a_{wmt} = 1, \qquad w \in \text{Ẁ}, t \in \text{Ţ} \tag{11}$$

Equation (12) match operations status with needed number of labour.

$$\sum_{k=1}^{K}\sum_{t=1}^{T}\sum_{w=1}^{W} \theta_{nmkt}\, a_{wmt} = \sum_{k=1}^{K}\sum_{t=1}^{T} k\ \theta_{nmkt}\, , \quad n \in \text{Ņ}, m \in \text{M̧}, \tag{12}$$

Equation (13) force labour to remain in workstation for the whole duration of operation.

$$\sum_{k=1}^{K}\sum_{t=d_{nmk}}^{T}\sum_{l=t-d_{nmk}+1}^{W} \theta_{nmkt}\, a_{wml} = \sum_{k=1}^{K}\sum_{t=1}^{T} a_{wml} d_{nmk} \theta_{nmkt}\, , n \in \text{Ņ}, m \in \text{M̧}, w \in \text{Ẁ} \tag{13}$$

4 Case Study

The case which is adopted in this study is a modular prefabrication factory that produces bathroom pods located in Melbourne, Australia. Figure 1 shows twelve processes in the production line corresponding to their order in the real fabrication layout. S and L are indications for workstations and labour, respectively. Table 1 shows workstations operation in sequence. At the moment, no crosstrained worker employed in this production line equivalent to no flexibility scenario in which traditionally one worker is allocated to each workstation. There are three bottlenecks in this production line in labour, carpenter and electrician

Table 1. Workstations' operation

Work station	Operation	Work station	Operation
S1	Labourer	S7	Carpenter
S2	Caulker	S8	Electrician
S3	Mechanical contractor	S9	Water-proofer
S4	Tiler	S10	Glazer
S5	Plumber	S11	Joiner
S6	Plasterer	S12	Painter

workstation. Site manager of case study factory believed single skilled workforce should be allocated to bottlenecks. Figure 2 is an illustration of this decision. Figure 3 and 4 illustrate direct capacity balancing and chaining multiskilling strategies which already investigated in off-site construction [7,8]. Red lines show secondary skills making single skilled labour multiskilled. Last strategy is hiring multiskilled workforce and allocate them to bottlenecks which is already investigated in linear construction projects [17].

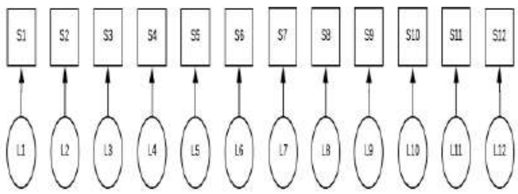

Figure 1. No flexibility

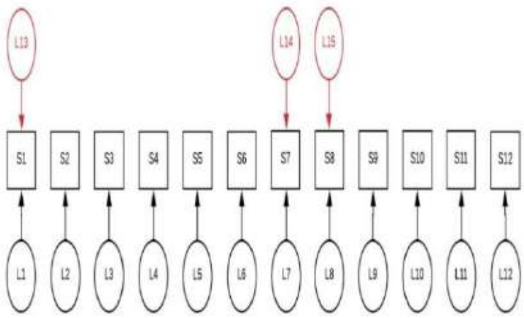

Figure 2. Hiring singleskilled crew

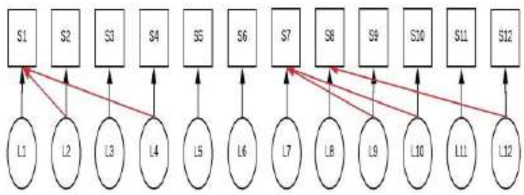

Figure 3. Direct capacity balancing

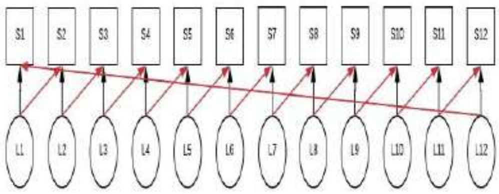

Figure 4. Chaining

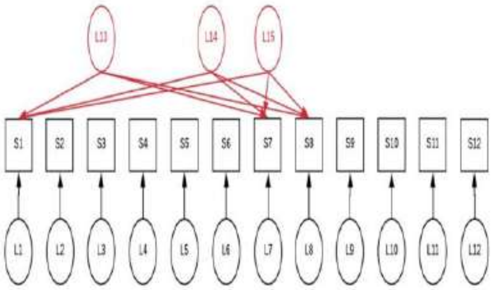

Figure 5. Hiring crosstrained crew

5 Results

Table 2 reflects outputs of computation pertaining to different human resource strategies' in terms of makespan and cost for production of 10 bathroom pods. No flexibility, hiring singleskilled crew, direct capacity balancing, chaining and hiring crosstrained crew abbreviated as NF, HSC, DCB, Ch and HMC, respectively. Also, makespan, makespan variation, cost and cost fluctuations abbreviated as M, MV, C and CF. Considering no flexibility strategy, makespan is 44 days with labour cost of 73776 AUD. To deal with bottlenecks site manager suggested to hire three single skilled workforce and allocate them to bottlenecks. Despite, by applying this strategy there is 27% improvement in makespan however significant amount of 78% enhancement in labour cost suggest this is not a good strategy. Direct capacity balancing led to 32% improvement in makespan and 25% decrease in labour cost which makes this strategy attractive. Implementing chaining leads to 27% decreasing in makespan and 26% enhancement in labour costs. The result of hiring crosstrained workforce is significant by bringing the most improvement in makespan equivalent to 41% and enhancement in labour cost equivalent to 17% which makes this strategy appropriate to deal with tight deadlines.

Table 2. Performance measure corresponding to different human resource strategies

	Human resource strategies				
	NF	HSC	DCB	Ch	HMC
M	44	32	30	32	26

6 Conclusion

Review of literature exposed optimisation of multi-skilled human resource problem in off-site construction is a promising area of research. Flowshop environment is recognised appropriate to incorporate prefabricated construction principles. A mathematical programming approach adopted to model scheduling processes in prefabrication context to allocate crosstrained crew to appropriate operations to optimise production makespan. An open source programming interface and a commercial solver employed in coding process. The findings of this study facilitate decision making with regard to appropriate crosstraining configuration considering makespan and labour cost. Also, this study presents a new understanding with regard to interaction of crosstraining configurations, labour costs and production makespan as a measure of productivity. Formulations which are presented in this study have the potential to incorporate other performance measures such as idleness and tardiness which can be used in future studies. Other industries in which productivity directly interacts with the number of human resource can use principles of this study.

Abstract –

This paper extends the development of a responsive built-environment capable of expressing intelligence with respect to both ICTs and Adaptive Architecture. The present implementation is built with mutually informing *Design-to-Robotic-Production & -Operation* (D2RP&O) strategies and methods developed at *Delft University of Technology* (TUD). With respect to D2RP, a responsive stage built with deliberately differentiated and function-specific components is revisited and modified. With respect to D2RO, a partially meshed, self-healing, and highly heterogeneous *Wireless Sensor and Actuator Network* (WSAN) is expanded to integrate proprietary-yet-free cloud-based services. This WSAN is equipped with *Machine Learning* (ML) mechanisms based on *Support Vector Machine* (SVM) classifiers for *Human Activity Recognition* (HAR). The frequency and/or absence of certain activities, in conjunction with processed data streamed from environment-embedded sensing mechanisms, trigger actuations in the built-environment in order to mitigate fatigue, encourage activity / interactivity; and to promote general well-being in the user. A voice-enabled mechanism based on Amazon®'s *Alexa Voice Service* (AVS) is integrated into the ecosystem to connect the built-environment with services and resources in the *World Wide Web* (WWW). Furthermore, a notifications mechanism based on Google®'s Gmail© API as well as Twilio®'s REST© API enable instances of fatigue to be reported to third-parties. The present interdisciplinary development attempts to promote an alternative approach to existing *Ambient Intelligence* (AmI) and *Ambient Assisted Living* (AAL) frameworks.

1 Background and Introduction

This paper builds on the implementation presented in the *34th International Symposium on Automation and Robotics in Construction* (ISARC) 2017 [1]. As such, it continues to promote the concept of *high-resolution intelligence* in the built-environment driven *by Design-to-Robotic-Production & -Operation* (D2RP&O) [2] strategies and methods developed at *Delft University of Technology* (TUD). D2RP&O establishes an unprecedented direct link between design, robotic production, and operation. While D2RP is informed by variations of structural, programmatic, performative (both physically and computationally), and assembly considerations, D2RO operates as a distributed and decentralized system architecture, which is employed to serve as the nervous system of the building. The resulting built-environment is characterized by adaptiveness and interactivity with respect to ICTs as well as to *Adaptive Architecture*.

The present development continues to build on the responsive stage by combining the previously detailed features and scenarios (see [1]) with the following new features both with respect to the built-environment:

1. *Proof-of-concept* implementation of global and local ventilation systems in order to ascertain both optimal temperature and humidity ranges (as determined by the *Comité Europeen de Normalisation* (CEN) Standard EN15251-2007 [3]; and air-quality via a variety of air pollution (see Figure 2, Section 3.1).

And with respect to *remote / cloud-based services*:

2. Integration of *Amazon*®'s *Alexa Voice Service* (AVS) [4] into the system (see Figure 3, Section 0);
3. Integration of (a) SMS notification capabilities via Twilio®'s *REST© API* [5] and Siemens®*'s T35 GSM* component/shield and standard prepaid SIM-card (see Figure 4, Section 3.3); (b) email notification capabilities via Google®'s Gmail© API [6].

As well as with respect to a new modified deployment scenario, where the adaptive stage invites the user to engage in activity if prolonged physical inactivity is detected (Figure 5, items 21 and 22).

2 Concept and Approach

The present implementation expands on a previously developed WSAN [1] to include four main subsystems, briefly summarized as follows:

1. *Local System*: A variety of Microcontroller Units (MCUs) and development platforms (e.g., Raspberri Pi 3 (RPi3) and Zero W (RPiZW)) serve as nodes dependent on a local structured environment. More powerful nodes may be clustered dynamically to yield a single node with higher computational power depending on load-requirements. All nodes exchange data in a combination of wired (e.g., Ethernet, USB, Serial) and wireless (WiFi, BLE, and ZigBee) protocols, depending on latency and frequency requirements.
2. *Wearable devices*: A set of three LightBlue Beans™ (LBBs) conform the location-dependent wearables while a Fitbit® Charge HR™ activity tracker represents the location-independent wearable. The LBBs detect movement in the upper-body, upper- and lower-extremities and advises the system to listen for *Open Sound Control* (OSC) packets corresponding to accelerometer data sent from a smartphone for *Human Activity Recognition* (HAR). The activity tracker enables a constant feed of physiological data while the user is outside of the structured environment.
3. *Ad hoc Support devices*: In the last five years, smartphones have become convenient and ubiquitous tools for HAR via *Machine Learning* (ML) [7, 8], which in conjunction with their battery life and rechargeability render them a preferred means of accelerometer-data gathering in intelligent built-environment implementations.
4. *Remote / Cloud Services*: Six cloud-based services conform this subsystem: (I) external ML mechanism via MATLAB® (in case the local ML mechanism fails); (II) data exchange with Fitbit®'s servers via its API [9]; (III) cloud data-storage and -plotting via Plotly®'s API [10]; (IV) Amazon®'s *Alexa Voice Service* [4]; (V) automated SMS notifications, both via Twilio®'s API [5] as well as via a T35 GSM module; and (VI) automated email notifications via Gmail©'s API [6].

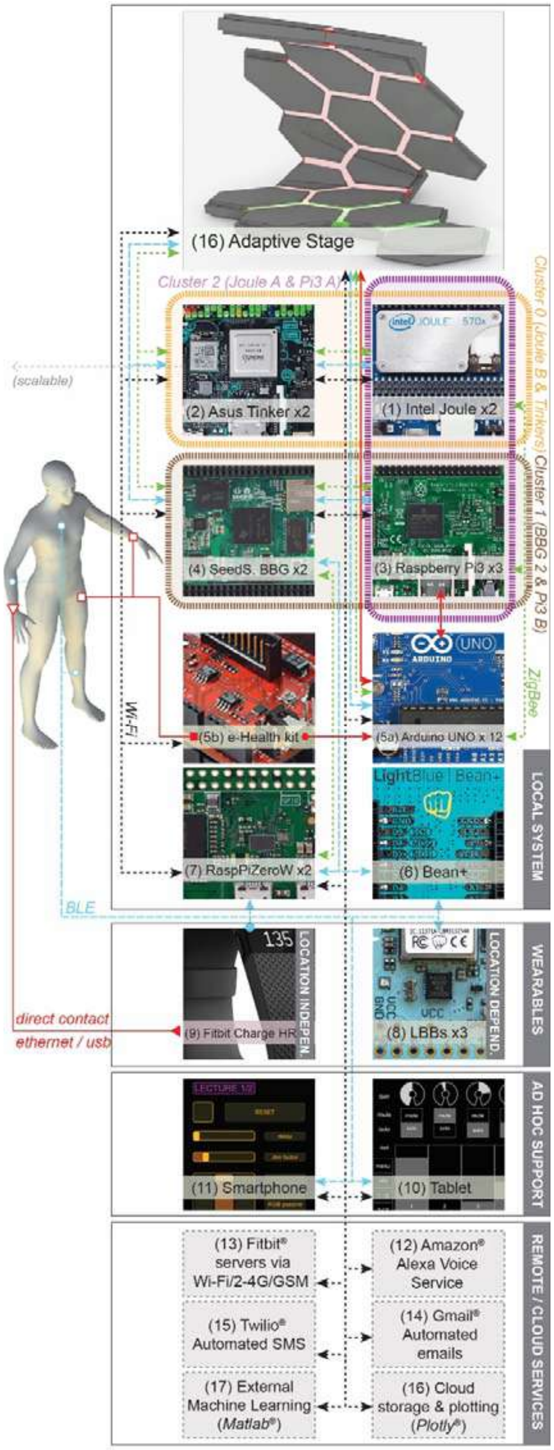

Figure 1. Heterogeneous System Architecture.

3 Methodology and Implementation

3.1 Global / local ventilation mechanism

This mechanism is first implemented and tested via an abstracted surrogate model equipped with twelve DHT-22 temperature and humidity sensors, twelve air-quality sensors (viz., three of each MQ-3 *Alcohol*, MQ-4 *Methane*, MQ-7 *Carbon Monoxide*, and MQ-8 *Hydrogen Gas*), and twelve small DC-motor fans connected to three RPiZWs and one RPi3 (see Figure 2, *Top*). Since the *General-purpose input/output* pins (GPIOs) of these devices are digital while the air-quality sensors are analog, 10-Bit MCP3008 ADCs are used to create a bridge.

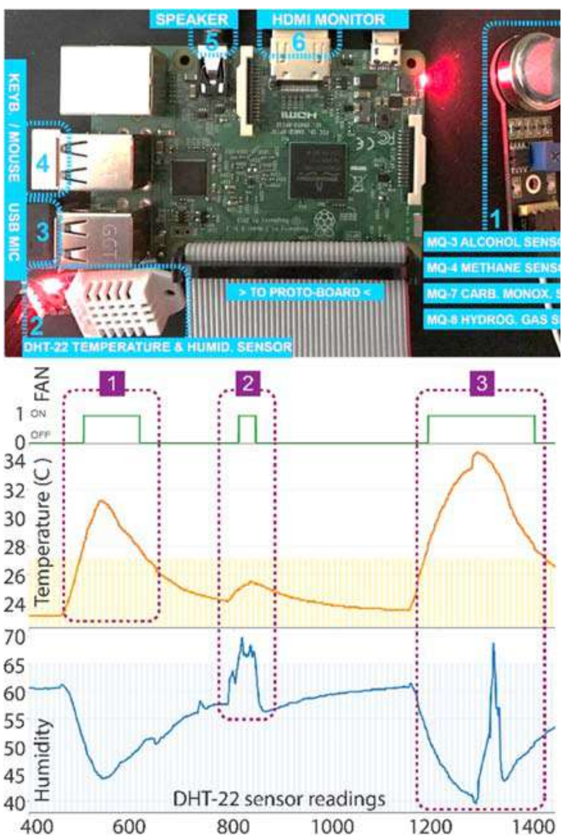

Figure 2. Top: Typical node: (1) Air-quality sensors: *MQ-3 Alcohol* or *MQ-4 Methane* or *MQ-7 Carbon Monoxide* or *MQ-8 Hydrogen Gas*; (2) *Temp. & Hum.* sensor; (3) USB Mic.; (4) Keyboard / Mouse (only necessary for config.); (5) Speaker; and (6) HDMI Monitor (optional). Bottom: Activation of ventilation fans in relation to temperature and relative humidity comfort thresholds (shaded).

As corroborated by the *Comité Européen de Normalisation* (CEN) Standard EN15251-2007 [3] as well as the *American Society of Heaeting, Refrigerating and Air-Conditioning Engineers* (ASHRAE) Standard 55-2013 and Standard 62.1-2013 [11], the *Thermal Environmental Conditions for Human Occupancy* with respect to comfort should be 67 to 82° F. (~19.5 – 27.8° C.) [12], while relative humidity in occupied spaces be less than 65% in order to discourage microbial. Furthermore, independent of human comfort considerations, frequent and consistent ventilation reduces the concentration of toxins in the air as well as the prevalence of airborne diseases [13].

In this TRL-5 setup, if the collective temperature or humidity levels exceed said recommended limits for comfort, all the fans activate, thereby drawing fresh air into the inhabited space (i.e., Global ventilation concept). If, however, certain areas exceed either or both limits, only those fans within and surrounding them activate (i.e., Local ventilation concept) (see Figure 2, *Bottom*). The same concept holds for instances of air-pollution

3.2 Voice-control mechanism via *Alexa Voice Service*

This mechanism is implemented and tested (see Figure 3) via the same RPi3 mentioned in the previous section (see Figure 2, *Top*), an open-source repository using Amazon®'s API [14], and a generic microphone as well as repurposed speakers. A secondary device is also built based on an RPiZW node both to serve as backup and to instantiate an emphatically low-cost (i.e., USD ~$15, as of writing) alternative to even the most affordable of Amazon®'s Echo™ product (viz., the Echo Dot™, at USD $49.99 [15]). The flexibility of developing custom—and more affordable—Alexa-enabled Devices permits virtually any built-environment device, whether deployed in an architectural or an urban context, to capitalize from AVS.

Two main objectives inform the present integration. The first is to enable a powerful and scalable voice-control mechanism within the present development. The second is to demonstrate a cohesive technological heterogeneity between an open-source WSAN and a proprietary commercial service without additional cost (with respect to Fitbit® and Gmail©) or with minimum cost (with respect to Twilio®). This latter consideration connects a local intelligent-built environment with vast resources in the WWW, enabling the user to engage in a variety of activities from streaming music to purchasing groceries via devices fundamentally embedded into the built-environment.

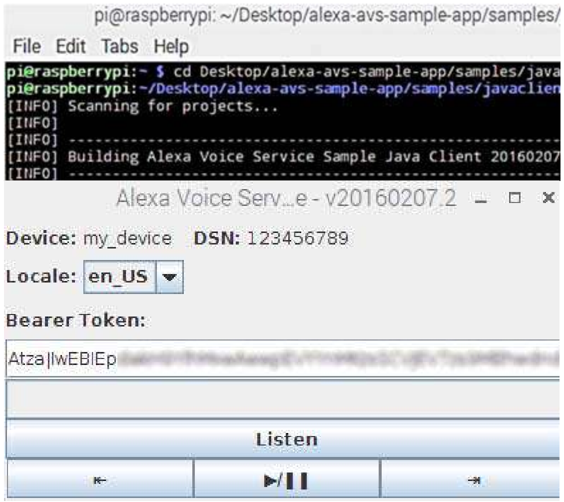

Figure 3. Top: Java Client service initialization. Bottom: AVS Java Client interface initialization.

3.3 Intervention via SMS and email notification mechanisms

This mechanism, inherited from an earlier implementation [16], is presently implemented and tested via a RPiZW node, a smartphone, and Twilio®'s as well as Gmail©'s APIs. Additionally, a non-web-based contingency device was developed using a Siemens® T35 GSM shield mounted on an Arduino® UNO™. The main objective with this implementation is to setup the foundations of an increasingly comprehensive intervention framework capable of reacting to emergency events, both with respect to the inhabitants of the built-environment and with this environment per se.

The Twilio® implementation represents a cost-effective SMS service, while the T35 GSM setup represents a standard prepaid SMS service. A scenario may be entertained where the built-environment's WiFi service is unavailable for a period of time, yet the integrity of the WSAN's *Local System* remains uncompromised as its constituents remain networked via ZigBee and BLE. In such a scenario, an emergency event may be reported via the T35 GSM setup, as it relies on standard cellular communication. Conversely, another scenario may also be entertained, where cellular services are unavailable due to lack of coverage. In this scenario, emergency events may be reported via Twilio®'s SMS service to any location worldwide.

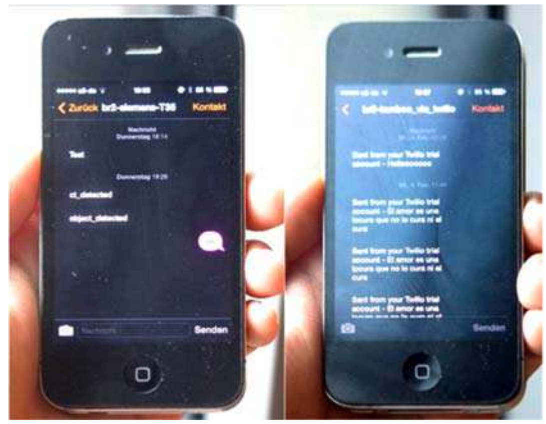

Figure 4. Left: SMS via WiFi (Twilio®). Right: SMS via *Siemens T35 GSM* module.

3.4 Closed-loop Runtime Implementation

In order to describe how the above-detailed mechanisms integrate into the proposed development, a point-by-point runtime description is provided as follows:

1. The *Local System*, as the core of the WSAN and backbone of the ICT ecosystem, initializes and establishes the network in multiple communication layers (WiFi, BLE, ZigBee). For security reasons, only registered MAC addresses are provided with IP addresses. Once the network is established, all *Linux*-running systems update and upgrade.
2. *Wearables* communications initialize. The WSAN draws available data from Fitbit®'s servers and begins to listen for LBB notifications as well as to listen and record BLE / OSC accelerometer data.
3. *Remote / Cloud-based Services* communications initialize—i.e., *OAuth 2.0* tokens are provided, authentication and authorization are established. Received accelerometer data are streamed to and plotted by Plotly® used for local HAR, if a suitable classification model is present.
4. Since the deployment context is that of GSM3, the system checks if the responsive stage is being used by a lecturer.
5. If a lecturer is on-stage, the system checks if a suitable ML classification model is available.
6. If no ML models are available, local HAR considerations are omitted from subsequent decision-making processes—e.g., whether to activate ventilation systems if the lecturer is assumed to be agitated via Fitbit® data (see points 12 and 13).
7. Presupposing the availability of the SVM model

mentioned in point 3, the HAR mechanism is initialized—i.e., processed accelerometer data are set against the model and prediction begins in real-time.

8. All sensing systems—embedded, ambulant, and location dependent wearable—are initialized and verified.
9. Raw data are gathered, cleaned, processed, and made available across the entire network.
10. The data from point 9 are written into the (i) local ML and (ii) remote ML datasets (optional) for a subsequent model generation.
11. Similarly, said data are streamed, plotted online, and made available for remote monitoring.
12. When the system detects the presence of a lecturer on stage, it determines that the lecturer is probably physically agitated if (i) sweat sensors (see Figure 1, item 5b) detect perspiration; (ii) temperature and humidity sensors detect an increase in temperature and relative humidity in the overall environment in general, and in user-occupied areas in particular; (iii) the wearable LBBs detect an increase in body temperature; and (iv) the most recent Fitbit® data evidence existing and sustained physical activity.
13. Having determined a high probability of physical agitation, all the fans in the ventilation system activate until readings return to CEN recommendations. In the interest of time, this ventilation mechanism is developed and tested via a scaled surrogate setup. The ICT-configuration concept presented is asserted to function across a variety of physical forms within human scale.
14. After symptoms of agitation cease (e.g., heart-rate normalizes, body temperature falls within recommended levels, and perspiration is not detected), the system continues to check if the temperature and humidity readings of the environment comply with CEN recommendations.
15. As a strategy for responsible energy consumption, if the environment's temperature and humidity readings remain too elevated for comfort after a given period of global ventilation (in this runtime: two minutes), the ventilation system switches to ventilate only the areas surrounding the user. If external conditions raise temperatures across the entire environment, it is pointless to condition unoccupied areas.
16. In parallel to point 14, the system also checks for air-quality via its MQ-*n* sensors (see Figure 2, *Top*) independently of temperature and humidity readings.

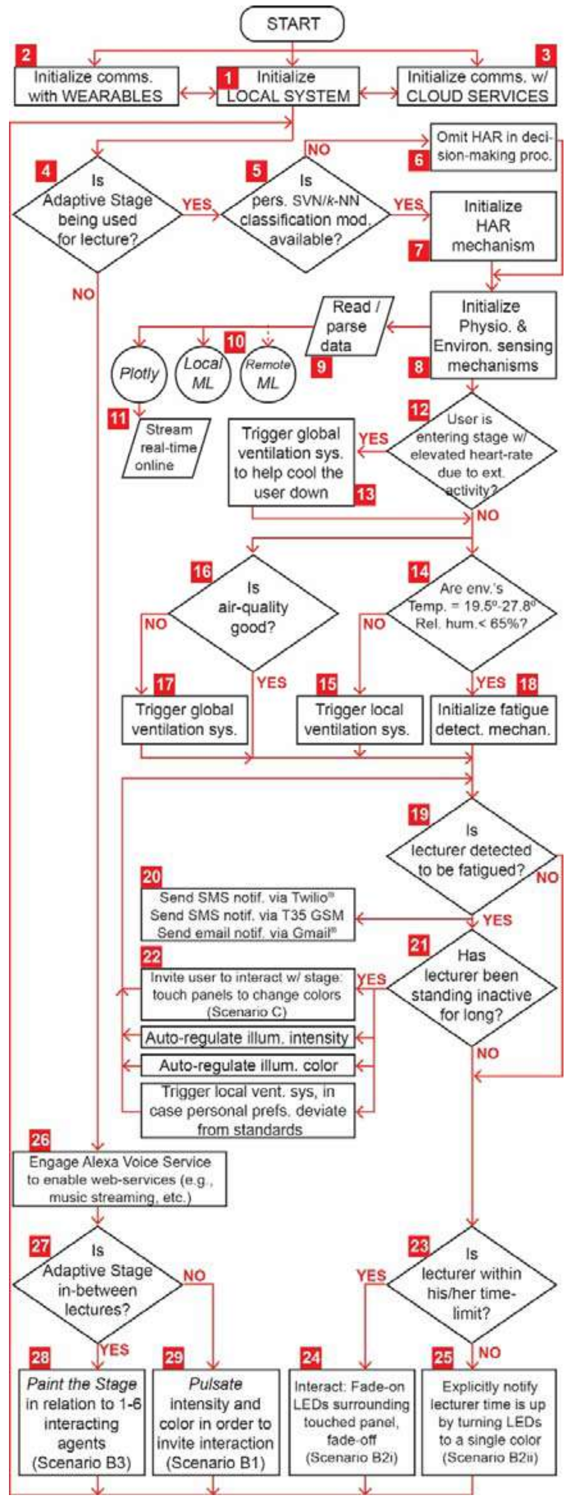

Figure 5. Runtime decision-tree.

17. The strategies for mitigating high-concentrations of toxins and reducing the prevalence of airborne diseases differ from the temperature and humidity strategies above in that global ventilation is engaged for the duration of detected poor air-quality. Even across unoccupied spaces, it remains in the occupant's interest to sustain air-quality.
18. Following point 14, if the lecturer is not agitated, and if the thermal conditions of the occupied space are optimal, the system begins to watch for potential symptoms of fatigue. In this development, fatigue is considered a possible consequence of sustained agitation and/or of normal wear while engaged in *Activities of Daily Living* (ADLs). That is to say, fatigue may be brought upon by concentrated and extraneous physical activity and/or simply by growing tired engaging in ADLs throughout the day. The fatigue-detection mechanism used in this development is inherited from ISARC 2017's implementation [1]—that is to say, it is a limited adaptation and modification of the *human state estimation system* developed by Nakaso *et al*. [17].
19. The fatigue-detection system relies on a camera—in this case a Microsoft® Kinect™ V2—and a face and eyelid-aperture detection classification model developed in MATLAB. If the lecturer is detected to be probably fatigued—e.g., his/her eyelids droop, activity levels decrease, acceleration in movement decreases—then the following two intervention mechanisms activate:
20. SMS notifications regarding the lecturer's state, including average heart-rate, temperature, acceleration, steps taken, and distance covered are sent via Twilio® and via T35 GSM. These notifications are shorter than the one sent via Gmail©, where an hour-by-hour overview of activity levels—in some predetermined period of time—are fully detailed. The degree of detail may vary depending on the purpose of the notification. In this development, these SMSs and email are triggered by detection of fatigue, yet these mechanisms serve as indicators of promising application potential.
21. In conjunction with triggering the above passive intervention mechanisms (i.e., such that notify yet do not mitigate or promote), the system considers activity data for the last hour to determine the amount and concentration of inactivity. If the lecturer has continuously stood still for longer than fifteen minutes, the system considers this inactivity as an exacerbating factor in the detected fatigue.

Figure 6. Interactive stage in action at GSM3 conference.

22. Accordingly, the responsive stage triggers four active intervention mechanisms (i.e., such that mitigate and/or promote) sequentially (see Figure 5, item 22). That is, upon detecting prolonged inactivity, components in the responsive stage fade-on varying colors and intensities to encourage the lecturer to touch them (see Figure 5, item 22, first row). This, along other scenarios (i.e., Figure 5, items 24, 25, 28, 29, and 26 assisting) turn the stage into *de facto* playware. The second and third active intervention mechanisms (see Figure 5, item 22, second and third rows) auto-regulate overall illumination intensity and color of the stage's LEDs in case these be exacerbating factors of the detected fatigue. Finally, the fourth active intervention mechanism triggers local ventilation in case the lecturer's preferences deviate from recommended thermal conditions, and this be an exacerbating factor of the detected fatigue (see Figure 5, item 22, fourth row). In order to avoid looping between points 19-22 indefinitely, a reconfigurable time-out mechanism is set in order for the system to move forward, if there are no indications of improvement within twenty minutes.
23. Assuming a time-out from the previous point, or a lack of fatigue detection from point 19, the system proceeds to check if the lecturer is within his/her allotted time-limit.
24. If the lecturer is within this time-limit, the stage enables the lecturer to activate instances of fade-on / fade-off by touching components for visual interaction. This scenario ends when the time-limit is reached.
25. If he/she is outside this time-limit, all LEDs turn on

to a single color as a visual queue to the lecturer that time is up. This scenario ends when the moderator confirms thus via OSC confirmation. Having concluded this or the preceding scenario, the system returns to point 4.

26. Returning to point 4, having explored the consequences of the reactive stage being occupied by a lecturer, the consequences of it not being occupied are now detailed. If the stage is empty, then AVS may be engaged for playful and/or entertainment purposes. That is, AVS is habilitated as soon as the WSAN is conformed (back in point 3), but in this development, it is only engaged when the stage is empty. In practice, as was carried out in initial sample runs of this point-by-point outline, AVS was engaged in a lecturer scenario.
27. At this point the system decides to engage one of two other inherited play / entertainment scenarios depending on whether it is in-between lectures or not. In this development, the state confirmation is provided via OSC confirmation.
28. If the stage is in-between lectures, the scenario in item 28, Figure 5 activates. In this scenario, the audience is invited to interact with the stage by *painting it*. That is, depending on the position and movement of identified body-parts of up to six people (via Microsoft® Kinect™ V2), different regions of the stage will change in color and intensity in direct correlation with the articulation of said parts. This scenario ends when a lecturer wearing the LBBs returns to the stage.
29. If, however, the stage is simply on a day off, the scenario in item 29, Figure 5 activates. In this scenario, the stage pulsates like a *beating heart* in order to invite interaction from anyone in a passive manner. This scenario ends via OSC confirmation. Having concluded this or the preceding scenario, the system returns to point 4.

4 Discussion and Conclusion

The detailed development attempts to promote D2RP&O strategies and methods as enablers of an alternative approach to intelligence in the built-environment, here identified as high-resolution intelligence. This approach merges ICTs as well as Adaptive Architecture considerations in order to yield a holistically and comprehensively adaptive, reactive, and interactive dwelling space capable of providing local and remote services. In this paper, these objectives were illustrated via the extension of a proof-of-concept implementation whose subsystems were developed to high TRLs and tested in naturalistic scenarios. Particular to this paper, three new features or mechanisms are presented and described, each retaining promising potential for expansion. In particular, the first mechanism, viz., Amazon®'s AVS is an especially important complement to the system in that its scope of service is open-ended. Via *Amazon Skills Kit* [18], custom skills may be designed and developed to accommodate environment-specific and purpose-built cost-effective devices, each capable of independent Internet access, effectively turning the dwelling space into a society of IoTs and people [19]. Furthermore, the possibilities extent to the urban scale, where public spaces may be envisioned to possess service capabilities that promote security, provide guidance, and support comfortable lifestyles.

At present, and in addition to on-going work on AVS's customized skills as well as more sophisticated ML mechanisms, work is being conducted to design and to develop an enclosable and integrated environment where an integrated ventilation system may ascertain *Interior Environmental Quality* [20], which is an indicator of comfort. It depends on thermal, acoustic, illumination, ventilation, and related parameters [21], and thus far only illumination, ventilation, and partial thermal aspects have been considered. Although IEQ lacks a globally accepted index [21], it is known that when its parameters deviate from comfortable thresholds, stress mechanisms are occasioned in the human body that—if left unmitigated—may potentially cause or exacerbate disorders and diseases [22]. Such considerations prompt an urgent reassessment of prevalent architectural strategies, especially since people spend the majority of their time indoors [23].

Acknowledgement

This paper has profited from the contribution of TUD Robotic Building researchers, tutors, and students. In particular, the authors acknowledge students Benjamin Kemper and Daniel Fischer for the physical development of the GSM adaptive stage detailed in this paper.

Abstract –

Automation is generally assumed to improve project productivity. However, not enough research is done in the area of quantitative methods to evaluate productivity improvements through automation in construction. The aim of this study is to develop a methodology for analyzing productivity of any given automation system for construction. A case study of an automation system developed in-house is used for illustration and validation. This system involves automated connections of column modules and coordinated lifting of the column assembly. A laboratory experiment has been done using this system for constructing column structures using modular blocks. The experimental results are compared with their equivalent manual processes. These studies are conducted using EZStrobe simulations which are calibrated using experimental data. Of the various project performance parameters, only time has been included in this study. The results would throw light on the impact of automation on construction activities on-site.

Keywords –

Construction Automation; Modular Construction; EZStrobe

1 Introduction

Automation in construction industry has generated significant interest in the recent times. In many Asian countries, there is significant housing demand for addressing the growing population. Automated modular construction can potentially address this challenge by improving productivity through savings in time and cost. Even though it is generally understood that automated construction can reduce time and cost of projects, not enough research is done in the area of quantitative methods to evaluate productivity improvements through automation in construction. The general aim of this study is to develop a generic methodology for analysing productivity of any given automation system for construction. More specifically, our focus is on using simulation tools such as EZStrobe in combination with site measurements or laboratory experiments for predicting productivity parameters of different possible processes for a task.

2 Literature Review

Recently, there is renewed interest in performance analysis of construction projects using simulations. Many examples of simulation studies in different types of projects can be found in the literature [1-9]. The use of Discrete Event Simulation (DES) using tools such as EZStrobe is particularly gaining attention. Researches are done on the possibilities of combining Genetic Algorithm multi-objective optimization (GA) and Discrete Event Simulation (DES) using High-Performance Computing (HPC) to address the issues of time and cost in construction projects [10]. Limitations of queue-based DES and proposed a non-que-based DES have been studied [11]; There have been studies on the means of improving productivity of construction operations in New Zealand using EZStrobe simulation tool. These studies focused on improvement in planning using data from bridge launching operation [12]. Researchers have also used EZStrobe to study the productivity management of road construction in Thailand and arrive at optimised construction members with least unit cost [13]. There have also been studies on various simulation software used in construction industry and analysed their strengths and limitations [14]. Studies on Simphony simulation tool, its strengths and applications have also been conducted. The tool handles both discrete event as well as continuous simulations [15]. Some works have been done to develop activity-based cycle diagram for bridge construction process and applied it in simulation using

EZStrobe and studied its effectiveness [16].

Based on a review of recent literature in the area of simulation-based studies, it is very evident that there is hardly any work with regards to automation in modular construction. It is a significant area that requires attention and more research work is needed to answer the question: how much improvement in productivity can be achieved through automation in modular construction. This paper briefly illustrates a methodology for assessing productivity in automated construction.

2.1 Knowledge gap identified in the literature review

1. Various authors have worked in the area of modelling construction operations [17-29]. These works are focussed on certain areas such as earthwork, etc. There is hardly any research focussing on productivity studies of automation in modular construction of building structures [30-32].
2. A methodology that compares the automation of modular construction with manual modular construction and field construction practice has not been done so far.

3 Illustration of a Process-Performance-Assessment Methodology

A "Process-Performance-Assessment" methodology has been developed to achieve the objectives of this study. This involves performing discrete event simulations to calculate the time taken to complete the activities of the process. The productivity is computed by using the basic data related to the duration of completion of relevant activities. The overall construction process consists of a decomposition of tasks. Each task is further broken down into activities and sub-activities. The relationships between the activities are captured in the form of activity-cycle-diagrams (ACDs). The probability distribution of activities at the lowest level in the decomposition hierarchy are defined based on site data or laboratory experiments.

In order to illustrate the applicability of this methodology to a practical construction task, a specific example of column assembly is used here. The time performance of an automated construction scheme described in Figure 1 is evaluated using this methodology. It needs to be mentioned that the overall research involves the study of other parameters such as cost which are excluded in this paper. It is admitted that the cost of the automation unit is important from the point of large scale construction; however, this is outside the scope of this paper.

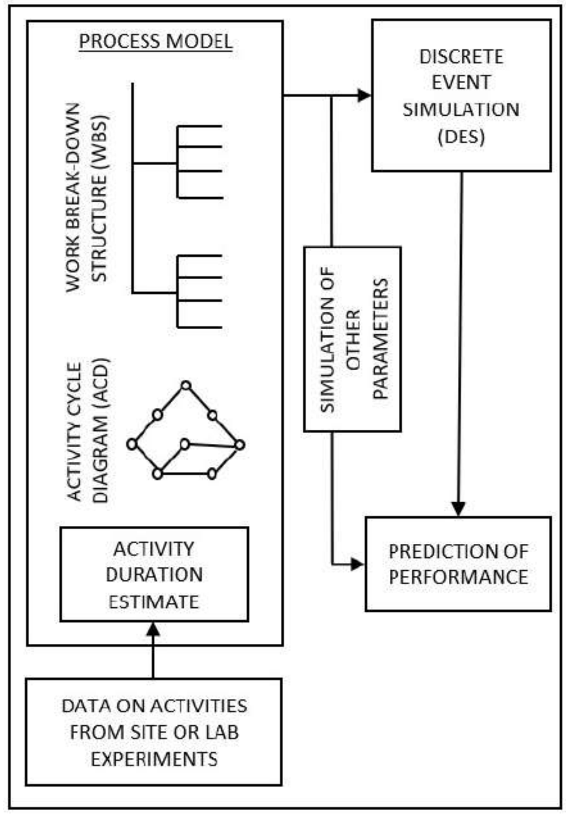

Figure 1. Process-performance-assessment methodology

Previously, an automated scheme using timber modules for the construction of structural frames of buildings has been demonstrated [32]. The idea proposed here is to construct the top floor first and then lift the top part in small steps in order to assemble the modules for lower floors. This will help in performing all the construction activities at the ground floor. This will also support automation since the assembly system can be permanently installed on the ground. The structure is constructed using small timber modules that can be easily assembled. The structural frame of the roof is constructed first. These are lifted using hoists and the columns are inserted below. Both the beams and columns are made of small modules.

The above automation scheme was later adapted for the construction of practical full-scale structures for residential buildings of 1-3 floors. An automated column assembly machine, shown in Figure 2, has been manufactured to illustrate the scheme. As an application example, the process-performance-assessment methodology is used to evaluate this construction scheme. The performance of the scheme is compared with equivalent manual processes in order to bring out the advantages of automation.

Figure 2. Modular column assembly by automation process: bottom to top assembly

Performance assessment involves two stages in this exploratory study:

Stage 1: collection of real time data of three construction processes: a) which is non-modular and non-automated; b) non-automated (manual) and modular; and c) automated and modular.

Stage 2: simulation study of the above three construction processes.

In this exploratory study, a typical column assembly construction is considered. A comparative study of automated process (Case-1) and manual process (Case-2) of modular column assembly; and field-based process of conventional Reinforced Cement Concrete (RCC) column construction (Case-3) is done. Further, simulation-based comparison of all these processes are done. Finally, an assessment of the productivity performance of automation process is analysed and reviewed.

3.1 Description of modular column and RCC Column

The modular column consists of a set of steel modular blocks with a set of connections. In this case, we have eight rectangular modules of dimension 400 (L) x 200(B) x 400(H) mm, as shown in Figure 3. These modules when stacked one above the other and connected will give a total height of 3200 mm. The RCC column is of dimension 300 x 200 x 3200. Reinforcement: 14mm rods 6 no.s; 8mm square hoops@ 100mm c/c and 25mm cover.

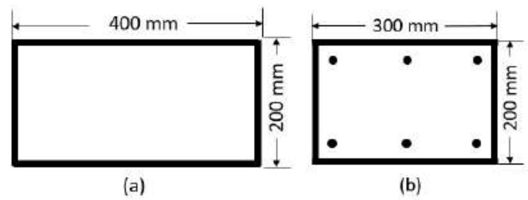

Figure 3. (a) Block module for column assembly and (b) Plan of RCC column

Assumption: It is assumed that the base foundation work is already completed. The column work is extended above the same. In the case of modular assembly, it is assumed that the top base of foundation has connecting component with respect to the first column module block. In the case of RCC construction, it is assumed that the top base of the foundation has extended reinforcement rods which shall be lapped with the column reinforcement during the RCC column execution work. The column reinforcement is already prepared by labour by tying the main rods and stirrups and it only needs to be attached by lapping to the foundation reinforcement. Shuttering is cleaned and oiled. Concrete batch is ready for pouring. Curing is done for 28 days.

4 Exploratory Study based on Laboratory and Field Experiments

The three cases mentioned previously are discussed below.

4.1 Case-1: Modular column assembly by automation process: bottom to top assembly

In Case-1, 8 modules to be assembled are stacked close to the automated assembly machine. Upon starting the machine by a technician, the lifting base would move to its initial position. The technician picks one module at a time, takes it to the machine and places it on the lifting base. The machine lifts up the module till it touches the partially assembled column above and makes the connection between the two using steel pins. Then the new column assembly is temporarily supported by load holding pins and the lifting base is lowered. The process is repeated until all the modules are connected.

4.1.1 Activities of Case-1 as modelled in the simulation tool

1. Start the column assembly process
2. Lifting of block 1: initial position: move to stack: hold one block: lift the block: move to assembly location: place in assembly location
3. Lifting of next block: initial position: move to stack: hold one block: lift the block: move to assembly location: place in assembly location above previous block.
4. Lifting of connector: initial position: move to stack: hold one connector: lift the connector: move to assembly location: place between current and previous block: Connection between blocks
5. Repeat steps 3 and 4 till total number of blocks is 8.
6. Stop the process.

4.1.2 Data collection for Case-1

The process of automated modular column assembly was performed in a laboratory setup in order to estimate the duration of activities involved. The experiment was repeated three times. In a typical experiment, the whole process was completed in 19 minutes and 1 seconds. Time taken for various activities are shown in Table 1.

Table 1. Typical observations of process duration in Case-1

Sl.no.	Process		Sub-activity	Duration (sec.)	TOT. duration (sec.)
1	At Initial Position	a	At Initial position	5	5
2	Lifting of block-1	a	move to stack	10	
		b	hold one block	4	
		c	move to assembly location	10	
		d	place in assembly location	4	
		e	Release the block	4	32
15	Lifting of block-8	a	move to stack	40	
		b	hold one block	4	
		c	move to assembly location	45	
		d	place in assembly location above previous block	4	
		e	Release the block	4	97
17	Back to initial position	a	Back to Initial position	45	45
	TOTAL		IN SECONDS		1146
			IN MINUTES		19.1

4.2 Case-2: Modular column assembly by manual process: bottom to top assembly

In Case-2, two labours are engaged in picking the module and positioning in the assembly location. One labour is positioned at the assembly location while the other moves to and from the stock. The moving labour picks one module at a time, moves to the assembly position and then both the labours place the module in position and check the correctness of positioning. Then the labour moves to take the next module and place it on top of the previous one.

4.2.1 Activities of Case-2 as modelled in the simulation tool

1. Start the column assembly process
2. Lifting of block 1: initial position: move to stack: hold one block: lift the block: move to assembly location: place in assembly location
3. Lifting of block 2: initial position: move to stack: hold one block: lift the block: move to assembly location: place in assembly location above previous block.
4. Lifting of connector-1: initial position: move to stack: hold one connector: lift the connector: move to assembly location: place between current and previous block: Connection between blocks
5. Repeat steps 3 and 4 till total number of blocks is 4.
6. Lifting of next block: initial position: move to stack: hold one block: lift the block: move to assembly location: board on base stool: place in assembly location above previous block: aboard from base stool
7. Lifting of next connector: initial position: move to stack: hold one connector: lift the connector: move to assembly location: board on base stool: place between current and previous block: Connection between blocks: aboard on base stool
8. Repeat steps 6 and 7 till total number of blocks is 8.
9. Stop the process.

4.2.2 Data collection for Case-2

The above procedure was tested in an experimental study and the time taken for each activity was recorded. Since this is only an exploratory study meant for illustration of the methodology, experiments were not repeated multiple times. Time lags were noticed in discussions, decision making, moving between the stock and assembly; positioning; connecting; and boarding and aboarding the base-stool for modules that were positioned above 1.6m. There were also issues of safety due to improper handling of modules during the assembly process. The whole process was completed in 1 hour 51 minutes and 24 seconds.

4.3 Case-3: RCC column construction by manual process

In Case-3, the sequence is Reinforcement placement; Shuttering; Concreting; De-shuttering and Curing. Six labours were engaged- two for reinforcement arrangements; two for shuttering and de-shuttering; and two for curing process. Initially, two labours were engaged in assembling the reinforcement by taking the already prepared reinforcement to be positioned at the RCC column assembly location. The reinforcements were tied by lapping with the rods projecting from the base of footing. Later two labours bring the shutters from the stock and position them at the lower part of the column, provide spacers and fasten the shutter panels. The two labours into concreting prepare the batch and take first batch to fill up to the top of shuttering level. The column is let to set for twenty-four hours and then it is de-shuttered by the two labourers and further positioned up to the next level and the same process is repeated. And finally, the shuttering is extended up to the top of the 3.6m column and concreting process is completed. After the setting and the de-shuttering, the column is cured by wrapping around with wet gunny sacks. The column is sprayed with water at 6 am and 6pm for 28 days starting from day-1 of de-shuttering of first batch casting till day-28 of the curing of the third batch casting.

4.3.1 Activities of Case-3 as modelled in the simulation tool

1. Start the RCC column assembly process
2. Reinforcement placement and tying:
   (a) initial position
   (b) move to stack: hold the rebar: lift the rebar: move to assembly location: place in assembly location: lap with the base rebar: tie with the base rebar
   (c) back to position
3. Shuttering:
   (a) Initial position
   (b) Move to stack: hold shuttering: lift shuttering: move to assembly location: place in assembly location: align in assembly location: fasten the shuttering
   (c) Back to position
4. Concreting:
   (a) Initial position
   (b) Move to concrete batch: hold one portion of concrete: lift the portion of concrete: move to assembly location: position in assembly location: pour the concrete
   (c) Back to position
5. De-shuttering:
   (a) Initial position
   (b) Move to assembly location: align in assembly location: un-fasten the shuttering: hold shuttering: lift shuttering: move to stack
   (c) Back to position
6. Repeat steps 3,4 and 5: twice, each after 24 hours.
7. Curing:
   (a) Initial position
   (b) Move to stock: pick gunny bag: Move to assembly location: Wrap around column
   (c) Move to water pipe source: turn on water: spray on column:
   (d) Move to water pipe source: turn off water: Back to initial position
   (e) Repeat steps c. and e. after 12 hours
   (f) Back to initial position
8. Repeat step-7 c-f till count is 28.
9. Stop the RCC column assembly process

4.3.2 Data collection for Case-3

Observations were done on construction sites in order to estimate the time for basic activities of the above process. Using this data, an estimate of the total time taken was made. The estimated total duration of the RCC column casting process was 31 days 4 hours 15 minutes and 19 seconds.

5 Simulation Study

EZStrobe is a general-purpose domain independent simulation tool that has been widely applied to construction operation studies. It functions primarily based on Activity-Cycle-Diagrams (ACD) and is used for productivity and optimization studies in construction. The process model consists of multiple queues representing activities that are repeated. The present simulation study is conducted for three scenarios namely: (1) process of column construction using modular blocks through automation; (2) process of column construction using modular blocks done manually; and, (3) manual RCC column construction process.

In the EZStrobe simulation model for Case -1, shown in Figure 4, the **Queue element** “Block” is assigned 8 numbers indicating the 8 modular blocks for the column assembly. It is linked to “Load” and releases one modular block at a given cycle. The **Conditional activity element** “Load” is linked to the Queue elements “Block”, “Holder_Idle” and “Move”. “Load” is assigned the duration in the range of 28 to 68. **Queue element** “Holder_Idle” is assigned 1 number indicating that at any given time, the holder of the assembly unit picks one modular unit. It is linked to “Load” in a cyclic loop. The **Bound activity** "Move" is linked to "Load" and "Assemble" as predecessor and successor activities respectively. "Move" is assigned the duration in the range of 20 to 68. "Move" activity functions after the "Block" loads one module to the holder of the automation unit. **Bound activity** "Assemble" is linked to "Move" as predecessor; and "Assembled_units" and "Release" as successor activities respectively. "Assemble" is assigned the duration in the range of 8 and 24. The module, after moving from the stock held by the holder of the automation unit, is placed at the assembly position.

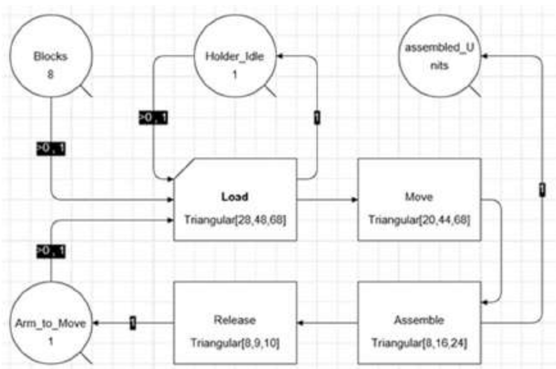

Figure 4. EZStrobe model of workflow for Case-1

Queue element "assembled_units" indicates the number of modular blocks assembled at the column assembly position. The **Bound activity** "Release" is linked to "Assemble" and "Arm_to_move" as predecessor and successor activities respectively. "Release" is assigned the duration in the range of 8 to 10. "Release" activity functions after a module block is assembled in position by the holder of the automation unit. **Queue element** "Arm_to_move" is the moving arm of the automation unit at whose end is the holder. The "arm_to_move" functions the moving between the stock and the assembly location for taking, placing and reverting to stock of modular blocks.

In Figure 5, EZStrobe simulation snapshot of Case-1 is shown. The EZSrtobe simulation controller displays the time taken for simulation with graphical display of stage of simulation. With the option of "Animate" and controlled "Animation Speed" we visualize the sequence of activities taking place. Here, we note the activities between assembling the block and releasing. The "triangular" indicates the minimum, mean and maximum time taken for the activity.

On running the simulation, a report is generated wherein there are series of parameters displayed and numerical values generated after completing the simulation runs. Some of the parameters are time of report, total amount of resource, average content, minimum content, maximum content and so on.

Up on simulation run, the durations of their assembly process are arrived. It is noted that Case-1 has the least duration of 18m 5sec.; Case-2 with the second least time duration of 1h 47m 38 sec., whereas, Case-3 took an execution time of 31d 4h 13m 57 sec. It also closely correlates with the field-based and laboratory measurements.

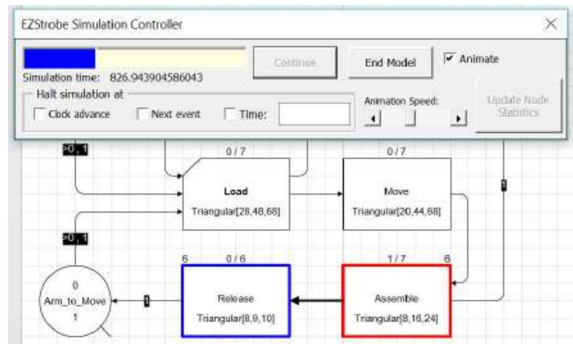

Figure 5. Simulation snapshot for Case-1

6 Comparative Results

The three cases represent three distinct approaches to construct a column and they show significant aspects of the assembly process. In Case-1 (i.e. Modular column assembly by automation process), it is noted that once the automation unit was stationed and positioned, the column assembling using the block is a cyclic process that went without any hindrance, obstacle or technical snag. The time duration taken for each activity and sub-activity is controlled and hence each repetitive activity took the same time duration. In Case-2 (i.e. Modular column assembly by manual process), it is observed that the two-labour executing the process had on and off discussions, deliberations, slowing and speeding up, erroneous assembling, etc. Further, they had to use a base-stool to climb above the height of 1.6m for assembling the modules that added time for work completions. There was also risk of tripping and falling; losing grip of the module from hand. Therefore, safety was also in question in this process. In Case-3 (i.e. RCC column construction by manual process), teams of two performed the tasks of reinforcement placement; shuttering; concreting; de-shuttering; and curing. And thus, this process involved the maximum labour resource. Also, the efficiency and quality of work kept varying throughout the execution. This impacted on the time delays and therefore on the overall productivity of the column construction process. In terms of time duration from these experiments, Case-1 took the shortest, while Case-3 took the longest duration. The simulation analysis further validates this.

7 Summary and Conclusion

This paper illustrated a process-performance-assessment methodology by which the productivity of automated modular construction can be evaluated. A selected automated modular construction process was compared with manual modular construction and equivalent common construction practice at site. A typical case of column construction was studied with modular blocks which were assembled manually as well as through automation. Equivalent study was carried out for an RCC column construction. All these cases were studied through EZStrobe based simulation and analysed. Results indicate that significant savings in construction time can be achieved through automation. Furthermore, the study demonstrates how a process simulation tool can be used to evaluate the overall performance of construction processes.

Future research involves testing the methodology on more complex tasks, collecting more on-site data and refining the methodology. Further research is planned to look into the decomposition of processes which shall lead to the greater degree of understanding on the levels of automation required in the construction process. This methodology also throws light on the positive impact of automation in the productivity of not only the assembly process but on further study shall also do so on the total project performance.

Abstract –

Interactive verification of construction works should provide for compliance between planned vs. completed works. The task of its fulfilment (especially for larger investment projects) is rather time and labor consuming. There is potential to reduce the duration of a verification process as well as to ensure the results are more accurate and clear with the use of digital tools and specialized software, moreover, substantial part of the process may be automated.

Faster and more accurate capturing of a data regarding actual position and shape of the construction works, resp. its parts, as well as the information about the quality of works has the potential to reduce number of disputes caused by unclear measurement data evaluation.

The technology of Terrestrial Laser Scanning (TLS) is suitable for this purpose allowing efficient data collection and automation of the process of verification. The article provides a case study comparing traditional approach vs. use of TLS for earthworks verification and the impact of different methods of measurement on the price.

Earthworks, Cost estimation, Quantity take-off, TLS

1 Introduction

Prior to the creation of the bill of quantity, the quantity surveyor must know the technology defined by project to set appropriate and indicative price. Indicative price includes items from the pricing database considering all relevant regulations and standards (safety, hygiene and fire protection). It is necessary to use the same or similar specifications and name conventions defined in national standard “STN 73 3050 Earthworks. General provisions” and at the same time in the software (based on reliable pricing database) where the indicative price was calculated. The bill of quantity is an integral part of the project to ensure that each tenderer can estimate the price according to the extent of work, without the risk of possible demand for additional extra work which can lead to budget overrun. The price estimation need to be well structured allowing to attach complete tasks list to invoice. This may be done after agreed period or frequency (weekly, monthly), on a task base or after complete delivery of work.

2 Terminology and Legislation

Pricing databases are based on **classification of the building construction TSKP** (Classification of Building Construction, Instruction No. 13/1977 of the Ministry of Construction of the Czechoslovak Republic on 30 December 1977 in co-operation with the Ministry of Construction of the SSR and in agreement with the FSÚ pursuant to Section 16 paragraph 2 b of Act No. 21 / 1971 Coll.) and **classification of works TSP** (Classification of Construction Works, declared by the Ministry of Construction and Regional Development Methodology No 1/2004, which entered into force on 1 January 2005. The class was issued on the basis of the Annex to Commission Regulation (EC) No 204/2002 on the statistical classification of production by activity in the European Community declaring the classification of construction works to be binding on the Member States of the European Union and on the basis of the Decree of the Statistical Office of the Slovak Republic No. 632/2002 Coll., which gives the statistical classification of production as amended issued on the basis of Act No. 540/2001 Coll. on State Statistics)[6]. According to TSKP, the earthworks are listed under code 800 - 1 Earthworks and according to the TSP Earthworks are listed under the code 01. Therefore, proper specification of the items is required.

For the proper use of items, it is also necessary to know the geology including the composition of soil that will be subject of earthworks from geological surveys. It is therefore necessary to know their class of rippability (*rippability is the ease with which soil or rock can be mechanically excavated)*, which is on national level classified in 7 classes. [1]

- 1st class - loose rocks - can be easily loaded by shovel, loader.
- 2nd class - rippable rocks - rippable by digging spade, loader.
- 3rd class - diggable rocks - rippable by digging spade, loader.
- 4th Class - solid crumbly rocks – rippable by spike, excavator
- 5th Class - Solid rocks with easy rippability – rippable by ripper, heavy excavator (over 40 tons), explosives.
- 6th Class - Solid rocks with difficult rippability - rippable by heavy rippers, explosives.
- 7th Class - Solid rocks with difficult rippability - rippable by explosives.

The items of the bill of quantity must be formally prepared so that all parties involved in the construction process have the same and unequivocal idea of the subject and that it would not be necessary to demand the extra work during the execution. In the case of a high-quality project, this requirement is fulfilled, because the most important influence on the price calculation of works on larger buildings is the chosen technology. The method of measurement is given by individual database makers. Example: The amount of excavation is determined in m^3 of soil volume in the unripped state from the dimensions given by the project, defined from the level of the adjacent terrain, while the adjacent terrain can be:

- for all terrain excavations, natural or terrain for the viewing of the orphanage or the carp after removal of the reinforced surfaces,
- in the shafts and rocks the bottom of each trench, except the bottom of the shafts and grooves,
- for pits, the bottom of the excavation or excavation or the bottom of the trench for the flowing water flows. [2]

The handling volume of the excavation obtained by the excavations in the dry environment and underwater subsoil (horizontal displacement, loading, etc.) is determined by the unripped soil volume on the trench. The volume of handling of the excavation obtained by the other excavations under water is determined in the solid state. [2]

3 Case study

The greenhouse construction of the object "SO08 Laguna" consisted in the first stage of the excavation of the Lagoon itself. Excavated soil was transferred and stored within the site (the property of investor). Next task was creation of waterproofing layer supplied with geotextile and drainage system for pumping the rain water into Lagoon. After the first stage of excavations, quantity quoted in the invoice was doubted by investor. Contractor declared that approximately half of the work was completed. Investor returned the invoice after control measurement was performed and asked for correction of values. The issue was, the results of the measurement of contractor and the investor varied. In both cases, the measurement was performed by a length scale (band).

Figure 1 Preparation of excavation works, Lagoon

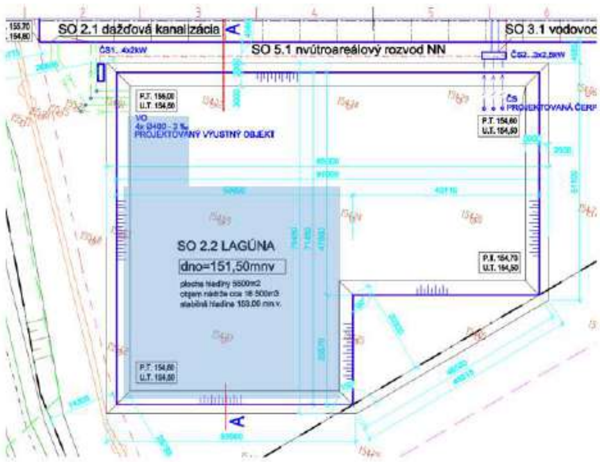

Figure 2 Layout of the Lagoon with identification of executed excavation (blue hatch)

Both the Contractor or the Investor (with notice from the other party) has the right to invite an third-party authorized person for independent measurement or to avoid dispute by specifying the subject of billing of earthworks (measurement and quantification) using an court expert in the form of a private expert opinion under *160/2015 Z.z. Civil Procedure Code, § 209* (If such a report has all the requisites prescribed and a clause that the expert is aware of the consequences of a knowingly false expert's opinion, then the procedure is followed as if it were an expert judgment ordered by the court).

3.1 Measurement and Legislation

An expert or authorized person has more options or devices to measure and verify the size of the work that was done. Differences in measurements by the construction manager and supervisor have arisen due to the use of various measuring instruments and various measurement errors. Measurement is a summary of activities to determine the value of the measured quantity. This value should be given along with the tolerance in which the right value of the measured quantity or the numbers corresponds to the corresponding values of the measurement result. This is particularly important today, where large numbers of computers are used for processing results. We do not get the correct value of the measured value by any measurement, since each measurement is made with error. The error characterizes the accuracy of the measurement by specifying deviation.

The base length is the meter (unit of length meter, symbol m is the length of the path that the light passes under the vacuum in 1/299 792 458 seconds) [4]

- a measurement unit is the specific value of a physical or technical quantity that is defined and accepted by agreement with which other values of the same species are compared in order to express their magnitude in relation to that specific value of the quantity,
- measuring instrument is device for determining the value of the measured quantity, including the measure, the measuring instrument, its components, the auxiliary equipment and the measuring device,
- the type of measuring instrument shall be a definitive design of the measuring instrument of a given design in accordance with the type-related documentation in which all components influencing the metrological characteristics are defined, manufactured by the same manufacturer,

Usage of specified instruments:

- Designated instruments may only be used for the purpose if they are validated if required.
- The entrepreneur or other legal entity is obliged (and - to use the prescribed instruments in cases where their use is stipulated (§ 8) and for that purpose there is a type of measure stipulated by a generally binding legal regulation, unless a special regulation7) has not granted an exemption, b - keeps the used measuring instruments in proper technical condition)

Designated meters according to Annex no. 1 to Decree No. 210/2000 Z.z. - Types of measured meters are rolling meters, bands, folding meters and winches in length measurements.

According to Annex no. 50 to Decree No. 210/2000 Coll., The measuring instruments referred to in point 1 (a) be broken down according to the principle of measurement

- balancing instruments,
- folding scales,
- winches.

According to the accuracy of the material length measurement, weighing instruments are divided into three classes of accuracy. The maximum permissible errors of the weighing instrument for initial and subsequent in-service verification are given in Table no. 1. [4]

Table 1 The largest permissible error

Accuracy class	The largest permissible error (positive or negative) in % of measured length
I	0,25
II	0,5
III	1

To determine the amount of work done within the excavation object in construction progress, measurement can be made by a measure (band or other meter) preferably with an accuracy class I, or with existing software support devices. Current technologies offer, in addition to measuring, simplification of measurement itself and processing of measurement results. [5] Their accuracy is significantly higher and data processing shorter.

3.2 Selected devices

The Lagoon was measured by contractor using the measurement bands and the resulting quantities are written in Table 2. The table is based on the transcript of the work done from the invoice attachment. The requirement to verify the number of works carried out arose from the investor side. The 3D Leica ScanStation2 scanner and Leica DISTO D 910 was selected to measure the excavation work on the Lagoon facility.

The procedure for determining the volume of the lagoon object consisted of:

- terrestrial laser scanning of an object,
- measurement by laser distance measure
- processing of measured data and creation of a 3D model and calculation of excavation volume

The Leica ScanStation2 was used for the measurement [6; 7; 8]. The spatial shape of the Lagoon was measured from two positions with a scanning density of 50 mm x 50 mm / 50 m. Opinions were linked through four landing points. The registering points were the Leica HDS target marks, which were stabilized on the measuring statues. The positioning points were determined in the S-JTSK coordinate system using the SK-POS Slovenian Space Observation Service.

Figure 3 On-site scanning of the Lagoon

Based on the position, the Cyclone software transformed the coordinates of the points from the individual positions of the instrument into S-JTSK and Bpv. The internal (relative) accuracy of the transformation is defined by the mean spatial error σxyz = 3 mm. The absolute accuracy of the transformation is characterized by a value of σxyz = 10 mm. The result of the transformation is the single point cloud of the object.

In order to determine the actual Lagoon volume, all shrubs and grassland that stood above the terrain were removed in the first stage of the measured data from the cloud point. (Figure 4)

In the second phase, a triangular network (TIN model) of the measured object was created from the combined dot cloud. The TIN model was created for the Lagoon itself (excavation pit) as well as for the original terrain.

The TIN model of the original terrain was created from the points of the Laguna surrounding. The volume of the Lagoon was determined by the difference model of the TIN models of the excavation pit and the original terrain.

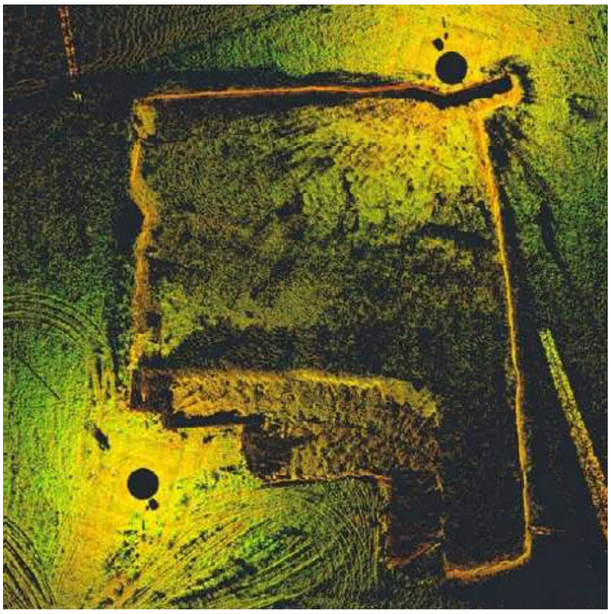

Figure 4 Point cloud, top view

3D view is generated using tools and commands in CAD programs. Moreover, it is possible to generate individual sections - Lagoon profiles and realized excavations. Using individual profiles and basic mathematical functions, volumes can be calculated, or model tools can generate volumes directly in the CAD program [9; 10; 11]. (Figure 5)

The second used tool for the measurement was Leica DISTO D 910. The Leica DISTO S910 (Figure 7) is the laser distance measurer that captures multiple, accurate measurements in three dimensions from a single location, radically improving the efficiency of common measuring tasks. The integrated Smart Base enables to measure distances (e.g. widths, distances) between any two points, angles or inclinations at the same time from one location.

Figure 5 Point cloud axonometry

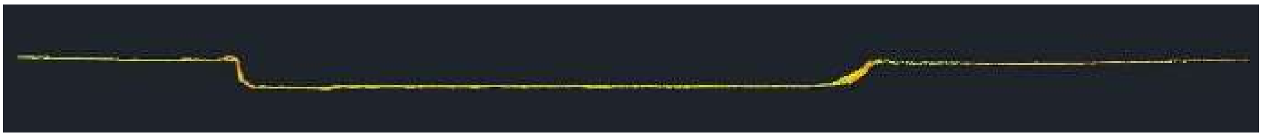

Figure 6 Point cloud, section through excavation

Figure 7 Measure with Leica S910

The Leica DISTO™ S910 can save all the measured points into a DXF file as a floor plan, wall layout or 3D point coordinates that can be downloaded to a PC via the USB interface. The schema of measurement is shown in Figure 8.

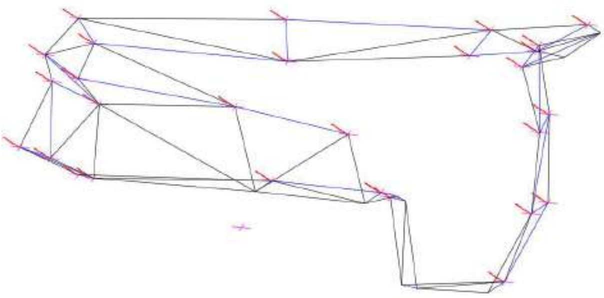

Figure 8 Measurement with Leica S910 – processed using CAD software

3.3 Measured values

In the table below, the values (dimensions) of each work are from the bill of quantity, as measured by the contractor versus scanner measurement (Tab. 3). Scanner surveys were carried out by an authorized surveyor. Cost of measurement by TLS exceeds the standard measurement (bandwidth or manual laser) available on the market, but the accuracy and processing of the results is on a diametrically different level. These instruments do not yet fall under the specified instruments, but the accuracy of the measurements is defined, and regular calibration is carried out. Scanner measurement and laser distance measure demonstrates a lower amount of actual execution of excavation work. Individual quantities multiplied by unit prices form a new total cost. The unit price is defined by the contract or by the open market [12; 13]. In the case of the use of the following materials in the excavations: concrete [14], underlying aggregates [15] or prospective materials [16], inaccurate measurement would result in increased price due to higher volume of material calculated.

Individual columns represent subsequently: number of the item, code of the task, task name, measuring unit, measurement value, unit price and price of task.

4 Conclusion

Measurement is a process that results in a measured value. Its accuracy often affects other aspects. The purpose of this case study was to compare the various measurement tools that allow to capture actual progress of work - in this case earth excavations. The measurement (volume of work) submitted by the contractor exceeded estimated quantity specified in the quantity take-off calculated from project documentation. To verify individual quantities, modern technologies and devices were used. TLS scanning and laser distance measurement in a combination with specialized software proven that the differences in the measured values are significant as the contractor used classical measurement methods.

As a result, the volume of 3 037.52 m^3 was measured by contractor. When multiplying by unit price, the amount of the work was calculated to € 44,651,544. By means of a verification, surveyor quantified the volume of works to 2 647.87 m^3 using TLS. After multiplying by unit price, the value equals to € 38,923,689. Secondary verification method – using distance laser measurement, the value of 2 745,523 m^3 was quoted. After multiplying by unit price, the value equals to € 40,359,188.

Both verification methods by professional devices (3D Leica ScanStation2 and Leica DISTO S 910) proven different – lower amounts of actual volume of work executed. The cost deviation between the calculation of contractor (using traditional technique) and surveyor is significant resulting in the reduction of costs by € 5,727.86 resp. € 4,292.35. In percentage terms, the savings are 9-12% compared to the original requirement of the contractor and that is considerable figure for both large and small-scale construction works in this sector. The cost of verification measurement is in most cases irrelevant to the potential savings of the investor and the digital technology needs to be an integral part of the construction industry.

A Data-driven Framework to Estimate Saving Potential of Buildings in Demand Response Events

X. Yu[a] and S. Ergan[a]

[a]Department of Civil and Urban Engineering, New York University, United States
E-mail: celiayu@nyu.edu, semiha@nyu.edu

Abstract –

In the U.S., the increasing electricity demand gives pressure on the power grids because of its limited capacity to serve demand. Instead of building new power plants to meet the increasing demand, Demand Response (DR) programs incentivize end-consumers to reduce certain electricity demand during certain periods (e.g., peak demand and emergency times). In the current practice, saving potential of buildings, i.e., the amount of electricity that end-consumers can save during an event, is usually determined using the technical specifications of equipment installed, which is unrealistic and leads to over or underestimation of the expected saving potential. In this study, the authors developed a data-driven framework to quantify the electricity saving potential in buildings. The framework was applied to nineteen campus buildings. Several prediction algorithms were used to fit models to the integrated datasets of these buildings, and models were evaluated using four criteria to avoid over-fitting and under-fitting. The best performance of the models resulting in 0.86 of R^2, which represents high capability to quantify the electricity saving potential. The contribution of this study is the proposed data-driven framework, which provides facility operators with reliable tools to accurately quantify saving potential of buildings. The conducted case study using the framework on 19 test buildings showed that facility operators could avoid unnecessary penalties by eliminating them to sign up for unrealistic targets, and help them to gain the most value out of the DR programs by knowing the true potential of their buildings.

1 Introduction

The electricity demand in the U.S. is in incline [1], which increases the pressure on power grids; hence the chance of electricity blackouts. In New York and California, electricity blackouts caused billions of dollars of loss to businesses and individuals [2][3]. Demand response (DR), one of the demand side management (DSM) techniques, is able to provide the necessary flexibility to the grid by incentivizing end-consumers to reduce their electricity demand during certain periods such as peak and emergency situations [4]. Meanwhile, building sector accounted for 74% of the total electricity consumption in 2016 [5], making buildings significant candidates for DR programs. In New York, buildings that were enrolled in DR programs managed to provide more than 31K MW/year of load curtailment and millions of benefits in recent years [6][7]. Hence, maximizing energy saving potential in buildings for DR is essential for peak reduction and energy savings.

The saving potential of a building (i.e., DR enrollment) refers to the amount of electricity that the building can save during a DR event. The problem in the current practice is that this potential is usually calculated based on simplified information such as design specifications of equipment in the building or historical metering data, resulting in the loss of opportunities to know the true energy-saving capacity of buildings. In the current practice, end-consumers usually work with third aggregators to determine the saving potential during DR events and customize their DR protocols. DR protocols are instructional statements for building operators to follow to operate major equipment in that building. For buildings which participated in DR program earlier, a yearly assessment is conducted by DR engineers and they will simply increase or decrease the DR enrollment by comparing the average performance on savings for events that happened in that year with the previous DR enrollments [30].

Buildings and the operation procedures are inherently much more complex than the simplified calculation due to their interconnections among their diverse systems [10]. Therefore, using the simplified calculation to estimate the energy saving potential can result in over or underestimation of the DR enrollment of buildings. Such performance issues were observed in the case-buildings analyzed for this study, as shown in Figure 1. The graph on the left indicates that *Building A* did not meet the DR enrollment (determined using the design information), which results in penalties for the end-consumer for exceeding the consumption beyond the enrollment value. The figure on the right illustrates that *Building B* saved more electricity during the event than the DR enrollment value, which indicates the potential money left on the table for the facility for not enrolling in more. Partly the problem was due to the lack of consideration of the context of the building during the event time such as different baseline values (i.e., the amount of the electricity that a building usually consumes under the same condition without DR operation), weather condition, and event time. These and similar examples from the literature [30] show that calculating saving potentials in DR programs simply using average benchmarking values from generic design specifications and not taking into account the context around event times result in a loss for building owners in either way. Hence, facility operators and third aggregators are in need of tools to accurately estimate the true potential of buildings by relying on integrated information including protocols, historical energy performance data, and contextual data around the event times (e.g., baseline values corresponding to the event times, weather data, etc.).

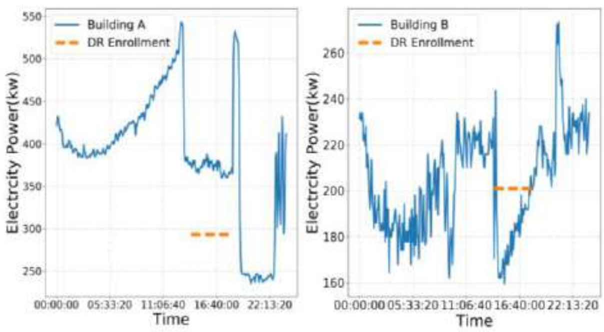

Figure 1. Performance of two buildings (Building A on the left, Building B on the right) during a peak event as compared to the DR enrollment (also marks the time range that an event occurred on the horizontal scale)

The objective of this paper is to quantify the true saving potential of buildings during DR events by integrated analysis of historical electricity consumption data, weather condition, DR protocol statements, and DR profiles (which provide information about DR event times, electricity consumption baselines, and DR enrolment values for buildings). Information from DR protocols can provide insights about buildings and equipment, and the electricity meter provides historical electricity consumption of buildings operated as the DR protocol instructions. In addition, the authors included weather condition information as it plays a crucial role in DR events and electricity consumption of buildings. A framework was developed by the authors for the stated objective, which is composed of two major modules: DR-dataset pre-processing and saving potential estimation. The details of the framework are presented in Section 3. The framework has been evaluated using data and protocols from nineteen buildings and six DR events that occurred in 2016.

The paper is structured as follows. A comprehensive review of the previous efforts on quantifying the saving potential of buildings in the literature has been provided in Section 2. In Section 3, the authors overview the framework and present the criteria to evaluate it. The implementation of the framework on nineteen buildings along with the results is discussed in Section 4. Section 4 also provides discussions on the challenges and future work. Conclusions are presented in Section 5.

2 Literature Review

There are three general types of models that have been used in previous studies to quantify electricity consumption and DR electricity saving potential: physical, statistical and simulation, and hybrid models [10]. Studies that developed physical models use equations and physics laws to predict saving potentials [8][9][18][19]. A large group of previous research studies concentrates on heating, ventilating, and air conditioning (HVAC) systems due to the fact that they account more than half of the energy consumption in buildings. Some of these studies developed simplified equivalent thermal parameters model to simulate saving potential for HVAC systems by adjusting the set-points [19-21]. While other studies implemented physical-statistical models to simulate the impact of adjusting parameters of HVAC systems on electricity consumption, which can further inform about the saving potential of HVAC systems during DR events [10][20][22][29]. Instead of using only HVAC system models, researchers also implemented physical models that include other systems that utilize electricity such as lighting, refrigerating, and appliances, and then quantified the saving potential by simulations of the testbeds [23][25]. These studies provide valuable insights of physical mechanism and potential knowledge. However, they usually are limited to the simplification of model equations and lack of consideration of the stochastic behaviors that happen in buildings- resulting in poor performance [10].

Statistical models, on the contrary, are developed based on experimental data. Large national level datasets of building energy use have been studied to identify the energy saving potential by comparing energy usage and data-driven saving analysis [26][27], yet the results from these studies are often in a very coarse-resolution, which cannot help DR engineers when determining the saving potential of a building for upcoming DR events. Researchers also compared the performance of both physical and simple statistical models for forecasting energy consumption in residential buildings as hybrid models and concluded that they both work with the slightly better performance than the statistical model (artificial neural network) [28]. Other than studies that emphasize the use of overall electricity consumption, load profiles of major household appliances were also utilized to identify their saving potential [24]. Despite the achievement of good results these models had in predictive modeling, they are often limited in the scope of certain purpose they aimed at in a restricted number of buildings/systems due to their inherent computational complexity [10].

This study is motivated by the need for accurately estimating the saving potential of different buildings during DR events. The framework developed in this study aimed at estimating the generic building-level saving potential instead of system-level saving potential by integrating the whole building energy consumption data, DR protocols, and contextual data around event times. This study differs from the studies in literature by providing a way to take into account contextual datasets that relate to DR assessment and analyze them in an integrated way using state of the art data-driven approaches.

3 Research Approach

3.1 Overview

The framework contains two main modules, which identify and extract the attributes to train the models, integrate datasets, and then fit models to estimate the electricity saving potential of buildings. The input of the DR dataset pre-processing is the DR protocol statements along with the building type, and a set of attributes for each building are extracted by the authors manually. Then, the extracted DR attributes dataset is integrated with other datasets from different sources, such as weather condition dataset, electricity meter dataset, and DR profiles (event time, electricity consumption baseline, DR enrollment). The second module, saving potential estimation, takes the integrated attributes dataset as input to fit machine learning models to estimate the electricity saving potential of buildings and provides the best performing model as a decision-making solution for facility operators for determining the true saving potential of buildings.

3.2 DR Dataset Pre-processing

In this study, the authors examined the DR protocols for a group of buildings to extract related attribute-pairs along with a building attribute: Building_type. The authors first categorized actions based on the equipment types and recorded the quantity of the impacted areas and equipment types. Details of this study are provided in a recent publication [11]. As stated in [11], DR protocols for buildings include five types of equipment: HVAC units (e.g., Air handling, fan coil, fan power units), fans, lights, elevators, and appliances. In this study, appliances are excluded because of its high dependence on occupancy data and lack of access to data on occupancy in spaces. For HVAC units, fans, and lights, the quantity of each equipment along with affected areas were extracted. Therefore, the data on attribute-pairs included: equipment_action and equipment_quantity for each equipment type.

The next step was to link the extracted data to the rest of the datasets. The weather information during the DR events is acquired from weather underground API [12], and the weather attributes included weather condition, temperature, humidity, and wind speed. The data on the DR profile of buildings included the electricity consumption baselines, the enrollment values and event times. More details of the datasets and the merging keys are provided in Section 4.2.

3.3 Saving Potential Estimation

3.3.1 Saving Potential Estimation Methodologies

In this module, the authors fitted several machine learning models to estimate the electricity saving potential of buildings. Because of the relatively small sample size and discrete categorical attributes in the studied problem, the authors chose decision tree regression model along with several boosting methods. There are mainly three types of decision trees: classification and regression trees (CART), C4.5, and C5.0 [13]. Among these decision trees, the CART is very similar to C4.5, yet it supports both categorical and continuous variables. Therefore CART is chosen to fit the dataset and estimate the electricity saving potential in this study. Furthermore, the authors used boosting algorithms such as Ada Boost and Random Forest to improve the performance of decision tree regression models. Both of the algorithms build multiple decision trees through iterations and take the average of the predicted value. Ada Boost is short for adaptive boost, which iterates the training process to build multiple decision trees and modifies the training data during each iteration and gives higher weight to the poorly modeled part [14]. Random forest algorithm, in addition to randomly selecting segmentations of the training data with replacement using the bootstrap method, also randomly selects the attributes when fitting the model.

3.3.2 Model Selection Criteria

One of the major advantages of the decision tree algorithm is that it is easier to interpret the result and can provide logic statements of the model [13][15]. However, it is also very easy to get over-fitted. In this study, the authors used four criteria, bias^2, variance, mean square error, and R^2, together to prune the model to avoid both over-fitting and under-fitting and meanwhile, aiming for adequately good prediction performance. Denoting N as the sample size of the training data, $\{f(1), f(2), \ldots, f(N)\}$ are the predicted values over the training data. The expected predicted value of the fitted model $f(x)$ is shown with $\overline{f(x)}$ (see Equation 1). Bias^2 captures the systematic error of the model (see Equation 2) [16]. When a model has a big bias^2 value, it indicates that the model is under-fitted, whereas big variance indicates the model is over fitted (see Equation 3).

$$\overline{f(x)} = 1/N \sum_{x=1}^{N} f(x) \quad (1)$$

$$Bias^2\left(f(x)\right) = \left(\overline{f(x)} - f(x)\right)^2 \quad (2)$$

$$Variance\left(f(x)\right) = E\left[\left(\overline{f(x)} - f(x)\right)^2\right] \quad (3)$$

The mean squared error (MSE) is composed of Bias^2 and Variance (see Equation 4), and measures the average squares of the errors, where Y denotes the observed data. Meanwhile, R^2 captures the capability of the model in explaining the observed data (see Equation 5).

$$MSE = 1/N \sum_{i=1}^{N} (f(i) - Y_i)^2 \quad (4)$$

$$R^2 = 1 - \left(\sum_{i=1}^{N} (f(i) - Y_i)^2 \Big/ \sum_{i=1}^{N} (Y_i - \bar{Y})^2 \right) \quad (5)$$

In Figure 2, the simplified relationship between variance, bias^2, and mean square error is demonstrated. As the complexity of the model increases, the Bias^2 decreases while the variance increases. There is an optimal point in the middle, where the variance meets with the Bias^2, and the mean square error is the lowest.

In this study, the authors visualized all four criteria to prune the models. For decision tree models, the authors iterated the depth of the tree from 1 to 10 to fit the models. For AdaBoost and Random Forest models, two parameters were included to iterate, the depth of the tree and the number of the tree estimators, both from 1 to 10. The optimal choice of the parameters was determined by the authors by visualizing the criteria, and the parameters with a lower bias, variance, MSE and higher R^2 were chosen. At last, the optimal models for each model were fitted and evaluated based on the average R^2 value among the cross-validation of the complete dataset.

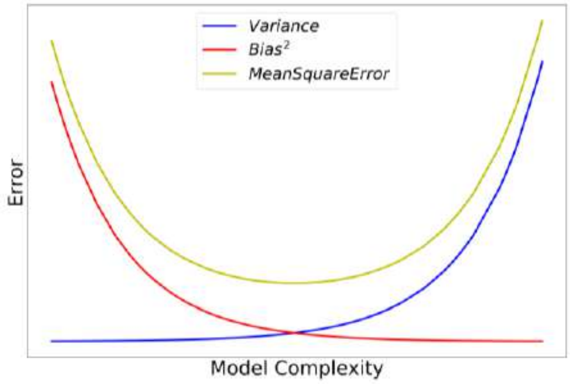

Figure 2. Simplified relationship between Bias^2, Variance, and MSE

4 Implementation of the Framework on a Case Study

4.1 Overview

The framework was tested on a case study of 19 campus buildings (including offices, academic buildings, and dorms) that participated in DR programs in 2016. There were six events that happened in 2016. During the events, data such as weather and electricity meter data was collected from different sources to quantify the saving potential of the buildings.

4.2 DR Dataset Pre-processing

The authors examined the 116 DR protocol statements for nineteen buildings manually to extract the DR attribute-pairs to fit the models. Table 1 listed three examples of the extracted attribute-pairs. As shown in Table 1, there are eight attributes identified from the protocol statements. However, not every protocol

Table 1. Three Examples of the Attribute-Pairs Extracted from the DR Protocols

Building ID	Building_ type	HVAC_ action	HVAC_ quantity	Light_ action	Light_ quantity	Fan_ action	Fan_ quantity	Elevator_ quantity
Building1	Office	Shut Off	4	Shut Off	5	Reduce Power	40%	1
Building2	Dorm	Shut Off	1	Shut Off	27	Shut Off	5	1
Building3	Office	Reduce Power	40%	Shut Off	4	None	-1	2

includes all the attributes, and such cases were reflected as none in the dataset. For example, the DR protocol for Building 3 in Table 1 does not contain any instruction for Fans. Therefore, the authors put 'None' as the Fan_action and '-1' as the Fan_quantity.

In addition to the attribute-pairs extracted from the DR protocol statements, the authors also collected the weather condition data, DR profile data, and electricity meter data during the event (based on event times from DR profiles). The description of all the datasets is shown in Table 2. The datasets are integrated with each other by merging keys. For example, the DR attribute-pairs were merged to the DR profiles by linking the dataset based on the building ID. The integrated dataset was pre-processed using forward filling method, which means that the missing value is filled with the nearest previous data.

Table 2. Description of the Datasets

Datasets	Variables	Merging Key
DR Attributes Pairs	Building_type, HVAC_action, HVAC_attribute, Light_action, Light_attribute, Fan_action, Fan_attribute, Elevator_attribute	Building ID
Weather Data	Weather Condition, Temperature, Humidity, Wind Speed	Date-time
DR Profiles	Baseline, Enrollment	Building ID
Electricity Meter Data	Electricity Consumption	Date-time; Building ID

4.3 Quantifying Saving Potential in Buildings

4.3.1 Decision Tree

With the integrated dataset from the previous section, the authors fitted the decision tree models and pruned it by iterating the depth of the trees from 1 to 10. Figure 4 demonstrates the results of the MSE, R^2, Variance, and Bias^2 of the decision trees with different depths. As shown in Figure 3, MSE and Bias^2 decrease when the depth of the tree increases, whereas R^2 and Variance increase when the depth of the tree increases. When the depth of the tree is four, Bias drops drastically with relatively low variance and MSE, and with a fairly good R^2. Therefore, the depth of the decision tree is determined as four, meaning that in this case, the model can provide sufficient capability in estimating the saving potential and not suffering over-fitting and under-fitting issues.

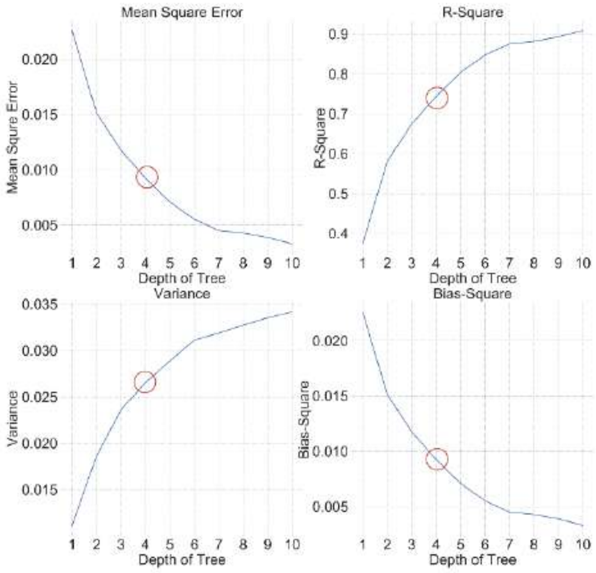

Figure 3. Comparison of MSE, R^2, Variance, and Bias^2 of the Decision Trees with Different Depth of the Trees

4.3.2 Ada Boosting

To improve the performance, the authors implemented Ada Boosting decision trees and pruned the parameters by iterating both the depth of the trees and number of the tree estimators from 1 to 10. The heat map of the four criteria is shown in Figure 4 with blue indicating a small value and red indicating a large value. As shown in Figure 2 and Figure 4, variance and bias^2 are negatively correlated. Hence the boxes with the color in middle range of the sidebar are selected as candidates. Furthermore, among the candidate boxes, the authors chose the parameters based on the R^2 and Occam's razor law, which means that the square with a higher R^2 and less depth of tree and number of estimators will be chosen.

Figure 4 shows that when the depth of the tree is equal to five and the number of tree estimators is four, the MSE, variance, and bias^2 are smaller than the surrounding cells (meaning that the model is better fitted than the surrounding models), along with a relatively high R^2 (meaning that the model is capable of estimating the saving potential of the buildings). Therefore, the pruning process of Ada Boosting results in five as the depth of the tree and four as the number of estimators.

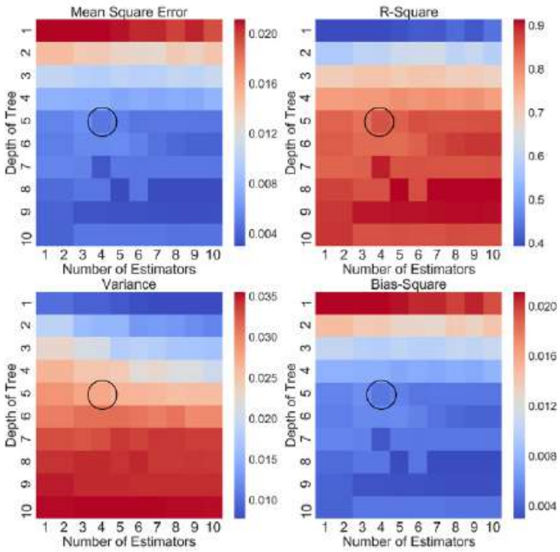

Figure 4. Heat map of MSE, R^2, Variance, and Bias^2 of the Ada Boost of Decision Trees with Different Depth of the Trees and Number of Estimator Trees

4.3.3 Random Forest

In addition to modifying the training sample to improve the performance, random forest fits the trees with different attributes from the integrated training dataset as well. The parameters for the random forest is the same as Ada boosting, the depth of the tree, and the number of tree estimators, and the best parameters are chosen based on the same process as Ada boosting as well. Figure 5 shows the heat map when pruning the random forest models. When the depth of the tree is six, and the number of tree estimators is four, the bias^2, variance, and MSE are all fairly small with a high R^2. Therefore, the best parameters for the random forest model, in this case, are six as the depth of tree and four as the number of estimators.

4.3.4 Comparison of the Models

The authors tested all the pruned models on the datasets using 20 folds cross-validation, which will randomly pick 70% of the data as the training sample to fit the model and 30% of the data as the testing sample to evaluate the performance for 20 times. The pruned parameters and average R^2 from the cross-validation are shown in Table 3. As shown in Table 3, random forest with six as the depth of the tree and four as the number of tree estimators has the best performance in explaining the DR dataset and resulting 0.862 as the R^2, which indicates that the framework has better capability of estimating the true saving potential of the buildings in different types and scales.

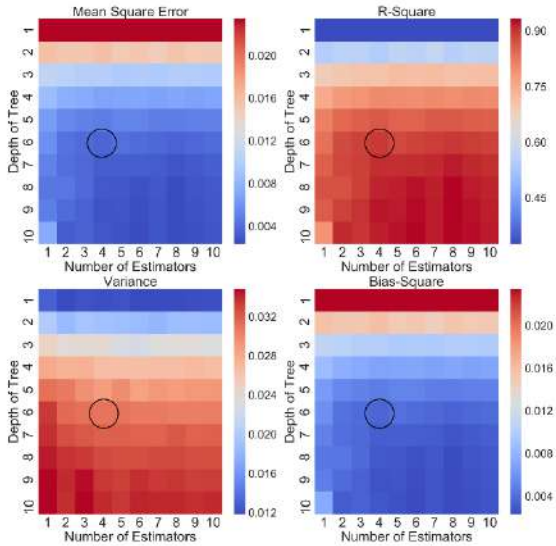

Figure 5. Heat map of MSE, R^2, Variance, and Bias^2 of the Random Forest of Decision Trees with Different Depth of the Trees and Number of Estimator Trees

The comparisons between the estimated electricity saving potential from the random forest model, the enrollment value of the buildings, and the actual curtailment during the DR events are shown in Figure 6. In Figure 6, X-axis represents the actual curtailment (percentage of the baseline) of the buildings, and Y-axis represents the estimated electricity saving potential (percentage of the baseline) during the events (predicted by random forest model or the enrollment value from the DR profile).

Table 3. Parameter and Performance of the Models

Model	Depth of Tree	Number of Trees	R^2
Decision Tree	4	-	0.743
Ada Boosting	5	4	0.828
Random Forest	6	4	0.862

The diagonal black line indicates the case when the actual curtailment is equal to the calculated electricity saving potential. The red dots illustrate the enrollment value from the DR profiles versus the actual curtailment, and the blue dots illustrate the estimated saving potential from the random forest model with respect to the actual curtailment. For the red dots, almost half of them indicates that the enrollment value is smaller than the actual curtailment during the events (the red dots that are at the right of the black line), which indicates over-performance of the buildings (i.e., facility operators signed up for a small enrollment value and resulting in saving more electricity) while half of them indicates that the enrollment value is larger than the actual curtailment (the red dots that are at the left of the black line), which indicates under-performance of the buildings (i.e., facility operators signed up for a large enrollment value and resulting in penalties due to less electricity saving). Meanwhile, the blue dots distribute closely around the black line, which demonstrates the capability of the framework for estimating the electricity saving potential for the studied campus buildings. These cases illustrated the potential of the framework in estimating the saving potential of buildings. By enlarging the training set and including more cases, the framework can have a more promising performance over a group of buildings that share common characteristics.

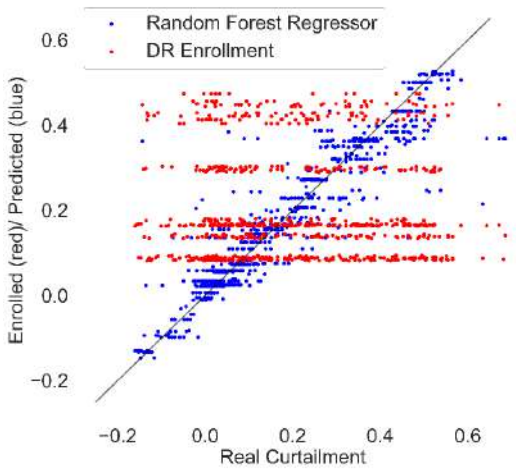

Figure 6. Comparison of MSE, R^2, Variance, and Bias of the Decision Trees with Different Depth of the Tree

4.4 Challenges and Future Work

When implementing the framework on the DR datasets, the authors faced multiple challenges. Firstly, DR protocol statements were not explicitly written, which result in inaccuracy and difficulties when estimating the electricity saving potential of buildings. For example, when a DR protocol statement instructs the facility managers to shut down the AHUs in common areas, it is hard to quantify the saving potential since the quantity of involved equipment remains vague. Secondly, occupancy status in buildings plays an essential role impacting the electricity consumption, which gives inherent complexity in predicting the electricity consumption. Furthermore, occupancy data is rarely available in buildings, and the available occupancy data usually contains a large amount of noise. These situations lead to difficulties when estimating the electricity saving potential considering the uncertainty of the occupancy status.

For future work, the authors plan to include more data to improve the performance of the framework presented in this study. In addition to extracting coarse building and equipment information from DR protocols, the authors intend to include Building Information Models (BIMs) to provide building and equipment configuration information to reduce the vagueness in DR protocol statements. Furthermore, the authors aim to collect DR related equipment sensor readings from building automation systems, which will provide much more details about the equipment behaviors during event times.

5 Conclusion

In this study, the authors presented a data-driven framework to estimate the electricity saving potential of buildings. The framework developed in this study fills the gap in the previous studies by providing a granular building-level data-driven approach to estimate the electricity saving potential for buildings by integrating various data sources containing data for DR events. By implementing the framework on 19 campus buildings that vary in type and scale, the authors demonstrated the capability of it in estimating the saving potential of buildings during DR events. The results from the case study indicate that the building owners and facility operators can benefit from the accurately determined saving potential by avoiding penalties and making the most out of the DR programs. The framework is extensible by integrating more equipment sensor data from BAS and BIM in the future to further improvement of the performance.

Gaussian Markov Random Fields for Localizing Reinforcing Bars in Concrete Infrastructure

Karthick Thiyagarajan*, Sarath Kodagoda, Linh Van Nguyen & Sathira Wickramanayake

Centre for Autonomous Systems, University of Technology Sydney, Australia.
E-mail: Karthick.Thiyagarajan@uts.edu.au*

Abstract -

Sensor technologies play a significant role in monitoring the health conditions of urban sewer assets. Currently, the concrete sewer systems are undergoing corrosion due to bacterial activities on the concrete surfaces. Therefore, water utilities use predictive models to estimate the corrosion by using observations such as relative humidity or surface moisture conditions. Surface moisture conditions can be estimated by electrical resistivity based moisture sensing. However, the measurements of such sensors are influenced by the proximal presence of reinforcing bars. To mitigate such effects, the moisture sensor needs to be optimally oriented on the concrete surface. This paper focuses on developing a machine learning model for localizing the reinforcing bars inside the concrete through non-invasive measurements. This work utilizes a resistivity meter that works based on the Wenner technique to obtain electrical measurements on the concrete sample by taking measurements at different angles. Then, the measured data is fed to a Gaussian Markov Random Fields based spatial prediction model. The spatial prediction outcome of the proposed model demonstrated the feasibility of localizing the reinforcing bars with reasonable accuracy for the measurements taken at different angles. This information is vital for decision-making while deploying the moisture sensors in sewer systems.

1 Introduction

Recently, robotic systems are largely viewed by scientists as a promising tool to navigate, explore and measure environmental health of hostile areas [1]. One such area is an urban sewer system, where long-term direct human exposure can cause occupational health hazards [2]. Exploiting robotic inspections in such infrastructures not only requires hi-tech robots but also advanced sensing technologies in order to provide credible information about the sewer assets. In this context, this work focuses on utilizing the sensor data and provide meaningful information for pertinent decision-making.

The underground sewer pipes are deteriorating mainly due to microbial induced concrete corrosion [3, 4]. This raises concerns among water utilities around the globe as the sewer asset rehabilitation costs are at an estimated annual value of over $100 millions [5, 6]. Presently, water utilities use data-driven machine learning models for estimating corrosion [7]. In such models, surface moisture conditions of the concrete sewers can be used as an observation for improved prediction [8, 9]. So, a new robust sensing technology was developed by us in collaboration with four water utilities in Australia. This technology estimates surface moisture levels based on non-invasive electrical resistivity measurements.

The technology was deployed and tested in a sewer pipe belonging to Sydney Water in Sydney, Australia. This evaluation demonstrated sensing feasibility under aggressive sewer conditions and capabilities for long-term moisture monitoring operations. However, the sensor measurements can be influenced by the reinforcing bars (rebars) inside the concrete and hence requiring onsite calibration. Therefore, the research problem is to determine the location and orientation of rebar embedded in concrete by using the same sensor rather than having to rely on expensive sensors such as ground penetratin radars. This allows appropriate localization of sensor installations to improve the reliability of moisture estimations.

In this paper, we propose a discretely indexed Gaussian Markov Random Fields (GMRFs) based data-driven machine learning model for spatially localizing the rebar embedded in concrete using electrical resistivity measurements. The proposed machine learning method is a computationally efficient alternative to the non-parametric Gaussian Process (GP) based models. In this work, we employ resistivity meter to perform non-invasive measurements of electrical resistivity variation on the concrete sample by utilizing four probe Wenner technique. The measurements were taken at different spatial location of the concrete sample by placing the resistivity meter on the concrete surface at different angles with respect to the rebar. Then, the measured data obtained from each angle is fed to the

GMRF model for experimental investigations.

The remainder of the paper is structured as follows: Section 2 elucidates the sensing technique and procedures followed for data collection. Section 3 formulates the theoretical considerations for spatial prediction. Section 4 presents the experimental results with analysis. Section 5 discusses the limitations of the work. Finally, Section 6 concludes the proposed work with future prospects.

2 Electrical Resistivity Measurements

An electrical resistivity meter was developed in the laboratory to measure surface electrical resistivity variations on the concrete. This device performs non-invasive measurements based on the Wenner technique [10], which uses four electrodes with an equal spacing distance between them. The two outer electrodes inject electrical current into the concrete material whereas the two inner electrodes measure the electrical potential differences. Then, the electrical resistivity of the concrete on the surface of interest can be determined by using Equation 1:

$$\rho = 2\pi a\Big(\frac{V}{I}\Big) \tag{1}$$

where ρ is the electrical resistivity of the concrete denoted in terms of kΩcm, $a = 40$mm is the spacing between the two electrodes, V is the electrical voltage signal measured by the inner two electrodes and I is the electrical current injected by the outer two electrodes.

The developed device is compact and works on the open-source electronic prototyping platform (Arduino Nano). It was evaluated on the benchmark scale and it produced measurements as desired. More information on the development of this resistivity meter is available in [11].

A concrete of thickness: 10 cm, width: 35 cm and length: 35 cm was made with a rebar having width: 1.2 cm, height: 1.2 cm and length: 30 cm was embedded into the concrete material at a 2 cm depth from the top surface of the concrete. This concrete was divided into several cells to perform measurements in those cells. Totally, the concrete was partitioned into 49 cells and each cell had a dimension of 4cm^2. The rebar runs through the column 4 of the (7×7) partitions. Electrical resistivity measurements in each cell were obtained by placing the inner two electrodes of the sensor at different angles. For each angle, two sets of data were taken in each cell.

3 Modelling for Spatial Prediction

3.1 Gaussian Markov Random Fields

GMRFs are a discretely indexed Gaussian Fields, which can be achieved through the observations of random variables in the spatial process [12]. It incorporates Gaussian Processes and also satisfies Markovian property [13]. This makes GMRFs a computationally efficient alternative to GP [14].

Let $s = (s_1, s_2, s_3, ..., s_n)^T$ with $s \sim \mathcal{N}(\mu, Q^{-1})$ referring to GMRFs given by the mean μ and a symmetric and positive definite precision matrix Q that represents the convex polytope in $\mathbb{R}^d$ ($\mathbb{R}$ denotes real numbers), and an inverse of the GP covariance matrix, $\sum$ [12, 15]. So, the density of s will be of the mathematical form as given in Equation 2:

$$p(s) = (2\pi)^{-\frac{n}{2}}\Big(det(Q)\Big)^{\frac{1}{2}} exp\Bigg\{-\frac{1}{2}(s-\mu)^T Q(s-\mu)\Bigg\} \tag{2}$$

The salient feature of the Markovian property is that the full conditional distribution of s_i $(1 \le i \le n)$ is only dependent on the elements set of the neighbourhood structure of the process and it is given by Equation 3

$$p(s_i|s_{-i}) = p(s_i|s_{Ni}) \tag{3}$$

where s_{-i} represents the elements in s apart from the element s_i, and s_{Ni} denotes the neighbourhood elements of s_i. Therefore, it is established that in the case of given neighbourhood elements, s_i element is independent on all other elements in s with the exception of the element s_{Ni}, which defines the conditional independence as $s_i \perp s_{-i,Ni}|s_{Ni}$ ($\perp$ denotes the independence of two variables) for $1 \le i \le n$. According to [12], μ is not related to pairwise conditional independence properties of s and therefore, afore stated characteristic is limited to the precision matrix Q. Generally, if s_i and s_j are conditionally independent, $s_i \perp s_{-j}|s_{-i,j}$ is equivalent to $Q_{ij} = 0$. This condition give rise to $Q_{ij} \neq 0$ when $j \in \{i, N_i\}$ and deduce the sparsity of Q that results significantly in computation performance.

3.2 Spatial Field Model by way of GMRFs

Let the finite set of spatially observed locations be $\psi = (\psi_1^T, \psi_2^T, \psi_3^T, ..., \psi_n^T)^T$. Each spatially observed location in ψ comprise of one electrical resistivity measurement data and consider $x(\psi) = (x(\psi_1), x(\psi_2), x(\psi_3), ..., x(\psi_n))^T$ as the vector of measurements in the spatial field [12]. In this work, the model utilized is similar to [15, 14], which is a summation of a large scale component, a random field and an identically distributed noise. The model is mathematically defined in Equation 4:

$$x(\psi) = \zeta(\psi)\beta + s(\psi) + \epsilon(\psi) \tag{4}$$

where $\zeta(\psi)\beta = \mathbb{E}(x(\psi))$ is the expectation of $(x(\psi))$ and $\mathbb{E}(\cdot)$ defines the expectation operator. $\zeta(\psi)$ is the covariates determined at spatial location ψ and β is the vector of mean parameters. s is a GMRFs with a n zero mean vector and a $n \times n$ precision matrix Q. $\epsilon(\psi)$ is the measurement noise with $\mu = 0$ and a known covariance matrix $\sigma_\epsilon^2 I_\epsilon$ at spatial locations ψ_i $(1 \leq i \leq n)$, where σ_ϵ^2 is assumed to be known and I_ϵ is the identity matrix, $n \times n$.

As in [16], the GMRF can precisely work as a GP when the continuous domain stochastic partial differential equations (SPDE) possess a solution with Matern covariance function [12], which is mathematically given by Equation 5:

$$cov(\gamma) = \frac{\sigma^2}{\Gamma(v)2^{v-1}}(\kappa\gamma)^v K_v(\kappa\gamma) \tag{5}$$

where γ indicates the Euclidean distance between the spatial locations, $\gamma = \|v_i - v_j\|$. The term σ^2 denotes the marginal variance and the term κ implies spatial parameters with v as the Matern smoothness and K_v represents the modified Bessel function [12]. The term $\zeta(\psi)\beta$, in this case denotes the mean function in the context of GP [17, 18].

3.3 Sensor Data Modelled by GMRFs Using SPDE Approach

The SPDE approach formulated by [19] demonstrates computational effectiveness while used in the spatial process. This approach incorporates finite element method [20] to focus the SPDE onto a basis representation, which includes piece-wise linear basis functions described by a triangulation that pertains to the interested regions [12]. Assuming that the spatial process $s(p)$ is observed at N locations where $p = (p_1^T, p_2^T, p_3^T, ..., p_n^T)^T$, then the initial vertices of the triangle are set at those spatial locations. Further, in order to achieve spatial prediction, more vertices of the triangles are added to realize a large triangulation.

The GMRF model is developed on the basis function representation for the given triangulation of the domain Q [12]. Therefore, $s(p)$ is given as in Equation 6:

$$s(p) = \sum_{i=1}^{n} f_i(p) w_i \tag{6}$$

where $\{f_i(p)\}$ denotes the basis functions that are piece-wise linear on each triangle [12]. In the i^{th} vertex of the mesh, $f_i(p)$ of the functions $\{f_i(p)\}$ is 1, and 0 for all other vertices. The term $\{w_i\}$ denotes the Gaussian distributed weight. At each triangle vertex i, the value of the spatial field is given by $\{w_i\}$ [12]. Thus, the SPDE approach incorporating finite element method establishes the link between the GP and GMRFs with feasible computation efficacy. The precision matrix Q of size $n \times n$ is determined by computing the Equation 7:

$$Q = \tau^2(\kappa^4 D + 2\kappa^2 H + HD^{-1}H) \tag{7}$$

where τ controls the variance, D and H are the $n \times n$ matrices with $D_{ij} = \langle f_i, f_j \rangle$ and $H_{ij} = \langle \Delta f_i, \Delta f_j \rangle$.

The total number of triangulation vertices defines the dimension of Q in the region of interest. Thus, Q can be seen as a function of κ and τ. Lets define the hyper-parameter vector as $\Phi = (\log(\tau), \log(\kappa))$. Now, it can be said that the sparse property of Q is embraced by the GMRFs representation built by the linear basis functions. The inherent random field at the n vertices of the triangulation is defined by GMRFs with μ as

$$s|\Phi \sim \mathcal{N}(\mu, Q^{-1}) \tag{8}$$

In the interest of mapping between the basis function representation located at n vertex of the triangulation and random field at resistivity meter locations having N dimension, let us consider the projector matrix as B, whose size is $N \times n$. B projects the modelled inherent random field at the vertices of the triangulation to the data locations.

In reference to the spatial field model presented in the preceding section, the measurements at N locations of the spatial field can be given by Equation 9:

$$x|s, \Phi, \beta, \sigma_\epsilon^2 \sim \mathcal{N}(\zeta(p)\beta + Bs, \sigma_\epsilon^2 I_N) \tag{9}$$

where $\zeta(p)$ refers to $N \times q$ matrix of covariates, β and Φ are the estimated parameters of the maximum likelihood approach [18], I_N refers the identity matrix $N \times N$.

If all the model parameters are learned, the joint distributions of x and s are calculated by adopting the technique in [21, 12], which is given by Equation 10:

$$s|x, \Phi, \beta, \sigma_\epsilon^2, B \sim \mathcal{N}\left(\begin{bmatrix} 0 \\ \zeta(p)\beta \end{bmatrix}, \begin{bmatrix} Q^{-1} & Q^{-1}B^T \\ B^T Q^{-1} & \sigma_\epsilon^2 I + BQ^{-1}B^T \end{bmatrix} \right) \tag{10}$$

The full conditional distribution of s given by x is also Gaussian with respect to probabilistic theory [12]. By using block-wise inversion approach [22] and the Schur complement, the Gaussian expressed in Equation 10 can be mathematically written as in Equation 11:

$$s|x, \Phi, \beta, \sigma_\epsilon^2, B \sim \mathcal{N}\left(\mu_{s|x}, Q_{s|x}^{-1}\right) \tag{11}$$

where $\mu_{s|x}$ denotes the vector of posterior means and the term $Q_{s|x}$ denotes the posterior Q. They are given as follows:

$$\mu_{s|x} = \zeta(\psi)\beta + Q_{s|x}^{-1}(\sigma_\epsilon^2 I_N)^{-1}(x - \zeta(p)\beta) \tag{12}$$

$$Q_{s|x} = Q + B^T(\sigma_\epsilon^2 I_N)^{-1}B \tag{13}$$

Equation 12 factorizes the sparse matrix $Q_{s|x}$. However, $Q_{s|x}$ is not dependent on the collection of sensor measurements [15, 12].

4 Experimental Results

4.1 GMRFs Spatial Prediction Performance

This section investigates the spatial prediction performance of the GMRFs model. In this regard, this evaluation was carried out by placing the resistivity meter at an angle 90° and three sets of data were taken in the 49 partitions. Among the 49 partitions, 20 were used for training the GMRFs model and 29 were used for testing. The spatial prediction results for the three different datasets are shown in Figure 1, Figure 2 and Figure 3.

In order to evaluate the spatial prediction performance efficacy of the GMRFs model, Mean Absolute Error (MAE) and Root Mean Square Error (RMSE) were used as metrics, which was computed based on the data of measured values and the predicted values. Table 1 tabulates the computed metric values for the three different datasets, where it can be observed that the MAE and RMSE are reasonably low and therefore, the results indicate that the GMRFs model can be utilized for localizing the rebar.

4.2 GMRFs Spatial Predictions for Measurements Obtained from Different Angles

This section presents the results of the GMRFs predictions for localizing the rebar based on non-invasive

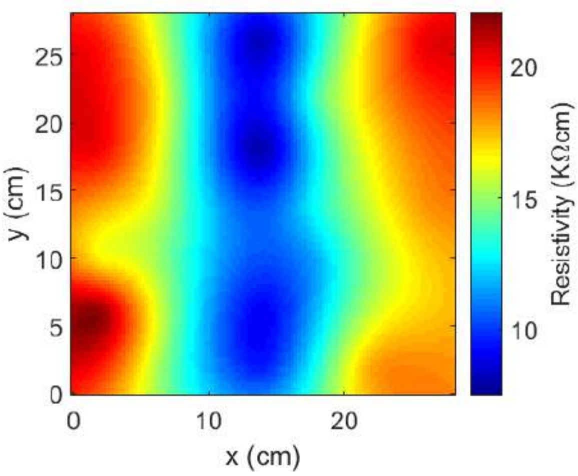

Figure 1. Dataset-1: Spatial prediction using GMRFs by taking resistivity measurements at 90°.

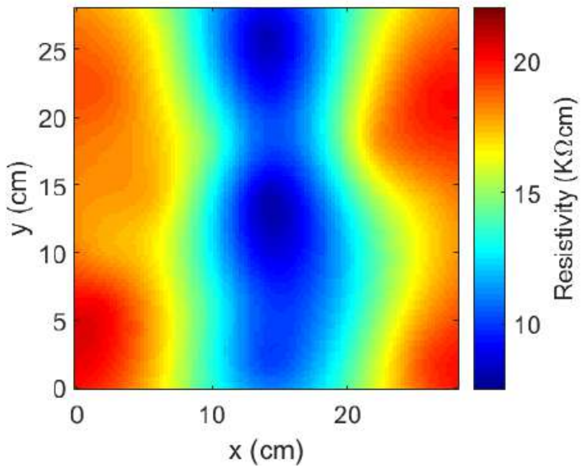

Figure 2. Dataset-2: Spatial prediction using GMRFs by taking resistivity measurements at 90°.

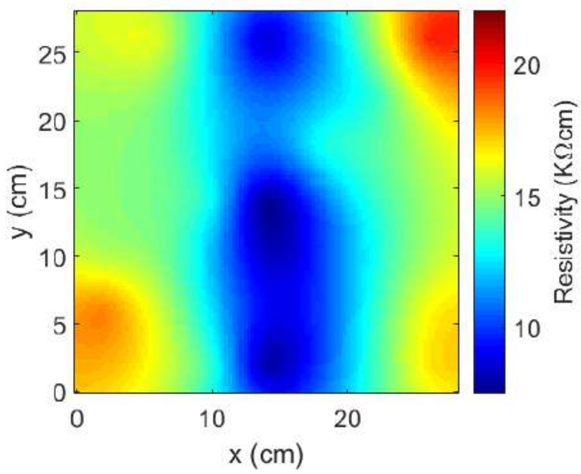

Figure 3. Dataset-3: Spatial prediction using GMRFs by taking resistivity measurements at 90°.

Table 1. GMRFs Spatial Prediction Performance

Datasets	MAE (kΩcm)	RMSE (kΩcm)
Dataset-1	0.50	1.69
Dataset-2	0.61	1.60
Dataset-3	0.28	1.37

electrical resistivity measurements. The measurements were taken by placing the resistivity meter at different angles such as 0°, 30°, 45°, 60° and 90°. The angle 0° is perpendicular to the rebar whereas the angle 90° is parallel to the rebar.

Figure 4 shows the spatial prediction for the measurements taken at an angle 0°, where it can be observed that area of low resistivity denotes the presence of rebar. Similarly, Figure 5 shows the spatial prediction for the measurements taken at an angle 30°, Figure 6 shows the spatial prediction for the measurements taken at an angle 45°, Figure 7 shows the spatial prediction for the measurements taken at an angle 60° and Figure 8 shows the spatial prediction for the measurements taken at an angle 90°.

From the figures showing the spatial prediction using GMRFs, the low resistivity area represents the influence of the rebar located inside the concrete. It can be said that the measurements taken at different angles such as 0°, 30°, 45°, 60° and 90° can be utilized to locate the rebar embedded in the concrete through GMRFs based spatial prediction model. This information of rebar placement can be used for optimal moisture sensor installations. However, it can be observed from the Figure 4 that the measurements taken at the angle 0° has less rebar influence compared to other angles.

5 Discussion

In the reported work, we performed electrical resistivity measurements on the concrete that has a rebar at 2 cm depth from the top concrete surface. In order to locate the rebar inside the concrete, whose rebar is placed at different depths lower than 2 cm, modifications need to be done in the sensing technique by changing the

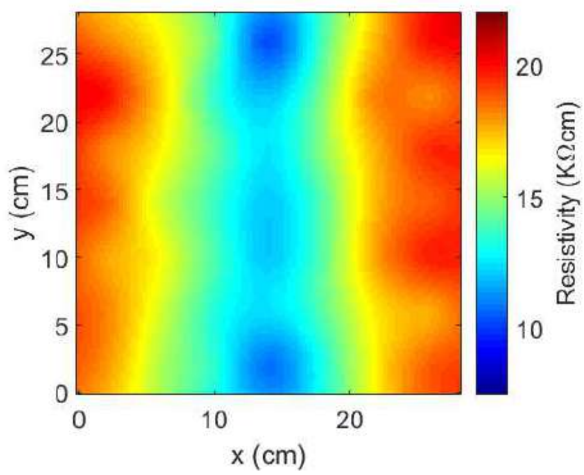

Figure 4. GMRFs prediction at 0° measurements.

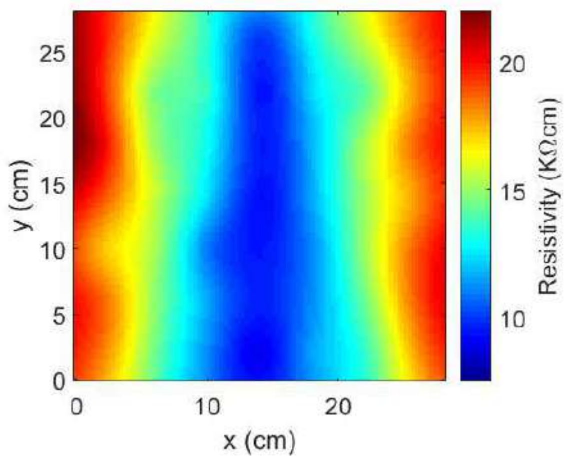

Figure 6. GMRFs prediction at 45° measurements.

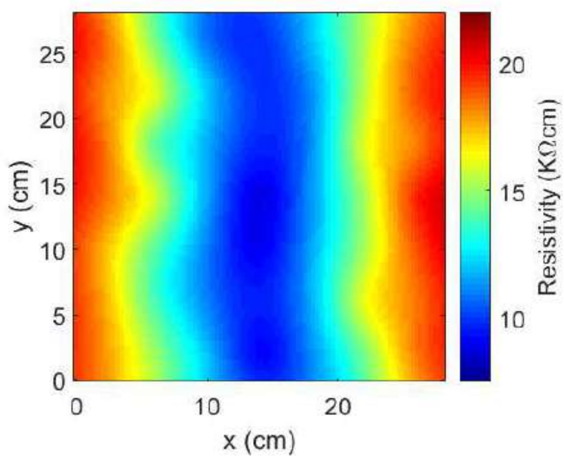

Figure 7. GMRFs prediction at 60° measurements.

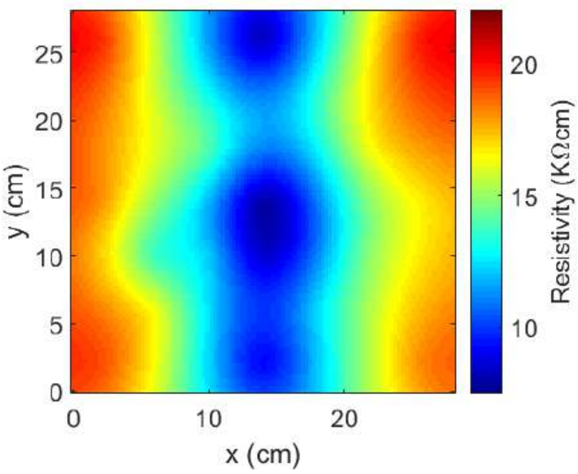

Figure 8. GMRFs prediction at 90° measurements.

operating frequency. Presently, the device used in this work is set to perform measurements with 40 Hertz. However, it is possible to change the frequency of the device based on the application. Also, the rebars that are located near the measuring surface of the concrete only has influence during moisture measurements for 40 Hertz. Higher the operating frequency higher is the penetration depth of electrical signals into the concrete.

With the operating frequency of 40 Hertz, given the unknown conditions of the rebar at sewer pipes, the electrical resistivity measurements taken at different angles through GMRFs spatial prediction model can shed light on the rebar location. Therefore, this information is vital to place the electrical resistivity meter for surface moisture estimation in sewer systems.

6 Conclusions

This paper proposed a machine learning model using GMRFs for localizing the rebar in concrete infrastructures. In this context, the work reported has led to the following three major contributions:

- We experimentally demonstrated that non-invasive electrical resistivity measurements based on Wenner technique has influence to the embedded rebar of the concrete and henceforth, the measured data can be utilized to determine the rebar location.

- The proposed GMRFs model for spatial prediction based on electrical resistivity measurements has produced satisfactory results and the statistical evaluation results computed from three different datasets demonstrate that the spatial prediction performance of the GMRF model is reasonably accurate and can be used for localizing the rebar.

- GMRFs spatial prediction based on the measurements at different angles such as 0°, 30°, 45°, 60° and 90° demonstrated that rebar can be identified irrespective of measurement angles. However, there was less influence of rebar when the measurements were taken perpendicular to the rebar.

Overall, the proposed work can improve the way surface moisture conditions are quantified inside the concrete sewer systems. In the future, the reported work will be extended to perform measurements on larger concrete having rebar meshes. Then, in-situ evaluation will be conducted within the Sydney based municipal sewer system. Eventually, the field results will be reported in the appropriate journal.

Abstract

Independently Driven Quadruped Crawler Robot(IDQCR) can rescue survivors rapidly in case of disaster situations. In order to prevent rollover, the IDQCR must level out the operator cabin to overcome rough terrain and do posture control when gripper is carrying heavy things of the robot. In this paper, we define a mathematical model based on differential kinematics for posture control and discuss the influence of the posture control to upper body of IDQCR on. In order to verify the proposed mathematical model, we simulated with DAFUL and MATLAB/Simulink, which can analyze dynamics.

Rollover; Influence of Upper Body; Independently Driven Quadruped Crawler; Posture Control; Disaster Response Robot; Wheel-legged System;

1 Introduction

Globally, occurrence frequencies of disasters such as conflagration and earthquake are increasing gradually [1]. When huge disasters occur, survivors are possibly under collapsed debris and rescue is not easy when a fire occurs. The existing survivor rescue systems needs plenty of rescue time because of various variables and additional collapse can make the situation worse[2].

For this reason, it is necessary to develop the robot for rescue and the robot must be able to travel on rough terrain. As a requirement of robots for the disaster, the ability to overcome the roughness, ease of operation and promptness must be satisfied.

Firstly, the ability to overcome obstacles allows four independent legs to freely pass obstacles by attaching a crawler that can easily overcome obstacles.

Secondly, the ease of operation is that the existing excavators have to control the four legs directly by the driver, but IDQCR is easy to control the joints and crawler speed of each leg automatically according to the terrain.

Thirdly, in the event of a disaster such as a large-scale earthquake or a fire, other heavy equipment or vehicles can't be operated properly due to collapsed debris, but the IDQCR can be quickly put into the field.

Various systems for safe operation for preventing rollover in the disaster environment have been proposed [3-6]. The DARPA Robotics Challenge, the symposium to perform missions in disaster situations, is being studied mainly in humanoid robots [7]. In addition, control methods for improving the driving systems of military robots have been studied, but research on the control techniques applied to the driving systems of large robots such as IDQCR has not been conducted [8].

Previous studies have concentrated on posture control considering only the lower body of the robot [9]. In this paper, we study the effect of the robot on the posture control by integrating the lower body and the upper body of the robot when overcoming the rough terrain. We propose a mathematical model for the posture control of the IDQCR driving system and verify the results by simulation considering the weight of the robot upper body. We entered the weight for each part of the upper body and tried to demonstrate the posture control by simulating the pose of stretching the two arms, which are the worst situation.

2 Introduction for Posture Control System of Disaster Response Robot

Fig. 1 shows the appearance of Independently Driven Quadruped Crawler Robot (IDQCR).

Four independent leg mechanisms can make the operator cabin horizontal when driving or working on rough terrain, with a crawler to easily overcome obstacles.

The legs mechanism independently drives the four hydraulic cylinders attached to the chassis to implement the up and down movements of the robot. The four hydraulic cylinders attached to the inside of the legs mechanism adjust the distance between the legs.

Fig. 2, the four hydraulic cylinders attached to the chassis are related to the driving system and show the relation with the posture control.

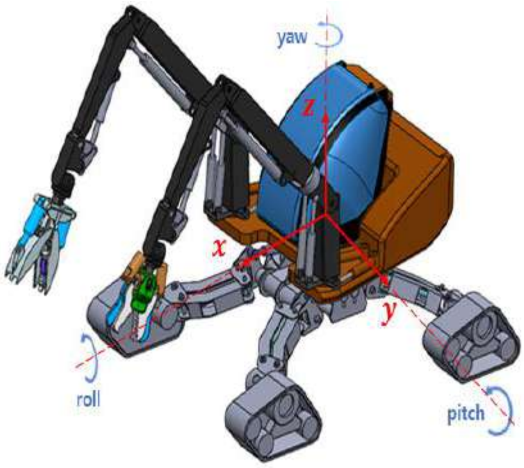

Figure 1. Independently Driven Quadruped Crawler Robot with integrated lower and upper body

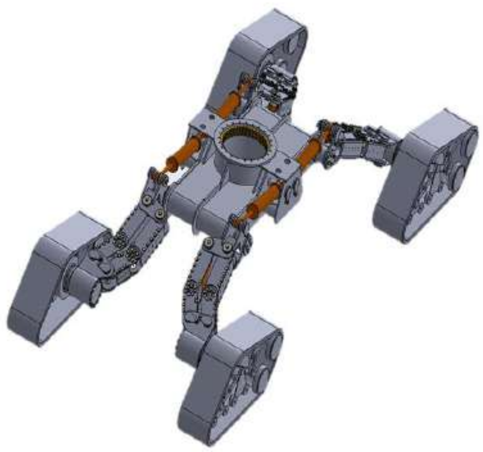

Figure 2. Independently Driven Quadruped Crawler system for posture control

The posture control of the driving system is related to up and down movement, roll and pitch motion of the robot. the posture control of the working system uses the four hydraulic cylinders inside the leg mechanism to expand the area of the support polygon [10].

The upper part of the robot consists of cabin, chassis, arm, 8 hydraulic cylinders and 2 grippers. The eight hydraulic cylinders are designed to have four degrees of freedom for each arm of IDQCR.

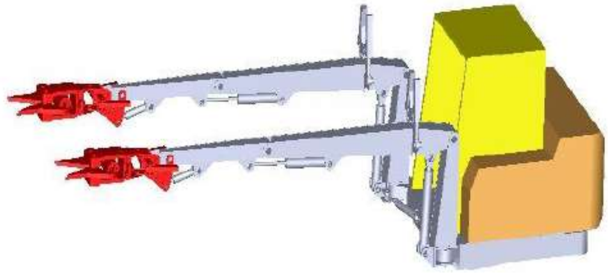

Figure 3. The worst posture of upper body posture of IDQCR

Fig. 3, the most worst posture of the upper body posture of IDQCR is the posture in which the two arms are stretched straight. If there is no rollover in that posture, there is no rollover.

3 Posture Control of Disaster Response Robot

3.1 Coordinate Frame for Robot

Prior to setting differential kinematics model, the setting of coordinate system must be preceded. Figure. 4 shows the schematic diagram of the system. {A} is global coordinate. The origin of {B} is located in the centre of mass of IDQCR in the driving system. z_B is an unit vector in the direction of outer product with y_B and x_B. y_B is an unit vector in the left direction of the robot and x_B is an unit vector in the front direction of the robot.

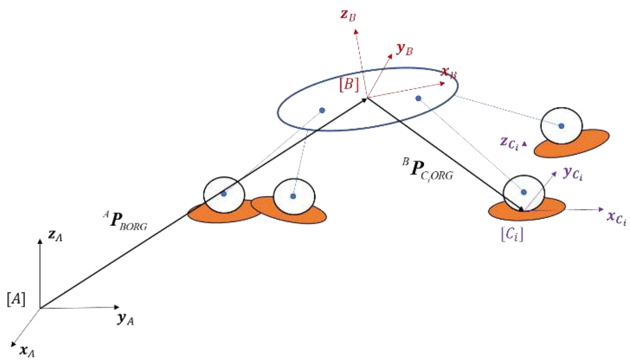

Figure 4. The schematic diagram of the system

3.2 Differential Kinematic Model of Robot

With respect to the coordinate system{A}, the velocity of the origin of frame $\{C_i\}$ is denoted by ${}^{A}V_{C_iORG}$ and can be obtained by the following equation (1).

$$ {}^{A}V_{C_iORG} = {}^{A}V_{BORG} + {}^{A}\Omega_B \times {}^{A}_{B}R\, {}^{B}P_{C_iORG} + {}^{A}_{B}R\, {}^{B}V_{C_iORG} \quad (1) $$

${}^{A}V_{BORG}$ is a linear velocity of the origin of {B} relative to frame {A} and ${}^{A}\Omega_B$ is the angular velocity of frame {B} relative to frame {A}. ${}^{A}_{B}R$ is the rotation matrix of {B} relative to frame {A}. ${}^{B}P_{C_iORG}$ is the position vector of the coordinate system $\{C_i\}$ relative to frame {B}. ${}^{B}V_{C_iORG}$ is linear velocity of the origin of frame $\{C_i\}$ relative to frame {B}. ${}^{B}V_{C_iORG}$ can be expressed as the product of the Jacobian matrix J_i and the joint angular velocity of the leg and the sprocket $\dot{q}_i = [\dot{\alpha}_i\ \dot{\beta}_i]$ of the crawler. Assuming that there is no slip between the crawler and the ground, ${}^{A}V_{C_iORG} = 0$ and then equation (2) can be derived.

$$ {}^{C_i}({}^{A}V_{C_iORG}) = L_i\dot{X} + J_i^*\dot{q}_i = 0 \quad (2) $$

3.3 Jacobian Matrix

$J_i^*\dot{q}_i$ of equation (2) is divided into two velocity components as equation (3).

$$ J_i^*\dot{q}_i = {}^{C_i}({}^{B}V_{\dot{\alpha}_i}) + {}^{C_i}({}^{B}V_{\dot{\beta}_i}) \quad (3) $$

${}^{B}V_{\dot{\alpha}_i}$ is a component related to the joint velocity $\dot{\alpha}_i$ of ${}^{B}V_{C_iORG}$ and ${}^{B}V_{\dot{\beta}_i}$ is a component related to the joint angular velocity $\dot{\beta}_i$ of crawler sprocket of ${}^{B}V_{C_iORG}$. ${}^{C_i}({}^{B}V_{\dot{\alpha}_i})$ and ${}^{C_i}({}^{B}V_{\dot{\beta}_i})$ can be obtained by the following equations (4) and (5).

$$ J_i^*\dot{q}_i = {}^{C_i}_{B}R\, J_{\dot{\alpha}_i}(\dot{\alpha}_i) + \dot{\beta}_i(-r\ 0\ 0)^T \quad (4) $$

$$ J_i^*\dot{q}_i = [{}^{C_i}_{B}R \begin{bmatrix} -l sin\alpha_i \\ 0 \\ -l cos\alpha_i \end{bmatrix} \begin{bmatrix} -r \\ 0 \\ 0 \end{bmatrix}] \begin{bmatrix} \dot{\alpha}_i \\ \dot{\beta}_i \end{bmatrix} \quad (5) $$

$J_{\dot{\alpha}_i}$ is a Jacobian matrix of ${}^{B}V_{\dot{\alpha}_i}$, r is a radius of sprocket and l is the link parameter between the joint and the crawler sprocket.

3.4 Domain between the Joint and the Crawler Sprocket.

$\dot{X} = [{}^{B}({}^{A}\dot{V}_{BORG})^T\ \ {}^{B}({}^{A}\Omega_B)^T]^T$ is a 6×1 matrix that consists of the linear velocity vector and angular velocity vector. Let ${}^{B}({}^{A}V_{BORG}) = [v_x\ v_y\ v_z]^T$ and ${}^{B}({}^{A}\Omega_B) = [w_x\ w_y\ w_z]^T$.

Then, $\dot{X} = [v_x\ v_y\ v_z\ w_x\ w_y\ w_z]^T$. We need to change the control parameter domain from $\dot{X} = [v_x\ v_y\ v_z\ w_x\ w_y\ w_z]^T$ to $\dot{H} = [v_x\ v_y\ \dot{z}_{avg}\ \dot{\phi}\ \dot{\theta}\ \dot{\psi}]^T$. Where $z_{avg} = \sum_i^k z_i$. z_i is value of ${}^{B}P_{C_iORG}$ in z_B direction and k is the number of legs. $\dot{\phi}$ is the roll angle rate, $\dot{\theta}$ is the pitch angle rate and $\dot{\psi}$ is the yaw angle rate. Figure. 5 is showing overall notation and coordinate.

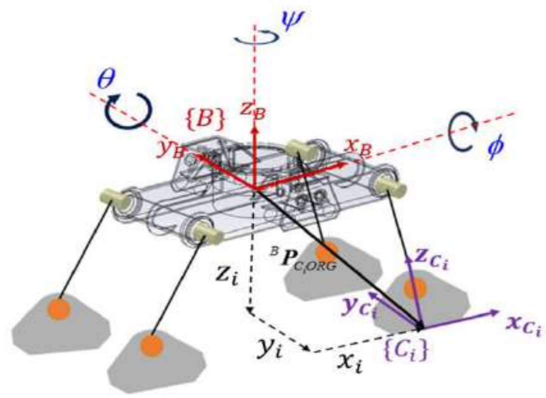

Figure 5. The description of the mentioned notation

A relationship between v_z and $\dot{z}_{avg}$ is equation (6).

$$ v_z = -\dot{z}_{avg} + w_y x_{avg} - w_x y_{avg} \quad (6) $$

Where $x_{avg} = \sum_i^k x_i$ and $y_{avg} = \sum_i^k y_i$. x_i and y_i are values of ${}^{B}P_{C_iORG}$ in x_B and y_B direction respectively. Since we want to control $\phi = 0°$ and $\theta = 0°$. $w_y = \dot{\theta}\cos(\phi) + \dot{\psi}\cos(\theta)\sin(\phi) \cong \dot{\theta}\cos(\phi)$ and $y_{avg} = 0$. Then, the equation (6) can be (7).

$$ v_z \cong -\dot{z}_{avg} + \dot{\theta}\cos(\phi) \quad (7) $$

By using the relationship between Euler angle and angular velocity, 'xyz' transformation, a relationship between $\dot{X}$ and $\dot{H}$ can be derived as (8).

$$\begin{bmatrix} v_x \\ v_y \\ v_z \\ \Omega_x \\ \Omega_y \\ \Omega_z \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & -1 & 0 & c_\phi x_{avg} & 0 \\ & & & 1 & 0 & -s_\theta \\ & 0_{3\times3} & & 0 & c_\theta & c_\theta s_\phi \\ & & & 0 & -s_\theta & c_\theta c_\phi \end{bmatrix} \begin{bmatrix} v_x \\ v_y \\ \dot{z}_{avg} \\ \dot{\phi} \\ \dot{\theta} \\ \dot{\psi} \end{bmatrix} \quad (8)$$

Resultingly, rate of crawler and body velocity, in other words relation between task and joint space in this machine can be derived like (9).

$$\dot{q} = -(J^*)^+ \mathrm{LU}\dot{H} \quad (9)$$

U is 6 by 6 matrix in (8). By using this equation (9), CLIK (Closed Loop Inverse Kinematics) algorithm was applied to method about rollover prevent and simulation used it.

4 Influence of Upper Body Posture

In the existing lower body posture control algorithm, the weight of the upper body of the IDQCR and the weight of the object gripped by the gripper are not considered. In order to travel while performing work and posture control, it is necessary to consider the result of influence of the upper body posture and to implement an additional rollover prevention algorithm. We can determine the influence on the rollover in several various posture and determine the worst posture.

4.1 When both arms are driven dependently

We divided the cases where two grippers hold one object in two cases.

4.1.1 Case 1

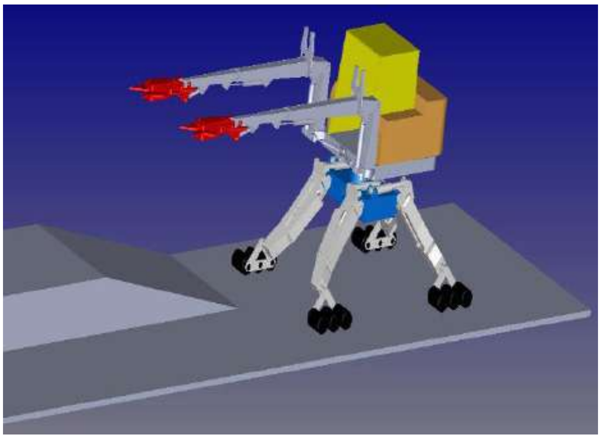

Figure 6. when both arms are stretched straight in the direction of robot's movement

The most basic posture like figure. 6 is when the two arms stretched straight in the direction of the robot's motion. Figure. 7 shows the case where the upper body is rotated 90 degree in the Yaw direction.

4.1.2 Case 2

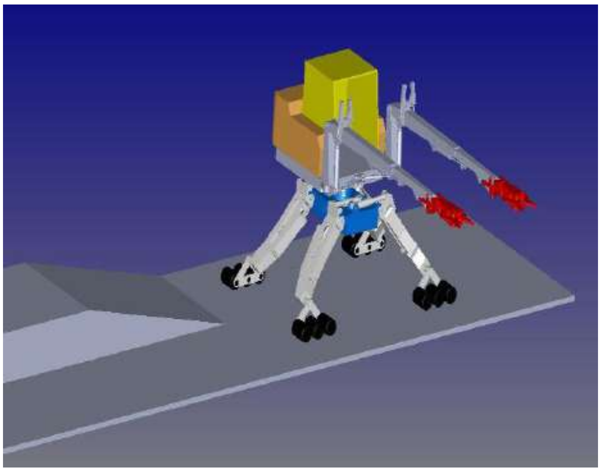

Figure 7. when the upper body is rotated 90° in the Yaw direction.

4.2 When both arms are driven independently

4.2.1 Case 3

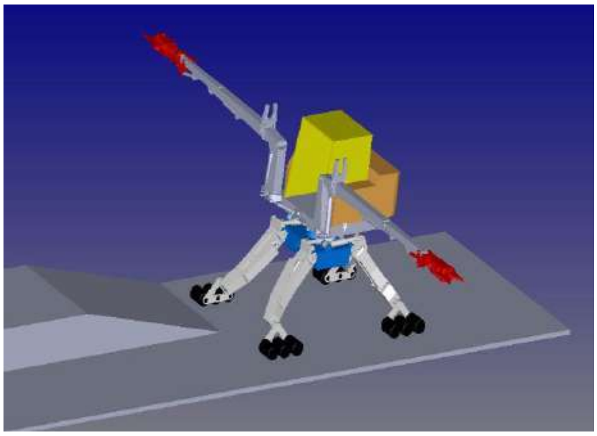

Figure 8. Two grippers hold two objects each

Figure. 8 shows that each grippers hold objects with different weight.

5 Simulation Analysis and Results

In order to verify the proposed mathematical model, we simulated with DAFUL and MATLAB/Simulink, which can analyze dynamics [11]. The simulation conditions are shown in Figure 9, Figure 10, the performance of the proposed model was verified by setting the roll angle to 35 ° and the pitch angle to 25 °.

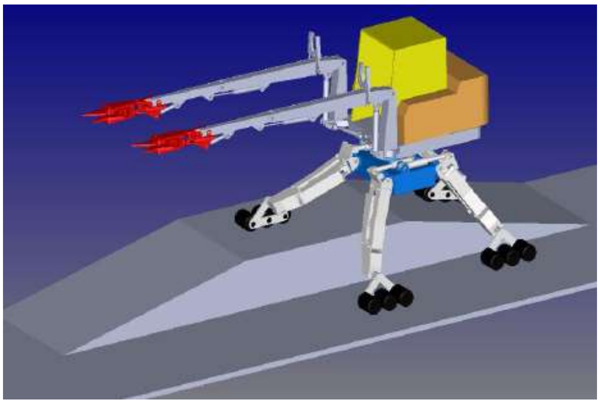

Figure 9. Simulation Condition of Roll angle (35°)

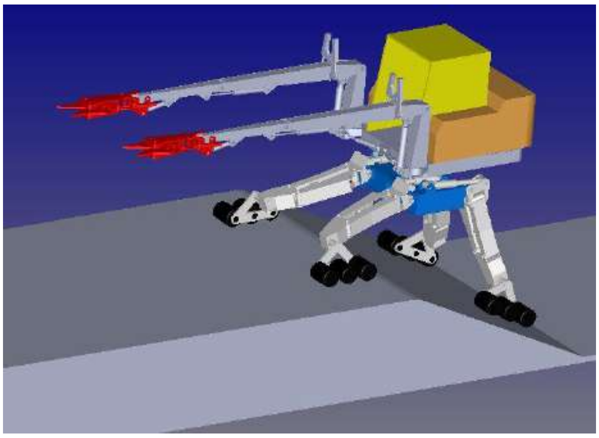

Figure 10. Simulation Condition of Pitch angle (25°)

5.1 Simulation of Roll and Pitch angle

Figure 11 and Figure 12 is the result of the roll angle and pitch angle considering the weight of the upper body of the robot. Figure 11 shows that the robot cannot be rolled over but the cabin is not perfectly horizontal, Figure 12 shows the result of rolled over in the ground-falling period while maintaining the roll angle to 0° in the ground-rising period. In the roll and pitch values analyzed from the mathematical model proposed above, the posture control is perfect for the robot considering only the lower body, but when the robot integrated with the upper body, the robot becomes unstable.

In figure 13 We could confirm the rollover result when simulating the grippers with more than 1.4t objects. An algorithm is needed to find a stable posture when the robot reaches the rollover threshold.

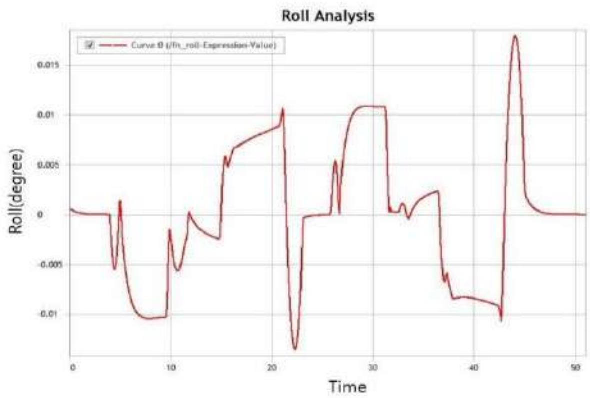

Figure 11. Result of Roll angle

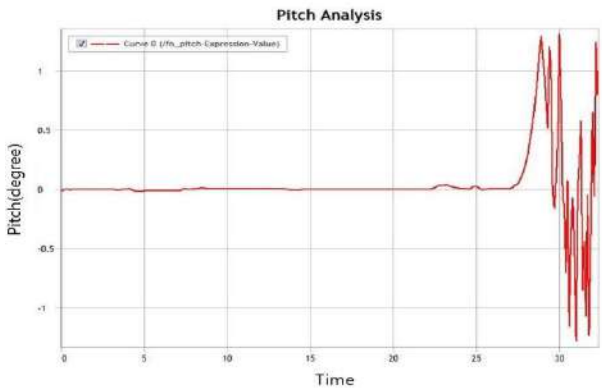

Figure 12. Result of Pitch angle

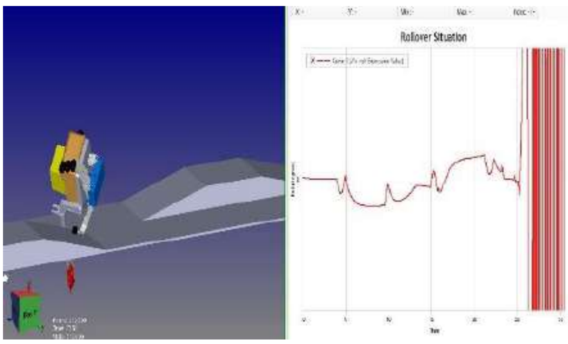

Figure 13. Result of Rollover situation

5.2 Simulation Result of Various Posture

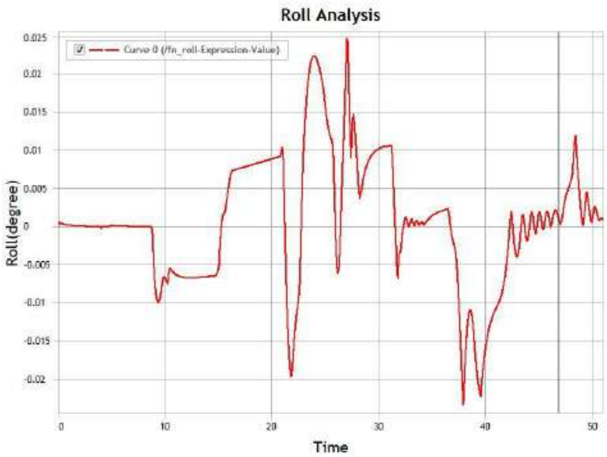

Figure 14. Result of Case 3

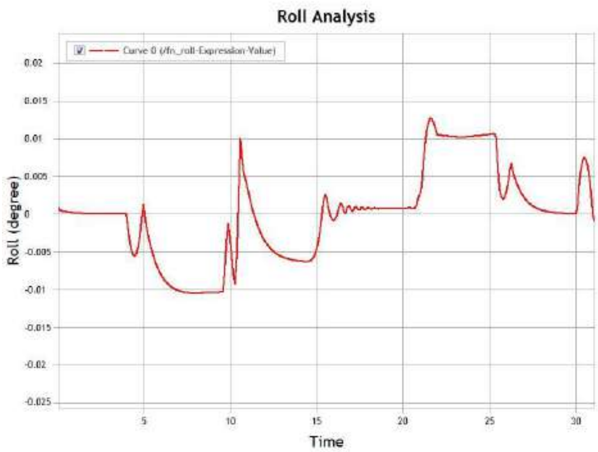

Figure 15. Result of Case 2

Figure 14 is a graph showing the results of Case 3, and Figure 15 is a graph showing the results of Case 2. The graphs in Figures 14 and 15 show that the Roll angle is shaking a lot and we can confirm unstable results.

6 Conclusion and Future Work

In this paper, we propose a mathematical model for the posture control of the IDQCR driving system.
In addition to, the results were confirmed and verified by simulation considering the weight of the upper body of the robot. The proposed mathematical model confirmed that the cabin maintains the horizontal position but does not achieve perfect posture control. It has been confirmed that the rollover occurs when the gripper is weighed more than 1.4t and we confirmed unstable results when simulate various posture. In order to compensate the rollover, an additional algorithm is need to prevent rollover control as well as a posture control algorithm when the overturn limit occurs.

Abstract

When multiple video cameras are set up to monitor construction activities, onsite construction resources (e.g. equipment and workers) might be captured by two or more cameras at the same time. It becomes important to identify whether the resources captured into separate camera views refer to the same one on the site. Otherwise, the automatic reporting of onsite resources utilization will produce repetive countings. This paper proposes a novel method for matching onsite construction resources in multiple camera views. The method relies on the visual features of a construction site and the spatial relationships of the resources on the site as matching cues. It starts with searching potential matching candidates between the camera views following their epipolar constraints. Then, the candidates' local triangular coordinates are calculated to define matching costs. This way, the matching of multiple construction resources between camera views could be solved through combinatorial optimization. The proposed method has been tested to match workers, equipment and traffic cones within the images and videos captured from construction sites. The test results showed that the method could reach an average of 93% matching accuracy.

Keywords

Onsite resources matching; Epipolar geometry; Combinatorial optimization; Multiple camera views

1 Introduction

The recent fast development of digital camera technology made it possible to set up multiple cameras to monitor construction sites [1]. These cameras can capture the detailed information on the utilization of construction resources (e.g. equipment, workforce, and materials), which could help to facilitate several construction management tasks [1]. For example, the working states of construction equipment were analyzed to estimate its productivity [2]. Also, equipment poses could be extracted to improve onsite safety in equipment operations [3].

When there are multiple cameras on a construction site, they typically have overlapping fields of view (FOVs). It is important to match the visual appearances of construction resources captured in the overlapping FOVs to find out which visual appearances refer to the same construction resource onsite. The successful matching is expected to reduce the repetitive counting and identification of construction resources. Also, it is one of essential steps to locate the resources on the site from the triangulation [4]. Moreover, if one resource is heavily occluded in one camera view, it could still be detected and tracked, as long as its occlusion in another camera view is not severe.

So far, several research studies have been proposed to match the visual appearances of generic objects of interest under multiple camera views. For example, Hu et al. [5] relied on a set of feature points through the Scale-Invariant Feature Transform (SIFT) [6, 7], Speeded Up Robust Features (SURF) [8], etc., to describe and match the object visual appearances in different camera views. Cai and Aggarwal [9] facilitated the object matching by referring to the epipolar constraint. According to the epipolar constraint, it was indicated that the projection of an object point in one camera view could generate a line (i.e. the epipolar line) in another camera view on which its corresponding projection must lie [9]. This way, the searching space is narrowed down to a line.

Most of existing generic matching methods have a limited use on construction sites. This is partly because construction video cameras are typicall set up at heights with wide camera baselines and large differences in view orientation. As a result, the construction resources in each camera view appear small with large variations. It could be difficult to find sufficient common object visual feature points for the matching purpose. On the other hand, the use of the epipolar line could not match the resources one to one, although it does help to limit the matching search space. When the visual appearances of multiple similar construction resources lie along the same epipolar line, the matching fails with the sole use of epipolar constraints.

The goal of this paper is to address these limitations by proposing a novel method for matching the visual appearances of construction resources between camera views. The method is built upon the visual features on a construction site, as well as the spatial relationships of the construction resources on the site. Specifically, potential matching candidates between camera views are first found following the epipolar constraints. Then, the local triangular coordinates of the candidates in each camera view are calculated. It is assumed that the same resource in different camera views should have the same local triangular coordinates. This way, the matching of multiple construction resources between two camera views could be solved by minimizing the matching cost through the combinatorial optimization.

The effectiveness of the proposed method has been tested with the images collected from a real construction site. The tests were conducted under different weather and illumination conditions. According to the test results, it was found that the overall matching accuracy could reach 93% (93% for construction workers, 100% for excavators, and 92% for traffic cones separately). Moreover, the proposed method was compared with the research work of Lee et al. [4]. The comparison results indicated that the proposed method could successfully match small-sized construction resources even if their visual appearances in one camera view lie on the same epipolar line.

2 Related Work

So far, numerous generic object matching methods have been created. These methods could be classified into two categories based on their matching cues. The methods in the first category relied on the visual features of the objects in each camera view; and the methods in the second category relied on the spatial relationships of the objects under the camera views.

2.1 Matching with Visual Features

Under the matching with visual features, the visual appearances of an object under different camera views are first characterized by a set of local point or area features [10]. Then, the matching is directly conducted by checking whether the visual appearances in camera views have the same local point or area features. If the same point or area features are found, it indicates that these visual appearances refer to the same object. Otherwise, they belong to different objects.

Examples of point feature detectors and descriptors include SIFT [6, 7], SURF [8], etc. The SIFT features are typically robust to the orientation changes of camera views; however, they might be sparse for matching object visual appearances between camera views. The SURF features could be detected in a faster way; but they are not fully affine invariant [11].

Compared with point features, the area features typically refer to the visual patterns in small, local image windows. Those area-feature based matching methods first find seed points and propagate from these points into small image windows. Then, the cross-correlation of the visual patterns in these windows is conducted for the matching purpose. For example, Pratt [12] used the local image intensities for the cross-correlation; and Rashidi et al. [13] adopted the adaptive color difference.

In general, the area-feature based matching methods could produce dense matching results [14] and are robust to local affine distortions. However, the matching might still fail. This is especially true when distinctive visual patterns could not be found in the local image windows, or when the patterns experienced significant deformations from the image transformations [15].

2.2 Matching with Spatial Relationships

The epipolar geometry is one of the common common spatial relationships that have been investigated in the matching procedure. In the epipolar geometry, if the projection of a three-dimensional (3D) point X on the left view is known, its epipolar line on the right view could be calculated. Morover, the projection of the point X on the right view must be on the line. Such spatial contratint signficnatly reduces the search space in the matching process [16].

Zhang et al. [17] used the Least Median of Squares (LMedS) to find the epipolar geometry between two camera views. The method of Lee et al. [4] then relied on the epipolar geometry to match onsite construction workers captured in two camera views by considering the locations of the workers in the camera views as well as their distances to the corresponding epipoar lines. Their matching recall and precision could reach 71.4% and 98.7%, respectively [4]. Recently, Konstantinou and Brilakis [18] proposed an idea that combined the epipolar geometry with the shift of the workers' centroids and visual features across video frames to improve the matching accuracy.

2.3 Gaps in Body of Knowledge

There are several limitaitons, when adopting the existing methods to match construction resources. First, the video cameras are typically set up at height on construction sites. Their shooting distance to the onsite construction resources (mobile equipment, workers, etc.) is long. As a result, the resources captured in the camera views always appear small, which makes it difficult to find effective point or area visual features to characterize them.

Second, most of existing matching methods based on visual features failed to match construction resources, when they have similar visual appearances. For example, all taffic cones look similar. Therefore, methods based on visual features for matching traffic cones between camera views have errors .

In addition, the matching methods based on spatial relationship might also fail due to the errors introduced in the calculation of the epipolar lines. For example, both methods proposed by Lee et al. [4] and Konstaninou and Brilakis [18] assumed the centroid of the bounding box of a worker as his/her location in one camera view, and determined the corresponding epipolar line in another view. When the worker is partially occluded in the first view, the centroid of the bounding box does not reflect his or her accurate location. As a result, the epipolar line in the second view is deviated to another worker instead, and the matching error is produced.

3 Objective and Proposed Methodology

The main objective of this paper is to propose a novel method for automatically matching onsite construction resources (e.g. mobile equipment, worker, and temporary facility) captured into camera views. The method is expected to be robust to the changes due to dynamic site activities as well as different illumination and weathe conditions. Also, it is common that construction onsite resources experience occlusions in the camera views. The proposed method is required to be able to match the resources even if they are partially occluded.

This paper focuses on matching excavators, workers, and traffic cones on a construction site. They represent three types of onsite resources, i.e. mobile equipment, labor, and temporary facilities. These resources of interest are first identified through the visual detection and/or tracking. However, many detection and tracking methods have been developed in the past, which could be used in this research.. This paper selected the Single Shot multi-box Detection (SSD) detection method [23] and the Kernelized Correlation Filters (KCF) tracking method [24].. However, other methods could be applied as well.

There are two main steps in the proposed method. The first step is to detect and match the visual feature points of the overall construction site under different camera views. The visual feature points help to establish the epipolar geometry within each pair of camera views, so that the potential matching candidates could be found. The second step is to generate a dynamic triangular mesh in each camera view with the visual feature points of the site. The triangular coordinates of the potential matching candidates in the corresponding meshes are calculated. It is assumed that the same resource in different camera views should have the same local triangular coordinates. Therefore, the difference in the triangular coordinates is defined as the matching cost. The successful matching of multiple onsite resources in different camera views should find a minimum sum of matching costs through combinatorial optimization.

The overall framework of the proposed method is illustrated in Figure 1. The following two sections introduce the details of the steps in the framework. It is worth noting that the matching method proposed in this paper does not require that the cameras are of the same type.

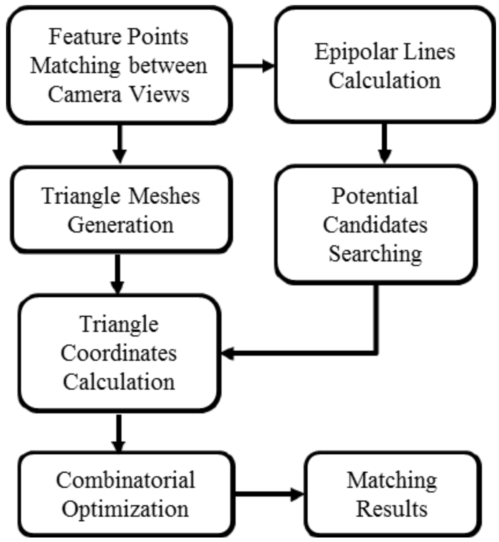

Figure 1: Proposed framework

3.1 Search for Potential Candidates

The purpose of the search for matching candidates is to reduce the matching space and improve the potential matching accuracy. The work here is similar to the previous research study proposed by Lee et al. [4]. Suppose there are two camera views, i.e. CamView1 and CamView2. An initial set of matched feature points in both camera views is first identified with the SIFT detector/descriptor [6, 7]. The selection of this detector/descriptor is mainly due to its robustness to large perspective and/or scale changes [25]. The matched feature points are further refined with the RANdom Sample Consensus (RANSAC) method [26], according to the suggestions from Hartley and Zisserman [27].

The refined feature points are used to generate a 3×3 fundamental matrix. The matrix indicates the hidden epipolar constraint between the two camera views. This way, for each resource of interest in CamView1, its corresponding epipolar line in CamView2 could be determined. The distances of the resources of interest in CamView2 to the epipolar line are calculated. Only those resources with distances equal to or smaller than their size are kept as the potential candidates for matching.

3.2 Pairwise Matching with Combinatorial Optimization

When the potential candaidates are found, the proposed method tries to address the matching problem between camera views with combinatorial optimization. Specifically, suppose there are n resources of interest {O_1, O2, O3, …, O_n} identified in CamView1, and their m matching candidates in CamView2 from the previous step are {C1, C2, C3, …, Cm}. Then, an n by m matrix, M, can be formulated as shown in Eq. 1.

$$M = \begin{bmatrix} M_{11} & \cdots & M_{1m} \\ \vdots & \ddots & \vdots \\ M_{n1} & \cdots & M_{nm} \end{bmatrix} \quad (1)$$

Where the element, M_{ij}, in the matrix indicates the matching cost, if the i[th] resource (Oi) in CamView1 is assumed to match with the j[th] candidate (Cj) in CamView2. The specific matching cost, Mij, is calculated as follows. First, the Delaunay triangulation process [28] is applied upon the correctly matched feature points in CamView1 to generate a triangular mesh (TM1). The mesh (TM1) is further projected to CamView2 to form another triangular mesh (TM2). The local triangle coordinates of each resource in TM1 and each candidate in TM2 are calculated. As for the ith resource (Oi) in CamView1 and the jth candidate (Cj) in CamView2, their matching cost is defined as the difference in terms of their triangle coordinates, as shown in Eq. 2.

$$M_{ij} = \sqrt{(O_{i1} - C_{j1})^2 + (O_{i2} - C_{j2})^2 + (O_{i3} - C_{j3})^2} \quad (2)$$

Where $\{O_{i1}, O_{i2}, O_{i3}\}$ and $\{C_{j1}, C_{j2}, C_{j3}\}$ are the triangle coordinates of the resource (Oi) and the candidate (Cj) in TM1 and TM2 separately. If the candidate (Cj) is not in the list of potetnials candidates for the resource (Oi), their matching cost is then set as +∞.

When the matching costs in the matrix, M, are all determined, the matching between the resources in CamView1 and the candidates in CamView2 is transformed into an assignment problem. Here, the Hungarian algorithm [28] is adopted to find the best assignment with the total minimum matching costs. It is worth noting that M does not have to be a square matrix. The matching could still be made when the number of the objects of interest in CamView1 is not the same as the number of the candidates in CamView2.

4 Implementation and Results

4.1 Implementation

The matching method proposed in this paper has been implemented in Python platform under the support of the OpenCV and Munkres libraries [29, 30]. It was tested on a Microsoft Windows 10 64-bit operating system. The hardware configuration for the tests includes an Intel® Core™ i7-7700HQ CPU (Central Processing Unit) @ 2.80 GHz, a 16 GB memory, and an NVIDIA GeForce GTX 1070 GDDR5 @ 8.0 GB GPU (Graphic Processing Unit).

4.2 Results

The images and videos from real construction sites in Canada were used for the tests. One example is illustrated in Figure 2. On the site, four high definition video cameras were placed to record daily construction activities for a period of 6 months (August, 2015 ~ Feburary, 2016). 51 videos with the total size of 1.3 TBs were collected for analysis. These videos were captured under different environmental conditions (e.g. daytime vs. nighttime; and sunny vs. rainy vs. snowy).

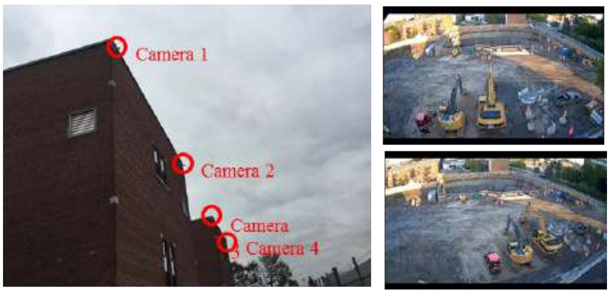

Figure 2: Example of the sites for tests

The videos were used to test the tests of matching workers, excavators and traffic cones. Figure 3 shows the examples of the matching results from the tests. It can be seen that the workers, excavators and traffic cones could be matched between camera views. Also, the matching of the resources is possible even when they experienced occlusions. For example, one excavator is partially occluded by another one in one camera view. The method could still identify the matched excavators in the other camera view. Figure 4 shows the matching examples under different environmental conditions.

Figure 3: Examples of matching workers, excavators, and traffic cones

Figure 4: Examples of testing under different environmental conditons

All matching results have been compiled in Table 1. It could be seen that the average matching accuracy of the proposed method is 93% (construction workers: 93%, excavators: 100%, and traffic cones: 92%). Also, the matching proposed method was compared with the research work of Lee et al. [4]. As shown in Figure 5, the work of Lee et al. [4] could not always successfully match construction resources when they are close to the same epipolar lines and/or partially occluded. The method proposed in this paper addressed such challenges well.

Table 1: Summary of matching results

	Correct Pairs	**Total Pairs**	**Accuracy**
Workers	213	229	93%
Excavators	40	40	100%
Traffic Cones	100	109	92%

Total	353	378	94%

Figure 5: Comparison between Lee et al. [4] (top) and the proposed method (bottom)

4.3 Discussion

According to the test results, it was noted that environmental conditions showed little impacts on the effectiveness of the proposed method. In most cases, the matching accuracy could reach above 90%.

On the other hand, the matching accuracy of the proposed method might be reduced when the size of the resources of interest becomes small. For example, the size of the workers or traffic cones is smaller than the size of the excavators in the tests. That might explain why the matching accuracy for excavators was 100%, while the accuracy rates for matching workers and traffic cones are 93% and 92%, respectively. In addition, the workers and traffic cones could be close to each other in the tests, which also made the matching more challenging.

Another important factor influencing the matching accuracy of the proposed method lies in the camera setup conditions (e.g. the shooting angle between two camera views). The number of common visual feature points detected under each view is reduced when both cameras have a wide view angle. Few feature points will affect the accuracy of the fundamental matrix as well as the generation of the triangular meshes.

5 Conclusions and Future Work

The accurate and robust matching of onsite construction resources of interest under different camera views is still challenging. This paper proposed a novel matching method, which solve the matching problem with combinatorial optimization. Compared with the previous work, the method works even when the resources are close to each other. The method has been tested with the images and videos collected from a real construction site in Canada. The matching was conducted under different lighting and weather conditions. The test results showed that the accuracy rates for matching construction workers, excavators, and traffic cones were 93%, 100%, and 92%, respectively. Overall, the matching accuracy could reach 93%. This paper did not evaluate the relationship between the matching accuracy and the onsite camera setups. Therefore, in the future, the focus will be placed on studying the impacts of the camera setups (e.g. camera distance and shooting angles) on the matching accuracy.

Parametric BIM Façade Module Development For Diagrid Twisted Structures

Tahir Akkoyunlu, Assist. Prof., PhD. [a]

[a]Department of Architecture, Istanbul Medipol University", Turkey
E-mail: takkoyunlu@medipol.edu.tr,

Abstract:

Building Information Modelling (BIM) is an epochal phenomenon in AEC. Most of the developed countries has already adopted BIM by regulations. Biggest projects around the world executing by BIM which provides more effective project management process. Whole construction progress including; feasibility, design, construction and commissioning became digital visualization. Any required analysis can be done via this model template.

In fact, requesting the complex and sophisticated structures' construction is the main catalyst of developing BIM. Mankind start to design and construct cutting-edges and pushing limit structures. Twisted towers are one of the significant instance of like these structures. This study embrace the twisted towers' façade design which has one of the most complex patterns. So it is thought that if such these towers' façade system can be organized and customized limitlessly, most of the façades systems will be solved for the optimum result.

This study aims to reveal a method which can be used for to develop easily alternative façade systems for construction projects even they have very complex design. One of the most complex structures the twisted diagrid systems which are constructed currently around the world was selected. BIM and computational programming have been used to improve the module.

BIM, Building information modelling, parametric design, computational BIM, visual programming, twisted towers.

1 Introduction

Over the last 10 years, diagrid structures have proven to be highly adaptable in structuring a wide range of building types, spans and forms. In most applications, diagrids provide structural support to buildings that are non-rectilinear, adapting well to highly angular buildings and curved forms. [1]

Until the latter half of the 20th century architectural and structural features of such high-rise buildings had remained almost the same with the prismatic box-type structure being the predominant form. Architects started breaking out of this more than century old trend/convention during the later decades of the 20th century [2]. Today's prevalent use of diagrids in tall buildings is due to their structural efficiency and aesthetic potential. For a very tall building, its structural design is generally governed by its lateral stiffness. Compared to conventional orthogonal structures for tall buildings such as framed tubes, diagrid structures carry lateral wind loads much more efficiently by their diagonal members' axial action [3].

Shawn Ursini, says; Advances in construction, engineering and architectural computer programs have enabled this type of architecture to flourish, but it has required a fundamental rethink of tall buildings.

By the way, Eastman et.al [4] define Building Information Modeling (BIM) as a new approach to design, construction, and facility management in which a digital representation of the building process is used to facilitate the exchange and interoperability of information in digital format.

It is no coincidence that the birth of the contemporary diagrid building type came at a time when computer-assisted drawing was hitting its stride. The development of Building Information Modelling (BIM) has been critical to ensuring the successful design and fabrication of highly complex structures [1]Construction of diagrids is more challenging compared to conventional structural systems for tall buildings because the system is relatively new and the joints of diagrid structures are more complicated than those of conventional orthogonal structures [3]. This paper aims to emerge that a proposal module based on parametric BIM which can ensure to make decision easily during diagrid structures design to facade systems of diagrid. This issue is one of the main parts of the skyscrapers cause of their energy consuming. While the most extensive area of the buildings are façades, the design decisions that comprises materials, shapes and geometry are very curious. Similarly with the other parts of the Architectural, Engineering and Construction (AEC) industry façade design can be no longer executed by BIM and parametric modules. The pilot design “Agora Garden” designed by Vincent Collebaut has been chosen as a twisted tower and modelled within Autodesk Revit. It constructed with gardens on the façades’. In this study, its façade design joined to parametric module that built with Dynamo. It has developed as a decision maker which considering environmental effects on the façade.

2 Features & Examples Of Twisted Towers As Diagrid Structures

As diagrid systems twisted towers have become a game changer for AEC. As it has been mentioned above, while structures of diagrid systems accept no fault in computation, it should be designed precisely. Traditional building design methods cannot provide to architects and engineers to carry out the design and construction process for such these building types. The concept of diagrid is not new at all: people have always been intuitively familiar with the inherent stability of triangular structures [8] Placement of diagonals is the oldest and most natural solution in steel structures, and has had widespread applications, receiving great popularity among engineers and architects; however the past architects considered diagonals highly obstructive and usually embedded them within the building interior cores [5] All the contents of construction such as; structural optimization, foundation, spatial decisions can be analyzed via BIM. One of the most curious titles of the project for these types is façade design. Since façade systems have significant roles on energy assumption, building functionality and aesthetic of building design of it is quite sophisticated process. While BIM ensure to design detailed model of the façade systems of the twisted buildings, parametric components ease to reach optimization result which is the useful façade design and material [9].

A high-rise structure where its form is the result of a combination of angled facades on the Z axis is termed as Twisted Tower [2]. Innovative and highly sophisticated digital design tools lends immense capabilities to architects and structural engineers to design highly complex geometrical structures which can be materialised making use of cutting edge technologies, traditional as well as specially developed building materials and highly efficient building practices. Recent decades have seen many high-rise buildings with twisted structures. Most of these have achieved iconic status and have become notable landmarks bringing fame to their locality [1].

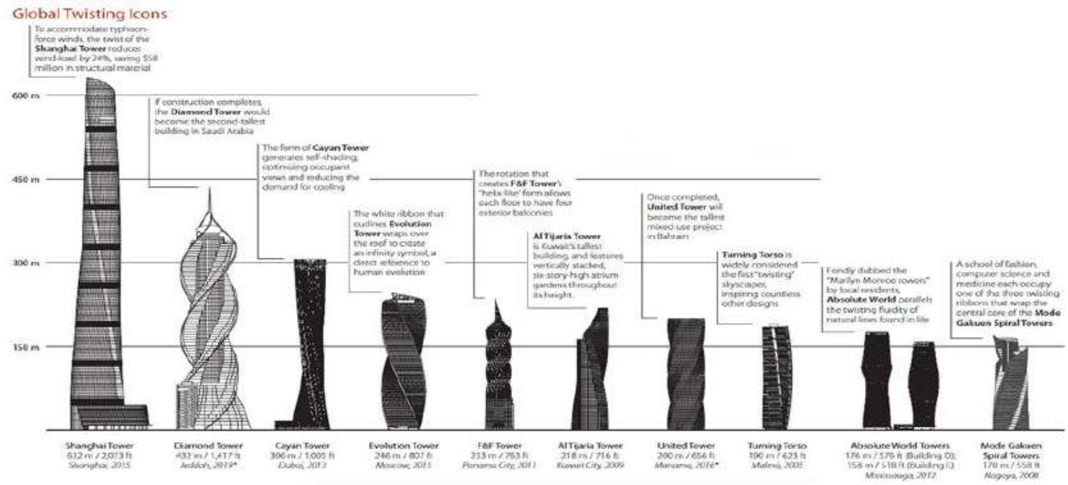

Figure 1. The tallest diagrid twisted towers around the world

A twister is a building with floors that lie horizontally rotated around a vertical axis. This axis usually lies in the centre of the floor plan. Often there is a cylindrical core, around which floor-wings lie. The structural members, mullions and contours all circle helically upward around the rotation axis, resulting in a non-orthogonal superstructure. In a simple Twister all floors are identical and rectangular; they are positioned with a fixed incremental rotation. This type of design can make a building more aerodynamic and energy efficient, leading to an increasing number of twisted tall buildings entering the planning stages throughout the world.

The design for Capital Gate in Abu Dhabi makes a more unobtrusive gesture on the façade regarding the location of the diagrid situated behind the triangular glazing. While the two-storey module size, designed to support the building's 18^0 lean, constitutes one of the smallest modules to date, the member sizes are large and to translate this to the visual appearance of the façade would have been quite overbearing. Instead, a slight colour change at the visible grid is used to acknowledge the pattern of the diagrid structure [10]. In general, these sorts of twisted building forms tend to subdue the reading of the module through the façade.

Figure 2. Famous diagrid structures with façades

3 BIM Model Of The Twisted Tower

Principally in the concept of this study, a selected twisted tower has been the template of the study and it has been modelled as BIM. While selecting the project It is considered that the structure is already completed and opened to use the and the building should have twisted floors and façades together. Some twisted towers have only twisted façades not floors. It is thought that twisted floors with twisted façades give more opportunities for variable joints and so variety design solutions.

3.1 Selected Twisted Tower As a Template

Design of Vincent Callebaut Architecture "Agora Garden" (Figure: 3) has been found proper with the requirements that indicated at the top. Vincent Callebaut defines the tower as : "The 21 storey tower which is currently under construction in the Xinjin District of Taipei City, Taiwan, is directly modeled after a strand of DNA — a double helix twisting 90-degrees from base to top with each level turning by 4.5 degrees.

Figure 3. Selected twisted tower (Agora Garden) model to develop parametric module

According to the architects, this unique form provides solutions to 4 main objectives:

- To be perfectly integrated in the North / South pyramidal profile of the Building Volume along with its East / West rhomboidal profile as well as the North-South reverse pyramid profile.
- To generate a maximum of cascades for suspended open-air gardens, not part of the floor area ratio.
- To offer every resident exceptional panoramic views of the Taipei skyline by multiplying the transversal views, especially towards the very close Taipei 101 tower and the Central Business District."
- To generate from a flexible standardized level a progressive geometry which ensures the privacy of each apartment by avoiding direct visual axes.

3.2 Generating The Digital BIM Model Of The Twisted Tower

The BIM model of the tower was created by using Autodesk Revit. Since the main purpose of this study is optimizing the façade geometry, only the components related with façade was modelled (Figure: 4) The core of the tower as a circle has been placed with parametric properties such as radius. Beside this the vierendeel parts was modelled as floors from ground level to 21st level. The angel of the floor around Z axis changed as

4,5 degree floor by floor. At the end, the first floor has been rotated 90 degree when it reached at 21st level.

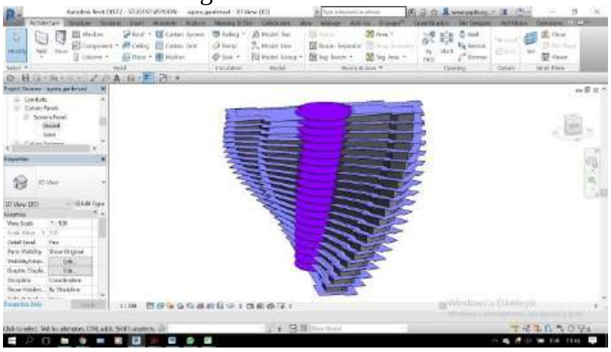

Figure 4. Selected tower's BIM model creation (from Autodesk Revit)

The parametric network was generated by Dynamo (Figure: 5). The rotation of the floors can be customized and the walls placed automatically thanks to parametric network.

The network of floors placement and rotation was established within the visual programming (Figure: 4). The main purpose of the network is to set a template of adjustable rotational floors for BIM. This is not only providing to design twisted structures easily and effectively rather than manual methods also generates to reach the optimal solution of the façade design. It is probably emerge that the angle of the storey floors' rotation required to be changed. The existing project has glass walls for exterior. Owing to its green architecture and design considerations this twisted tower hasn't any curtain wall system or any façades. Despite this status, a parametric façade grid system which enables to adjust via variety of analysis, has been generated (Figure: 5). The grids of façade can be changed by geometry included 3d rotation and translation.

The façade design method was offered with visual parametric programming. Once in Revit interface, mass modelling is used for general façade shape. Since twisted towers generally have curvilinear surface, mass modelling with points should be used for façade. For quite specific façade design mass surface converted as divided surface (Picture :). The countless alternatives can be endeavoured to reach the optimum design even though the shell associated with multiple shapes and amorphous geometries thanks to divided surface. The whole cell of the divided surface might be customizated such as colour, dimension, etc. customization. The "divded surface" node which is in visual programming Dynamo was used for this progress

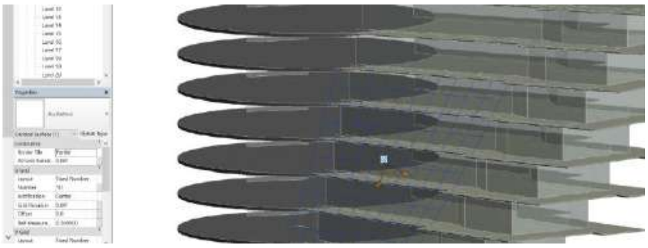

Figure 5. Façade developlent on the BIM model

3.3 Parametric Networks and Features Of The BIM Model

Design stages that applied parametric method are programming, site planning, massing, structure planning, and facade planning. The objectives of the method are project's time efficient, human related advantages (non-determinant decision-making, creativity, pattern recognizing, and advantages by using computers [6]. As mentioned above, the variables of the model has been defined within the parametric network. The panels and mullions of the façade can be changed thanks to this network. The network of the Dynamo loop enables to designers creating many façade alternatives included variety panel dimensions & materials, join types and etc easily for this type of towers. Once, the elements which is composing the surface of the BIM model select via the node of the "select model elements". The floor edges was defined as lines which can be manipulated by their start-end points and by their angles. The storey number of the tower linked to the Dynamo network and it can be tried for any number. Façade surface placed at given storeys and floors' edge.

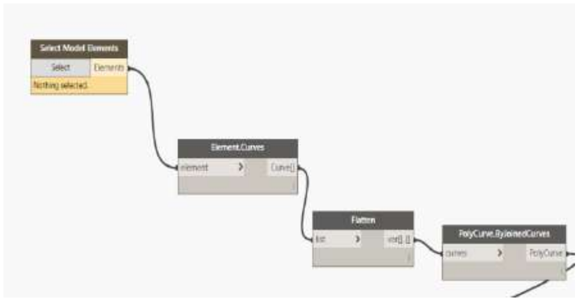

Figure 6. Parametric module development process

The caotic data from the edge lines of the floors arranged with list and list filter nodes. It gives variety opportunities such that any edge of the floor can be unchanged when the others manipulated. The joint component such as rivets and screws can be placed and count even among many alternatives. The grid system enabling to design variety façade options can be placed with any distance from the floors. As adaptive family 3d amorphed panels which dimensions' can be changed via Dynamo nodes generated, it is possible to place a prominent panel system in any geometry on the façade grid system.

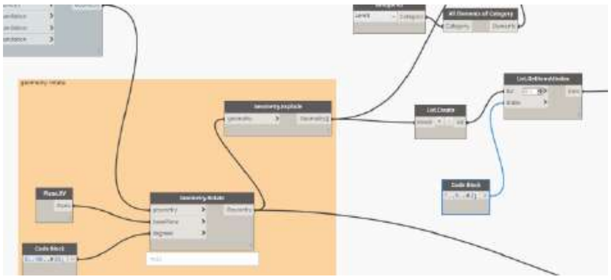

Figure 7. Filtering among multi lines

4 Using the BIM Façade Module As Decision Making Tool

On the instance of the BIM model, multi façade panel geometries, different colour of the façades and the angle of the grids was analysed as per shading and solar lighting. The analysis has been summerized, note that variety types of analysis can be done on the façade systems. Dynamo nodes were used for trying various alternatives to get the optimum solution (Figure. 8).

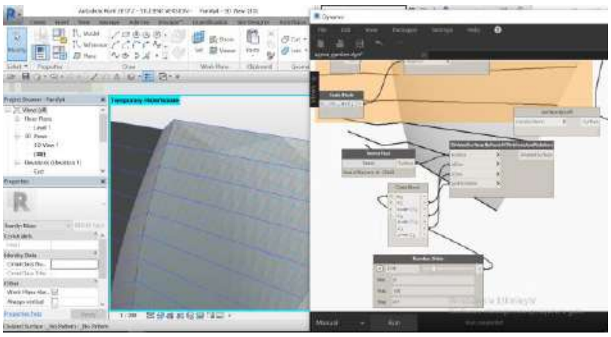

Figure 8 : Fine tuning for optimum façade panel geometry

As mentioned above the façade analysis has been executed on the panel geometry and panel colours. Combinations with the color and geometry of the panel has been connected by the nodes of Dynamo. The colour of the panels has been placed randomly by the "math random" node. It can be inferred from the analysis that how the contrast of colours effect on the interier light and shadow. In addition to this the light and shadow map of the project can be created. The lighting level and shading area was measured depends on the façade combinations. Not only horizontal and vertical grid distance has been connected by the parametric formula but also the angles of the grid lines put into the formula. In addition the mullions' angles and materials might be customized along to the light sourcing and shadow analysis. The network enables to the experts that they make the analysis such as: energy, sunlight, shadow and artificial light.

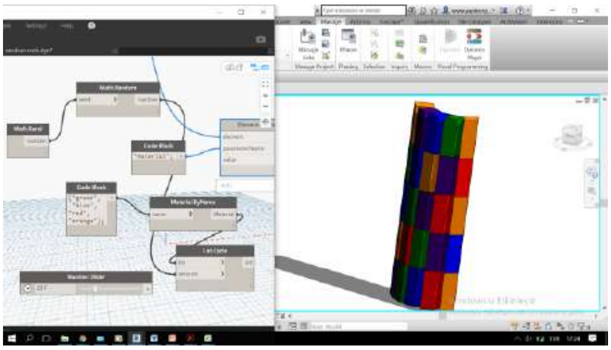

Figure 9. Façade colouring by Dynamo

Twisted geometry provides that more alternatives can be created rather than straight face. If the façade geometry were straight the combination types with geometry & colour would be 10 times less than twisted.

5 Conclusions and Further Studies

Façades are the widest areas of the buildings. They should be analyzed efficiently for energy saving and comfort. Variety alternatives should be tried to reach the most effective solution. In traditional methods only few façade options can be analyzed cause of cost and time especially. If the structure have complex surface, it is much more harder. A BIM based parametric module was generated. This module is unique with regards to specify just for twisted towers. As twisted towers' have rotated floors and curvilinear surfaces in sync, they deserve more efficient façade analysis and most effective selection. Such these modules enable to designers and constructors to reach most efficient solution at the end of so many analysis. The selected twisted façade gives to search more alternatives and it provided to get the best solution as far as possible.

BIM and parametric design getting more curious role in AEC in consequence of seeking energy efficiency buildings whose analysis are complex and cautic. The practical and open source modules should be generated for every unique structures. Additionally, augmented reality (AR) or virtual reality (VR) options which enables to evaluate to the building façade performance to professionals, architects or engineers will be enhanced. Such these modules can be assisted to the analysis developments.

It is thought that the twisted surfaces provides more advanteges to the AEC to construct more sustainable structures and new materials competible with such these shapes will be invented from the nature. Building such these sophisticated buildings and those all analysis are no longer easier than the past thanks to BIM and parametric design tools.

Abstract –

Construction work involves a number of repetitive and physically demanding tasks. Exposure to these labor intensive tasks with awkward postures result in an increase in biomechanical risk factors that may lead to work-related musculoskeletal disorders (WMSDs). Thus, it is essential to provide training for apprentice-level workers to adopt safe working postures. Recent advancements in sensing technologies have enabled us to automatically collect body motion data and analyze posture. The present work presents an automated posture assessment method using inertial measurement units (IMUs) allowing for in-depth ergonomic analysis via kinematic data. A case study on masonry work was performed and body motion data from masons with varying experience levels were collected. For the posture analysis, we first investigated the risk of working posture between experience groups using observation-based posture assessment methods (RULA and REBA), then compared the assessment scores between experience groups. Finally, a prototype training tool based on working posture was introduced. The experimental results show that the automated collection and analysis of motion data can provide greater understanding of working postures adopted by workers with different experience levels with the potential to be used as a training tool in apprenticeship programs.

1 Introduction

In the construction industry, workers are frequently exposed to tasks that contribute to work-related musculoskeletal disorders (WMSDs), including overexertion during lifting, repetitive tasks, and awkward postures [1, 2]. Among construction workers, masons are more prone to WMSDs due to frequent lifting and static postures used while handling heavy building materials [3]. In 2010, the masonry trade was found to have the highest rate of overexertion injuries (66.5 per 10,000 full-time equivalent workers) and the second highest rate of back injuries (45.3 per 10,000 full-time equivalent workers) within selected construction subsectors [1]. Furthermore, repetitive tasks have shown to be related to an increase in physical fatigue levels, which can result in greater incidence of accidents and lowered productivity. Hence, it is of great importance to analyze ergonomic risks associated with construction tasks to mitigate the prevalence of WMSDs among construction workers.

Observation-based posture assessment methods have been widely used to identify and monitor potential ergonomic risks associated with WMSDs [4]. These methods include the Rapid Entire Body Assessment (REBA) [5], Rapid Upper Limb Assessment (RULA) [6], and Ovako Working posture Analyzing System (OWAS) [7], which produces risk levels based on input elements such as posture, work duration, and repetition [8]. Traditionally, observation-based assessments require an ergonomist or task analyst to visually assess a worker's posture during an activity in real-time or post-evaluate using a video recording [9]. Body joint angles are the primary input element to describe posture; however, is difficult to obtain precise and reliable input values due to human errors in visual assessments [10].

Recent advancements in motion capture systems have spurred their use in several applications from visual effects in entertainment to biomechanics and sports performance. Motion capture systems based on wearable inertial measurement units (IMUs) can automatically and accurately track motion data. Wearable IMUs are less expensive compared to other motion capture systems, can be used in most site conditions, and do not obstruct the natural motion of wearers. Thus, these wearable IMUs can be used to collect input elements (i.e. body joint angles) with greater accuracy for observation-based assessment methods.

Previous research efforts reported that less experienced workers showed higher lost-workday claims

[1] and significantly lower productivity than experienced workers [11]. Specifically, Alwasel et al. [11] investigated the joint force and moments of masons who were grouped based on experience level, during a bricklaying task. The results showed that joint forces and moments were lowest in the group with the highest level of experience compared to the groups with less experience. Given that the experienced masons adopted safer and more productive methods in their work, it is possible to identify proper, task-specific working postures to develop training tools for inexperienced, apprentice-level workers.

This paper first compares WMSD risk levels of masons with varying levels of experience using existing posture assessment methods (i.e. RULA and REBA). Secondly, a prototype training tool based on working posture is introduced. A case study on masonry work was performed to demonstrate the motion data collection process during a bricklaying task. Based on the motion data, working postures were determined and used as inputs to the RULA and REBA posture assessment methods. Potential issues about the posture assessment methods are discussed.

2 Literature Review

Many ergonomic assessment methods require inputs that describe posture since they are associated with joint force and moment generation contributing to the risk of WMSDs [12, 13]. Posture-based ergonomic assessment methods such as the RULA and REBA posture assessment methods evaluate the stresses on the musculoskeletal system and risk for WMSDs primarily using joint angles with reference to movement planes. RULA and REBA have been commonly applied in the construction industry to study the movement of workers. McGorry and Lin [14] used the RULA method to compare and demonstrate the utility of a proposed methodology that evaluates arm posture and grip strength in tool handling. Kim et al. [15] used the REBA method to estimate the risk of WMSDs in panel erection to improve panel specifications and workplace design. Using the RULA and REBA body part diagrams, a risk score and its prescribed action level for ergonomic intervention can be found. However, since these assessments are traditionally based on visual observations of joint angle, the results are prone to inaccuracies across different observers [10].

Due to the development of sensing technologies, various types of motion sensing systems have been introduced to improve the efficiency and accuracy of posture assessments. Popular among these sensing technologies are vision-based assessments, which use video cameras for object identification and tracking, and inertial measurement units (IMUs), which obtain motion data with accelerometers, gyroscopes, and magnetometers. For example, Ray and Teizer [16] used a Kinect range camera to classify work tasks as ergonomic or non-ergonomic. Alwasel et al. [11] used an IMU-based sensor suit and 3D Static Strength Prediction Program [17] to estimate joint forces and moments in a bricklaying task. Research efforts in WMSDs in the construction industry utilizing sensing technologies, to date, have been focused on posture detection, posture classification, and comparison of working posture to ergonomic standards. However, few studies have examined the differences in working postures adopted by workers with growing levels of experience. In this research, we investigate risk levels associated with working postures adopted by masons of varying levels of expertise using an automated risk assessment tool.

3 Methodology

In Ontario, Canada, the three-year masonry apprenticeship consists of on-site and in-school training. Upon completion, the apprentice can apply to become certified as a journeyman. Forty-five participants were recruited from the Brick and Stone Masonry Apprenticeship Program offered by the Ontario Masonry Training Centre. The experiment was conducted at two institutions: Conestoga College in Waterloo, Ontario, and the Canadian Masonry Design Centre (CMDC) in Mississauga, Ontario. The participants were separated into four cohorts based on years of experience: novice with no experience, apprentice with 1-year experience, apprentice with 3-years of experience, and journeyman with 5 or more years of experience (Table 1).

Table 1. Number of participants

	Novice	1 Year	3 Years	Journeymen	Total
Conestoga	5	4	7	5	21
CMDC	12	5	6	1	24
Total	**17**	**9**	**13**	**6**	**45**

Wireless motion capture suits, MVN Awinda from Xsense [18] and Perception neuron from Noitom Ltd. [19] were used to collect participants' motion data. The suits contain seventeen inertial measurement units (IMUs), and each sensor is composed of a three-axis accelerometer, three-axis gyroscope, and three-axis magnetometer. The suits collected motion data at a 125 Hz sampling frequency. The experiments were recorded using camcorders to label and segment the data in the data processing phase. Prior to the experiment, a calibration session was performed for each participant to ensure conformity between the models generated from the motion data and the participant's body. Each participant was instructed to complete a pre-built lead wall using forty-five concrete masonry units (CMUs), thus each bricklaying task consisted of forty-five individual lifts. Figure 1 shows the experimental setup with the lead wall. The pre-built lead wall was six-courses high and consisted of twenty-seven blocks. The participants completed the wall using CMUs from the second course to the sixth course. The CMU blocks were placed on three pallets approximately 1 meter away from the lead wall. Two panels of mortar were positioned between the three pallets and were continuously supplied by helpers. The CMUs are CSA"A" - Type "A" concrete units and each weigh 16.6 kg with dimensions of 390 x 190 x 100 mm (Canadian Concrete Masonry Producer Association).

Figure 1. Experimental setup.

After the completion of the bricklaying task, motion data from the IMU suits were extracted as Biovision Hierarchy (BVH) type files containing 3D joint orientation over time. Then, joint angles required for the RULA and REBA posture assessment methods were calculated using the International Society of Biomechanics (ISB) recommendations [20, 21]. As shown in Figure 2, a local coordinate system is defined for each body segment using joint centers, then the Euler angles between adjoining segments' coordinate systems were calculated [22].

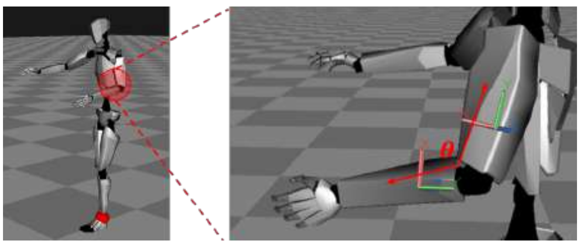

Figure 2. Joint angle based on Local coordinate system

The calculated joint angles were used to assign posture scores in both assessment methods. The RULA and REBA assessment methods consist of two body region sections to obtain a final score representing the risk for MSDs: 1) arm and wrist analysis, 2) neck, trunk, and leg analysis. The posture score according to the segment angle is first obtained, and then the score of each section is calculated considering additional adjustments such as external force and frequency. A final score is assigned by combining the previous two posture scores. The final RULA score ranges from 1 to 7 and final REBA score ranges from 1 to 15, which correspond to four and five risk levels respectively. Table 2 shows the final score range and corresponding risk level.

Table 2. Score range of RULA and REBA

RULA	
Score	Level of MSD risk
1-2	Acceptable posture
3-4	Further investigation, change may be needed
5-6	Further investigation, change soon
7	Investigate and implement change
REBA	
Score	Level of MSD risk
1	Negligible risk, no action required
2-3	Low risk, change may be needed
4-7	Medium risk, further investigation, change soon
8-10	High risk, investigate and implement change
11+	Very high risk, implement change

In this study, both the right- and left-side of body segment angles were obtained, however only the side with the higher score contributed to the final score. Since the wearable IMU suits collected 125 frames of motion data per second, a RULA and REBA score was assigned to each frame. Since each lift varies in duration, the maximum assessment score was selected for each lift. Considering more than 70% of all lift motions were two-handed lifts, the assessment scores were analyzed by selecting only two-handed lifts. Finally, the average final scores of each experience group were used for comparison.

4 Result and Discussion

4.1 Average RULA and REBA scores

Table 3 shows the average RULA and REBA score of four groups with different levels of experience. The overall average score of RULA is 6.95 and of REBA is

10.94, both indicating high risk for MSDs. In the score comparison between experience groups, the average RULA score was highest in the 3-years group, while the average REBA score was the highest in the journeymen group. The novice group showed the lowest score in both assessment tools. It is important to note that the variance of average scores among experience groups were not significant in both assessment tools. Specifically, the difference between the highest score and the lowest score is only 0.11 and 0.35.

Table 3. Average final score of RULA and REBA

Group	**RULA**		**REBA**	
	Average	SD	Average	SD
Novice	6.88	0.39	10.74	0.97
1 Year	6.96	0.22	10.89	0.97
3 Years	6.99	0.11	11.02	0.81
Journeymen	6.98	0.14	11.09	0.78

To build the lead wall, participants placed forty-five CMUs in five courses, from the second course to the sixth course. A detailed risk assessment score by course is shown in Table 4. Both assessment tools showed a lower final score when placing CMUs in the third and fourth courses in all groups. Since the third and fourth course are approximately at hip-height, the result may be due to less back- and arm-bending.

Table 4. Average score of RULA and REBA by course

Groups	**Average RULA score by courses**				
	2	3	4	5	6
Novice	6.94	6.84	6.80	6.89	6.92
1 Year	7.00	6.94	6.90	6.95	7.00
3 Years	7.00	6.99	6.97	7.00	6.99
Journeymen	7.00	7.00	6.92	6.98	7.00
Groups	**Average REBA score by courses**				
	2	3	4	5	6
Novice	10.98	10.62	10.44	10.67	10.99
1 Year	10.72	10.71	10.95	10.93	11.07
3 Years	11.18	10.90	10.90	10.89	11.21
Journeymen	11.07	10.67	10.92	11.22	11.34

The added external load in RULA and REBA is one of the important adjustment factors for the final score. In particular, when an external load greater than 22 lbs (10 kg) is applied, an additional 2 or 3 scores were applied resulting in a higher final score. The CMUs used in this study was 16.6 kg, and both assessment tools showed a very high-risk final score regardless of the various segment angles obtained by the participants. Therefore, in the case of heavy material handling tasks such as masonry work, the practicality of posture assessment methods may be limited since they do not provide significant results to differentiate between experience groups.

4.2 Prototype training tool

Although the average RULA and REBA scores were not able to provide results with significant differences between experience groups, the tools can indicate the risk of each body segment according to the joint angles. Thus, we developed a prototype training tool that provides independent joint scores and adopts the joint angle ranges used in the REBA scoring system since it provides whole body postural risk reflecting both upper- and lower-limbs joint angles. The training tool uses a color-map to reflect risk levels at selected joints. The angle range and risk level indicator is shown in Table 5.

Table 5. REBA Score-based Tool - Risk Level Indicator

Body Segment	Angle (degree)	Score	Risk Level Indicator
Shoulder	0 – 20	1	
	20 – 45	2	
	45 – 90	3	
	> 90	4	
Elbow	60 – 100	1	
	0 – 60 or > 100	2	
Wrist	0 – 15	1	
	> 15	2	
Neck	0 – 10	1	
	10 – 20 or 0 <	2	
Truck	0	1	
	0 – 20 or 0 <	2	
	20 – 60	3	
	> 60	4	
Leg	0	1	
	30 – 60	2	
	> 60	3	

Figure 3 shows a snapshot of the training tool applied to Participant #2 in the journeymen group. As shown in Figure 3, the red color indicates that the back and arm angles are unsafe for the participant. To correct the posture and maintain low risk levels, the participant must reduce the flexion angle of the back and shoulder by bending more at the knees and reduce the flexion angle of the arm by keeping the CMU block closer to the body.

Actual posture **Model in training tool**

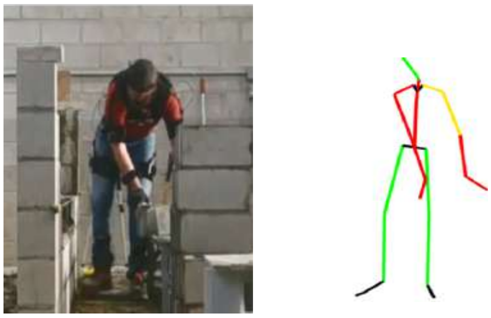

Figure 3. The snapshot of prototype training tool

As demonstrated, the training tool which continuously collects motion data, can inform its user of safe and unsafe working postures for the entire work duration. This allows the user to proactively correct unsafe postures and reduce the risk of WMSDs. The training tool has the potential to be used in apprenticeship programs to establish safe working postures.

5 Conclusion

The practice of safe working postures in construction work help workers maintain good health and productivity levels. Current observation-based posture assessment methods are subject to human error and lack precision. Recent developments of IMUs allow for the continuous collection of motion data which are more reliable for use in posture assessments. In this paper, motion data was collected from forty-five participants with different experience levels ranging from novice to more than 5-years of masonry experience. We analyzed the working postures of the participants while performing a bricklaying task using IMU suits.

Risk levels for WMSDs were determined and compared for each group using posture assessment methods, RULA and REBA. The results showed that the average maximum assessment scores across experience groups for RULA is between 6.88 and 6.99, and REBA is between 10.74 and 11.09. The results of the assessment methods showed that the assessments may not be able to differentiate between the working postures of workers with different levels of experience. Both assessment methods indicated that the risk levels for WMSDs were lowest when the participants were handling CMUs between the knee and hip level. We also presented a prototype training tool that was developed based on joint angle inputs used in the REBA scoring system. The training tool identifies unsafe postures using motion data collected during a work task so that its user can make necessary adjustments.

Future work will compare results obtained from the posture assessment tools presented in this study, with those obtained using biomechanical analysis (e.g., using 3D Static Strength Prediction Program). The biomechanical analysis will be used to determine joint forces and moments generated during the bricklaying task and to develop a biomechanical-based training tool. In addition, studies on work proficiency and productivity using training methods will be conducted.

Abstract –

The widespread application of offsite facilities has encouraged the construction industry to make use of manufacturing approaches to develop efficient production systems. To fully realize the advantages of offsite construction, management must be able to effectively schedule production activities to increase productivity and improve time efficiency. This necessitates a tool capable of dynamically responding to real-time production data throughout the process. Radio-frequency identification (RFID) has proven to be a useful technology to provide real-time location data for products moving through a production line and is often used as part of a reporting tool; however, the information provided by RFID also allows for proactive scheduling, which facilitates production line balancing. Maintaining a balanced production line in a variability-prone process requires the end-user to possess knowledge of the production line and the schedule and be able to effectively communicate the production requirements to employees on the production floor. Contextual information, obtained from RFID and measured against job information and production time data, can be delivered to production floor supervisors in real-time in order to enable timely and informed decision-making on the plant floor. This paper introduces a framework for effective production line balancing using data collected by RFID to dynamically update the production schedule and provide more data to help drive better decisions from production floor supervisors.

1 Introduction

A balanced production line is vital in offsite construction manufacturing, given that it decreases wait time and increases the productivity of the entire line. The aim of production line balancing is to divide the necessary tasks into a minimum number of workstations to optimize the total production cycle time [1]. Production line balancing can be considered a Lean tool and is often implemented during the design or setup of a new production line [2]. The line balancing problem has been studied for several years and can be formulated in various ways. One of the original formulations of the problem is the Simple Assembly Line Balancing Problem (SALBP) [3], where tasks are assigned to workstations and precedence relationships are defined. Tasks are then assigned to stations based on the precedence relationships while the takt time, or line cycle time, is used as a constraint to limit station times, thus minimizing the total number of required stations [4]. One of the primary limitations of SALBP solutions is that the inputs and constraints are considered static, while a production line is usually a dynamic operation. Continuous improvement initiatives, constant management input on the production line, and customizable products are examples of inputs that result in an increasingly dynamic problem. Jaikumar and Bohn [5] recognize that the "knowledge, learning, problem solving, and contingencies" introduced to the process by both the production line workers and the management team play a key role in the balancing of the production line.

Maintaining effective communication between management and production line workers is extremely important to ensure that the final product is built to the desired quality, and in the desired time. Production managers must communicate the requirements for supply chain, labor balancing, and production requirements. In order to make these decisions, the production managers require information from the production line, the desired schedule, and the inventory supply chain. The study by Heilala et al. [6] underscores the value of employing simulation with actual data to provide production managers with the information they require to identify potential problems and react to them appropriately. The use of real data and simulation can reduce the time required for information collection by the production manager and allow for effective decisions to be made in less time. Decision support tools, including Gantt charts and scheduling software, aid production managers in making decisions about the schedule and operation of the production line, and also provide an improved method of communicating the findings to production line workers; however, success with decision support systems requires that information be received from other systems, which is difficult to implement [7]. Gantt [8] himself recognized early on that having management specify tasks for workers to accomplish will increase productivity, and the effect will be even greater if any issues are foreseen and managed by the supervisor.

Radio-frequency identification (RFID) is widely used by industry to track components in the production line. Literature proposes the use of RFID technology in tracking precast concrete pieces [9], material delivery vehicles, and construction workers onsite [10]. The basic premise behind RFID systems is similar to barcode technology, but the RFID system stores the data (identification number, code, other object-related information) in tags making it retrievable by specialized readers. Depending on their power source, tags can be recognized as passive or active [10], where passive tags depend on the reader to operate and have shorter read ranges, and active tags use internal batteries for their power supply, which makes their read ranges significantly higher, they have a limited lifetime of 5-10 years and are more expensive due to their local power source. Overall, the specifications of RFID include their power source, read range, read rate, frequency and data storage capacity, and operational life time and cost [9].
Because of the RFID reader's ability to communicate with several tags at the same time, the contents of elements loaded into a manufacturing facility can be captured [11]. While RFID gates are used at pre-designed locations to identify the arrival dates of material to the station, the primary task includes reporting the identification information to the system for further processing [12]. According to Song et al. [13], implementing RFID technology at laydown yards and portal gates paves the way for time savings in material identification, increasing accuracy and shortening time for establishing information on material availability at the plant for further project planning and resource allocation.

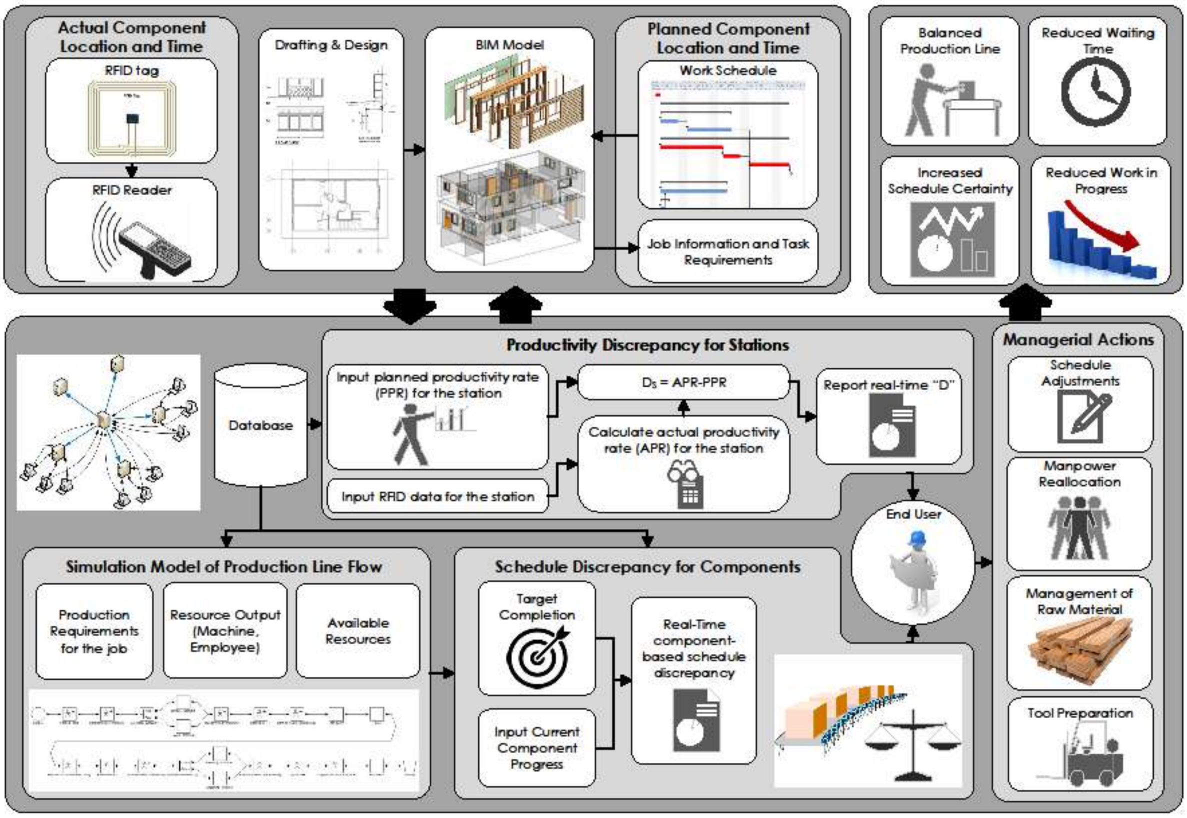

Figure 1. Overview of proposed framework

2 Motivation

A pull system is preferable in a manufacturing setting given that it reduces the work in progress in the facility. Operating a pull system requires knowledge of when each component needs to be completed and how long it will take. This knowledge is usually gained by production managers through years of experience, which leaves the production vulnerable to errors and sudden variations, such as changes in staff. Managers are aided in decision making through reporting, scheduling, and production tracking carried out with the use of RFID data, estimators, and planning departments; however, there is a significant time discrepancy between when information becomes available, when it can be analyzed by the corresponding department, and when it is communicated to the production manager, who only then can make adjustments on the plant floor.

The framework proposed in this paper aims to reduce the time to evaluate and present decision makers with relevant data, allow for the integration of the current plant state into the plan, and to ensure a pull system by planning production progress based on the delivery time for each component.

3 Proposed Framework

The proposed framework utilizes building information modeling (BIM), radio-frequency identification (RFID), and the known work schedule to provide information to production managers or other decision makers in a production facility with reduced delay and necessary manpower. This information will be used to allow the production manager to make more effective, educated decisions while on the plant floor. Figure 1 presents the proposed framework, which is discussed in more detail in the following sections.

3.1 Actual Component Location and Time

The RFID system feeds the last known location of production components to the database. The level of detail for the RFID location is dependent on the number and location of RFID readers in the plant. While the RFID system cannot locate the exact coordinates of any component in the plant, it is able to track the current station each component is in, when it arrives at the station, and how long it has been at the station. This data is used to set the starting point for the simulation model based on the true current state of production in the plant. Using RFID data to determine the current state of the plant reduces the time required for plant managers to collect information about the plant through pure observation.

3.2 Planned Component Location and Time

The information for the planned component location and time is gathered from the work schedule, which will detail the required completion dates for each job; and, the job information and task requirements, together with input from drafting and design and the BIM model, will determine the expected time for the processing of each task in the production line.

3.3 Productivity Discrepancy for Stations

The productivity discrepancy within each station (D_S) refers to the difference between the planned productivity rate (PPR) and the actual productivity rate (APR) for the station. This measure is useful to the end user as it will help to quickly identify the performance of each station compared to that which is expected. These metrics will be available to the end user through a visualization system that enables quick identification of the relative performance of the departments.

3.4 Simulation Model of Production Line Flow

Operating a pull system requires knowledge of the processing time of each station in order to ensure that components will be pulled through the system in a manner that minimizes idle and wait times. The simulation model will use the required completion date for each project along with the BIM model, job information, and task requirements from the database, which will enable the calculation of processing times for each job at each station based on the characteristics specific to each job. The simulation model will then determine how the jobs will run through the production line and interact with one another in order to identify where in the production line each job should currently be in order to meet the required deadline (or as near to it as possible). The simulation model is resource-dependent and built to illustrate the actual case in the plant, including required equipment and its availability, utilization of manpower resources and their limitations, and sequence of production activities required to complete each job.

3.5 Schedule Discrepancy for Components

From the information in the database and the output of the simulation model, the difference between where each component of each job is in the production line and where it should be can be calculated. This discrepancy is important and distinct from the productivity discrepancy of the stations because, even if all stations are meeting or exceeding their target productivity, certain components may be behind the projected schedule that would allow them to be completed by their required completion time.

3.6 Managerial Actions

The information provided to the end user (production manager) will allow for better knowledge regarding the current state of and requirements for production in the plant. The production manager will then be able to make schedule adjustments, such as pulling a component that is ahead of schedule off of the line to allow a component that is behind schedule to accelerate, reallocating manpower to different stations to balance station productivity and requirements based on job types, managing raw material to ensure that there is no wait time or idle time, and preparing tools for certain jobs that are upcoming in the schedule.

4 Proposed Implementation

4.1 Visualization System

To ensure that the end user has consistent access to the production statistics, it is preferred to have a visualization system that can be brought into the production area. This can include the use of tablets or smartphones by the production manager, for which a sketch of the proposed interface is presented in Figure 2. Here, a red bar in the station productivity area (left of view) indicates that a station's productivity is lower than expected, while a green bar indicates the station's productivity is meeting or exceeding that which is planned.

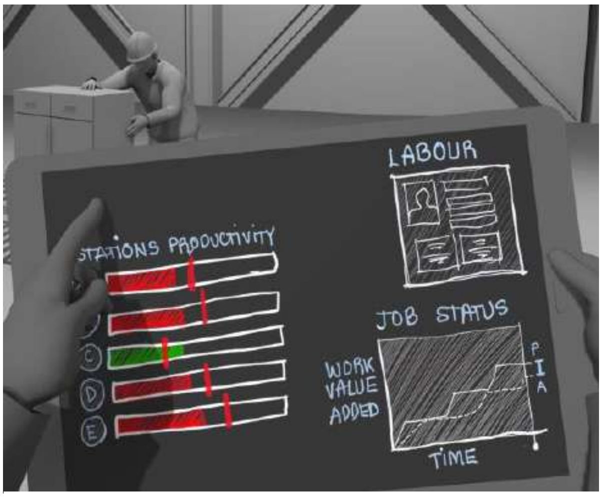

Figure 2. Tablet data display

4.2 Cabinet Manufacturer Case Study

To illustrate some scenarios where the proposed framework would improve on current plant operations, the case of a cabinet manufacturer is described. Change orders, defects and rework, and schedule adjustments all occur in a manufacturing facility and often require production managers to make immediate decisions while on the plant floor. At the time of these decisions, the only information available to the production manager involves statistics and updates gathered at previous meetings or by the manager through current production reporting tools, which often have a significant delay, as well as any information gathered throughout the day by means of observation. This leads to the possibility that the production manager is forced to make decisions based on incomplete information, or that decisions need to be delayed while the required information is gathered. A typical layout for a cabinet manufacturing facility is presented in Figure 3.

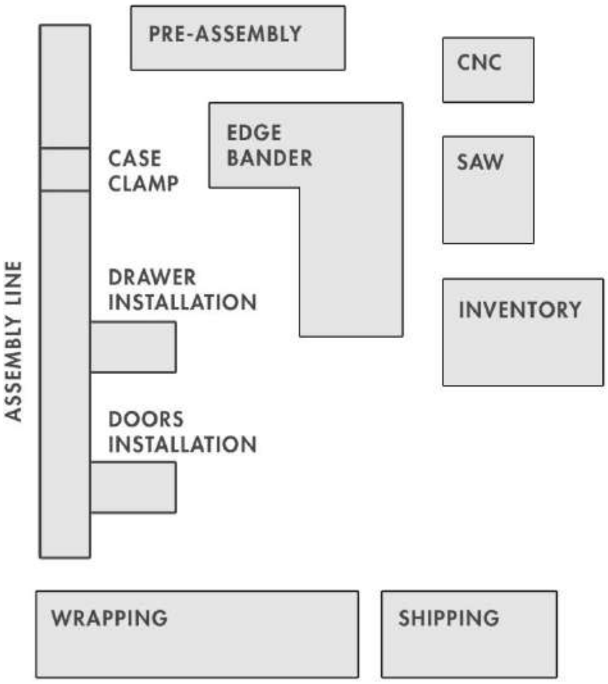

Figure 3. Typical cabinet manufacturer plant layout

One example of a common change that often requires intervention on the plant floor by the production manager is a change in delivery date or schedule change due to material shortage. Most of the cabinets manufactured at the case study facility are designed to be installed in new houses. The date on which the cabinets are needed is dependent on the construction schedule of the house, which can be highly variable. Since the case study plant works closely with partner homebuilders, they have access to construction information and can use this to update the project completion dates to help ensure they are operating a pull system. With the implementation of the proposed system, production managers would be able to track components on a real-time basis, see the outcome of a schedule change on the production line, and be able to make decisions to allow jobs to be processed based on their corresponding deadlines. For example, if one customer of the case study plant is not prepared for the delivery of their cabinets, finishing these cabinets will not benefit the manufacturing plant, as they will then have to store the completed product until it can be delivered. With a daily production of about 200 cabinet boxes per day, and 6-7 boxes fitting on each skid (which covers an area of 1.2 m^2), 31 skids are filled each day. Since the plant only ships orders three days per week, a floor area of 74.4 m^2 is required to store completed jobs between shipping dates. Storing additional finished product reduces the available storage area and reduces production effort available for urgent jobs. The production manager can make changes based on the priorities apparent to them from the information available through the proposed framework to ensure that the production facility maintains a pull system and that wasted storage space is reduced. Also, by the means of the proposed framework, managers would be able to schedule based on the current shipping date of jobs and the estimated production time. The estimated production time remaining is calculated based on the data obtained from RFID and production estimates based on the job characteristics gathered from the BIM model.

The production manager will also be able to monitor the day-to-day production of each station and use this to make labor adjustments to balance the production line. Creating a balanced production line with a variable product such as cabinets is difficult since, with current systems, it is difficult for the production manager to receive continuous details about the plant operations. With the proposed system, the expected workload of each station could be calculated based on job characteristics from the BIM model, and the actual performance relative to the schedule would be consistently available based on the data obtained from RFID, as seen in Figure 2. The production manager could use this information to identify training requirements, to monitor labor efficiency, and to reallocate workers in the plant to ensure each station is keeping up with the schedule. In the case study plant, the pre-assembly area requires the most manual labor and triggers the next activities on the line; therefore, this area has a significant impact on the output of the production line. With the use of the proposed system, the level of productivity at this station would be represented by a red bar, indicating to the production manager that a decision must be made to help increase the productivity at this station. The production manager could then make an educated decision to reallocate workers from another station presenting a green bar (indicating that station is exceeding the planned productivity) to help balance the line. The manager could also decide to implement training for the workers in the pre-assembly area, or to recommend other improvements based on their experience and observations.

Finally, the proposed framework can help to identify and deal with the adverse impacts of rework. For the production manager, being able to instantly show the location of all job components by using the proposed system with up-to-date RFID data, track the job completion progress, or locate a BIM model based on the station being viewed and the job that is currently at that station greatly reduces the time required for valuable information to be located compared to traditional systems. For example, if the case study plant receives a report from a customer about a missing component in the package delivered to their site, the production manager will have instant access to the RFID data for that job and is able to quickly locate the last location at which that component was scanned to help identify the issue.

5 Opportunities and Challenges of Proposed Framework

The proposed framework is intended to address the need to maintain crew work continuity in a construction manufacturing setting. Various interruptions to production line flow, such as plant shutdown, equipment maintenance, employee turnover, variations in productivity, and rework, make it difficult to effectively balance the production line and consistently meet the plant schedule. The proposed framework provides opportunities for improved accessibility of tracking data, efficient communication, real-time schedule monitoring, and innovative data visualization. Figure 2 and Figure 4 present conceptual illustrations of the system from the point of view of the end user.

Common scheduling techniques tend to be complicated to visualize and they lack the means to display the productivity of activities. For example, consider a plant with a productivity rate of 5 jobs per day, where each job consists of 20 units (i.e., 100 units/day); if each includes 6 sequential activities, this would produce a 600-activity network, which may be relatively complicated to schedule and visualize. With the proposed framework, tracking data is easily accessed by the production manager using the system. As illustrated in Figure 2, the production manager can use the system to see the relative station productivities, as well as the more detailed statistics relevant to a selected station or job.

The proposed system will decrease the time required for a production manager to view data required for making effective management decisions, but will still require them to be able to identify the particular job or location they want to see and navigate through the user interface to find the required data.

In the future, this system could be improved through the use of AR as a tool to help the production manager visualize the information; however, current AR technology requires some improvement to ensure that the safety and maneuverability of the manager using the system can be maintained.

5.1 Future Visualization Improvements

The visualization solution would ideally match the complexity of the data presented to the user while considering elements of user experience (UX) specific to factory environments. For instance, safety is a major concern on construction sites and in manufacturing facilities. Computer equipment such as a tablet must be relatively rugged compared to standard office equipment and may require protection from environmental elements such as dust proof enclosures to protect from saw dust. Depending on the manufacturing facilities, these types of considerations must be accounted for. The simplest solution would be to use existing technologies such as tablets and smartphones. Graphs and charts would present the user with context-sensitive data. At the time of writing this paper, 2D data visualization technologies and techniques are mature and relatively user friendly to implement. In his study, Tufte provides guidelines for visualization of complex data [22], making this solution highly feasible; however, it is not without its challenges. Most importantly, tablet screens can distract the user from their environment and could lead to safety issues.

A preferable solution would be to implement augmented reality elements in the visualization. Such a system would ideally use a head mounted display, such as Google Glass or Microsoft Hololens, to overlay the data over the factory view of the user. This would allow the user to move around the factory environment without having their hands occupied and without having their attention diverted back and forth to a screen—a distraction that could be a safety hazard. Furthermore, overlaying data on a real-life scene could enable more effective and contextual data visualization. For instance, 3D CAD models could be overlaid on existing components. This could be coupled with data which describes the length of time needed to complete the operation in the current station, the length of time required for all remaining production for the specific component, or additional information about the job. Figure 4 illustrates how an AR system of this kind would appear to the user.

Detailed implementation of this kind would be contingent on the development of improved technologies that can track the locations of factory elements in real time and with a high degree of location accuracy. As more elements are tracked more data is collected in real time and is run through the simulation. The implementation of a system such as this is also dependent on the development and integration of an AR system that can update quickly enough to satisfy the needs of the proposed framework and allow the system to move wirelessly throughout the plant.

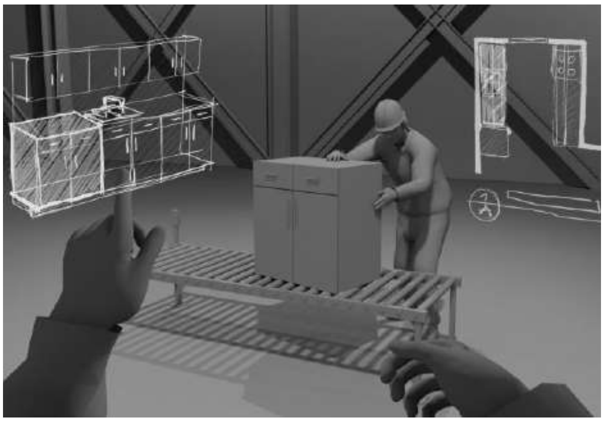

Figure 4. AR overlay of BIM model

6 Conclusion

An effective manufacturing facility requires efficient data exchange between the office and the production line, which enables production managers to make decisions based on the most current information available. The framework proposed in this paper enables the automation of the data exchange and its presentation to the production manager.

The present study integrates the RFID system into the scheduling process and presents the results to the production floor manager. Implementation of the proposed framework provides increased access to tracking data, reduces waste in the communication process, increases the scheduling certainty, and innovatively presents real-time production data to the end user.

Data is currently presented to the user through hand-held devices, such as tablets of smartphones, but could be transferred to AR systems in the future to allow for hands-free viewing, and to enable the user to remain mindful of their surroundings. This transfer should only occur if the system allows for wireless movement throughout the production facility and enables the user to maintain a natural field of view for safety reasons.

Abstract –

Efficient inspection and maintenance of bridges are vital for improving safety and sustainability of infrastructure systems. Recently, Light Detection and Ranging (LiDAR) scanners are used for detecting surface defects. The LiDAR scanner can be mounted on an Unmanned Aerial Vehicle (UAV), which provides easier accessibility to most parts of the structure and can fly close to the structure. There are two types of mobile LiDAR scanners: 2D and 3D. A 2D scanner is more affordable, but it can only scan points on a plane. However, a 2D scanner can be transferred into 3D scanner by rotating the scanner using a servo motor. This paper aims to design a platform for LiDAR-equipped UAV for structural inspection using an affordable 2D scanner. First, the requirements and other design considerations are introduced. Then, the design details and the hardware and software integration steps of the LiDAR-equipped UAV platform are discussed. The initial test of the platform showed that it can provide acceptable accuracy for detecting large defects.

Keywords –

LiDAR; UAV; Structural Inspection

1 Introduction

Efficient inspection and maintenance of bridges and other structures are vital for improving safety and sustainability of infrastructure systems. Traditionally, visual inspection using non-equipped eyes and manual measurements are used for detecting surface defects, which may lead to subjective results. This approach is time-consuming and unsafe, especially for inspecting the inaccessible elements of a bridge [1].

Recently, 3D Light Detection and Ranging (LiDAR) scanners [2] and cameras [3] are used for detecting surface defects (e.g. cracks) using computer vision methods. In general, LiDAR technology is more expensive than cameras, and defect detection results may miss some edge points. However, it is a promising method, not only for detecting the location and size of the defects but also for computing their depth and volume [4, 5]. Also, unlike digital images, the generated point clouds are not affected by lighting, and their analysis does not require supplementary information [6].

The LiDAR scanner can be mounted on a tripod [1] (i.e. terrestrial scanning) or on an Unmanned Aerial Vehicle (UAV) [7, 8] (i.e. aerial scanning). Although terrestrial scanning provides high stability for the scanner and less vibration, it is not time efficient. The aerial scanning provides easier accessibility to most parts of the structure and can fly close to the structure. Consequently, higher coverage of the inspected surfaces and more accurate results can be achieved.

In addition, the LiDAR-equipped UAV eliminates the inspectors' falling risks encountered in the traditional inspection method. The risk of damages caused by the UAV is low because of its size, weight, and controllability [10]. The Special Flight Operation Certification (SFOC), required by the Canadian Aviation Regulations, includes the plan of operation respecting specific safety rules, such as the distance between the operators and UAV, keeping people away from the flight site, and flying the UAV in the Line of View (LoV) [11].

LiDAR-equipped UAVs are used in different applications such as surveying [12], inspection [13], navigation [14], and agriculture [15]. There are two types of mobile LiDAR scanners: two dimensional (2D) and three dimensional (3D). A 2D scanner is more affordable, but it can only scan points on a plane, while a 3D scanner can capture the point cloud of the surrounding space, which makes the data more accurate. However, a 2D scanner can be transferred into 3D scanner by rotating the scanner using a servo motor [16] or by moving the scanner on a robot/UAV while collecting the point cloud [17]. The accurate rotational positions of the servo or the Simultaneous Localization And Mapping (SLAM) algorithm can be used to register the collected data. For example, in the research of Winkvist et al. [17] and Bachrach et al. [14], a 2D

LiDAR is mounted on the top of a UAV, and SLAM is used for generating the point cloud taking advantage of the vertical movement of the UAV. In order to increase the Field of View (FoV) of the scanner, in the ARIA project [16] a servo mounted on the UAV is used to rotate the scanner while the UAV is flying, which leads to collecting 3D point clouds for inspection and navigation purposes. However, the details of the platform design for integrating the UAV, the servo and the scanner are not available in the literature.

The objective of this paper is to design a platform for LiDAR-equipped UAV for structural inspection using an affordable 2D scanner. The remaining sections of the paper are as follows: First, the requirements and other design considerations are introduced in Section 2. Section 3 provides the design details and the hardware and software integration steps. Section 4 provides an initial test of the platform. Section 5 provides the conclusion and summary of future work.

(a) MIT RANGE [14]

(b) CMU ARIA [29]

(c) Stormbee [28]

Figure 1. Scanner position on top of UAV in (a) and (b), and under UAV in (c)

2 Design Considerations

In order to have a successful design of the LiDAR-equipped UAV, the following should be considered:

2.1 Objectives

The maximum coverage of the surface of the inspected structure and the minimum cost are the two main objectives of an efficient inspection using the LiDAR-equipped UAV. The main costs of this method are the equipment cost and the flight cost. The flight cost depends on the time of the flight. The full coverage may not be achieved because of the obstacle near the inspected structure, which can limit the visibility of the LiDAR. So, the path planning goal is finding a collision-free path with minimum time-of-flight and maximum coverage.

2.2 Requirements

In order to choose the most appropriate LiDAR-equipped UAV, all the following requirements should be considered with respect to the budget.

(1) Mounting location: Most of the commercially available solutions have the scanner mounted under the UAV because they are designed for surveying purposes (Figure 1(c)). However, for structural inspection purposes, the LiDAR can be mounted either on top (Figure 1(a) and (b)) or under the UAV depending on the location of the inspected area of the structure.

(2) Metrology method: There are two types of metrology methods for LiDAR: Time-of-Flight (ToF) and Phase Shift (PS). ToF is used for long range of measurement with the accuracy of 4-10 mm at 100 m. Unlike ToF, PS is practical for short range of measurement with 2-4 mm at 20 m [1].

(3) Maximum payload: The maximum payload is the weight that the UAV is capable to carry. Therefore, the weight of all carried devices (e.g. scanner, minicomputer, batteries, and GPS) should not exceed this threshold. The payload affects the UAV time of flight because carrying a heavier payload consumes more energy. As the weight of the scanner is one of the major weights in the payload of the UAV, it should be carefully considered. Providing a light and accurate scanner is expensive, and choosing the best option depends on the available budget. Moreover, extra batteries are needed to supply the power for the scanner and other electronic parts attached to the UAV (e.g. servo, microcomputer, etc.).

(4) Size of UAV: The UAV should be big enough to carry the scanner and other equipment, and small enough to fly safely as close as possible to the inspected surface.

2.3 Constraints

There are several constraints which should be considered during the planning.

(1) Minimum and maximum distances: A specific distance range should be considered during inspection based on safety and the characteristics of the scanner. The density of the scanned point cloud decreases with longer distances.

(2) Battery capacity: The battery capacity has effects on the time of flight. As mentioned above, although adding more batteries helps the UAV to fly further, it increases the weight of the system.

(3) Vibration: The vibration of the LiDAR-equipped

UAV during inspection causes errors. A suitable design of a LiDAR-equipped UAV, which includes designing an appropriate engine and body shape, installing dampers, etc., can decrease the vibration [18].
(4) Degrees of Freedom (DoFs): Each UAV has six DoFs: three displacements (x, y, and z) and three rotations (roll, pitch, and yaw). In general, the pitch and roll of the UAV are constrained to keep the UAV in a horizontal position.
(5) LiDAR parameters: The 2D and 3D scanners have one and two FoVs, respectively. The FoV is an important parameter in the visibility analysis. Furthermore, other important parameters of the scanner are the angular resolution ($\Delta\theta$), incidence angle (θ), and beam diameter (Figure). The accuracy of a point cloud is mainly related to the measurement resolution, angular resolution and scanning speed. In the case of the 2D scanner integrated with a servo, the angular resolution and the speed of the servo affect the accuracy of the generated point cloud.

2.4 Other considerations

(1) Safe operation: Mounting additional devices should not change the center of gravity of the UAV because it effects on the stability of the UAV. Also, the additional devices should not interrupt the GPS signals.
(2) Real time: The LiDAR-equipped UAV platform has to collect a large amount of point cloud data to be used in real time for path planning and obstacle detection.

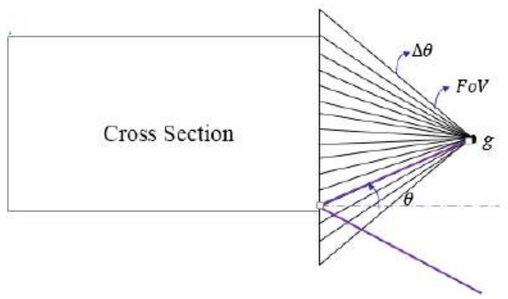

Figure 2. Some specifications of the LiDAR

3 Platform Design

UAV selection

DJI Matrice 100 [19] is used in this platform because it is customizable and has expansion bays to mount the scanner and other devices on top or below the UAV. Also, its radius is less than one meter, which makes it agile and able to enter narrow spaces near the inspection surfaces. The specifications of this UAV are shown in Table 1. The maximum payload is about 1.2 Kg.

Table 1. UAV specifications

Specification	Value
Max takeoff weight	3.60 Kg
Net weight	2.43 Kg
Battery	5700 mAh – 22.8V
Diameter	996 mm
Hovering time (no payload)	28 minutes

LiDAR selection

Hokuyo UTM-30LX 2D laser range finder is used for data collection because of its light weight and affordable price [20]. The specifications of this scanner are shown in Table 2.

Table 2. Scanner specifications [19]

Specification	Value
Detection range	0.1 ~ 30m
Accuracy	±30mm (under 10m)
Horizontal FoV	270º
Angular resolution	0.25º
Scan speed	43,200 points per second
Weight	210 g (without cables)

Servo selection

In order to enable the scanner to generate a 3D point cloud, a servo is used to rotate it. Dynamixel MX-28T is a robotic actuator servo that can control the movement of the scanner with a minimum step of 0.088º, which means the angular resolution of the platform is 0.088º. By rotating the scanner 180º, the vertical FoV of the scanning becomes 360º.

The servo uses an adapter (USB2Dynamixel) to connect to the microcomputer and another adapter (SMPS2Dynamixel) to connect to the battery. Both the servo and the scanner need a 12V power supply.

Microcomputer selection

To control the scanner and the servo, and to collect data from them in real time, DJI MANIFOLD microcomputer is selected in this platform because it is compatible with the UAV [21]. The power for MANIFOLD is supplied directly from the UAV.

Electronic connectors

An isolated voltage regulating board is designed and built to convert the 25V power of UAV's port into 12V. This board makes it possible to run the scanner and servo without adding an extra battery. The weight of the voltage regulating board is 72 g.

Interfacing parts using 3D printing

Although previous research exists about interfacing a servo with 2D LiDAR [22] , the integration with the

UAV requires additional interfaces to control the direction of the scanning. Three different interfacing parts are designed and 3D printed to attach the scanner and the servo to each other and to the UAV. The designed parts are shown in Figure 3. Figures 3 (c) and (d) show the parts for attaching the servo to the UAV in vertical or inclined positions, respectively.

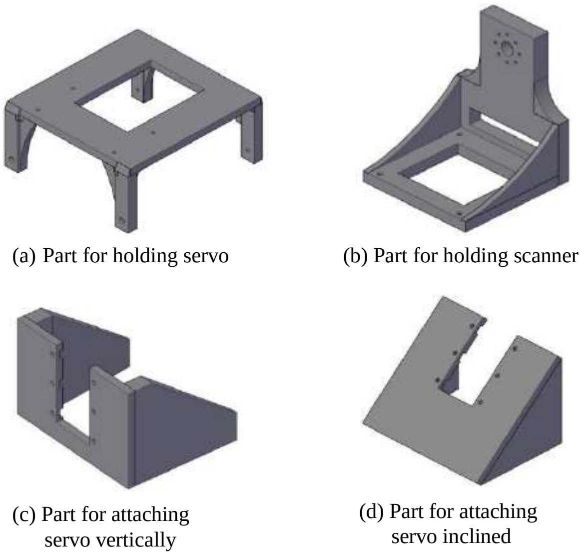

Figure 3. Design of interfacing parts for 3D printing

3.1 Integration

To integrate the components, hardware and software integrations are required. These are discussed in the following sections.

3.1.1 Hardware Integration

Figure 4 shows the integration of the hardware components of the platform. Table 3 shows the summary of hardware specifications and their connectivity to each other. The total weight of the integrated platform is 3.13 Kg, which is less than the maximum takeoff weight of the UAV.

In this platform, the scanner rotates 180º (from -90º to 90º). It stops for 0.1 s when changing direction from clockwise to counterclockwise. This stop causes some errors in the registration process of the point cloud. It is possible to rotate the scanner continuously in one direction by adding a slip-ring between the scanner and the servo to eliminate the rotation of the cables of the scanner. Figure 5 shows the interfacing part for mounting the servo on the UAV vertically or with inclination, and the corresponding configurations of the LiDAR-equipped UAV platform.

3.1.2 Software Integration

Spin Hokuyo Robot Operating System (ROS) software package is installed on the microcomputer to create 3D point clouds in real time [23]. This software works under Ubuntu operating system and contains the code to control the servo and the scanner to generate a 3D point cloud. Spin Hokuyo has five nodes for the following purposes: (1) two nodes (tilt motor and tilt transform) for controlling the servo and assembling point cloud messages; (2) one node (Hokuyo robot filter) to remove unnecessary points that are related to the body of the operating robot. It eliminates all the points inside the radius of 50 centimeters; (3) one node (scan to PCL (Point Cloud Library)) to convert the scanned data into point cloud messages; and (4) one node (PCL assembler client) to combine all the published point cloud messages into one point cloud message. Spin Hokuyo can adjust the initial, start and end positions of the servo and its rotation speed. The SLAM algorithm can be used in the software package to enable the platform to scan during the UAV flight.

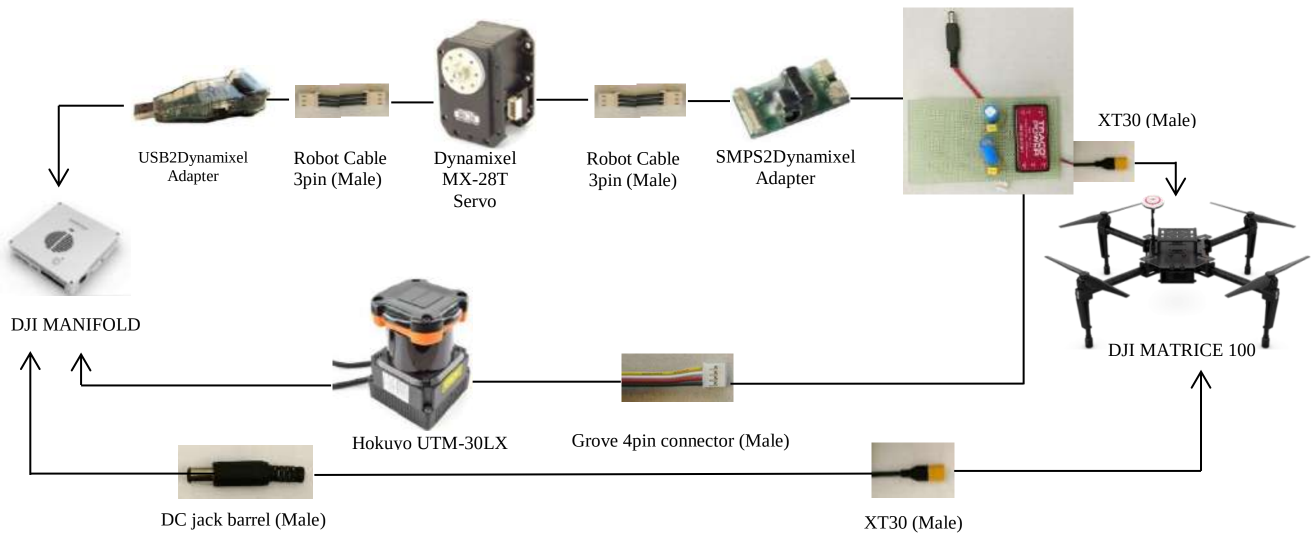

Figure 4. Hardware integration

Table 3. Summary table of hardware components

Component	Function	Voltage (V)	Current (A)	Weight (g)	Attached to
Hokuyo UTM-30LX	Laser Scanning	12	1.0	210	MANIFOLD, Voltage Regulator Board
MANIFOLD	Controlling scanner and Servo	14-26	Up to 10	197	UAV, USB2Dynamixel Adapter, scanner
Dynamixel MX28T	Rotating scanner	12	1.4	72	USB2Dynamixel Adapter, SMPS2Dynamixel Adapter
USB2Dynamixel Adapter	Connect servo to MANIFOLD	N/A	N/A	28	Servo, MANIFOLD
SMPS2Dynamixel Adapter	Power supply for servo	12	1.4	14	Servo, Voltage Regulator Board
Voltage Regulator Board	Regulate the voltage to 12V	9-36	3.3	72	SMPS2Dynamixel Adapter, scanner, UAV
Part for holding servo	Connect servo and scanner to UAV	N/A	N/A	45	UAV, 3D printed servo part
Part for attaching servo vertically	Connect servo to the table part	N/A	N/A	26	Servo, 3D printed table part
Part for attaching servo inclined	Connect servo to the table part	N/A	N/A	29	Servo, 3D printed table part
Part for holding scanner	Connect scanner to servo	N/A	N/A	31	Servo, scanner

After scanning, the point cloud that is generated by Spin Hokuyo can be visualized in Rviz (ROS 3D visualization tool) [24]. Rosbag package records the output messages of spin Hokuyo and save them as Bag file [25]. There is a node named *Bag to PCL* in PCL-ROS package, which reads the Bag file and converts ROS point cloud messages to PCD (Point Cloud Data) files [26] CloudCompare software can open and visualize PCD point cloud files, and convert them to other point cloud file formats, such as LAS, LAZ and E57 [27].

In this work, Spin Hokuyo is used in a stationary mode for initial testing as explained in Section 4. When integrated with In the case of flying on a UAV, because the GPS signals may not be available when the UAV is flying under a bridge., Therefore, other localization methods can be investigated, such as integrating an onboard Inertial Measurement Unit (IMU) with Visual Odometry (VO), Simultaneous Localization and Mapping (SLAM) algorithms, or Lidar Odometry and Mapping (LOAM) [16].

4 Initial Testing

Before moving to outdoor flying tests of the designed platform, the initial test is performed in an indoor environment, and it is limited to testing the LiDAR system (LiDAR, servo, microcomputer, battery, interface elements and connectors) when the drone is stationary. The width, length and height of the room are 4, 7 and 3 m, respectively. The generated point cloud is shown in Figure 6(a). Color distribution of the point cloud is based on elevation. The horizontal and vertical FoVs of the LiDAR system in this test are 270º and 360º, respectively. The LiDAR scans the environment in 2D lines, and each line contains 1,080 points. The number of lines of scanning in a sweep is dependent on the rotation speed of the servo. In this test, the rotation speed was set on 0.5 radians per second. Each sweep is π radians, so, one sweep was taken about 6.28 s to complete. The LiDAR scans 40 lines in a second, so, one sweep should contain about 251 lines and almost 270,000 points. The point cloud shown in Figure 6(a) is generated by 13 sweeps, and contains 3.2 million points. Each sweep has about 250,000 points. Some points are eliminated by the filtering node.

In order to check the accuracy of the collected point cloud, the same space was scanned with a higher accuracy 3D LiDAR scanner (FARO Focus3D) to generate a ground truth point cloud. FARO Focus3D is a 3D laser scanner with the accuracy of 2 mm, which can scan about one million points per second [26][22].

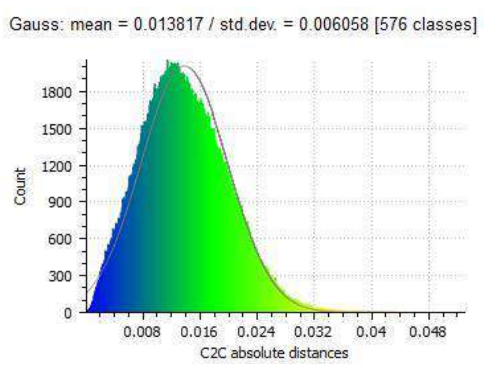
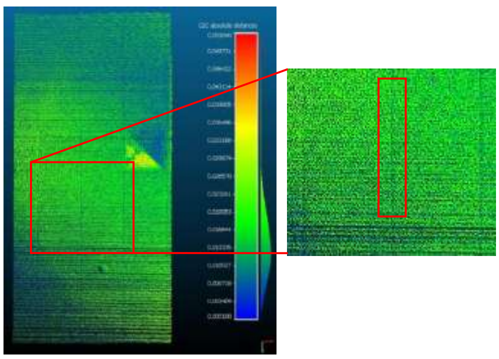
(b) Segment of point cloud

(c) Reference segment using FARO



(d) Comparison distance distribution histogram (m)



(e) Compared segment coloured based on distances from the reference segment

Figure 6. Initial testing results

A segment of the ceiling with the dimensions of 2.3 m × 4.7 m is selected (Figure 6(b)) and compared as cloud-to-cloud distance by CloudCompare software, where the distance of each point of the compared cloud is measured to its nearest neighbor in the reference cloud.

The two point clouds were aligned to each other manually in CloudCompare by picking five equivalent point pairs. Each segment contains about 250,000 points. The segment point cloud from FARO (Figure 6(c)) is considered as the reference cloud. The distance distribution histogram of the comparison is shown in Figure 6(d). Gaussian distribution is used in this computation, and the mean of the distribution is 1.4 cm with the standard deviation of 0.6 cm.

As shown in Figure 6(e), the gaps between the drop ceilings tiles of the room are visible. The width of these gaps is about 2 cm, which is greater than the calculated error. Assuming that these gaps are similar in size to some large cracks that could be detected on the actual structure during inspection, the accuracy of the point cloud collected by the platform can be considered enough to detect this size of cracks.

5 Conclusion and future work

In this study, a LiDAR-equipped UAV platform is designed to collect 3D point cloud data using a 2D LiDAR scanner. The design satisfies the main identified requirements and constraints for structural inspection. The platform is realized and tested in an indoor environment in a stationary mode.

Our future work includes: (1) applying the LOAM method integrated with an IMU to register the point cloud when the UAV is flying, and (2) testing the platform in the outdoor environment and defining the size of the defects that can be detected based on the accuracy of the data..

Acknowledgment

We would like to thank Mr. Raymond Bruton and Mr. Dmitry Rozhdestvenskiy for their help in the hardware integration.

Abstract –

Automation has been an active research topic in the construction industry for many years to improve the accuracy, reliability, and efficiency of the construction process. This study identifies global research trends in automation in construction during the past 15 years by analyzing papers published in the journal *Automation in Construction*. Text mining, data clustering, and keyword network analysis were applied to identify emerging technologies.

According to the clustering of the most recent three years' research, the main topics fall into seven categories: BIM(building information modeling), optimization, data acquisition, big data and AI, 3-D printing, wearable devices, and others. Over the various regions and periods, the results showed that the research focus has shifted from traditional mechanical automation to construction data acquisition, management, and analysis, introducing a new historical period in construction automation.

Keywords –

***K*-means clustering, Text mining, Keyword network, Trend analysis, Construction automation**

1 Introduction

Construction automation can improve construction quality, work productivity, and safety. Under the trend Industry 4.0, studies of smart construction technologies related to machine learning and the internet of things (IoT) and information and communications technologies (ICT) are currently the focus of active research.

Research trend analysis is essential to securing core source technology through R&D, and it is also essential to assess current technology status and to identify promising research areas for construction automation. Therefore, it is important to assess the current state of technology and to identify promising research fields in construction automation [1–5].

As the primary outcome of basic research, a research paper contains detailed and specific descriptions of the research activities, so papers are rich and valuable data for understanding innovations and changes in technology [6]. Therefore, the use of research data for understanding the status of the technologies of construction automation can be considered as a significant analysis method.

Text mining is a representative, quantitative research method using natural language processing (NLP), and is currently used to extract keywords from large amounts of unstructured data and to derive implications through clustering [7]. In this paper, we apply machine learning based on the *K*-means clustering method to cluster research papers into several groups covering individual research topics. Core technologies by categorical groups are identified through the retrospective analysis method.

Keyword network analysis can be used in various studies, such as coincidence analysis of main keywords, social network analysis, and papers and patents citation analysis. This technique is currently used in various fields, such as social science, physics, and economics [8]. We used keyword network analysis to follow historical trends and to anticipate future patterns of research keywords.

The purpose of this study is to contribute to proactive research and development by comparing and analyzing research papers related to domestic and foreign construction automation technology in depth. Also, keyword-based semantic approach suggested a possibility of effectiveness in the analysis of technological trends, prospects in the construction field.

2 Theoretical Background

2.1 Literature Review

Several studies on trend analysis and prediction using research papers and patents have been conducted for construction automation. Son and Kim identified global trends and issues in automation and robotics technology in the construction industry by analyzing papers published in the proceedings of the International Symposium on Automation and Robotics in Construction (ISARC) [9]. Balaguer and Abderrahim analyzed robotics and automation in construction [10].

However, since 2010, there has been no analysis of trends in construction automation research. This study identify the state-of-the-art research trends in construction automation to reveal promising technologies in the past 15 years.

2.2 Text Mining

Text mining refers to extracting information from unstructured text data in natural languages. It extracts and processes hidden patterns or relationships and finds useful and meaningful information. It is based on NLP. The process of text mining consists of data collection, preprocessing, analysis, and visualization of extracted data.

2.3 TF-IDF

TF-IDF is a weight value for each word used in text mining. It is a statistical weight used to determine the importance of a word in a specific document.

Term frequency (TF) is a value indicating how often the selected word appears in a document. Higher values indicate that the term is more important in the document. If the word is frequently used within a set of documents, it generates a high document frequency. The reciprocal of this value is called the inverse document frequency (IDF). TF-IDF is the product of TF and IDF [11].

The IDF value is determined by the nature of the document family. For example, the word “construction” does not appear very often among general documents, so its IDF value is high and it can be a keyword in documents. However, if the document family is a collection of construction papers, “construction” becomes a cliché, and other words will receive high weight values.

2.3.1 Mathematical Background

The simplest method to calculate the TF is to use the total frequency of the word appearing in the document. If the total frequency of word t in document d is $f(t, d)$, then the simplest TF calculation method is expressed as $TF(t, d) = f(t, d)$.

Another way to calculate the TF value is called increasing frequency, adjusting the word frequency according to the length of the document as follows:

$$\mathrm{tf}(t,d) = 0.5 + 0.5 \cdot \frac{f_{t,d}}{\max\{f_{t',d} : t' \in d\}}$$

IDF indicates how frequently a word appears in an entire document set. It can be obtained by dividing the total number of documents by the number of documents containing the word and then taking the log.

$$\mathrm{idf}(t,D) = \log \frac{N}{|\{d \in D : t \in d\}|}$$

If a word appears frequently in a particular document but only a small number of documents contain the word, the TF-IDF value is high. Therefore, the TF-IDF value is utilized to filter words that are common in all documents. Because the IDF log value is always one or more, the IDF value and the TF-IDF value are always zero or more. As the number of documents containing a certain word increases, the value in the log function becomes closer to one. In this case, the IDF value and the TF-IDF value converge to zero:

$$\mathrm{tfidf}(t,d,D) = \mathrm{tf}(t,d) \times \mathrm{idf}(t,D)$$

2.4 Keyword Network Analysis

To obtain a correlation and historical tracking of keywords, we used keyword network analysis. A keyword network consists of main streams, nodes, and links. A keyword is extracted from the author’s keyword list and indexing keywords provided by *Automation in Construction*. This keyword-based analysis creates several groups of keyword networks with relationships between keywords, and the results afford a sense of the evolution of research trends in construction automation.

2.5 Clustering Method

A clustering method is an analytical technique in which objects are grouped into clusters so that individuals having similar characteristics are grouped together.

In text mining, the extracted keywords are vectorized, and the correlations between documents and words are extracted based on a distance, such as Euclidean distance, cosine similarity, or Manhattan distance between words to perform clustering.

The main purpose of data clustering is to identify the characteristic of each clustered class, and *K*-means clustering, *K*-nearest neighbors clustering, and principal component analysis are the main methods used to cluster the data.

This study used *K*-means clustering after text mining. This method clusters a given data set into *K* classes according to the median values, and it is an efficient method for finding clusters from large amounts of data.

3 Research Analysis

To analyze the research trends in the automation of construction, three main analyses were carried out in this paper. First, the number of papers published over the past 14 years was surveyed to observe global trends in the research and to find quantitative contributions. Second, studies over the past 15 years were divided into five-year periods, to derive the correlation for each research keyword over time through keyword network analysis. Finally, research methods and subjects were extracted and clustered over the past three years to investigate the latest research trends.

3.1 Data Collection

In this study, 1880 research papers were collected, published by *Automation in Construction*, during the period between 2004 and 2018. An R program was used to conduct keyword extraction, preprocessing, frequency acquisition, and *K*-means clustering.

3.2 Relative Research Contributions by Country

Figure 1 quantitatively shows research trends in the world’s automation in the construction area from 2004 to 2017. The graph shows the number of research papers related to construction automation published in each country over those 14 years. The research scope of this paper covers papers published until February 2018; however, the papers published in 2018 were excluded from this analysis to show annual trends.

From 2010 to 2013, a quantitative expansion in research around the overall region is observed, while numbers remained almost steady in the earlier period. The United States’ contribution to the total number of papers has been very dominant overall. However, China showed remarkable growth from 2012 to 2013. This is an indirect indicator that China’s research investment toward automation construction is growing explosively. It has been predicted since the late 2000s that China will become a leading country in future automation research along with the increasing R&D in construction technology [12].

3.3 Keyword Network

To visualize and analyze the trend flow of construction automation over the past 15 years,

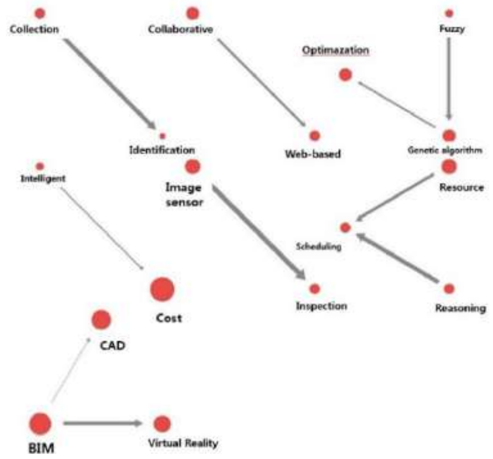

Figure 2. Keyword network, 2004–2008

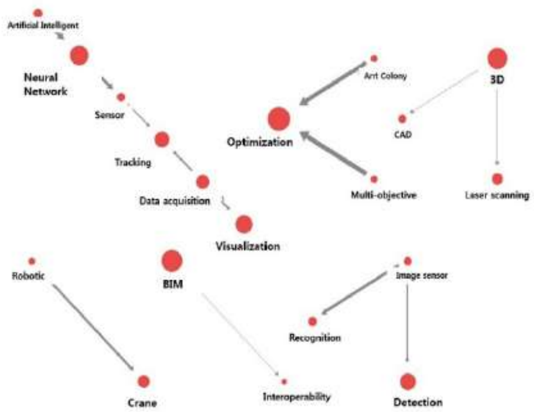

Figure 3. Keyword network, 2009–2013

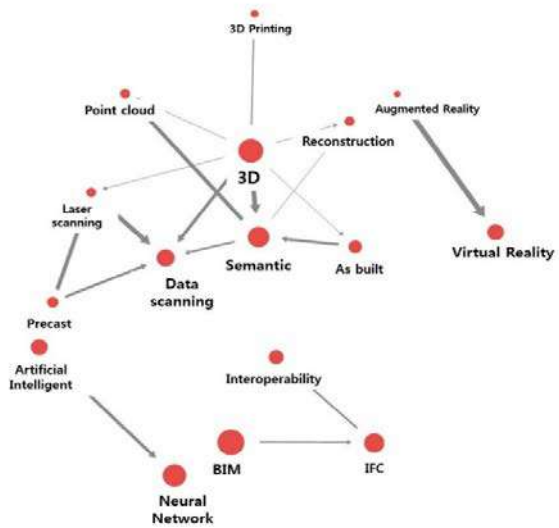

Figure 4. Keyword network, 2014–2018

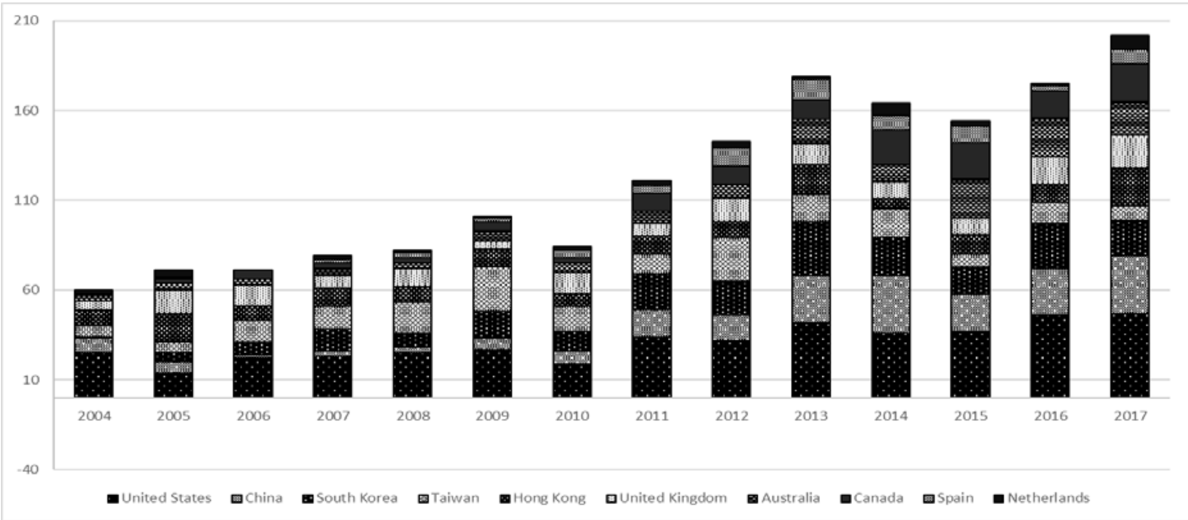

Figure 1. Relative research contributions by country, period 2004–2017

abstracts were gathered in five-year groups, keywords were extracted, and the correlations between keywords are visualized through the following network diagrams. In these diagrams, a larger circle indicates higher frequency and significance of the keyword. The direction of each arrow indicates the dependencies between keywords. A keyword without an arrow link means a separated technical factor keyword.

As shown in Figs. 2–4, research on BIM technology elements is maintained at a high level, and industry foundation classes (IFCs) and interoperability are active research fields. This suggests that the two technologies play important roles both as technology providers and technology adopters in construction automation.

Optimization studies are evolving and proceeding steadily with methodologies such as fuzzy theory, ant colony, genetic algorithm, particle swarm theory, and neural network theory on cost and scheduling, off-site placement, delivery, and simulation.

In the 2014–2018 period, improvements in emerging research areas such as laser scanning and 3-D reconstruction through point-cloud were observed. Further research on the visualization of buildings using drones and conversion between 2-D and 3-D drawing is expected. Real-time detection and tracking of construction equipment and workers with image sensors, augmented reality, virtual reality, and artificial intelligence can be identified as independent technology fields, and these fields are expected to be actively related with construction automation in future.

3.4 Research Trend during the Past Three Years

For research papers in 2015–2017 plus the 113 research papers in early 2018, *K*-means clustering was conducted to extract and analyze the main research topics and keywords for a total of 469 research papers.

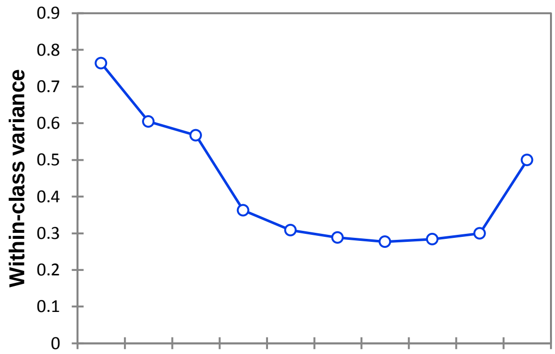

Figure 5. Variance within classes according to the *K*-value in *K*-means clustering

The *K*-value that minimizes the variance of the mean distance for each cluster was selected through repetition. Figure 5 shows the variation of variance according to *K*-value.

The topics and keywords extracted from each group after selecting a *K*-value of 7 are shown in Table 1. The number below the topic title is the number of research papers containing that topic.

Table 1 Extracted topics and keywords of the 2015–2018 group

Topic	Keywords
BIM (110)	CAD, 3D, 4D, management, IFC, data, interoperability, simulation, assessment
Optimization (57)	Algorithm, network, scheduling, layout, multi object, planning, swarm, harmony, genetic, ant

	colony, path
Data acquisition, (56)	Reconstruction, point cloud, detection, image sensing, RTLS, RFID, laser scanning, identification, inspection, monitoring, visualization
Big data, AI (29)	Neural, network, machine learning, energy, IoT, decision, monitoring, surveillance
Wearable devices (13)	Safety, worker, health, device, monitoring, occupational, physiology, sensing, management, hazard, identification
3-D Printing (12)	Fabrication, contour crafting, additive, adhesion, concrete, interlayer, pavement, structural
Other (192)	Energy, decision-making, safety, environment, equipment, earthwork, tunnel, bridge, assembly, mobile, musculoskeletal, prefabricate, excavator, interaction

In the clustering process, six methodology keywords for construction automation were extracted to improve clustering efficiency, and then the scope and objects of the classified categories were analyzed. The topics were divided into seven main categories; BIM, optimization, data acquisition, big data and AI, 3-D printing, wearable devices, and other.

BIM has become a common keyword in most fields, from architecture to civil engineering, and has been actively studied in all fields. Interoperability has been very actively studied to solve the problems of data sharing and consistency through an IFC.

In data acquisition, construction information was acquired through 2-D and 3-D image sensing and laser scanning. Extensive research was conducted on equipment and worker movements through site monitoring, maintenance of buildings through detection of damage sites, and 3-D reconstruction through point clouds.

Optimization has been applied to various fields, such as off-site yard and form placement, crane and lift operation, critical path analysis, and construction material management using different algorithms. Many studies have utilized experimental and evolutionary methods such as artificial intelligence, neural network theory, and big data.

In addition to the BIM and data acquisition topics, because the several technical elements have converged, it was difficult to specify papers as applying only to one research field. For example, laser scanning and BIM technology have been utilized together to analyze construction errors between as-built and as-designed through comparisons [13].

For wearable devices, studies on safety and risk management through real-time tracking were mainly performed by attaching sensors to workers.

There were also 192 papers not belonging to the above topic categories (grouped as “other”), and their keywords throughout the category were mainly related to construction data.

4 Conclusion

Text mining and *K*-means clustering were applied to research papers to analyze research trends and promising technologies for construction automation. The abstracts of 1880 papers published between 2003 and 2018 were analyzed in this study.

The construction industry mainly depends on manpower and is very vulnerable to variations in conditions. Different regional environments mean that no two projects are identical, which increases the dependency on experience and past performance. This leads to great difficulty in accumulating and utilizing well-organized quantitative construction information data.

Our research has discovered the changes in direction and focus of construction automation, from robotics development and machine automation to IT technologies. Construction robot development was very strong during the 1990s and was expected to be still the main research topic in construction automation [10]. However, only 13 robotics-related papers were found in the clustering analysis of the past three years of research. This was a relatively low research status compared with other topics. This implies that construction automation is not only replacing the labor force by adopting new construction methods but also by acquiring, analyzing, processing, and managing construction knowledge data using emerging technologies, such as big data processing, IoT, and artificial intelligence technologies.

A limitation of this research is that this paper gathered only abstract data rather than complete research papers; however, it is important that we used quantitative analysis methods rather than a qualitative method such as the Delphi technique or a survey. It was difficult to verify the characteristics and details of each research case. In addition, unique studies were treated as outliers and assigned to clusters that have less correlation in the clustering process.

By analyzing correlations with a keyword network diagram, current research trends and issues in construction automation were identified. In subsequent research, we expect that by tracking the knowledge transfer process through each paper's influence factor and identifying collaborative research networks based on research institutes and countries, quantitative and qualitative analysis of research flow and development will be possible.

Abstract

Construction laborers perform multiple labor intensive and physically demanding tasks, which exposes them to the risk of work related musculoskeletal disorders. When construction laborers sustain these injuries, they are typically reassigned to other tasks. The body motion involved in carrying out the assigned task should have limited use of the affected body part(s). This has implications on the productivity and health of a reassigned laborer. Traditional approach to reassigning laborers are subjective and ignores the effect of the tasks on the affected body part. To address this limitation, an ergonomic analysis framework is proposed to quantify the risk factors associated with body parts during the execution of construction tasks, so as to enable the reassignment of construction laborers to tasks that will impose the least strain on the affected body part. Preliminary results are provided to demonstrate feasibility.

Keywords –

Construction laborers; Work-related musculoskeletal disorders; Reassignment; Wearable technology

1 Introduction

In the construction industry, Work-related musculoskeletal disorders (WMSDs) make up about 37% of injuries experienced by the workers [3]. Of the injured workers, construction laborers are most likely to develop WMSDs because of the physically demanding nature of their tasks. The type of WMSDs usually sustained from these tasks are soreness and pains, carpal tunnel syndrome, sprains, strains and tears, and tendonitis (Figure 1). The most prevalent of these injuries are sprains, strains and tears. Figure 2 shows the rate of occurrence of this injuries amongst laborers in comparison to the overall construction industry. BLS [4] also shows that construction laborers are injured at the rate of 79.5 musculoskeletal disorders (MSDs) per 10,000 workers, while the overall construction industry's musculoskeletal injury rate is 49.2. Thus improving work safety practices of construction laborers is important.

Construction laborers perform a variety of tasks including removing debris and possible hazards, loading and unloading materials, bracing and unbracing scaffolding, digging and backfilling trenches and compacting earth to prepare for construction [5]. When they are injured, their supervisors typically reassign them to less strenuous tasks. This allows the laborer to continue working on the job and prevents the contractor or subcontractor from taking on a lost time injury on their experience modification rate (EMR) safety rating. Reassigning workers to less strenuous task is highly subjective and error-prone, as there is no means of verifying that the worker will be able to assume the postures required for the task. Each of these injuries affect different parts of the body and also restricts the movement of one or more limbs. Table 1 shows the types of MSDs and affected parts of the body. The degree of restriction on the limbs is determined from the postures and each posture is constrained by different muscle loadings, body and joint rotations [2], degree of bent of body parts [8], exposure to vibration and repetitive movements. Thus, to ensure that an injured worker remains on the job, while also being productive, it is important to reassign him to tasks that poses the least risk to the affected body part(s). Construction tasks are characterized by postures that involves multiple risk factors, this poses the following questions: (1) How can we reassign workers to tasks that poses the least risk to their injury, while also ensuring that they are productive? (2) How do we quantify the long term effect of this task on their health? This is important because there is currently no metric for assessing the potential effect the assigned tasks on the affected body part (or existing injuries) and potential of the injured worker to be productive on the reassigned task.

In-spite of the fact that a growing number of workers in the construction industry have WMSD, previous industry and research efforts have been focused on risk assessment [2,6,12,13,15] and prevention of WMSDs [10,14,16]. There have been limited efforts on how to keep injured workers on the job while also maintaining productivity. Furthermore, there have been limited focus on unskilled workers such as construction laborers and helpers.

The objective of this study is to propose an ergonomic analysis framework to (1) quantify the risk factors of postures, body parts and joints of tasks typically performed by construction laborers; (2) reassign injured construction laborers to tasks that will impose the least strain on the affected body part.

Table 1. MSDs and affected body parts [7,11]

MSD	Common affected body parts
Carpal tunnel syndrome	Fingers, hands, wrists
Tendonitis	Shoulder, waist
Soreness and pains	Neck, back, joints
Sprains and Strains	Joints (ankle, knee, elbow, shoulder), neck, lower back

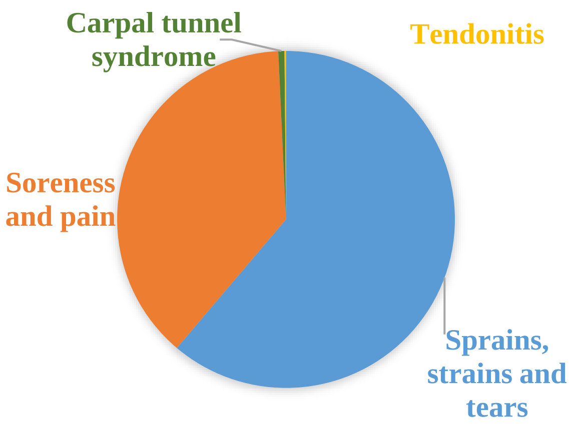

Figure 1. Proportion of occurrence of WMSDs amongst construction laborers

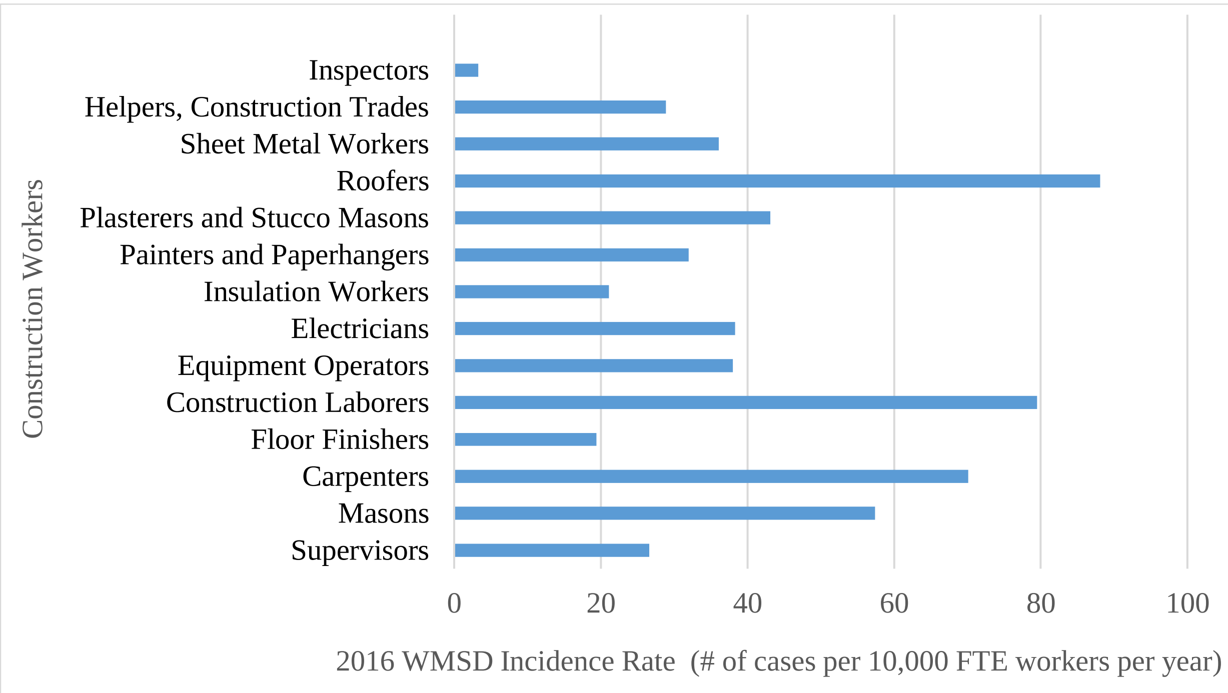

Figure 2. Rate of WMSDs amongst selected construction occupations for 2016

2 Framework for Construction Worker Reassignment

The proposed framework, shown in Figure 3, consists of the following stages: (1) Creating 3D human motion model to imitate tasks that construction laborers typically perform. In addition to this, actual body motion will also be generated from the lab and construction sites using image and component based sensing systems e.g. depth cameras and inertia measurement unit. Since it may not be physically feasible to capture all construction tasks, some of the tasks will be generated in the simulation model and complimented with the physically obtained motions; (2) Import the motion data from the body sensors into the 3D visualization platform; (3) Export the body posture data (from stage 1 and stage 2) from the 3D visualization into a database; (4) Store exported data in a database. The exported data are task, postures, associated body parts and loadings, joint angles and loadings; (5) optimize the data associated with each body part and joints (from stage 4) to predict construction tasks with the least risk to the affected body part; (6) Display suitable the task(s) and ranking(s)/associated effects on the affected part.

Depending on how the human body motion is being generated, the input could be the task process, task schedule, load, work environment and workspace design (i.e. if using the 3D Model) or the input could be the raw data depicting the body motion.

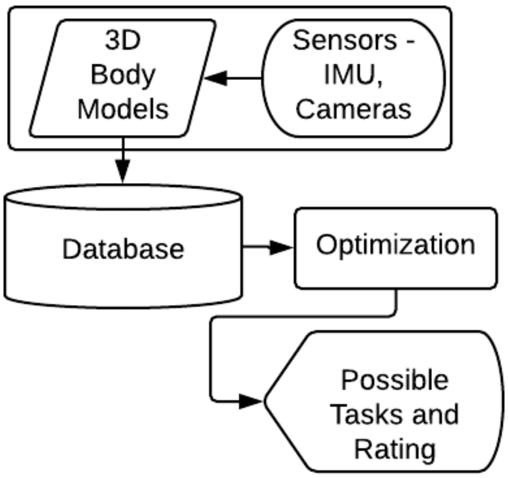

Figure 3. Framework for construction trade reassignment.

3 Preliminary Results

3.1 Sensing System

This study used the Inertia 3DSuit motion capture suit (Figure 4), which is a full body human motion capture system. The suit is based on 3D miniature inertial motion unit (IMU) sensors which includes tri-axial accelerometers, gyroscopes and magnetometers. The suit is equipped with an on-board signal processor and data fusion algorithm which extracts data from the sensors, processes the data and outputs the orientation of the sensors. The suit consists of 18 orientation sensors connected to a mobile bus processing unit which powers and receives data from the sensors via a serial protocol. The received data is wirelessly transmitted to any computer at the rate of 60Hz, to create a body skeleton of the tracked individual.

Figure 4. Inertia 3DSuit infrastructure showing the location of the IMU sensors.

3.2 Case Study

To illustrate the performance of the proposed framework, this case study describes a scenario of a worker who has knee disorder. The site manager has the option of reassigning the worker to one of the following three tasks: stacking wooden boards (Lifting); laying plumbing pipes (Plumbing) and installing lighting systems (Electrical). As part of an initial data collection, we designed an experiment to assess the motions, postures, body parts and joints of a subject while performing all three tasks in a laboratory setting. Prior to commencing the experiment, the computer was connected to a Linksys wireless router so as to aid capturing of motion data. The subject wore the suit and connected it to the wireless router. On calibrating the suit, the subject commenced each of the tasks. For example, while lifting and stacking the boards, the motion was recorded. The motion produced three key repetitive postures – Squatting, walking, and bending (Figure 5). At the end of the task, the recording was stopped and the data was saved. This process was repeated for each of the tasks. The extracted data was analyzed using Biovision software and exported as a .bvh file, which was visualized using Autodesk MotionBuilder. Figure 6 shows a typical bvh file. The posture and joint angles for each task was generated using Autodesk MotionBuilder.

(a) Swatting (b) Walking (c) Bending

Figure 5. Lifting Task Postures

3.3 Results

Table 2 shows the results of the case study discussed in the preceding section. The table shows the angles of the postures and affected joints of the three tasks.

The preliminary data consists of only the angles at the body joints for 3 tasks, as such, optimization is not required. For the purpose of identifying tasks with the least risk to the knee or that will not aggravate the existing condition of the knee, the angle at the knee will need to be compared for all the tasks. Andrews, et al. [1] identified that the risk of a disorder can be measured in terms of angle made by the affected part of the body i.e. the angle made by the knee in relation to the normal status i.e. when a worker is standing – when there is minimal physical stress on bones and muscles [9]. The larger the angle made by the knee, the higher the risk of injuries. Table 3 shows the risks for different knee flexion angles [1].

Table 3. Suggested sizes for measurement of knee flexion

Ergonomic Risk	Knee Flexion
Low	0^0-30^0
	30^0-60^0
	60^0-90^0
High	$>90^0$

From Table 2, by comparing the angles for the left and right knee, the 'Electrical' task appears to have the least angles and the least risk. However, in relation to Table 3, the risk to the knee of the laborer is still significantly high.

4 Conclusions and Future Work

This paper proposes a framework that uses human body motion analysis to reassign construction laborers. The framework uses body motion captured using 3D motion simulation software and motion sensors to capture tasks typically performed by laborers. The associated motion data of these tasks such as postures, affected body parts and joints, loadings on the body parts and joints, condition of the task environment, will be captured and stored for analysis. For any injured body part, these data will be optimized to predict construction tasks with the least effect on affected body parts. Preliminary work using a proprietary body suit has been presented.

For future work, a taxonomy of body motion of construction laborers for different construction tasks, will be developed.

Abstract

Buildings are typically designed to be aesthetically pleasing and cost effective, leaving out maintainability. This is partly because existing tools do not permit the involvement of facility managers or their inputs in the design phase. This has often resulted in the design of buildings with components or systems that cannot be accessed or are too costly to maintain. Such non-functional building components affects the performance and often, satisfaction of building occupants. Maintenance of inaccessible buildings components have also been known to have implications on the safety of facility managers. Therefore, this paper presents an approach that uses a gaming platform to engage facility managers in the design phase, while capturing their knowledge and experience for the purpose of improving existing design tools and platforms. The functionality and usability of the developed approach is demonstrated.

Keywords –

Maintainability; Gaming Engine; Building Information Modeling

1 Introduction

Designing buildings without the perspective of maintenance managers often results in facilities that are either costly to maintain or has components that cannot be accessed. For example, light fixtures that can only be reached with scaffolding, which cannot be brought into the building. This has also been known to have implications on the safety of maintenance personnel e.g. in situations where a scaffolding can be brought into the building and there is no resting platform because the floor has a stair as seen in Figure 1. Such unreachable and unmaintained components leads to facilities with high initial and operating cost, decreased performance and often, reduced satisfaction among building occupants.

If involved in the design process, facility managers (FM) can provide valuable input into building designs, such as the type of components typically needing maintenance and the amount of tolerances/clearance to be provided around the components for accessibility. Although building information models (BIM) are designed to facilitate communication and collaboration between project stakeholders, it still lacks the information, and knowledge required to aid facilities management. Moreover, many facility managers lack the necessary knowledge and skills to interact with BIM [4]. This poses the following questions: How can FMs be engaged in the design process without the need to learn how to use the design tool? How can maintenance knowledge be captured so as to inform future designs?

Gaming engines are increasingly being perceived as useful platforms for design review, knowledge capturing and training. This is clearly evident in the use of serious games in the engineering, education, healthcare and marketing sectors. The success of serious games in any industry sector has been ascribed to its ability to actively engage and immerse users while capturing their thoughts and decisions. Although, the serious games has been actively researched in the architecture, engineering and construction (AEC) education, the link to BIM in the context of facilities management has received limited attention. Integrating BIM and gaming technology offers tremendous benefits for the AEC industry, including improvements to BIM in the area of design review and knowledge capturing for improving existing BIM design tools. Hence, this paper presents a framework for capturing knowledge and experience of FMs for the purpose of improving BIM tools for maintainability.

2 Background

It is increasing being recognized that the design phase provides an opportunity to eliminate waste or inefficiencies attributed to inaccessible/ unmaintainable components before they appear in the constructed facility [1,3]. Current approaches do not permit the involvement of FMs in the design phase. This has led to inefficiencies such as shown in Figure 1. Previous research indicates that there are limited tools and technologies for enhancing the involvement of FMs in the design phase.

Over the years, various researchers have demonstrated the potentials for BIM for enhancing both design and construction processes e.g. clash detection, scheduling, cost estimation, progress monitoring and safety management. However, the use of BIM for the FM phase has received little attention [7]. Recently, Liu and RA Issa [5] developed a tool that uses BIM for checking the accessibility of building components. Although, the tool has some potential for improving building maintenance, the role of FMs is still limited. Furthermore, the developed tool does not incorporate the knowledge of FMs for future designs. Other research works have also developed processes for early involvement of facility managers [6] and owner requirements for building management [2]. In-spite of these efforts, opportunities exist for actively engaging the facility managers in the design review while also capturing their design decisions for enhancing future design tools and platforms.

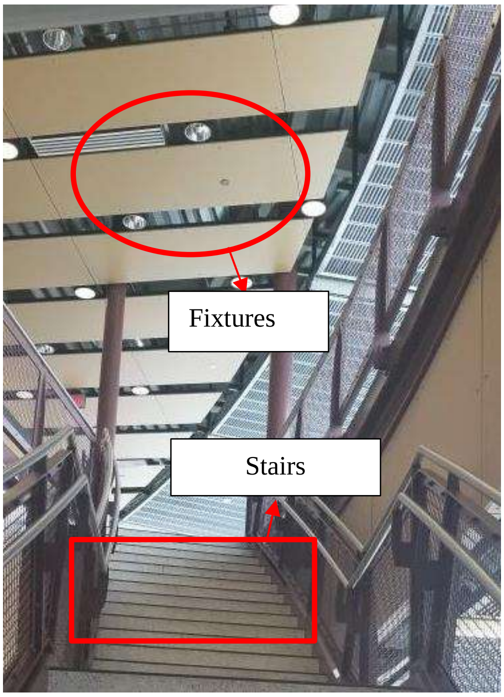

Figure 1. Inaccessible light fixture

3 Research Objectives

Design review decisions from diverse buildings and different facility managers can be continually captured, analyzed and linked to a building information model (BIM) to generate a rule-based building maintenance framework that enables cost effective designs and easier execution of maintenance tasks. Furthermore, data fusion of maintenance rules and component design can create information that once applied, will create knowledge that can improve the design and facility management phase.

The objectives of this work are as follows:

1. Develop a framework that captures and integrates maintenance decisions and rules with BIM. The framework includes a rule-based decision procedure for evaluating designs for maintainability.
2. Implement and verify the framework on a selected case study.

4 Framework

The proposed framework shown in Figure 2, integrates BIM for serious game design, and cloud computing technology, and prototyping a game application. The game is based on Autodesk Revit, Autodesk 3ds max, and Unity3D. Autodesk Revit is used to model the buildings while 3ds max software provides a platform to model, texture the buildings, and import the Revit model into Unity3D. The game was made interactive for design review in Visual studio C#.net using the Unity game development platform. The pseudocode of the developed game is shown in Figure 3.

The first step is to import BIM models into the gaming engine as shown in Figure 2. Since BIM models are developed with different proprietary software, the associated file assets need to be converted to a Unity3D compatible file. To import a Revit model into Unity3D, the model is initially converted to a .fbx format using Autodesk 3ds max. The .fbx file is then copied into a Unity3D project folder, where it can be opened as a Unity3D model.

On importing the design into Unity3D, the FM can select any floor he wishes to review. The FM can also select any floor space by initiating the ‘space’ menu. The building components are categorized into systems e.g. lighting, electrical, mechanical and plumping systems. On selecting any of the components in each of the spaces, the FM is automatically launched to the location of the component. He can query the components using the accessibility criteria of reachability and support. Reachability indicates if the components can be reached using any access equipment e.g. scaffold and scissors lift. On selecting any of the access equipment, the support criteria helps the FM decide if there is a platform to place the equipment. If the FM has an issue with any of the components, he can post comments or decisions regarding affected components. These comments are sent to the architect via SMTP mail server. Google SMTP server is setup to route the mail to the architect. The comments are also stored in a relational database using

OLE DB connection. Microsoft Sql Server (Mssql) was chosen because of its scalability, support SQL syntax, and compatibility with .NET applications.

In the future, it is anticipated that the industry might develop an open database server for storing and sharing facility maintenance decisions. These data can then be linked to a BIM model using an automated rule-based system. The rules will be developed for components to which comments have been posted. The rules will also be coded from the posted decisions of the components. Fusing the maintenance decisions from different facility managers will create valuable information that once updated and applied frequently will become knowledge for building designers. Moreover, the FM can also email the comments to the designer for corrective actions.

          Else
            User can inspect other fixture
```

Figure 3. Pseudocode of developed game

5 Case-Study

The proposed framework was applied to an education building so as to check the accessibility of the light fixtures. A 3D model of an existing educational building was created in Autodesk Revit. The BIM model included different types of mechanical, electrical and lighting components with some inaccessibility issues.

The BIM model was initially loaded into unity 3D using the 'Import Designs' button. On importing the model, an avatar of height 5.8ft is positioned in the model as shown in Figure 4. From the 'Floor' menu, the user selected the first floor. From the first floor, the user was able to access the spaces within the building. On selecting one of the spaces, he was prompted with the option of the type of components. From the 'Component Category', the user can select options from a list of mechanical, electrical, lighting and plumbing components. In this case, the user selected the lighting components. After selection, the user is presented with list of all the light fixtures in the building and he has to choose one of the fixtures.

After making his selection, the avatar was positioned under the fixture using the function: Vector3.transform.position = fixture.transform.position as illustrated in the pseudocode (Figure 5). This relieves the user or FM from the stress of learning the gaming tool. The user was able to define criteria for assessing the fixture using the 'Equipment Criteria' menu. This menu provides two options: Reach and Equipment Accessibility. With the 'Reach' option, the user was provided with options of using a ladder or scissors lift to reach the fixture. A typical stepped ladder has a height ranging from 4ft to 20ft. On selecting any height, the gaming tool adds the height of the avatar (5.8ft), the height of the ladder (20ft). The gaming tool determines the distance between the height of the light fixture and the combined height of the avatar and the ladder. This difference must be lesser or equal to safe reach distance of 0.33ft (4 inches). This is achieved by calling the function: sum(height_of_avatar,height_of_ladder) - fixture.Vector3.y.

If the distance is greater than 4 inches, it means the light fixture cannot be accessed. In this case study, the later was true and a comment was sent to the designer via the interface shown in Figure 6. The comment was communicated to the designer via SMTP mail server.

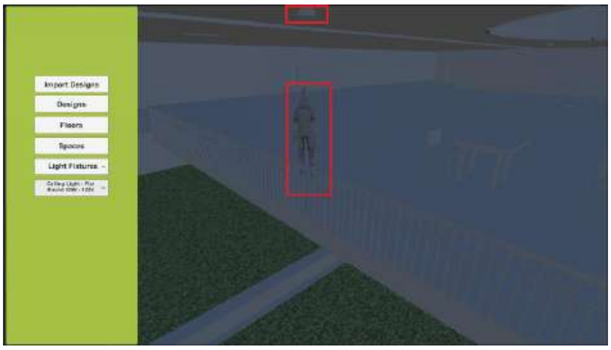

Figure 5. User positioned under the light fixture

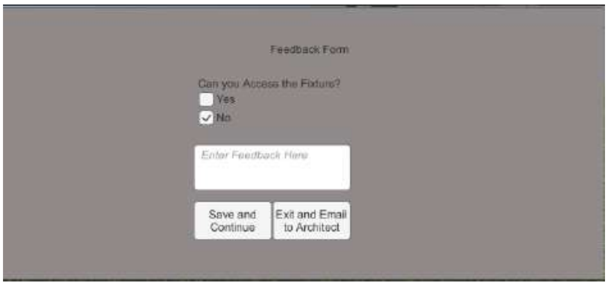

Figure 6. Platform for providing feedback or comments

6 Conclusions and Future Work

This paper presents preliminary results on the framework of a gaming tool for reviewing building designs for maintainability and capturing design decisions for improving existing BIM tools. The developed tool runs on two main platforms: Unity3D and Autodesk Revit. Preliminary results demonstrate the feasibility of using the gaming platform for the design review. The developed automated design review tool shows good capability of practical applications in checking the accessibility of building components and capturing decisions and comments. These comments can be linked to the respective components in BIM and rules can be developed to guide the building design. This offers tremendous opportunity for improving the BIM platforms while also ensuring that the facility management perspective is well represented in building designs.

Future work will focus on developing machine learning algorithms to filter through the comments and develop rules for building components. Research will also focus on the evaluation of the developed tool, development of more case studies, scenarios and best practices to encourage its usefulness.

Abstract

An effective realization of a building construction project -without incurring in congested site areas or decline of productivity- tightly depends on the construction activities planning process that, should consider and manage site workspaces availabilities. In this context, in the past couple of decades many research efforts have been spent in BIM which represents the process of preparation and use of a computer-generated Building Information Model (BIM) even if effective integrated methodologies and models to assist construction workspaces management are still missing in the field.

This contribution proposes an integrated model that aims to automate the creation of a building digital prototype, BIM-based, in which real site condition, in terms of workspaces allocation, are fully simulated. The outputs of a built-in algorithm to define the on-site workspaces configuration pattern based on the space syntax analysis together with a second one to automatically model workspaces geometries with minimizes input work are presented. Those algorithm are integrated in a coherent construction workspaces management workflow and tested on a simplified BIM of an industrial building, succeeding to allocate and model 611 workspaces required to construct 98 building items the BIM is composed of.

Keywords –

4D BIM; Construction workspace management; Scheduling; computational design.

1 Introduction

Whatever the type of building project under consideration, there is a need to produce a construction schedule that is considered a challenging activity for construction managers due to the number of variables they should consider especially resulting from the dynamic nature of the construction site. Considering its nature, which consist of different activities in limited area, it can be stated that '*workspace*' is the leading factor that is frequently overlooked in construction scheduling. In this sense, researches developed until now are limited in their ability to generate the workspace digital model for all activities of the building project for which workspaces are required. Most of them are focused on static 2D-based workspace models.

A practical motivation is that, since a building project is composed of a huge number activities, it is difficult for construction managers as well as researchers to automatically create at a time the workspace digital model for all the activities, due to the fact that it is a tedious work to generate the workspaces for many activities in the project using a 3D tool.

Riding this problem, the theoretical scope of this study is to automate the creation of a building digital prototype in which all the required workspaces to construct the building objects will be planned and modelled. To achieve this purpose, the use of 4D BIM and computational design will be integrated.

2 Background

2.1 Construction workspace management

Incorporating workspace considerations from the spatial and temporal perspective, in construction planning and scheduling, plays a pivotal role in proactively preventing work-space problems and decline of site productivity. According to [1], construction workspace management includes the following three branches.

1. First, *generation and allocation of workspaces*. In this regard, most of studies such as [2],[3],[4],[5] and [6] support the workspaces modelling by using manual mark-up in a 2D or 3D modelling environment. But, considering the number of required spaces for each construction activity to multiply by the huge number of activities a building project is composed of, design automation in spatial modelling is suggested but still missing in literature.

2. Second, *detection of spatial temporal conflicts*. In this context, three research branches can be identified: (a) detection of physical conflicts between the site workspaces; (b) detection of schedule conflict which means the detection of a temporal overlap between tasks that is mainly taken into account by the models which use traditional representation of the construction process (i.e., Gantt Chart and Network Diagrams); (c) site congestions identification [7] that considers the ratio between the volume of resources occupying a workspace and the volume of the workspace which is available on site for a given activity or a set of activities. Often defined as 'scheduling overlapping ratio' [8].
3. Third, *resolution of identified conflicts*. Regarding this aspect, the methodologies -proposed in literature- reveal the predominant use of mathematical models that, on one hand, are able to manage only a small part of a given building project due to the computational load entrusted to not specific calculation environment (e.g. Matlab), on the other hand require an extremely knowledgeable of the mathematical model itself which cannot be used by construction managers. For these reasons the almost always go unused.

3 Need and justification

Prevailing *activity-oriented* construction scheduling techniques -e.g., Gantt Chart, Network Diagram, Critical Path Method- are not able to consider spatial requirements of activities and for this reason the generated construction schedule is limited in capturing real site conditions. Moreover, more complex techniques -such as Line of Balance- have likewise insufficient ability for workspaces planning because they assume that only one labor crew is able to occupy each work-zone at a time and they lack of a 3-Dimensional representation and planning of spaces as well as spatial conflicts among themselves [9].

More recently, a new research trend of utilizing Building Information Modelling (BIM) and BIM-related technologies to assist construction scheduling is arising. It represents the process of preparation and use of a computer-generated Building Information Model [10], which is data-rich parametric digital representation of a building, from which relevant data, needed to support planning and scheduling of construction activities, could be extracted and used. But, in spite of its growing implementation, the use of BIM to improve construction planning has involved many efforts focusing on its technological aspects (i.e., 4D BIM-based tools) rather than on the integration with site planning models for construction workspaces management.

Therefore, an holistic workspaces planning model -BIM compliant- able to consider, simulate and analyze space availability and demand for each building object, included in a given BIM, is still missing and it could support construction managers in reasoning on the construction schedules that feature specific construction methods and concurrent execution of overlapping activities.

4 Methodology

4.1 Goal and Objectives

For the aforementioned reasons, the overall goal of this research is to define a BIM-based construction planning model that automates the creation of a building digital prototype in which real site condition, in terms of workspaces, are simulated and it should be able to guide an external user (i.e., construction manager) to define the construction sequence that guarantees the non-overlapping condition of the workspaces. In particular, this research makes the following contributions:

- it defines of a construction planning model which acts, logically and technically, on a given Building Information Model (IFC-based);
- it introduces an automated process for geometric planning and modelling of workspaces, within a BIM environment, by means of two built-in algorithm;
- it defines of a tool sets that communicate through an external data-base in which a construction manager introduces his experience in terms of workspaces requirements of construction methods;
- it guides a construction manager in defining the earliest construction sequence -visualized in 4D BIM-based simulation environment- of a given BIM to be processed.

The paper is organized as follows. First, the practical motivation for this research is introduced by using a case study together with the explanation of the working prototype. Next, an overview of the planning model and specifications about its operational framework and its computerization are given. Finally, an evaluation of this approach is provided, followed by a brief discussion of the on-going and future research.

4.2 Motivating case study and working prototype

This section describes a simplified case study that illustrates the practical motivation for this research on which the proposed workflow has been tested. An Information Model of an industrial building, structured according to the IFC-data schema, is the input of this research.

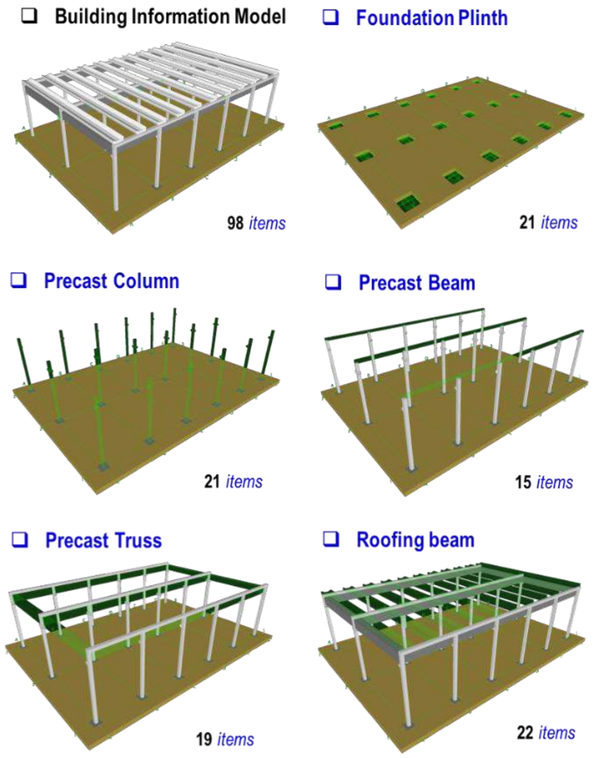

Figure 1. Building Object of the case study

Taking into account its structural subsystem but leaving aside the building finishing, the given BIM is composed of five objects types: (a) Foundation Plinth -eighteen items-; (b) *Precast Column* -eighteen items-; (c) *Precast Beam* -fifteen products-; (d) *Truss* -nineteen items- and (e) *Roofing Beam* -twenty-two elements-. Figure 1 shows the BIM filtered by type of building objects.

Trying to be a construction manager who receives the aforementioned BIM in order to define the optimal construction sequence, the proposed approach seeks to respond to the following open issues:

- Which kind of workspaces are necessary to install those five types of building objects?
- How all those workspaces should be located in site with reference to building object of which they handle the installation?
- Is it possible to automatically generate a workspaces allocation pattern using the construction manager's experience and automatically sculpt geometries of workspaces in a BIM modelling environment?
- Could it be possible to find and simulate a construction sequence by using a 4D BIM which, solving the issues mentioned above, guarantee the non-overlapping condition of workspaces?

It is clear that, to make BIMs useful for construction, all these specific information for construction site must be planned and explicit in the given information model in a way that construction managers can easily work with to better understand and plan their specific schedule which cannot be against to all those condition established in the model itself.

The architecture of the proposed solution to generate the building digital prototype in in which all the required workspaces are planned and simulated is represented in Figure 2.

The architecture shows that the planning process starts with three elements: first of all, a BIM and a structural schedule -due to the fact the latter does not depend on specific consideration but it defines the first scheduling constraints (e.g., plinths before columns, columns before beams, etc.)-; then the experience of the construction manager which is stored within an external database. It works as repository of information relevant to the workspace management process (planning and modelling) according to a predefined structure later specified.

The result is a 4D BIM Model that simulates all the required workspaces allocated in their optimal position that satisfies the conditions specified by the user (Figure 7). The computerization of such a theoretical algorithm will be described in the next paragraphs.

4.3 Problem solving approach and computerization

The proposed design process that reaches the aforementioned objects is composed by a number of operational modules in a coherent data management flow. They are graphically described in Figure 2 and briefly specified step-by-step as follows.

1. **Data extrapolation from the BIM**. Having at our disposal the BIM we are able to extract the following information: *number and types of building objects*, their *local placement on X, Y and Z-axis* (relative to the building grid axis). Those data are stored in an external database.
2. **Workspaces Database preparation**. For each object type a *Construction Method* (CM) is generated in an external database where the user adds a list of workspaces required by the CM itself in terms of *Labor Crew*, *Equipment*, *Hazard*, *Protected and Safety Spaces* according to his experience. For each space the following information are required: *Dimensions*, *Topological Interaction* with the other spaces and *Interaction Value*.
3. **Workspaces planning process**. Defined workspaces properties for each construction

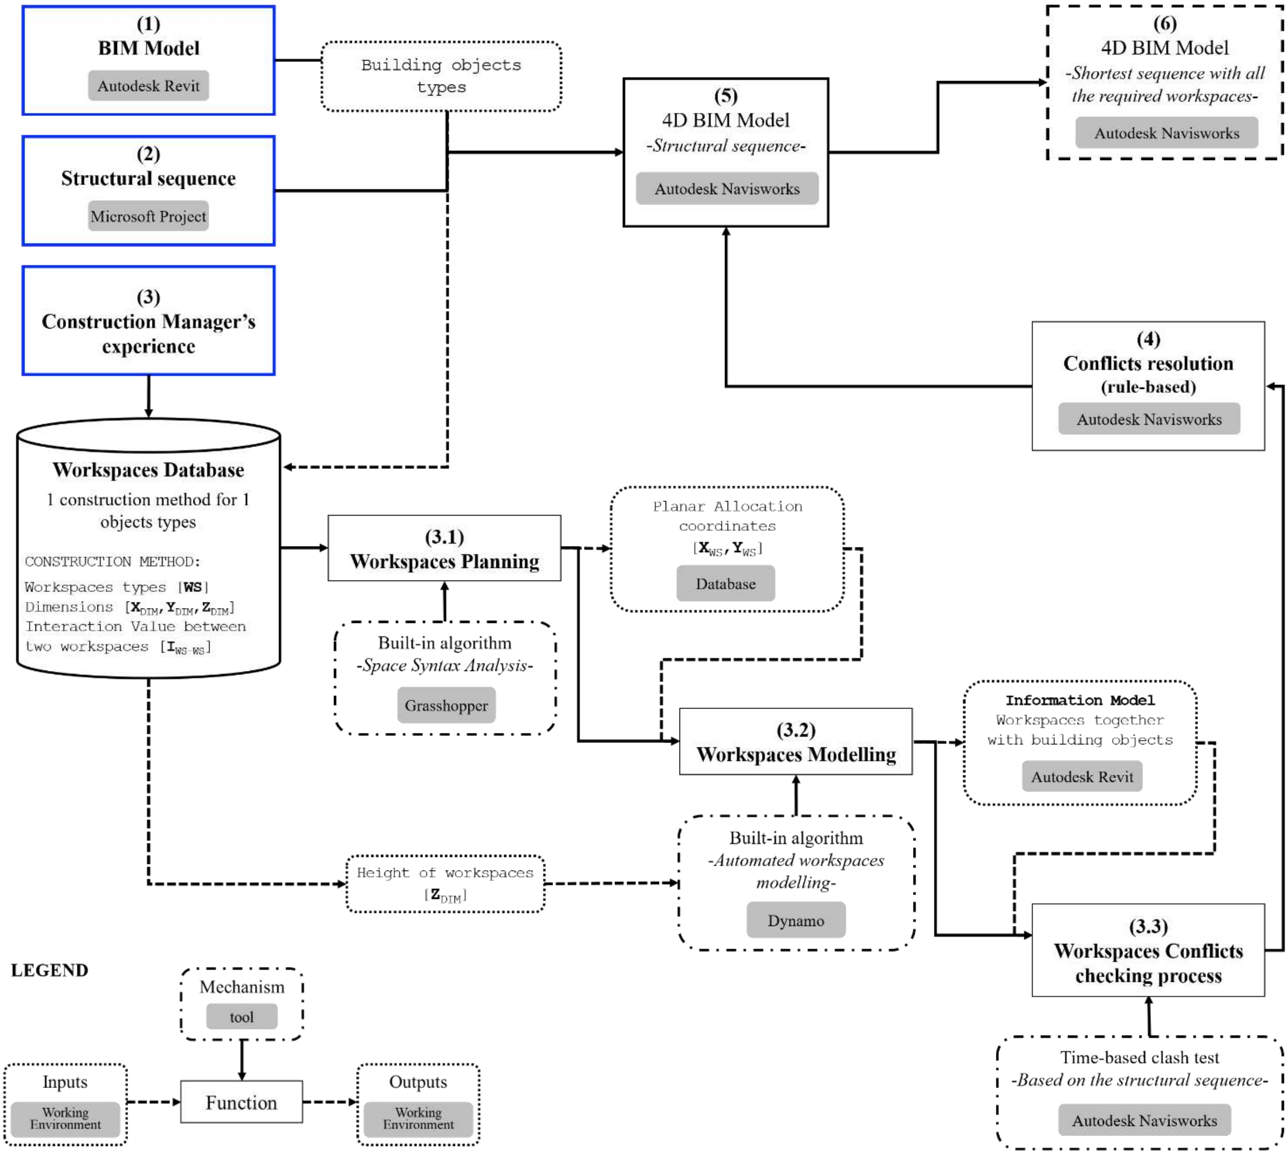

Figure 2. Data management flow to generate the building digital prototype with workspaces in Figure 7

method, it remains to find their optimal layout allocation with reference to the building objects. This is carried out by using a configurational analysis based on *Space Syntax Analysis*. The workspaces configuration pattern is generated in the form of a planar graph by using a bubble diagram which is deduced by Nourian's algorithm [11] and especially customized for our model. It read workspaces information and provides as output the workspaces allocation coordinates for each construction method (Figure 3).

4. **Workspaces modelling process**. Reading the allocation coordinates of workspaces referred to each building objects a Dynamo's script -an algorithm editing environment for computational design linked to a BIM modelling environment- automatically sculpts the geometries. By doing so each building objects is simulated with a cloud around itself that is the non-visible volume in the building needed for execution of works. As depicted in Figure 4 for each construction method and and fully in Figure 7, 611 workspaces have been automatically simulated.

5. **Workspaces conflicts checking process**. The BIM that now includes the building objects and all the needed spaces is loaded in a 4D BIM environment (*Autodesk Navisworks*) to carry out a time-bases clash test on the basis of the structural schedule. By doing so a clash report is extracted, an example in Figure 5, with the pair of conflicted workspaces.

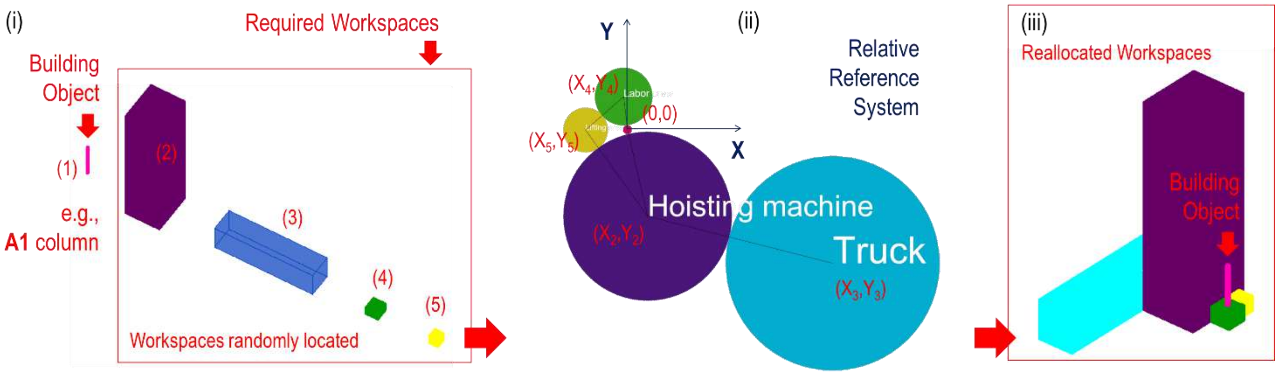

Figure 3.Planning process to find the workspaces allocation pattern around the precast column

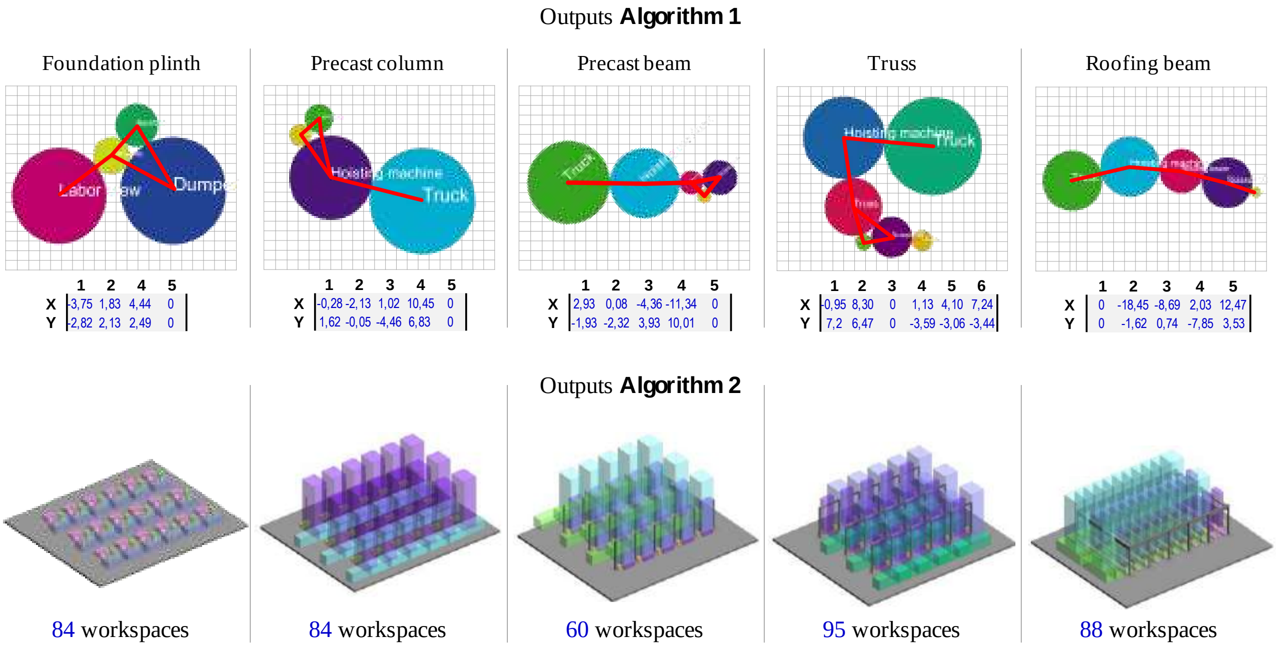

Figure 4. Graphical outputs of the workspaces configuration pattern for the five construction methods

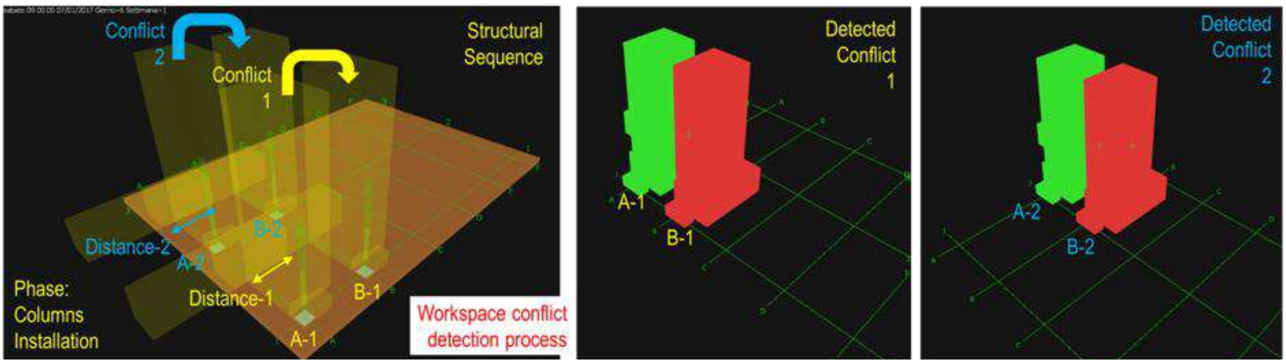

Figure 5. Graphical output of the workspaces conflict detection (*Navisworks Environment*)

In the same environment a scheduling rule is computerized that converts each conflict in a temporal relationship (finish-to-start) among the building objects whose spaces are conflicting.

The generated schedule can be considered the earliest construction sequence in the sense that if one activity will be shifted backwards a workspaces conflict will be detected.

Due to not enough spaces, the proposed workflow as well as the built-in algorithms are basically described in this contribution even if the outputs are presented and a more detailed explanation of the workspaces planning process is presented in the next paragraphs and Figure 6.

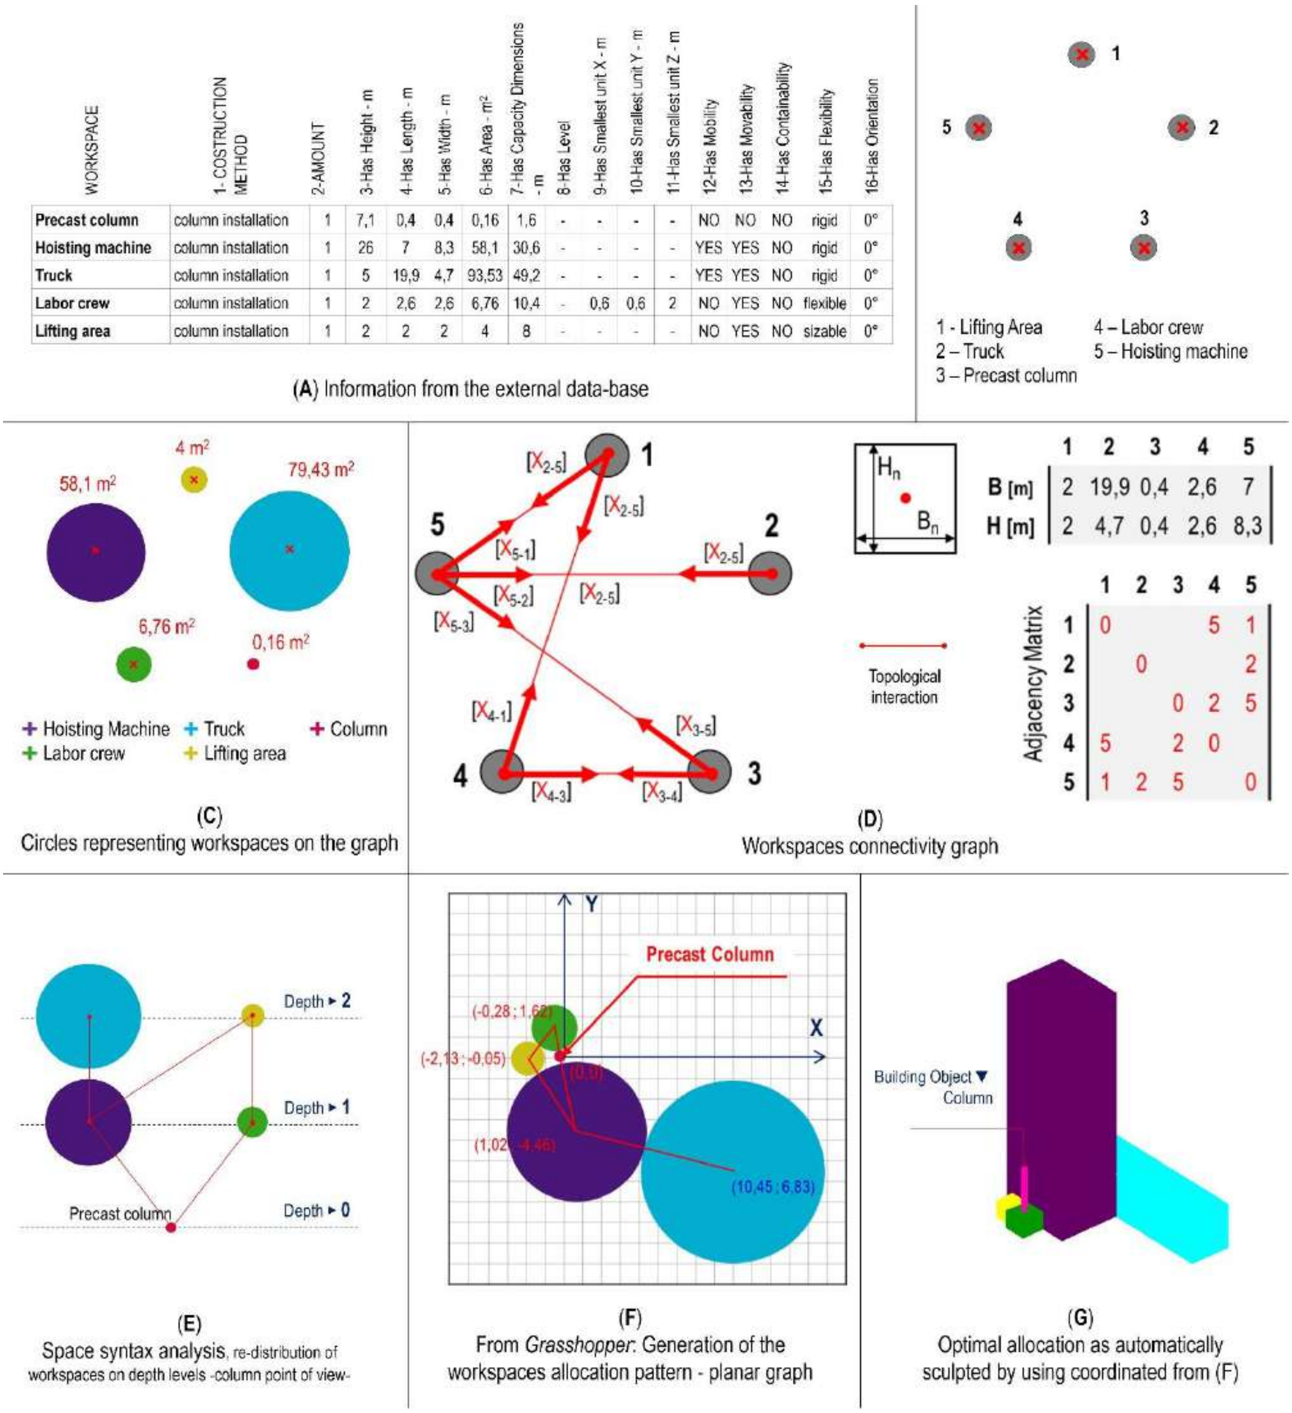
4.3.1 Workspaces planning: algorithm to generate the workspaces spatial allocation patterns

The proposed planning workflow is about going from an abstract graph description of workspaces topological structure and their interactions to find their optimal planar allocation with reference to the building object those spaces are linked. The computerization of such a concept has been possible with a built-in algorithm able to manage a parametric design workflow developed in *Grasshopper©*, (a graphical algorithm editor tightly integrated with a 3-D modelling environment). The proposed one is a customization of the one presented in [11]. It main operating steps are below presented and the graphically visualized in Figure 6 for the construction method of precast column installation.

1. **Workspaces graph representation**. As starting point, a number of randomly located points, representing the barycenter of the workspaces, are generated in a CAD environment by using a first operator. At the same time, two dimension values (*has_Lenght, has_Width*) and the identification numbers (*has_ID*) are imported from the external data-base. At this point, a set of operators, first assign colours to the workspaces to make them more recognizable and then generate one circle around each workspaces' center point. Their dimensions are deduced by the rectangular areas of workspaces as suggested by the user in the data-base itself; they are equal. In this way, a first workspaces map representation is generated. This is carried out for each construction methods included in the given BIM.
2. **Workspaces connectivity graph**. Subsequently, the representation of relationships between workspaces is managed by an operator that draws connections -by using a red line- between those pair of points that have a topological interaction (*has_Topological_Interaction*) set by the user within the data-base. The interaction value can be in a rank from 0 -*no interaction*- to 5 -i*ndispensable interaction*-.
3. **Space Syntax Analysis**. Having generated the connectivity graph, according to the space syntax analysis, an operator re-distributes the workspaces (circles) on deph-levels. A *depth* is the smallest number of syntactic steps (in topological meaning) that are needed to reach one space from another. Therefore, depending on the number of workspaces that each construction methods contains -e.g. five spaces for the column installation- one configuration for each space by using depth levels is generated. It represents the point of view of a labourer getting in position in that workspace on ‘depth-0’. The generated graphs are used for a visual validation from the construction manager (user) who has defined the workspaces requirements in the data-base itself.
4. **Generation of the workspaces allocation pattern**. Once the model is provided with workspaces connectivity values, the algorithm contains a force-directed graph-drawing operator which is able to generate a bubble diagram representing the optimal workspaces allocation pattern based on user-constraints set in the data-base. This function works translating the interaction values between workspaces (*has_Interaction_Value*) in a set of attractive forces. The forces act recursively on the graph vertices, seek a ‘relax’ situation for a graph, and provide the system with a graphical representation of the given solution. The output is a bubble diagram -once again one for each construction method included in the model- compliant with the specified workspaces dimensions and the connectivity values.
5. **Extrapolation of workspaces spatial coordinates**. Once a workspaces configuration pattern is deducted, the spatial allocation coordinates -on the X-axis and Y-axis- from the bubble diagram are extracted and stored in the external database. The model considers those workspaces as located at the same height (Z-axis) of their connected building object.

5 Discussion and future development

The obtained results show how the layout allocations of spaces cannot be considered never fixed but they strictly depend on both the chosen construction method and planning rules. Infact, the space syntax analysis, carried



WORKSPACE	1- COSTRUCTION METHOD	2-AMOUNT	3-Has Height - m	4-Has Length - m	5-Has Width - m	6-Has Area - m²	7-Has Capacity Dimensions - m	8-Has Level	9-Has Smallest unit X - m	10-Has Smallest unit Y - m	11-Has Smallest unit Z - m	12-Has Mobility	13-Has Movability	14-Has Containability	15-Has Flexibility	16-Has Orientation

out on five different construction methods, demonstrated that even if workspaces had the same dimensions, their layout allocations may be different depending on their relations as well as their interaction values.

Moreover, it demonstrates how important should be the integration of human experiences even in BIM-based scheduling models as well as the pretty unbreakable bond that exists between a construction schedule and the spatial allocation of workspaces and their topological interactions.

The proposed workflow, supported by the two integrated algorithm, was capable to plan and model 611 workspaces by binding the scheduling process to them (Figure 7). The same process would be unsustainable if manually managed or without a holistic and digitized planning process. This requirement increases if we think that if some changes occur (e.g., construction methods, workspaces, building product dimensions, etc.) all the entities should be modelled again. The presented construction scheduling workflow is a part of a wider research project the author are working on that aims to develop an *BIM-based Expert System* supported by an ontology based system architecture (for semantic modelling the construction process knowledge) integrated with a rule-based artificial intelligence (for workspaces management and schedule generation).

Abstract -

Recent research on facility management has focused on leveraging location-based services(LBS) to assist on-demand access to model information and on-site documentation. Researchers highlight that fast and robust indoor localization is of great importance for location-based facility management services, especially considering when using facility management services in a mobile computing context. Despite the importance of location data, most existing facility management systems do not support LBS due to the following reasons: 1) Signal-based indoor localization methods, such as WIFI, RFID, Bluetooth and Ultrasound, require installation of extra infrastructure in a building to support localization, 2) Visual-based indoor localization methods, such as LiDAR and camera, still depend on feature point detection and matching that require heavy computation and can be impacted by environmental conditions. In this paper, the authors present an end-to-end image-based localization framework to support facility operation and management using a convolutional neural network (CNN). The proposed framework contains two modules: mapping and localization. The mapping module takes a set of training images with their pose as input and trains a CNN model for the localization module. The localization module takes a single image and the trained model as input and outputs estimated camera pose (position and view angle). Compared to conventional methods, the proposed end-to-end image-based indoor localization framework does not require any infrastructure installed in a building and can achieve real-time 6-DoF localization that is robust to different lighting conditions and scenes with poor texture. The proposed framework was evaluated on publicly available datasets and the results show that end-to-end imaged-based method can achieve real-time 6-DoF localization with acceptable accuracy and a small map size.

1 Introduction

In this section, the authors give a brief introduction to location-based facility management and the status of current research.

1.1 Background

Locating and tracking people, equipment, and facility components within building supports many novel facility management applications such as asset monitoring [1, 2, 3], infrastructure inspection [4], cross-registration with BIM [5], and field reporting using mobile devices [6]. A location-based facility management system (LB-FMS) has a central geospatial database that stores facility information and allows all possible users to access or potentially change the data conveniently. LB-FMS is expected to streamline building operation activities, such as updating infrastructure status, documenting repair needs, managing work orders and inspection, through automatically linking the data collected by a mobile device at the scene to the facility management model. However, given the location of mobile device only, it's still challenging finding the correspondence at a component level, e.g, linking a window captured at the scene with its corresponding window element in the model. The primary concern that limits component-level registration is the lack of complete pose information (location and view angle). With location information only, there is an infinite number of possible ways to register a facility component to its model due to the freedom of rotation (Figure 1a). In comparison, with complete pose information, the correspondence could be easily established through ray tracing (Figure 1b). The resulting component-level correspondence can reduce the need for manually finding the corresponding component at the scene. In other words, an LB-FMS with complete pose information can be used for automating many of the aforementioned applications.

1.2 Previous Research

Current indoor localization approaches adopted in an LB-FMS can be generally divided into two categories: 1) Signal-based methods and 2) Visual-based methods. Signal-based methods, such as WIFI [7], RFID [8], Bluetooth [9] and Ultrasound [10], estimate locations by comparing recorded signal signatures with signals captured on site. For example, WIFI-based localization leverages the prior known router positions to estimate the signal

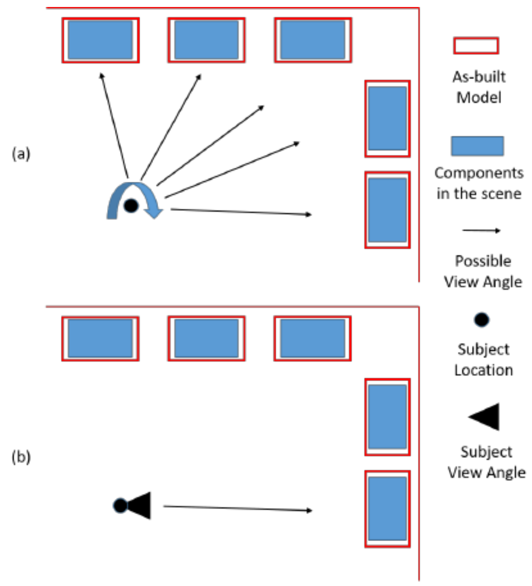

Figure 1. Finding corresponding as-built model for the object in a scene with locations only (a) vs. with poses (b)

strength at different locations within a building. When the client device receives signals from multiple routers, the position can then be estimated using triangulation. Other signal-based methods employ similar mechanisms as well. According to [11], signal-based methods have two primary limitations when applied in facility management applications: 1) They need to have the corresponding infrastructure, such as routers, beacons, RFID tags, or ultrasound receivers, installed in building to facilitate the localization service. 2) They can only output the location (X, Y, Z coordinates) but not the view angle (pitch, yaw, roll angles). Without the view angle information, locating facility components in the as-built model would be more difficult compared to the one with view angle information. Figure 1 demonstrates how pose information can reduce the search space for correspondence.

The visual-based localization methods, especially the image-based ones, are proposed to address the two limitations stated above. First of all, image-based methods do not need extra infrastructure to locate a person. Moreover, image-based localization methods can output location and view angle at the same time, making it much easier to estimate the location of what is being seen in a scene and linking it to what exists in a digital information model (such a 3D building information model). Typical image-based localization methods include image retrieval [12], direct 2D-3D feature matching [13], and end-to-end learning [14]. Image retrieval methods build a spatial database of a facility from geo-referenced images during mapping and retrieve the image that is most similar to the queried image for localization. Since the queried image is not likely to have identical poses (location and view angle) as the images in a database, image retrieval localization can only provide a rough estimation of the pose. Direct 2D-3D matching method reconstructs the 3D model using Structure-from-Motion (SfM) from images, and stores extracted feature points, such as Scale-Invariant Feature Transform (SIFT) in map (Figure 1). During localization, it compares the extracted feature points from the queried image to the ones in the database and estimates the camera pose using epipolar geometry. The localization accuracy can be very accurate (10-20 cm[10]) when feature point matching is successful. However, due to camera intrinsic differences, change of lighting condition and motion blur, direct 2D-3D matching could fail ungracefully even when a small subset of mismatched feature points exist. Another limitation of the 2D-3D matching method is computation complexity. An image usually has 300 to 500 feature points while a map is usually reconstructed from thousands of images. Therefore, locating one image requires finding the best match from millions of feature points which can take several seconds. Hence, existing 2D-3D matching method is also not scalable and might not be applicable for real-time localization needs.

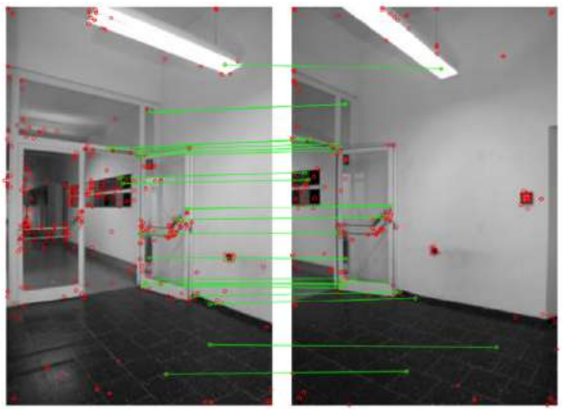

Figure 2. Feature-based Localization using SIFT Matching

Considering these limitations, the authors explored a new approach that learns to automatically extract useful features from images according to the desired objective (in our case, the objective is to minimize localization error), and that uses extracted features to estimate image poses. This approach is being referred to as end-to-end learning-based localization and Section 2 gives a brief introduction to it. Section 3 overviews how the proposed end-to-end image-based localization acts as an important module within a facility management system. Sections 4 and 5 describe the evaluation of the proposed approach with respect to its performance on a publicly available dataset and show the corresponding results obtained.

2 End-to-end Learning-based Localization

Convolutional Neural Network (CNN) [15] was originally proposed to address the image classification problem that can output a discrete label such as door and window given an image as input. CNN also works well in regression problems that require estimating continuous variables such as locations and view angles. In general, CNN is a powerful tool that can automatically learn how to extract useful features with respect to different objectives. End-to-end learning-based localization aims at training a CNN that maps an image to a pose. The localization process consists of two stages: mapping and localization. Basically, in the training (mapping) stage, the system takes a set of training images with ground truth pose and trains a Convolutional Neural Network(CNN) by minimizing the mean squared error(MSE) between the predicted pose and the ground truth pose. In the testing (localization) stage, the trained network takes an image as input and predicts the 6-DoF pose. The problem can be formally written as: given a set of images and their corresponding poses, find a function f that maps the input image $\mathbf{X}$ to its pose $\mathbf{y}$ through $\mathbf{y} = f(\mathbf{X})$ with the lowest localization error. The function f is defined by all the parameters of a CNN.

2.1 CNN Layers

A typical CNN architecture consists of several layers such as convolution, activation, transition, batch normalization (BN), and fully connection (FC). Below is a brief description of the functionality of each kind of layer.

2.1.1 Convolution

Convolution layers play a role of extracting features from input images in CNN. Given an image $\mathbf{X}$ (a tensor with size width × height × color channel), a convolution layer transforms the input by computing linear combination as below:

$$conv(\mathbf{X}) = \mathbf{w}^T\mathbf{x} + \mathbf{b} \tag{1}$$

where $\mathbf{w}$ is the weight vector of a convolution layer, $\mathbf{x}$ is the vector obtained from unrolling the input tensor $\mathbf{X}$, and $\mathbf{b}$ is the bias vector. With different weights, convolution layers are able to extract different features from the input that are useful for achieving the objective.

2.1.2 Activation

Activation layer provides non-linearity between two convolution layers so that the function model is not limited to linear space. A common choice of activation function is Rectified Linear Units(ReLU):

$$ReLU(\mathbf{x}) = max(\mathbf{x}, 0) \tag{2}$$

where $\mathbf{x}$ is the output from last layer.

2.1.3 Transition

Transition layer reduces the input size by averaging. For example, a 2×2 transition layer will average reduce an image with size $56 \times 56 \times 3$ to $28 \times 28 \times 3$. This is used for reducing the number of parameters the system needs to learn.

2.1.4 Batch Normalization

Batch normalization normalizes the input by subtracting its mean from the input and dividing it by the standard deviation. The goal of batch normalization is to improve the generalizability of the model.

2.2 CNN Architecture

In the proposed approach, the authors employ the DenseNet [16] structure for pose regression because of its strong capability of extracting visual features. Depending on the loss function, the extracted features can be used for both classification and regression task. In this problem, we changed the last FC layer to a Sigmoid layer for regression purpose. The adjusted FC layer contains 7 outputs, corresponding to 3 location coordinates(x,y,z) and 4 rotation coordinates(q_1, q_2, q_3, q_4 represented in quaternion format). Table 2.2 shows the DenseNet architecture. Notice that each conv layer listed in the table actually corresponds to a BN-ReLU activation-Conv sequence. The details of each layer can be found in [16].

2.3 Objective

One possible objective is to minimize the mean squared error (MSE) between the predicted pose and the ground truth pose as discussed in [14]. Specifically, denote the ground truth location as a translation vector $\mathbf{t} = [x, y, z]$ and the ground truth view angle as a rotation quaternion $\mathbf{q} = [q_1, q_2, q_3, q_4]$. Notice that the rotation quaternion can be converted back to the axis angle representation. Similarly, denote the predicted location and view angle as $\hat{\mathbf{t}}$ and $\hat{\mathbf{q}}$. The MSE loss of a single image $\mathcal{I}$ to be minimized can be represented as:

$$L(\mathcal{I}) = ||\mathbf{t} - \hat{\mathbf{t}}||_2 + \beta||\frac{\mathbf{q}}{||\mathbf{q}||} - \hat{\mathbf{q}}||_2 \tag{3}$$

where β is a hyperparameter that balances the rotation and translation error.

Table 1. DenseNet Architecture for Localization [16].

Layers	Output Size	DenseNet-121
Convolution	112×112	$7 \times 7 \times 2$ conv
Pooling	56×56	$3 \times 3 \times 2$ max
Dense Block(1)	56×56	$\begin{bmatrix} 1 \times 1 \\ 3 \times 3 \end{bmatrix} \times 6$ conv
Transition Layer(1)	56×56 28×28	1×1 conv $2 \times 2 \times 2$ avg
Dense Block(2)	28×28	$\begin{bmatrix} 1 \times 1 \\ 3 \times 3 \end{bmatrix} \times 12$ conv
Transition Layer(2)	28×28 14×14	1×1 conv $2 \times 2 \times 2$ avg
Dense Block(3)	14×14	$\begin{bmatrix} 1 \times 1 \\ 3 \times 3 \end{bmatrix} \times 24$ conv
Transition Layer(3)	14×14 7×7	1×1 conv $2 \times 2 \times 2$ avg
Dense Block(4)	7×7	$\begin{bmatrix} 1 \times 1 \\ 3 \times 3 \end{bmatrix} \times 16$ conv
Regression Layer	7×7 average pooling 7D fully-connected layer	

An alternative of the objective is to minimize the reprojection error [17]. Denote the ground truth 3D point as P, the reprojected 2D point as p, camera intrinsic (aperture, focal length, etc) as K, and the camera model as a transformation $\mathcal{T}$. The relationship between 3D points and 2D points can be represented as:

$$\begin{aligned} p &= \mathcal{T}_{K,\mathbf{t},\mathbf{q}}(P) \\ &= K[Q|\mathbf{t}]P \end{aligned} \tag{4}$$

where Q is the corresponding rotation matrix of $\mathbf{q}$ and N is the number of known 3D-2D matching pairs. The loss is then defined as:

$$L(\mathcal{I}) = \frac{1}{N} \sum_{P \in \mathcal{P}} \|\mathcal{T}_{K,\hat{\mathbf{t}},\hat{\mathbf{q}}}(P) - \mathcal{T}_{K,\mathbf{t},\mathbf{q}}(P)\|_2 \tag{5}$$

which aims at minimizing the reprojected error between the ground truth pose and the predicted pose. Though the second objective does not need the hyperparameter β, it requires a set of 3D points of the scene as prior, which is usually not available. Therefore, the authors employed the first objective in the proposed approach.

3 Overview of the Proposed Approach

To leverage the end-to-end learning-based localization in facility management, the authors propose an approach that contains four modules: mapping, localization, facility detection, and model update. The pipeline of the proposed approach is shown in Figure 3.

3.1 Mapping

The image-based mapping module takes images and their poses as the primary input but also accepts other

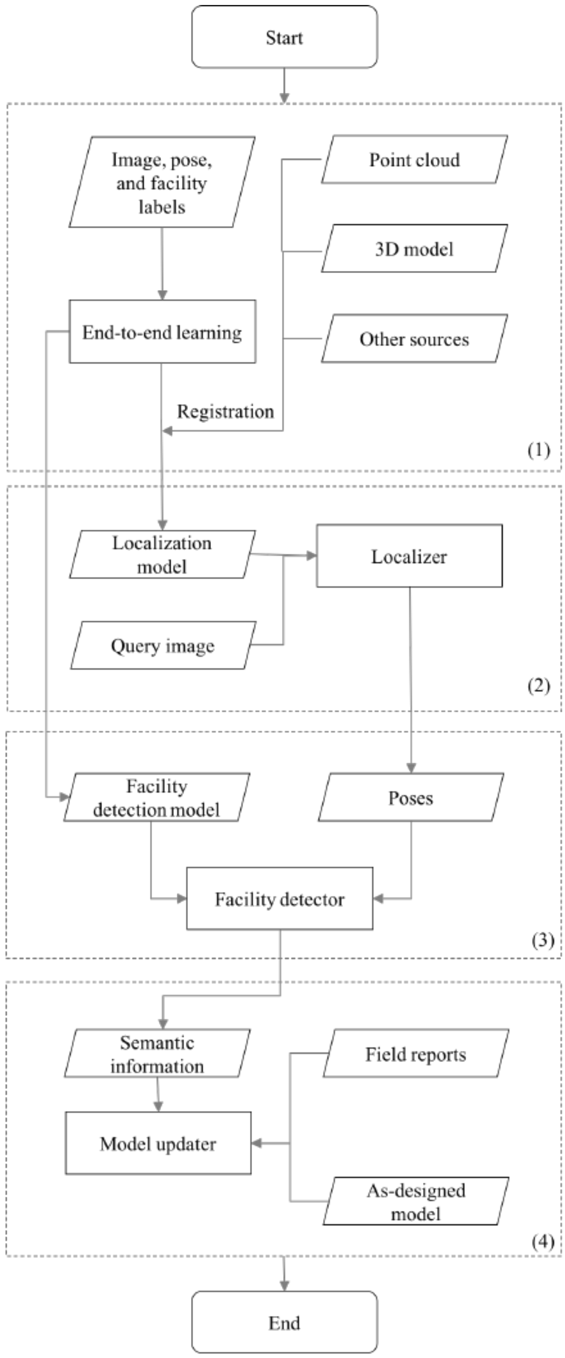

Figure 3. The Proposed Approach with Four Modules: (1) Mapping, (2) Localization, (3) Facility detection, (4) Model update.

data sources such as point cloud, 3D models, and a depth map. The output of the module is a trained network that can predict the camera pose given an image. As stated in Section 2, the goal of mapping is to find a function f with parameters $\mathbf{w}^*$ that minimizes the localization error on the training set:

$$\mathbf{w}^* = \underset{\mathbf{w}}{\operatorname{argmin}} \frac{1}{M} \sum_{i=1}^{M} L(\mathcal{I}_i|\mathbf{w}) \tag{6}$$

where M is the number of images in the training set and $L(\mathcal{I}_i|\mathbf{w})$ is the error of the prediction on the i-th image $\mathcal{I}_i$ given parameters $\mathbf{w}$.

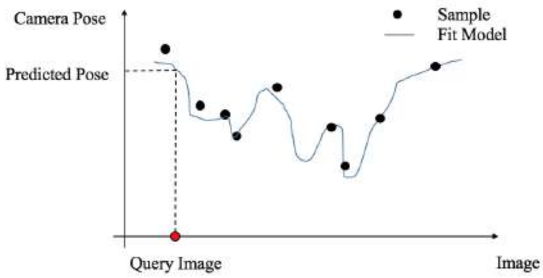

Figure 4. Simplified Representation of Mapping and Localization

Figure 4 shows a simplified representation of a mapping model where the x-axis is the image input, and the y-axis is the camera pose. Since the fitness function is non-linear, there is no closed-form solution of the optimization problem. Therefore, to find the optimal weights $\mathbf{w}^*$, we need to employ optimization methods such as gradient descend to gradually adjust the weights. The basic idea of optimization methods is to start from a random weight and moves along the direction where the loss function goes down. Usually, the data will be randomly split into three parts: a training set, a validation set, and a test set. The model is fit on the training set and usually stops optimization when the loss of validation set reaches the minimum. The test set is used for testing purpose only.

3.2 Localization

The image-based localization module (Part (2) in Figure 3) takes an image and the trained model from the mapping module as input, and outputs the 6-DoF localization result (x, y, z, pitch, yaw, roll) as shown in Figure 4. In the mapping(training) stage, the model is trained to extract features from images that are useful for determining image pose. To understand the mechanism of localization module, we can compare it with the conventional feature-based localization method. In the feature-based localization method, we manually extract the feature point from the image, match the feature point with the ones stored in a database, and estimate the location based on matching as shown in Figure 2. In contrast, end-to-end localization learns to extract relevant features by minimizing localization error. It does not require strict matching. Instead, the trained model tries to estimate the parameter of the function that maps an image to its pose.

Using end-to-end learning-based localization, the localizer does not need to detect feature points from the query image and conduct feature point matching. Instead, the pose is estimated purely by the image itself, which provides two advantages compared to the 2D-3D matching localization method. First, since the weights of the model and the query image have fixed size, the localization time is independent of the map size (Scalability). Second, CNN is able to output accurate pose even with downsized images. For example, to fit the training images into a single GPU with 11 GB of memory, a typical RGB image size used in CNN is $224 \times 224 \times 3$. In the contrast, the feature point detection requires high-resolution images as its input, such as RGB images with size $3000 \times 2000 \times 3$, to improve the feature point matching quality. The computation complexity of end-to-end learning-based localization is much smaller than the one of direct matching localization. Therefore, with proper choice of network architecture and image size, the localizer can provide real-time localization results.

With pose information, if the position of a facility component on an image is known, the component can be linked to a pre-registered as-built model through ray tracing as shown in Figure 5.

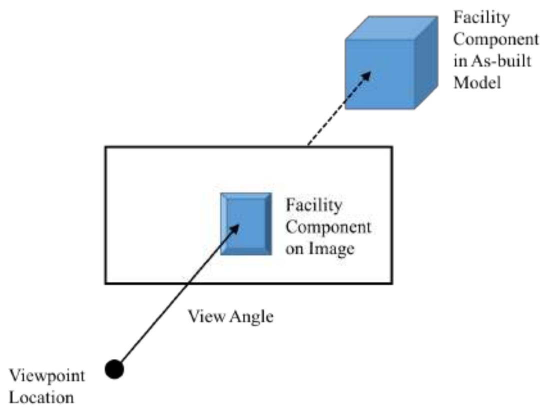

Figure 5. Finding corresponding model for detected facility components on image using pose information

4 Implementation and Experiment

Section 4 discusses the implementation details and presents preliminary results on two publicly available datasets. The authors tested both the proposed method and the state-of-art Structure-from-Motion (SfM) methods using Colmap Library [18] on two datasets and compared their performance.

4.1 Dataset

The authors tested the end-to-end learning-based localization module on two different datasets. The first one is the Navvis dataset [19]. The Navvis testbed is located on the first floor of the main site of Technical University of Munich(TUM) with an indoor track length of 434m. The dataset consists of 3146 high-resolution DSLR images whose size is 3456×5184, point cloud model of the scene, as well as the ground truth camera pose of each image. The ground truth provides the transformation matrix that can be decomposed into locations and view angles. The dataset also provides the camera intrinsic for 3D reprojection. The second dataset is the Baidu IDL indoor localization dataset [20]. The IDL dataset is captured at a mall, containing 682 training images captured from DSLR camera and more than 2000 query images captured from other cameras. In the experiment, the authors randomly split the dataset into three parts: 8/10 for training, 1/10 for validation, and 1/10 for testing. The training set is used for optimizing the parameters of the model, while the validation set is used for determining when to stop training as well as choosing the proper hyperparameter β. Then the authors evaluate the proposed approach on the test set.

4.2 Implementation

4.2.1 Preprocessing

Before training the model, the authors conducted the following preprocessing over the data:

1. Downsize all images to $256 \times 384 \times 3$ to accelerate training and localization. Compared to raw images, our GPU can process 64 compressed images in parallel.

2. Crop the image into four corners and a center using the size $224 \times 224 \times 3$. The authors did the cropping for two reasons. First, it is an effective way of data augmentation that allows the network to have more data for training. Second, the authors used the weights of a pretrained network on ImageNet to initialize the model, images on ImageNet uses the same size as well. Notice that cropping will not change the ground truth pose.

3. Randomly add 10% lighting noise (AlexNet-style PCA lighting noise [21]) to make the model more robust to different lighting conditions.

4. Normalize the image using the mean and standard deviation of ImageNet. Normalization guarantees that the same range of values for each of the inputs to the model, which can effectively prevent ill-conditioned model and accelerate optimization process.

4.2.2 Training

The authors implemented the proposed model using PyTorch. The pretained densenet-121 model from ImageNet is employed as the base net in the experiment. The last layer of DenseNet was replaced by a fully-connected layers that has 7 outputs where the first 3 outputs are x, y, and z, while the last 4 outputs are q_1, q_2, q_3, q_4. As mentioned in section 2.2, the objective function has a hyperparameter β that balances the location and the view angle error. In the experiment, we follow the suggestion in [14] and set the $\beta = 150$ for indoor scenes. The optimization method is Adaptive Moment Estimation(Adam) [22] and set the learning rate as $1e-4$, $\beta_1 = 0.9$, $\beta_2 = 0.999$ using the recommended settings utilized in [22]. The batch size is 64 which uses up to 11 GB of GPU memory. The model was trained on a desktop with Intel i7-7700k CPU, 32G RAM, and a Nvidia 1080Ti GPU.

4.3 Results

The performance of the localization module was evaluated from three perspectives: 1) accuracy, 2) robustness, and 3) efficiency. The average location error is $2.04m$ and the average view angle error is $11.3°$ on Navvis dataset, and $1.02m$ and $4.2°$ on IDL dataset. Figure **??** shows the localization result on Navvis dataset. In comparison, the SfM method failed to reconstruct a 3D model for Navvis dataset due to poor textures of the scene. On IDL dataset, the mean displacement and orientation error of the SfM method are $7.21m$ and $18°$ respectively due to the reconstruction ambiguity. Figure 7 shows the localization result on IDL dataset using SfM (a) and the proposed method (b). As shown in Figure 7, the SfM localization result has an ambiguity issue which is caused by incorrect feature point matching.

Figure 8 shows the translation and orientation error distribution respectively. On the IDL dataset, about 88% of the images has a translation error lower than $2m$. On Navvis dataset, about 93.3% images have a location error lower than $4m$. In comparison, the SfM method failed to reconstruct a 3D model on Navvis dataset and presented an ambiguity issue on IDL dataset. The reconstruction failure was due to the poor texture of the scene and low overlapping between images. In our experiment, the image

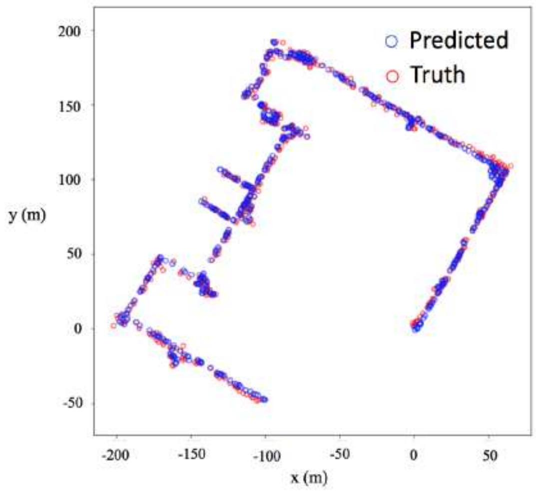

Figure 6. Localization Result using the proposed method on Navvis dataset.

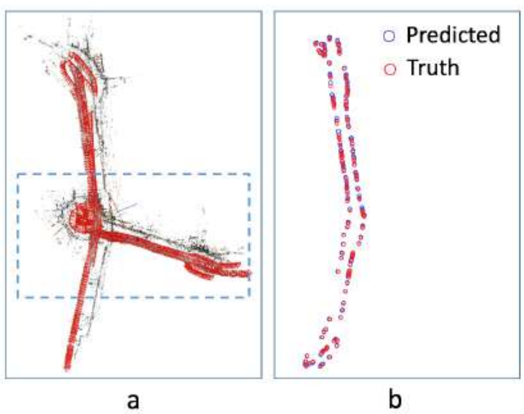

Figure 7. Localization Result from SfM (a) and the proposed method (b) on IDL dataset. The blue rectangle in (a) shows the reconstruction ambiguity.

registration rate on Navvis dataset is about 15%, which is not sufficient for 3D reconstruction. The ambiguity issue comes from the repetitive scenes in the indoor environment. When a scene presents similar pattern at different locations, incorrect feature matching will lead to ambiguity issues. According to the experiment results, the proposed method is robust to the aforementioned problems.

Regarding time and storage efficiency, during localization, predicting each query image takes averaged 0.04s on the aforementioned desktop using the proposed method. The map size of the proposed method is just the network itself, which is 35MB in total. In comparison, the state-of-art feature-based image localization method implemented in [23] needs an averaged 0.3s to finish localization in a map with only 900 registered images. Also, with 900 registered images and 400 feature points on each image (Each feature point is represented by 128 floating point numbers), the map size of the feature-based method reaches 175 MB and it will increase as the number of registered image increases. The fixed map size of the proposed method makes it more suitable for providing location services in a mobile computing context considering the limited memory resources of mobile devices.

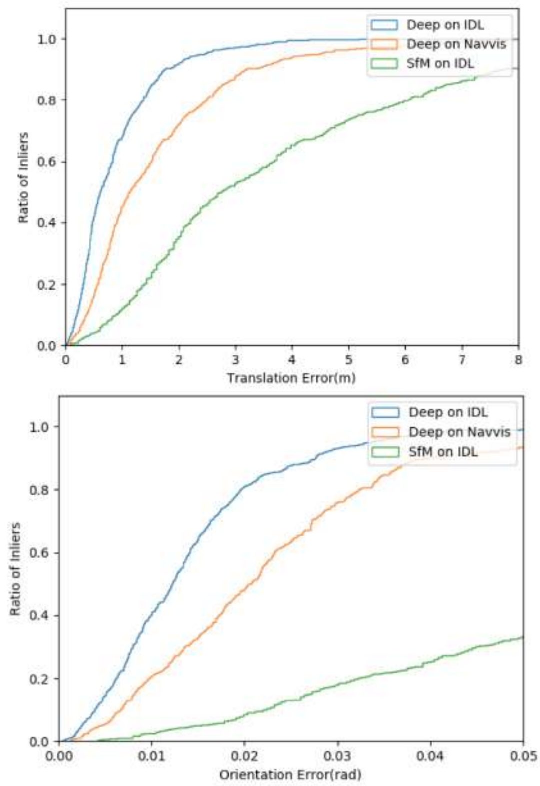

Figure 8. Translation and orientation error distribution on the testset of IDL dataset

5 Conclusion

In this paper, the authors explored an end-to-end image-based indoor localization method and proposed an approach of integrating it into a general facility management framework. Compared to signal-based localization methods, image-based methods do not require special infrastructure installed in the building and can output 6-DoF poses. Compared to conventional image retrieval and feature-based localization methods, end-to-end localization is robust to poor texture and repetitive scenes. Though feature-based methods can achieve high accuracy given accurate feature matching results, they are susceptible to inaccurate registration and reconstruction ambiguity as shown in the experiment. Moreover, end-to-end localization has a fixed map size and can provide real-time locations while the map size of feature-based methods will grow over time. Therefore, compared to feature-based methods, the proposed approach is more suitable for running on mobile devices such as cell phones or tablets.

In conclusion, end-to-end image-based localization is an alternative of indoor localization methods. It has the potential of being integrated with a facility component detection module to support facility management. However, there are also a few challenges when using end-to-end image-based localization. First, it requires ground truth poses (usually captured from a laser scanner) as input for training, which can be hard to capture in the industry due to the difficulty of cross-sensor calibration. Second, the performance of the proposed approach might be affected by image quality, over-lapping between images, texture richness, lighting conditions, and camera intrinsic difference. The authors will continue to evaluate the end-to-end image-based localization considering these variances and integrate it with the facility component detection module in future research.

Abstract –

Reinforcement engineering is one of the most important parts in projects of large reinforced concrete structures. Its quality directly affects the quality of the whole structure. As a matter of fact, many difficulties in rebar engineering remain to be solved, owing to its complexity and variability. Fortunately, the emerging BIM technology can overcome most of the difficulties. To efficiently build up a rebar model of a structure based on the Revit@ software, this study carried out a module for rebar modeling using the Revit@ API and the C# programming language. This module can establish the rebar part of structural elements, according to two-dimensional drawings of a structure. In addition, the module can provide an interface that is easy to be used for those who are not familiar with the standard detailing drawings. Simultaneously, this module generates a database regarding the rebar modeling, which can be further utilized in a future.

Keywords –

BIM; Rebar; Revit@ API; Secondary development

1 Introduction

Reinforcement engineering is one of the most important parts in projects of large reinforced concrete structures. Determining the costs of it is essential for the whole project. In addition, its quality directly affects the quality of the whole structure. Owing to its complexity and variability, many difficulties in rebar engineering remain to be solved. Fortunately, the emerging BIM technology can overcome most of the difficulties.

Building Information Modeling (BIM), as a new concept and technology, has been widely used by construction industries in the world since it was introduced. It can transform 2D drawings to a 3D model of a building structure. Because this 3D model allows for modifications to be made to the building's design during the stage of audit or construction, the amount of time and money needed to incorporate the changes is also reduced. In addition, the 3D model can provide 3D reviews, which can help constructors getting through the details of 2D drawings especially for the plan of reinforcement.

Many research studies have shown that the use of BIM technology for reinforcement engineering can provide satisfactory results. For example, Aram et al. (2011) mentioned that making use of BIM technology can improve productivity of the reinforcement in supply chains. Porwal and Hewage (2012) reported that if BIM technology can be used reasonably, it can reduce the loss of rebar. Pratoom and Tangwiboonpanich (2016) pointed out that the quantity of rebar resulting from the use of traditional methods is 17.76% more than that resulting from the use of BIM-based methods. Meanwhile, the application of BIM in China is just beginning, compared with the developed countries. How to take advantage of BIM technology has become the rising issues of the construction industry in China.

One of the issues nowadays is the deficiency in rebar modeling when using BIM software. For example, Cho et al. (2014) mentioned that a detailed structural model built by using Tekla@ cannot interface directly with some other software tools for structural design, such as ETAB@ and ADAPT@, while Revit@ Structure can. As a result, Revit@ Structure was used in their study to interface with ADAPT@. Still, the details of rebars for structural design needed to be improved, when building up the frame models by means of Revit@ Structure. Shao (2017) developed a plug-in using Revit Extensions 2014@ to carry out the modeling of rebar in beams, columns, slabs, walls and so on.

The Revit@ software is the most popular BIM software used by companies for design and construction in China. However, its functions for rebar modeling are limited. A series of tedious settings are required for the drawings of rebar when using Revit@. The lack of the proper functions in the software not only affects the working performance of the designers, but also hinders the application of BIM technology in the reinforcement engineering.

This study proposed a module using the Revit@ API and the C# programming language for rebar modeling. The module provides an interface that is easy to be used especially for those who are not familiar with the standard detailing drawings. This module includes the modeling of columns initially, but it can be extended to the modeling of beams, slabs, and walls in a future. This module can help to build rebar model efficiently and can promote BIM application in reinforcement engineering.

2 Method

Revit@ API provides certain functions that can access the graphical and parameter data of a building

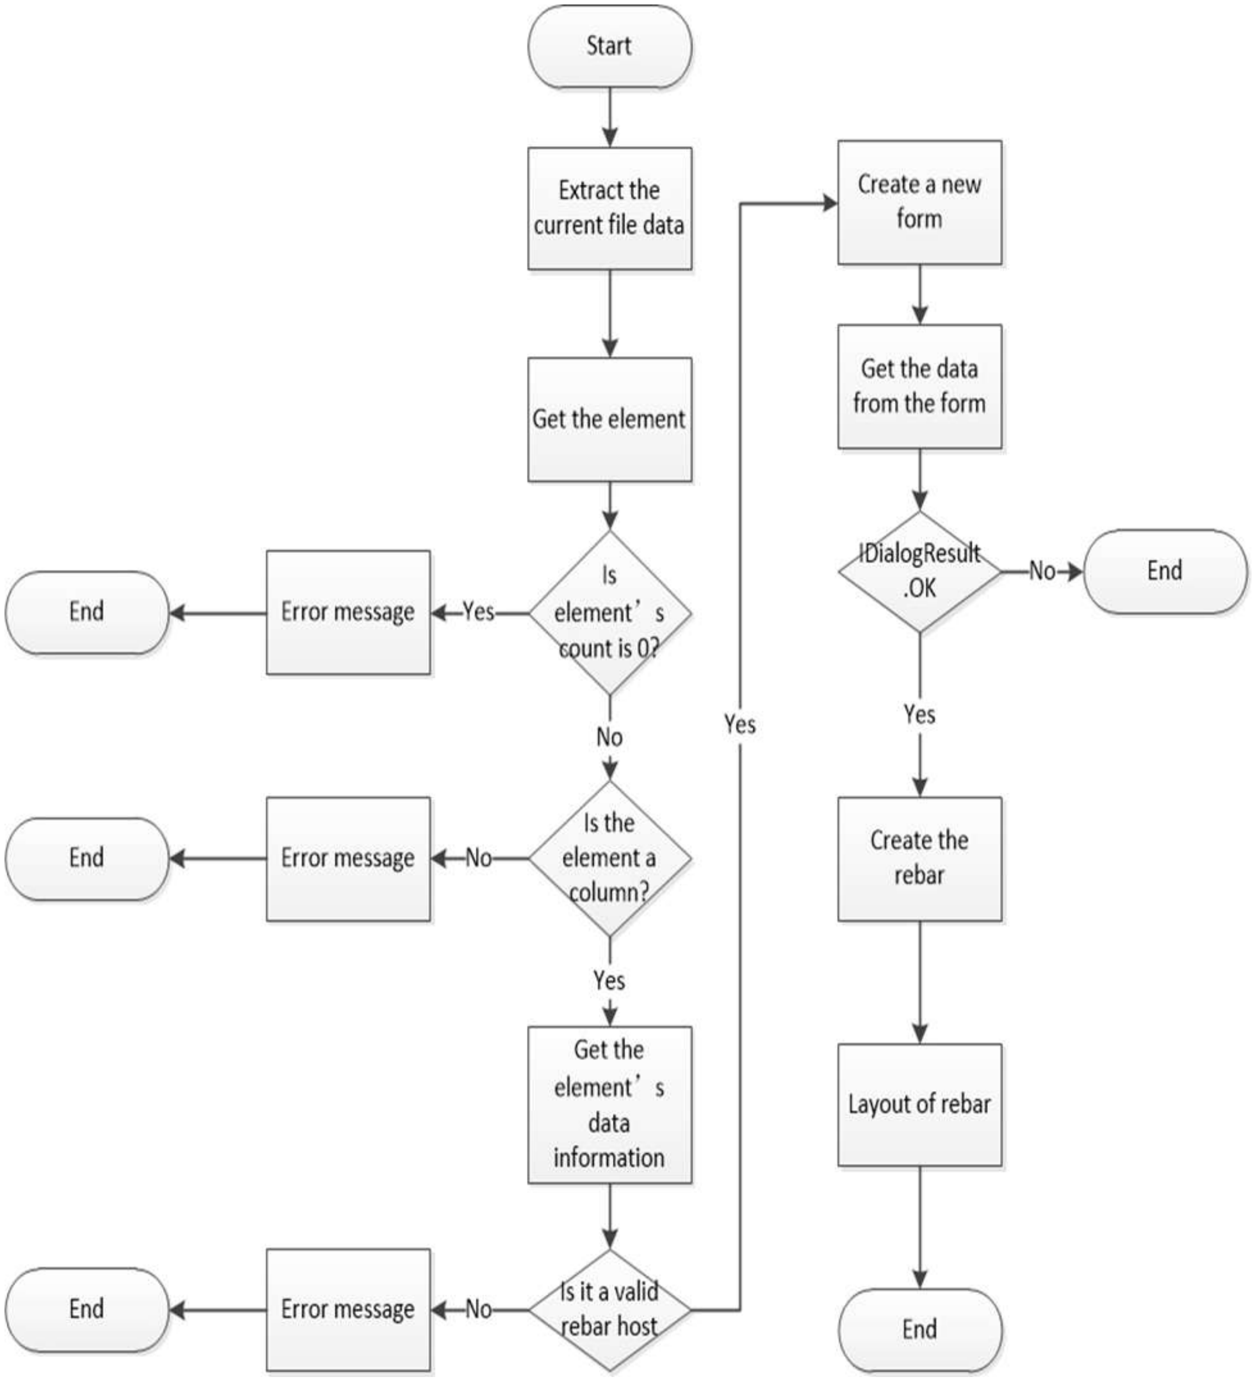

Figure 1. The flow chart of main program.

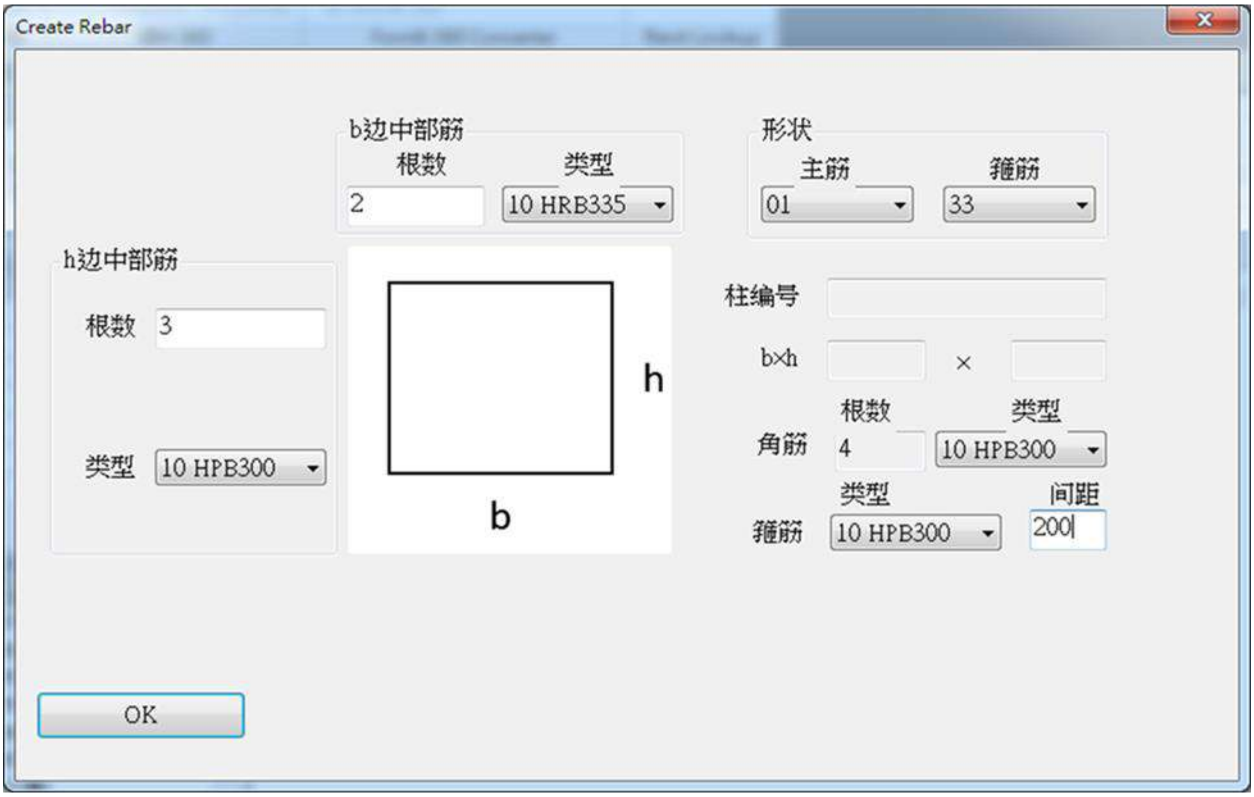

Figure 2. The user interface of column

information model. Besides, it can create, modify, and delete the structural elements in the model. Moreover, it can create plug-ins that can enhance the user's interface and automate the repetitive tasks. The C# programming language is the other tool used in this study, which is easy to learn for a beginner. Using the Revit@ API and the C# programming language, this study developed a module for rebar modeling. The steps of generating the rebar model in the component are roughly divided into: 1. Extract the current file data; 2. select the main body of the rebar; 3. ensure the type of the element; 4. define the rebar generation element; 5. restrict the rebar to the main body. Shown in Figure 1 is the flow chart of the main program in the module for creating rebar.

The brief introduction of the module follows. Firstly, the elements of a structure are established by means of Revit@. Once the desired element is selected for the arrangement of rebar, one can run the module. Shown in Figure 2 is the user interface in which the parameters related to the rebar can be assigned in the interface of the module. After clicking the "OK" button, the rebar are arranged in the element as planned.

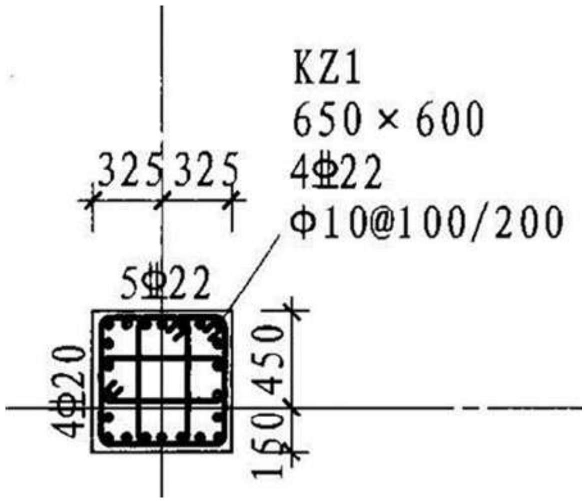

Figure 3. The tagging of column in the standard detailing drawings. （From B16G101-1[7]）

3 Results

Taking the element of column as an example, the parameters consist of the quantity, the number, the type, and the shape of the main bar, and the type, the spacing, and the shape of the stirrup as well.

At the left of the interface in the Figure 2, a user can input the quantity and choose the type of the main bar of

Figure 4. The rebar modelling for column

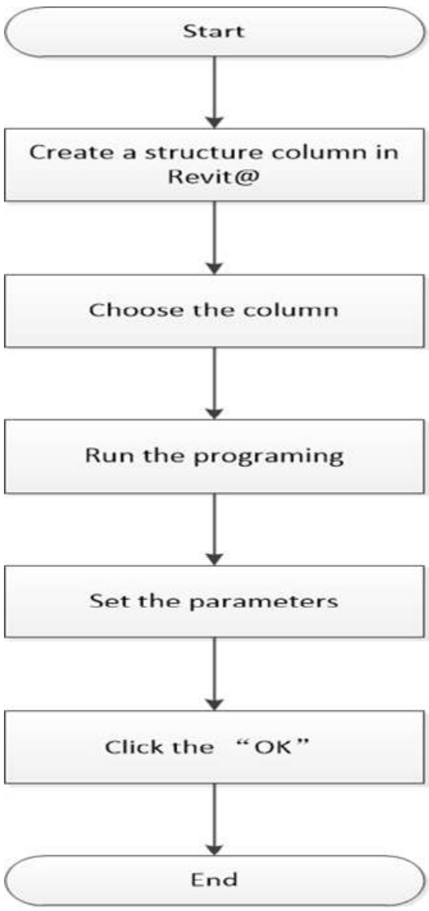

Figure 5. The flow chart of using the module

the "h" side. At the upper middle of the interface, a user can input the quantity and choose the type of the main bar of the "b" side. The lower middle of the interface shows the simple schematic diagram of column. At the upper right of the interface, a user can choose the shape of the main bar and stirrup. At the lower right of the interface, the serial number and the size of the column respectively show in the first and second lines. The third line gives the type of the main corner bars and the fourth line gives the type and the spacing of the stirrups. The user interface is like the standard alters as shown in the Figure 3. Shown in the Figure 4 is the rebar modeling resulting from the Figure 2. The flow chart of using the module is shown in Figure 5.

4 Conclusions

Currently, lots of BIM software for rebar modeling is deficient. Particularly, some of them cannot satisfy the needs of Chinese users, when using the Chinese building standard detailing drawings. This study developed a module for rebar modeling using the Revit@ API and the C# programming language. Revit@ is a convenient and popular BIM tool that can efficiently build up a rebar model of a structure. Compared to other BIM software，this module can result in a user interface that allows users to easily use the Chinese building standard design drawings. Even when one is not familiar with the standards, the module can be employed to create rebar modeling resulting from 2D construction drawings.

In the next study, the programing not only will finish the modeling of beams, slabs, and walls modeling, but also will create a database related with the model. People can use this module to build a detailed rebar modeling. The database will store all data about the rebar, such as quantity, type, shape, length, etc. Users can generate multi-purpose quality take-off reports extracted from the database, to promote BIM application in reinforcement engineering.

Abstract

Construction process simulation allows producing a virtual copy of an existing or planned construction site. The detailed analysis of construction processes and construction logistics with the support of simulation models creates a better understanding of the performance defining aspects. In many construction sites, the actual performances lag behind the planned levels. This is due to the insufficiency of planning instruments. The authors have performed an in-depth analysis of the internal supply chain of an actual tunnel construction project. While the presented study has focused on the inner outfitting of the existing tunnel, similar work has been done for the excavation processes by the authors. The paper reviews the role, simulation plays for construction planning and investigates the benefits of simulation as a step towards increased automation levels.

Keywords –

Simulation; Tunneling; Process Modeling;

1 Introduction

Within the construction industry, tunneling is a highly specialized discipline due to its very strict spatial restrictions. Whether for the actual tunnel excavation itself or for the subsequent inner outfitting of the structures, delivery routes and workspace are limited. This poses challenges for the organization and execution of the supply chain processes that are necessary to keep work going. Often, different processes compete for space and must therefore be scheduled in such a way that they don't conflict with each other.

Since the involved capital cost and ongoing operating expenses of large civil engineering projects are very high, reducing execution duration is a key target of planners. Therefore, planning should allow for a maximum degree of parallelization of works. If this target can be reached, mainly depends on the possibility to deliver the required material to the worksites on schedule. The study presented by the authors uses process simulation to investigate the robustness of the supply chain concept for the inner outfitting of a railway tunnel in Germany. The study has been part of the bidding documents of a contractor for the execution of the works. The project owner's tender called for a verification of the bidder's logistic concept by simulation with particular consideration of the logistic restrictions, evacuation routes and all material transports. The tender requirements for the simulation study included:

- Core processes and work cycles with references for the underlying performance data.
- Possible interactions between system elements.
- Sensitivity analysis and study of alternative scenarios and their influence on the project completion.
- Mitigation strategies for bottlenecks shown by the evaluation.
- Description and explanation of the simulation study methods.

2 Process Simulation in Tunnel Construction

Although simulation studies have been used successfully in the planning of tunnel construction projects, the usage of simulation usually has been restricted to high level planning for strategic management purposes. The application of simulation as a tool for the improvement of work level processes has been rare. Nido et al. provided the planners of the Holes Creek Tunnel in Ohio, USA with a cycle time analysis based on the Cyclone simulation framework [1]. Liu et al. used a Cyclone model to evaluate the mucking system for a hard rock tunnel project in Xinjiang, China [2]. Ioannou et al. used Stroboscope to optimize resource allocation for the Hanging Lake tunnel project in Colorado, USA [3]. Fernando et al. used the Symphony simulation environment to evaluate different options regarding the use of one or several tunnel boring machines (TBMs) and their related logistic systems in the North Edmonton

Sanitary Trunk in Alberta, Canada [4]. For the Glencoe tunnel project in Calgary, Canada. Al-Bataineh et al. have used a Simphony model to investigate the influence of different geology scenarios and to determine the cost / time parameters for these different layouts [5]. The general-purpose simulation framework Anylogic has been used in several studies for a detailed analysis of work processes in tunneling [6] and [7]. One focus of these studies has been improved performance prediction for tunneling projects with regards to the influence of jobsite logistics on production rates [8] and [9].

3 Work and Transport Processes in Tunnel Outfitting

Once the excavation and structural construction of a tunnel is completed, the inner outfitting can be performed. The project which has been analyzed in this study consists of two parallel railway tunnels of 4km length in Germany. The bored tunnels are transitioning into a cut and cover structure of 1km length at each end. All sections are to be equipped with a slab track system as well as walkways and driveways at each side of the track. A drainage system and cable ducts are installed below these structures.

The construction process is separated into discrete process cycles. Within the schedule, these are defined by distinct construction stages which are executed along individual work sites. For each work site, the corresponding material requirements and delivery paths are defined by the contractor's logistics concept. The general construction schedule can be separated into the following stages which again make up the core processes:

1. Construction of drainage pipes and filler
2. Pouring of concrete invert
3. Installation of cable ducts
4. Concreting of side walkway and driveway
5. Construction profile concrete
6. Installation slab track and rail cover

Generally, the processes in the east and west tunnel are identical. To reach logistic independence, the work in the cut and cover sections is performed after completion of the works in the bored tunnel sections.

4 Simulation Modeling

The simulation model has been implemented in the commercial simulation framework Anylogic. Anylogic supports the integration of different simulation paradigms in a single model. This includes system dynamics, discrete event and agent-based modelling approaches [10]. Furthermore, embedded object libraries allow efficient modeling of vehicles, road networks and railway systems. In the presented study, the individual construction processes have been modeled by statecharts, using the discrete event approach. A road network which is dynamically adjusted to the respective situation, especially the changes in the logistics restrictions in each construction stage has been used to model the vehicles of the supply chain within the construction site. The embedded road library of the Anylogic software has been used to implement the road network. The system boundaries have been set to the physical boundaries of the cut and cover sections. Figure 1 shows the jobsite layout and the model boundaries.

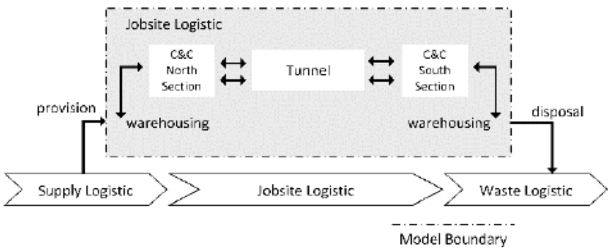

Figure 1 System- and Model Boundaries

It is assumed, that the external supply chain is always able to deliver the required performance. As an additional abstraction, the transport required for material disposal are ignored as they are minimal during the outfitting stage of construction. As construction only proceeds during dayshifts, transports during nightshifts are not modelled as well. Furthermore, personnel transport is assumed to take place between the material transports without disturbing them.

4.1 Modeling of Core Processes

The overall completion duration of the project is defined by its core processes and the resulting process chain. Each core process is defined by a set of properties which uniquely identify it and set its behavior within the overall model. The parameters are:

- Process Name
- Requirements for starting (logical or date)
- Separation into production intervals or sections
- Location of start and endpoints
- Required resources for execution
- Productivity per unit
- Material requirements (type and amount)
- Process related logistic restrictions
- Process related waiting durations

Due to slight differences in the execution logic, the processes for the outfitting of the bored tunnels and each cut and cover section are defined separately.

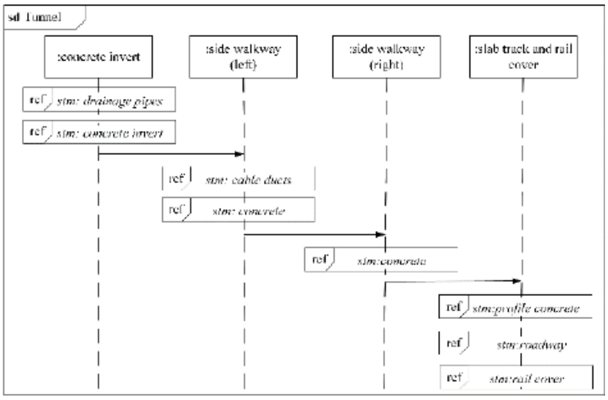

Figure 2 Logical order of process execution in the bored tunnels

Figure 2 shows the logical order of the process execution for different core processes as a SysML Sequence Diagram. Each of the core processes is implemented by a generic state chart. Functions, parameters and variables are used to customize the generic model to each respective process.

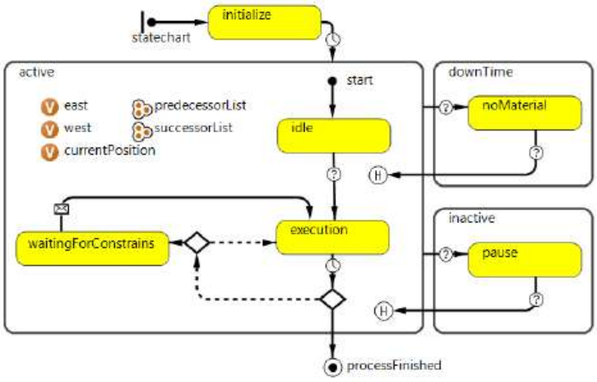

Figure 3 Generic statechart for work process modelling

The state chart shown in Figure 3 is used generically to model all work processes. For each work process, an individual instance of the state chart is generated. Within the chart, each rectangle reflects a particular state of the system. At any given moment, the system is on one particular state.

At the time of project start, all processes are in the state "initialize". The state "execution" is initiated, once the defined conditions are fulfilled (for example completion of the predecessor). Based on the process performance, the current position of the worksite is permanently updated. The variables "east" and "west" indicate in which tunnel the process takes place. The remaining available construction material are determined based on the processes consumption data. If the material is used up completely, the "working" state is interrupted and the system transitions into the "noMaterial" state. An underlying shift schedule defines when the system moves into the "pause" state. A history function "H" allows resuming work at the point where it stopped after an interruption. By using the "predecessorList" and "successorList" elements, the logical order of execution is defined. Communication functions organize the interaction with other model elements.

4.2 Modelling Transport Processes

The transport processes are modelled by the Anylogic embedded road traffic library. It uses movement processes and queues through which objects are moving according to a defined set of rules. The traffic model is separated into distinct sections that reflect the road sections that vehicles must pass through. For each section, different traffic conditions such as one-way traffic, two-way traffic and waiting points are defined. This allows modelling bottlenecks and passing locations for trucks.

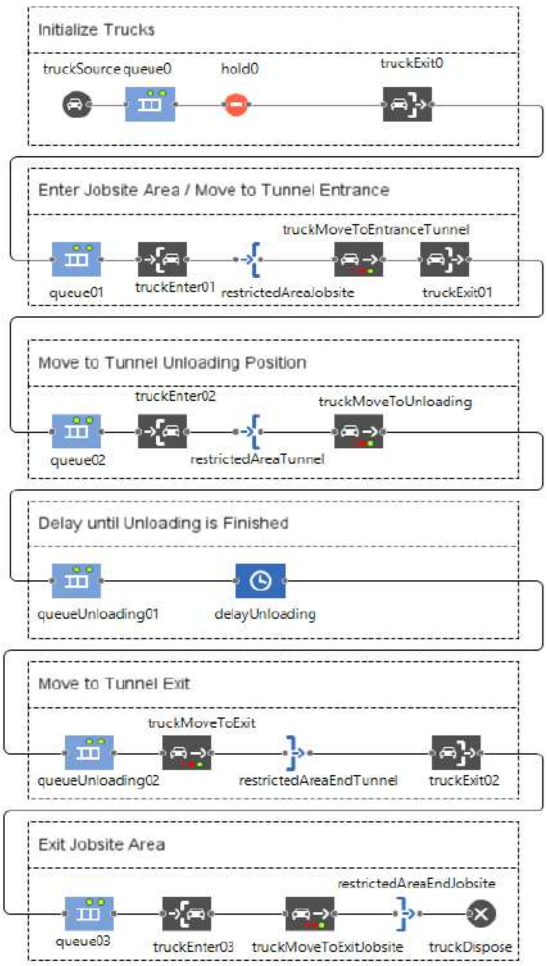

Figure 4 Dynamic traffic model for the site logistics

Figure 4 shows the logic structure of the road traffic model. The underlying logic of the model and its visualization are implemented separately. Figure 5 shows a screenshot of the traffic visualization within the simulation model. The driving paths are idealized as straight sections in the view. Inclination and curves are reflected by their effect on the driving speed of the vehicles.

Figure 5 Visualization of traffic processes

The key information for the transport processes are the following:

- Transport batch sizes
- Driving speed (full and empty) in different sections
- Driving routes / supply strategy
- Unloading durations

To deliver material to the different work sites, four different supply strategies can be distinguished:

1. Drive through from north to south. The full trucks enter the tunnel on the north side, unload the material at the work site and once empty, they drive out to the south.
2. Drive through from south to north. The full trucks enter the tunnel on the south side, unload the material at the work site and once empty, they drive out to the north.
3. Delivery from North. Trucks drive into the site backwards from the north side and after unloading dive out forwards to the north again.
4. Delivery from South. Trucks drive into the site backwards from the south side and after unloading dive out forwards to the south again.

For each work process, one particular supply strategy is defined in the simulation model. Once material is ordered by a work process, the associated transport strategy is assigned to the vehicle.

4.3 Interaction of System Elements

With regards to the logistic processes that supply the inner outfitting of the tunnels, especially the implementation of material orders and deliveries is of importance. The interaction of the individual construction processes is based on the embedded lists of predecessors and successors that define the possible execution order. Thus, the current state of all processes is permanently communicated between model elements to check if any process reached its requirements for work start or completion.

The transport processes are coupled with the construction processes by a material ordering system. For each work process, a set of variables and parameters defines the execution of material orders. Figure 6 shows this element within the simulation model. The element defines the required material type, its consumption rate, delivery batch size, performance rate and remaining material amount. The process “invert concreting” in the east tunnel requires for example the material invert concrete which is of the class “material” and is represented by the generic agent “agent material”. The required material is permanently compared to the available material. As soon as it becomes visible that the available material does not suffice for the completion of the current work section, a material order is triggered. This is executed within a defined time buffer to avoid downtime due to lack of material. The time buffer reflects the lead time for the order.

Each material order triggers a delivery process. With consideration of the information contained in the order, a suitable vehicle (truck / mobile mixer) is provided and starts driving to the work site which placed the order. The driving duration depends on the vehicle type, the transport route, transport strategy and interaction with other vehicles which could cause waiting durations at bottlenecks along the way. Upon arrival at the work site, a certain duration is needed for unloading after which the vehicles drive back out.

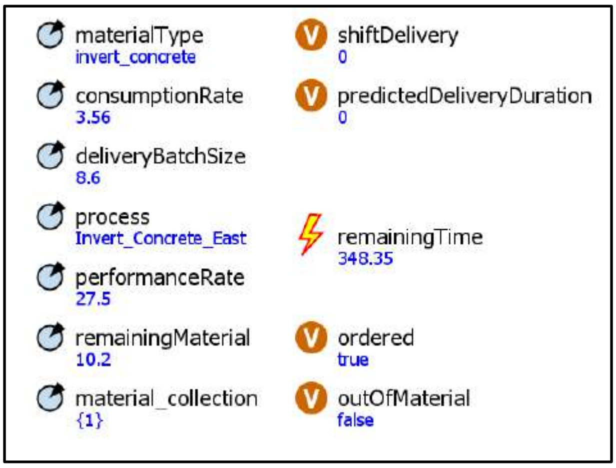

Figure 6 Control variables for the ordering process

4.4 Model Verification

Simulation models must be verified to ensure the correctness of the conclusions drawn from their results. A number of verification techniques are employed either during modeling or after completion of the model. The following methods have been used throughout the presented study:

- Completeness has been ensured by comparing all work processes from the project execution schedule with the event logs of the simulation model execution.
- The consistency of the model has been reviewed by checking the logical order and relation of all work processes in the simulation model and comparing them to the technical requirements defined in the project planning documents.
- The suitable level of detail has been confirmed as no performance relevant processes take place below the level of detail that has been modeled.
- To evaluate the plausibility of the results, the process logs during model execution and the material consumption patterns have been checked and compared to the planned amounts.

5 Simulation Results

The simulation model has been created based on the project execution schedule and the logistic concept that have been prepared by the bidder. The main purpose is the validation of the chosen logistics strategy. To evaluate the simulation results, construction performance with consideration of the supply chain simulation has been compared to the progress rates which have been assumed in the construction schedule. This comparison has been performed for different scenarios to determine sensitivity to varying progress rates. The first scenario is "standard", with all performance values and transport capacities assumed as in the planning documents. The second scenario is "fast completion" with increased construction performance rates (+10%) and the third one "reduced transport capacity" with reduced transport speeds (-10%) for all trucks. Figure 7 shows that even in the second scenario under aggravated circumstances, all work processes can be executed with an acceptable performance rate. Consequently, the same results could be verified for the other two evaluated scenarios. The results show, that the capacity of the proposed logistical system provides adequate buffers in the process chain to ensure an undisturbed construction progress even under hindered boundary condition. Thus, the simulation study verifies the bidder's logistics concept as sound and robust.

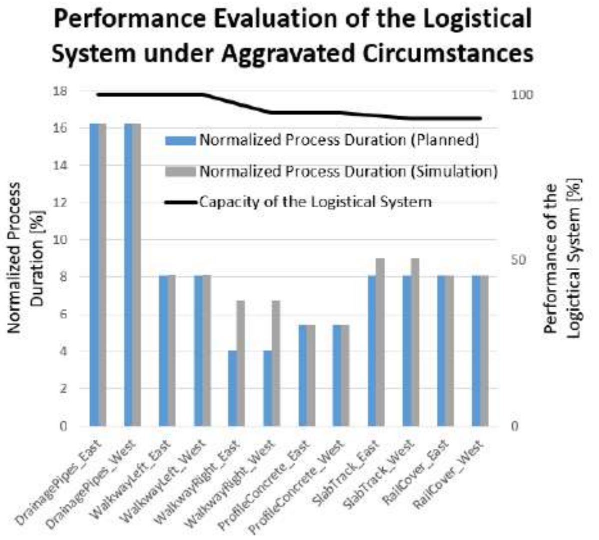

Figure 7 Simulation results for the second scenario with increased construction performance rates

Additionally, to the verification of the supply chain strategy, the simulation model can be used to derive valuable information on the expected traffic volume during different stages of project execution. Figure 8 shows the summary of required transports from and to the jobsite throughout the project. Such information is especially relevant to authorities if projects are located in congested urban areas.

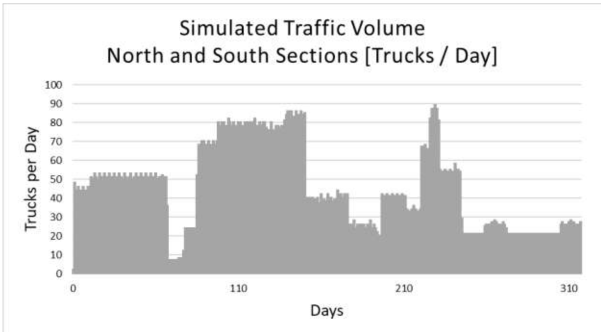

Figure 8 Traffic volume for standard scenario

6 Other Simulation Applications in Tunneling

While the study presented here is focusing on the inner outfitting of tunnels, much value can be added to tunneling projects by supporting their planning with simulation studies during planning the actual drilling. During this stage, large amounts of material are moved, and often special constraints highly restrict the available options for logistics. Cranes, trains, trucks and storage areas compete for scarce space. Figure 9 shows a 3D model of an urban tunneling jobsite on which two tunnel boring machines have to be supplied through a small shaft. In such conditions, the performance of the jobsite is often severely limited by logistic bottlenecks. Simulation studies help estimating these effects and assist the development of counter strategies.

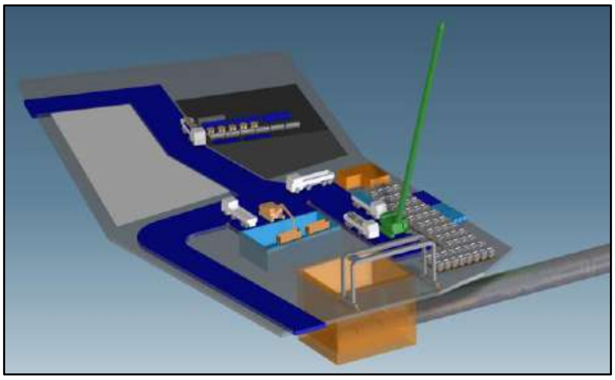

Figure 9 Screenshot of a simulation model for a tunneling site

7 Conclusion and Outlook

Simulation studies have helped dramatically increasing the productivity in the manufacturing sector. As currently the construction sector moves towards higher productivity rates and fields such as automation and robotics are entering the industry, simulation becomes an increasingly important factor in planning. The underlying knowledge about the interaction of processes is crucial for finding ways to automate them. The authors are confident that the construction industry bears great potential for productivity gains in the future.

Abstract

Over the past decades labour productivity in construction has been declining. The prevalent approach to estimating labour productivity is through an analysis of the trajectories of the construction entities. This analysis typically exploits four types of trajectory data: a) walking path trajectories, b) dense trajectories (posture), c) physiological rates such as heart rate (beats/minute) and respiratory rate (breaths/minute), and d) sound signals. The output of this analysis is the number of work cycles performed by construction workers. The total duration of these cycles is equal to the labour input of a task. However, all such methods do not meet the requirements for proactive monitoring of labour productivity in an accurate, non-obtrusive, time and cost efficient way for multiple workers. This paper proposes a method to address this shortcoming. It features a promising accuracy in terms of calculating the labour input.

Keywords – Productivity, monitoring, construction.

1 Introduction

In general, productivity is defined as the ratio of output to input [1]. Productivity rates are used by project managers during planning and scheduling in order to reduce the labour cost and improve the performance of workers. The construction sector has gradually created a significant labour productivity gap compared to other industries over the past five decades. It is estimated that only 50% of the total construction time is productive [2,3]. This is due to factors that affect on-site construction tasks negatively. Almost all of them are related to the way that productivity is monitored. Construction project managers currently evaluate worker performance based on questionnaires, manual observations, and work sampling practices [4–7]. Construction requires proactive monitoring of labour productivity in order to detect issues sufficiently early. However, this is not feasible as current practices are labour intensive and time consuming due to the large number of employees and the long lasting tasks. This paper presents a method to address this issue.

The remainder of this paper is structured as follows. Sections 2 analyses the current state of research in monitoring of labour productivity in construction. Section 3 presents an overview of the overall proposed method presented in this paper. Section 4 summarizes the outcomes of this paper.

2 Background

This paper reviews the latest studies that focus on monitoring of labour productivity. Current studies are divided in two main categories based on the methods they employ to infer productivity. The first contains the region-based studies that link the location of workers to regions of management interest (work zones) such as steel fixing zone, concrete pouring zone. The second consists of the activity-based studies that detect and link activities such as bending, hammering, and drilling to specific tasks.

Region-based studies monitor labour productivity through the time construction entities spend at zones of management interest (e.g. excavation zone, concrete pouring zone). In order to achieve this, the location of monitored entities is tracked across the jobsite. The studies of this category are sub-divided into tagged and tag-less. The tagged (RF tagged) studies employ tags which are physically attached on workers and earthmoving equipment. The most frequently used tags are the Global Positioning System (GPS), the Radio Frequency Identification system (RFID), and the Ultra-Wide band system (UWB). The above systems provide the input data of tagged studies. On this basis, the speed and the location of a haul truck were both combined for monitoring its productivity while performing an earthmoving operation [8]. If the haul truck's location was within the range of fixed known distances from specific work zones (e.g. load and dump zones), then the time during which its speed was equal to zero was converted into labour input. On the other hand, the labour productivity of workers, was monitored by linking their presence at predefined work zones [9–13]. For instance, if a concrete worker is located at zones “A” and “B” which are scheduled for concrete pouring, then the total time the worker spent in these zones is considered productive and equal to his/her labour input. The studies of this category also sub-divide the areas between the actual work zones into waiting and travelling zones, for a more detailed insight of worker productivity. The most important disadvantage of the tagged studies is that they can neither identify the unproductive time (idle time) nor the low productivity pace. For example, even if a worker is located in the correct work zone, but without performing any task due to shortage of materials or congestion he/she will be still considered productive. This is due to the fact that labour productivity is monitored only based on the presence of workers at work zones. The tagged studies do not provide any extra information about what really happens within these work zones. In addition, the purchase and maintenance of multiple tags impose a regular cost in the long term [14]. Last but not least, the physical attachment of tags creates a feeling of discomfort to workers [15]. The tag-less studies rely on computer vision-based 2D tracking methods in order to calculate the location of workers. This location is 2D instead of 3D. Therefore, entities are tracked only within the range of a camera's view. This type of tracking is non-obtrusive as it processes video data collected through surveillance cameras used for security purposes. The studies in this category convert the location data into labour productivity through two approaches. The first, links the presence of tracked entities (workers, earthmoving equipment) to specific work zones similar to tagged studies [16]. For this reason, the ambiguity about what really happens within these zones arises again. The second, fits the monitored entities to operation process models [17–19]. Such models [20,21]: a) break down the construction tasks into sub-tasks (semantic context), b) describe how the sub-tasks relate to specific work zones across the jobsite (spatial context), and c) define the sequential order (i.e. workflow) between the sub-tasks (temporal context). However, such approach relies on human intervention in order to adjust the appropriate process model to each entity. It takes 5-10minutes for an operator to achieve this. Such adjustments should be repeated for every entity on a daily basis. The large numbers of workers and earthmoving equipment entails that such type of studies will be labour intensive if applied in practice.

The activity-based studies firstly detect and secondly link activities to specific construction tasks in order to monitor labour productivity. These activities are the physical description of tasks. For example, a brick layer bends to pick up bricks and stretches his arms to place them. Bending and stretching are both activities that describe the brick laying task. This type of studies exploit posture, physiological (e.g. heart, breathing rate) and audio data. The posture-based studies have been used for monitoring both the labour productivity of earthmoving equipment [22,23] and construction workers [22–26]. Posture data are detected via feature descriptors such as the Histogram of Oriented Gradients [27] and skeletisation algorithms [28]. Machine learning-based algorithms such as Support Vector Machine Classifiers (SVMs) [29] and Artificial Neural Networks (ANNs) [30] are then trained to link (label) the detected activities to construction tasks. The highest achieved accuracy so far is equal to 59% [24]. In particular, this study was tested on workers while performing 11 types of tasks i.e. brick laying, transporting, plate cutting, drilling, re-bars fixing, nailing, plastering, shovelling, bolting, welding, and sawing. The authors admitted that this low accuracy was due to the fact that most of these tasks were not distinguishably described by posture data. On the other hand, posture-based studies perform very well (accuracy >80%) for the case of earthmoving equipment, as such entities have a small but well defined range of postures. For example, an excavation task performed by a dump truck is described only by two postures. The first depicts the unloading of materials and the second the transportation of materials. In addition, earthmoving equipment is used for only one type of tasks whereas workers perform a much larger variety. Physiological data such as heart rate (beats/minute), breathe rate (breaths/minute), body's force and angular rate [31–33] are acquired through physiological status monitoring (PSMs) and inertial measurement unit (IMU) wearable sensors. The physiological data are used for training machine learning-based classification methods similarly to the studies that exploit posture data. However, it has been proven that heart and breathe rates cannot establish any relationship with individual's labour productivity [31]. On the other hand, body's force and angular rate, extracted with accelerometers and gyroscopes of IMUs sensors, achieved a promising performance (≈80% accuracy) in terms of detecting and labelling activities such as hammering, sawing, turning a wrench, loading/unloading/pushing a wheelbarrow [32]. Physiological-based studies have been also successfully used for identifying abnormalities in the performance of workers (awkward postures) for health and safety purposes [33]. Their main limitation is that they rely on data collected with wearable sensors that give rise to privacy issues. Lastly, audio data which are recorded by microphones placed at construction jobsites have also been exploited for monitoring the productivity of construction entities [34,35]. These audio-based studies are applicable only to tasks that produce discrete sounds such as nailing, hammering, excavating, and drilling. Although they have managed to successfully remove background noise, they are still not designed to monitor the labour productivity of multiple entities that perform similar tasks simultaneously.

3 Methodology

Figure 1 illustrates a method for monitoring labour productivity of multiple workers at the same time. The skewed parallelogram shapes refer to methods and the circular to inputs/outputs. The method consists of two main sub-methods illustrated with black coloured skewed parallelogram shapes. The output of the first is the input for the second. The inputs of the method are video data streamed from multiple cameras, whilst the output of the method is the total productive and unproductive time spent by each worker. This paper hypothesizes that task productivity of construction workers can be monitored through their trajectory data.

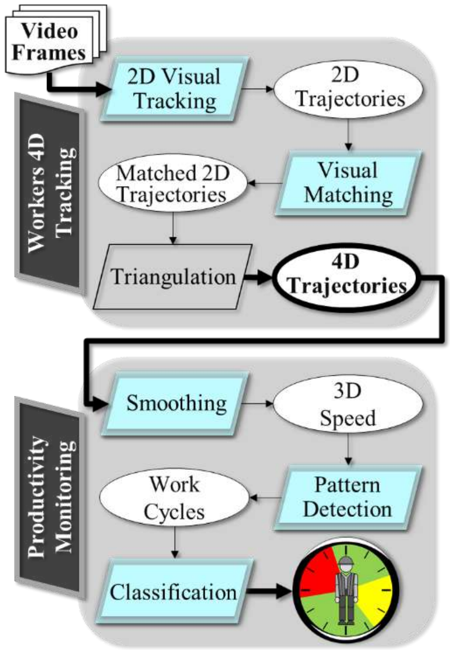

Figure 1. Method for automated construction worker task productivity monitoring.

The labour productivity is calculated by dividing a worker's total output over the total input [5]. The determination of output is quite straightforward through visual inspections (e.g. number of pipes installed, number of m^3 being excavated). Hence, this paper focuses only on the input. The main assumption of this paper is that all construction-related tasks fit to the same pattern. This pattern dictates that if a worker's "move" is followed sequentially by one "stop" and a second "move", then these three semantic events define a work cycle. This assumption is based on the fact that workers "stop" in order to perform a construction-related task and they "move" to start another. In construction, a work cycle is defined as the total time a worker spends on a task [4]. Hence, the duration of a work cycle is equal to the duration of the semantic "stop" event. Sequentially, the duration of all work cycles is equal to the labour input of a worker. Therefore, the labour input can be extracted by detecting these work cycles.

The first method of the proposed method is a computer vision-based method for 4D tracking of construction workers. This type of tracking is unobtrusive as it is tag-less. The input data are videos collected through the cameras of jobsites' surveillance systems. It returns one 4D trajectory for every worker as output. These 4D trajectories depict the 3D (X, Y, and Z) location of workers across the entire range of a jobsite over time. This 4D localization overcomes the limitation of previous tag-less studies that monitored workers only within a camera's view. An intra and an inter camera tracking are performed sequentially in order to achieve this 4D tracking [36]. The former matches workers under the same unique ID across subsequent frames of a camera, whilst the latter matches workers across multiple cameras. Then, a triangulation method [37], is applied in order to convert the 2D trajectories into 4D.

The second method of the proposed method is productivity monitoring. It uses the output of the 4D tracking method as input. Initially, a smoothing method removes the noise from the 4D trajectories. Then, the 4D trajectory of each worker is partitioned into smaller 4D sub-trajectories. The 3D speed values of these partitions are exploited to cluster them into work cycles based on the main assumption of this paper. The accurate detection of these work cycles addresses the second aim of this paper as their total duration is equal to the labour input of construction workers. The 3D speed values depict the motion of workers along the floor (XZ) and the vertical plane (Y). The detected work cycles are classified as: a) unproductive, b) normal productive, and c) abnormal productive. Initially, they are classified as either productive or unproductive through region-based classification that splits the jobsite into two types of areas, "active" and "inactive". The former contains the areas of the jobsite where tasks such as excavation, brick laying are performed. The latter consists of areas where no construction-related tasks take place. These are the: a) rest areas, b) materials' storage areas, and c) office areas. The work cycles that take place at "active" areas are classified as productive while those that take place at "inactive" areas are classified as unproductive. Then, the productive work cycles are further classified in order to detect potential abnormalities in the pace of the labour input. The durations of the productive work cycles are compared for this purpose. Those with the highest duration are classified as potentially abnormal and the rest as normal. This second classification is used as an indicator. It shows project managers whether something appears to be "wrong" with workers' productivity pace. Managers can then look into the video data at the time of the day the abnormalities occurred and check whether something was actually incorrect with these work cycles. This way problems are identified and treated fast. The productivity monitoring method does not need any prior knowledge about the type or the number of tasks workers perform. Therefore, labour productivity of multiple workers can be monitored at the same time. This entails proactivity.

4 Results

This section evaluates the performance of the method presented in this paper in terms of translating the trajectory data into labour input. This is achieved with a C# implementation in Microsoft Visual Studio.Net framework running in a Windows 8.1 operating system. The integrated development environment is Visual Studio 2013, using Windows Forms (WinForms). A desktop PC with the following specs is used: Intel core i7 CPU, 4.0GHz, and 32 GB RAM. The cameras used in the experiments are two GoPro cameras, black edition 4 with a 1920x1080 frame size, and selected 90^0 narrow field of view to reduce the distortion of camera fish eye effect. Both cameras are mounted in such a way that monitored workers are captured within their overlapping field of views.

Precision, recall, and accuracy metrics are used for the evaluation of this chapter's proposed method. Precision is the fraction of the total number of correctly detected work cycles (TP, True Positive) over the total number of incorrectly and correctly detected work cycles (TP + FP, True Positive + False Positive). Recall depicts the detection completion level and is equal to the total number of correctly detected work cycles (TP) divided by the total number of correctly detected and incorrectly not detected work cycles (TP + FN, True Positive + False Negative). Lastly, accuracy is defined by the number of correctly detected work cycles (TP) and the number of work cycles which were correctly not detected (TN, True Negative), over the total sum of work cycles.

The proposed method is tested on an electrical task (see Figure 2). This data set consists of two recordings (part A, B) with a duration of approximately 17minutes each. Both recordings were collected the same day. In total, steel worker performed 29 work cycles that depict the following sub-tasks: a) fixing steel re-bars, b) picking re-bars or equipment, and c) reading drawings. Only one is unproductive, whilst none of the productive work cycles corresponds to idle time.

Figure 2. Tested data set.

This section colours red the unproductive, yellow the abnormal productive and green the normal productive work cycles. Figure 3 illustrates the 4D trajectories of part B.

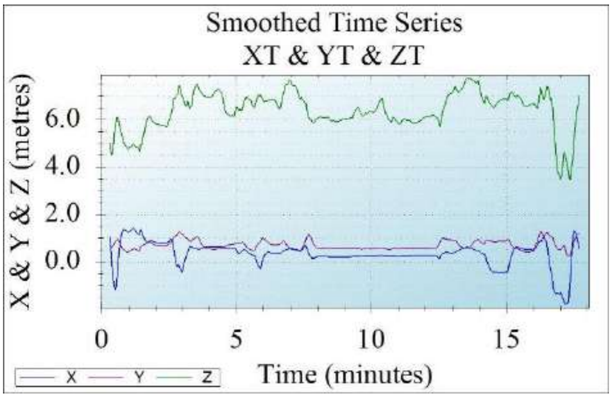

Figure 3. X, Y, Z trajectories over time (part B).

The proposed method detects 9 TP, 1 TN, 0 FP and 0 FN work cycles in part A, and 10 TP, 2 TN, 7 FN and 1FP work cycles in part B. Table 1 shows the ground truth of the manually collected work cycles vs the automated detected ones. The 3 TN results (#1, #11, and #12) result from the way trajectories are smoothed. The smoothing step k is equal to 19sec if divided by camera frame rate i.e. $\frac{k}{fps} = \frac{570}{30}$. Hence, all smoothed time series are 19sec shorter in length at the beginning compared to the unsmoothed. Hence, work cycles that fall within the initial 19sec cannot be detected. All TN results occur at the beginning of each recording. The missed #17 and the 1FP work cycles of part B are due to instabilities of the implemented computer vision-based 2D tracking method. All the rest FN work cycles are of short duration (< 4sec). This shows that that the proposed method does not perform well in terms of detecting work cycles of such short duration.

In Part A, the work cycle #3 shows that steel worker was unproductive i.e. definitely not performing the steel fixing task, for 4.15minutes. Work cycles #5, and #7 to #10 are all classified as normal productive whilst the work cycles with the largest duration #2, #4, and #6, are all classified as abnormal productive (see (a) Figure 4). In part B, nine out of ten work cycles of this recording, are returned as normal (#13, #15, #16, #22 to #25, #27 and #29) and only one is classified as abnormal (#20) (see (b) in Figure 4). The interesting observation about the recording of part A, is that the abnormal cycle has a duration of 11.56minutes which is by far the largest compared to the rest cycles of both parts A and B. This raises an ambiguity about the performance of steel worker during this time. It can be easily observed, if we check the video footages at the exact time the abnormal cycle #20 occurred, that steel worker could not fit a reinforcing steel bar in the formwork due to complexity of drawings. This is a common issue that affects labour productivity. If we sum all the TP normal and abnormal work cycles, then the labour input of the steel worker is equal to 28.29minutes for both parts (A, B). The manually calculated labour input is equal to 30.62minutes. Therefore, the proposed method measured the total labour input of the steel worker with an accuracy of 92%.

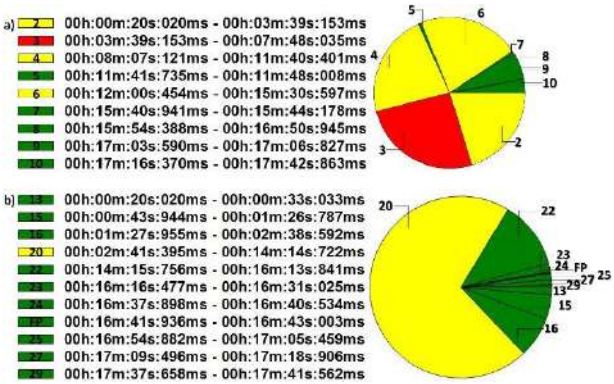

Figure 4: Detected work cycles of steel worker (red: unproductive, yellow: abnormal productive and green: normal productive).

5 Conclusions

The current state of research has not yet proposed a method that performs a non-obtrusive, accurate, cost efficient and generalized monitoring of labour productivity for construction workers. This paper presents a method that addresses these issues in order to detect repetitive patterns in the trajectories of construction workers that depict work cycles. The total duration of these work cycles is equal to the labour input of workers. The novelty of the proposed method lies in clustering. Firstly, the 4D trajectories of workers are smoothed in order to remove noise. Then, they are segmented into 4D sub-trajectories and classified as either "move" or "stop" semantic events. The former event depicts the motion of workers along the floor plane, whilst the latter depicts the motion of workers along the vertical plane. The classified 4D sub-trajectories are finally grouped into clusters based on the main assumption of this paper that: every work cycle is described by two semantic "move" events and one semantic "stop" event.

The main limitations of the method presented in this paper are the following. Firstly, work cycles that depict workers who while at "stop" do not perform any task (idle time) are mistakenly detected as productive. However, as previous studies [38–43] stated "idle" time is not of the main causes behind low labour productivity. Secondly, the productivity of workers who perform tasks mainly characterized by motion such as transferring materials, supervising work progress etc. cannot be monitored. This is because the “move” events depict the actual labour input instead of the “stop” events in such cases. This second limitation indicates that the automated monitoring of workers presented in this paper cannot be applied to the entire range of construction related tasks. Only if the proposed method was updated with the type of tasks of workers it would be possible to turn also the detected “move” events into labour input.

Abstract –

Current construction logistics planning in practice is executed as an experience-driven planning and proved as inefficient. Previous outcomes of Building Information Modelling (BIM) provide the fundamental of a digital construction logistics planning. However, an underlying logistics concept and a guidance from the production theory for applying BIM in logistics are missing.

This paper aims to elaborate existing problems in the construction logistics planning and initiate an exploration towards a digital logistics planning with a underlying concept of the on- and off-site material flow. A design methodology of OOA/D (Object-oriented Analysis and Design) is applied to the conceptual design of a digital on- and off-site logistics planning. An object-oriented definition of logistics element with a start from predefined BIM element and a use case about logistics Quantity Take-off (QTO) are explained. The research helps to reflect the material change in the construction logistics more accurately, and to further evoke the rethinking of the production theory in the construction field.

Keywords –
Logistics; Material Flow; BIM; OOA/D

1 Introduction

Logistics is the management of the flow of resource between the point of origin and the point of consumption in order to meet requirements of customers (owner or end-user) or corporations [1]. It is a tough task to achieve an efficient logistics planning in the construction field, because the resource flow of a construction project is broken between off-site and on-site domains. The critical reason is not the geographical separation but the non-conformant resource planning.

With the development of Information and Communication Technology (ICT), the manufacturing industry achieves better logistics planning and control by Product Data Management (PDM) system [2]. The fundamental of PDM is a series of well-structured digital Bill of Materials (BOMs), basically including Engineering BOM (EBOM), Plan BOM (PBOM), Manufacturing BOM (MBOM). The material flow in the manufacturing industry is clearer than it in the construction industry, however, the essence of it is the same. Actually, a construction BOM used at the material purchase stage is a typical EBOM, while a construction Bill of Quantity (BOQ) with schedule is equal to a MBOM. What is missing in construction is the PBOM, which essentially is a data form of the construction logistics planning.

Building Information Modelling (BIM) can be applied to build a digital logistics planning and supports its execution. It is a set of concepts, technics and digital methods to encode information of facilities about 3D design drawings, schedule, material characteristics, costs, and safety specifications etc. BIM model is an object-oriented representation and specified by but not limited to Industry Foundation classes IFC (ISO 16739) [3]. Further, the four-dimensional (4D) BIM (i.e. three dimensions plus time) is capable to improve construction scheduling and site monitoring [4], which can also improve the logistics management in a digital way.

However, an underlying logistics concept and a guidance from the production theory for applying BIM in logistics are missing. Meanwhile, current pattern of logistics planning and control in the construction practice is proved as inefficient, thus it cannot be adopted as the fundamental of the design of a digital logistics planning.

Therefore, this paper will provide an analysis of non-conformant resource planning and adopt the understanding of on- and off-site resource flow to a conceptual design of an efficient digital construction logistics planning. The focus of the digital construction logistics planning which will be introduced in this paper is on the materials, while related equipment or transportation tools are treated as constraint or supplementary conditions of materials.

2 Literature Review

Current construction logistics planning in practice is executed as an experience-driven planning with an as-designed site-layout and a series of periodic (e.g. daily, weekly, monthly) look-ahead schedules, and mainly relies on project QTO (Quantity Take Off), BOM and construction master schedule[5]. Generally, BOM is generated from QTO and is applied for the material purchase with a list of subtotals of each material type, which is a guidance document to calculate the periodic quantity of material supply[6]. Another document BOQ, which is also generated from QTO, is applied to calculate the periodic quantity of material consumption associated with a construction master schedule[7]. The problem is that the quantity of material supply does not match the quantity of material consumption, because of different levels of periodic measurement.

From the consumption perspective, a construction BOQ generally follows a division-component method (e.g. earth work, foundation work, frame shear-wall work) and it is the foundation of most 4D construction logistics planning. For example, Tulke and Hanff (2007) presented a solution for creating schedule based on data from BOQ and the building model[8]. From the supply perspective, a construction BOM applies an enterprise level of periodic measurement (e.g. project duration, sub-project duration) to dovetail with the enterprise accounting. It is possible to introduce in the construction schedule to make a detailed construction plan with material constraints[5]. However, a BOQ from the consumption side applies a periodic measurement based on the division-component project level, which is inconsistent with the supply side.

The difference in periodic measurement between enterprise level and division-component project level directly causes the mismatch of the periodic quantity of material supply and material consumption. It makes construction project management adopt a Just-in-Case strategy towards the material resource. According to the Just-in-Case strategy, the succeed of one or a series of construction tasks is the highest goal and any shortage of on-site inventory should be avoided, which may causes any of following problems, but not limited to the followings:

- Excessive amounts of orders
- Overstock on-site
- Waste of site capacity
- Difficulty in materials and related equipment maintenance
- Difficulty in site monitoring

It is worth noting that, even a good Just-in-Case plan cannot guarantee to avoid failure of a construction task in some situation e.g. major construction change, long term or continuous supply delay.

Therefore, an effective construction logistics planning is not only about the development of an excellent avoidance strategy. To understand and accurately grasp the information of the material flow, to overcome the incompatibility in the periodic measurement, and further to solve the mismatch of the quantity of material supply and consumption are main goals of this paper, which is an initial exploratory of a proactive on- and off-site construction logistics planning.

3 Methodology

There are various approaches to develop a construction logistics plan with as-designed building information and related on-site information. However, to grasp the off-site information properly and try to achieve a proactive digital logistics planning is a challenge, and therefore this paper only focuses on the conceptual design of it. A complete software design or a management mode is beyond the scope of this paper.

This paper adopts a design methodology of OOA/D (Object-oriented Analysis and Design) [9] and it contains two phases, as shown in Figure 1:

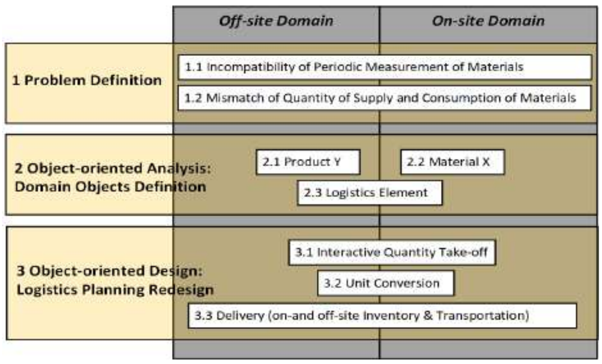

Figure 1. Paper Structure and OOA/D Methodology

1. **Practical Problem Definition**: as discussed previously, is to provide a basic understanding of the weakness of current construction logistics planning and guide the following analysis and design.
2. **Object-oriented Analysis**: with an emphasis on finding and describing the logistics objects or concepts in the problem domain. It is conducted to conduct an analysis of the basic features of the construction material flow from the off-site domain to on-site domain;
3. **Object-oriented Design**: with an emphasis on

defining specific logistics objects and how they collaborate to fulfil the requirements (e.g. attributes and methods). This paper also provides a use case to describe this design by applying Unified Modelling Language (UML).

It is worth noting that, a design and development of a proactive digital logistics planning with both on- and off-site information should be a Iterative process, and this paper provides only the initial efforts.

4 Object-oriented Analysis: On- and Off-site Material Flow

To initiate a construction logistics planning, the first task is to analyse the basic features of the construction material flow. As shown in Figure 2, a certain type of material (e.g. Material **X**) contains three basic status of the physical presences:

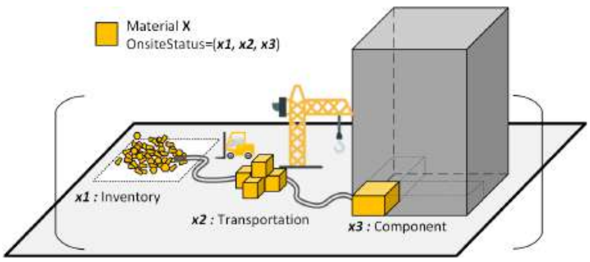

Figure 2. On-site status of the physical presences of Material **X**

- ***x1*** Inventory: on-site stocks of Material X;
- ***x2*** Transportation: Material X in on-site transit;
- ***x3*** Component: Material X placed in one or several construction components.

For an effective construction logistics planning, only considering on-site material flow is incomplete, because the start of a material flow is the off-site production rather than the on-site inventory. Figure 3 illustrates the on- and off-site material flow with a begin of final goods. This paper does not include a complete off-site process because of its scope, however, it can be considered when a construction logistics plan is established.

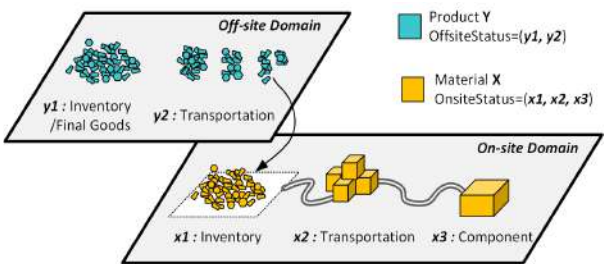

Figure 3. Status of the physical presences of Material **X** and Product Y along an on-and off-site material flow

As it is shown Figure 3, the off-site form of Material **X** named Product **Y**, in order to distinguish different domains i.e. off-site domain and on-site domain. The off-site data of Material **X** is handled by a supplier. It is more for the supplier to provide required data of Material **X** when it is treated as a kind of product. The physical presences of Product **Y** are:

- ***y1*** Inventory/Final Goods: Product Y ordered by construction project (Final Goods) and produced by a supplier (Inventory);
- ***y2*** Transportation: Product Y in off-site transit.

The difference between Final Goods and Inventory depends on whether the supplier needs to produce this kind of product (Final Goods) or can directly delivery it from the off-site inventory (Inventory). For example, when the production process of a kind of product is error-prone and the supplier usually hold no inventory, it is better for a construction project to treat y1 as Final Goods and pay attention to the status of the off-site production. In this case, an off-site production process look-ahead checking and guarding has been discussed [10].

5 Object-oriented Design: Logistics Element Definition with BIM

According to the nature of the on- and off-site material flow discussed before, it is not appropriate to simply treat a kind of material as a simple attribute of the construction component, which is the traditional way taken by a 4D BIM plan. It is to some degree an oversimplification of the real world and causes the difficulty in applying digital planning in construction logistics.

Actually, the material change of any construction task follows the Law of Conservation of Mass and the essential features of a kind of material does not change along the flow. It provides possibility to apply an OOA/D method to define the Logistics element. It is appropriate to define it from the start of a predefined BIM component (shared building element) which is a long-established practice, as shown in Figure 4:

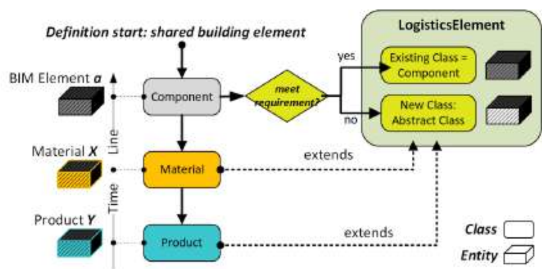

Figure 4. Logistics element definition with BIM

BIM model itself is an object-oriented representation and provides a series of well-designed properties or property sets, which can be applied for LogisticsElement definition. However, it is conditional because of the logistics requirement (see Figure). For example, if the predefined BIM Element ***a*** contains complete property for a logistics plan of Material ***X*** (on-site) and Product ***Y*** (off-site), the definition of them can directly refer to the existing class, otherwise it is required to define a new abstract class to share property.

However, to judge if the predefined BIM element meet the logistics requirement needs to consider both time and quantity parameter and pay attention to different types of materials input:

1. **Simultaneous Materials Input**: includes Single-Material Input (material 1) and Multi-Materials Input (material 1,2..n), as shown in Figure 5. The BIM element of a component contains basic property which can share with materials.

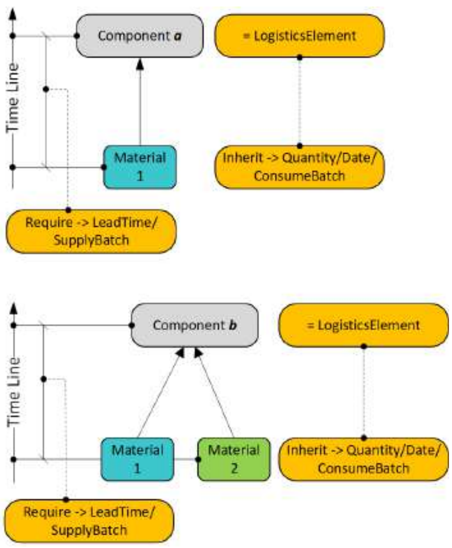

Figure 5. Pattern of the simultaneous materials input

2. **Successive Materials Input**: applies for the situation when the BIM element of a component cannot directly reflect the time and quantity features of every required material. A conversion method is required, for example, to allot quantity of material 1 and material 2 and define time constrains among material 1,2 and component ***c*** (see Figure 6).

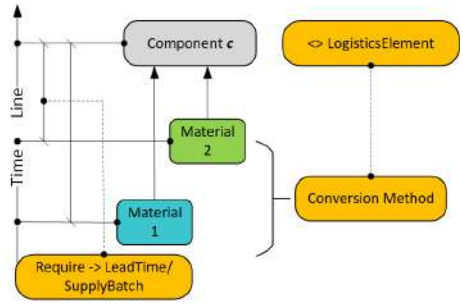

Figure 6. Pattern of the successive materials input

6 Use Case of Logistics Quantity Take-off

- To further understand how to consider the material change as a flow and apply the definition of logistics element to solve logistics planning problems, e.g. mismatch of the quantity of material supply and consumption, a use case of Logistics Quantity Take-off is written (see

Table 1) and explained as following:

Use Case: Logistics Quantity Take-off
Primary Actor: Material Manager, Supplier, Construction Worker, Project Manager
Stakeholders and Interests:

- Material Manager: Wants accurate quantity of construction components and related required materials. Wants sufficient information of supplier's products to support contract and trade.
- Supplier: Wants sufficient information of project required materials to support contract and trade.
- Construction Worker: Wants to finish regular work with no material problem.
- Project Manager: Wants accurate quantity of construction components, related required materials. Wants automatic and fast updates of site transpiration and inventory status.

Table 1. Description of the use case of Logistics Quantity Take-off

Actor Action	**System Responsibility**
1 **Material manager** starts a new **logistics quantity take-off**.	
2 **Material manager** selects **construction components** (known quantity).	3 Records each selected **construction component**, identifies its **material items**

	and calculates material subtotals of quantity with a **material catalog**.
4 **Material Manager** repeats steps 2-3 until indicates done.	5 Logs the completed calculation, presents **material item specification** and generates a classified list of **Quantity of Materials**.
6 **Material Manager** sends **Supplier** related partial list of **Quantity of Materials**, sends an **enquiry** and asks for a **product item specification**.	
7 **Supplier** sends the **product item specification** to **Material Manager**.	8 Handles **product item specification** and converts the **unit** and calculates product subtotals of quantity with a **product catalog**.
	9 Logs the completed conversion and presents a classified list of **Quantity of Products**.
10 **Material Manager** sends **Supplier** related partial list of **Quantity of Products** and an **offer**.	
11 **Supplier** gives an acceptance to the offer and both sides reach a **supply contract**.	12 Handles and records the **supply contract**.
13 **Material Manager** and **Supplier** decide the quantity of **product supply batch** (inventory input) according to the **product catalog**, **price policy**, **material consume batch** (inventory output) and **inventory policy**.	14 Records the **product catalog**, **price policy**, **material consume batch** (inventory output) and **inventory policy**, and calculates **product supply batch**.
	15 Logs the completed calculation and presents **a list of product supply batches**.
16 **Supplier** deliveries **product supply batch** according to the list.	17 Records each delivered **product supply batch** quantity and sends information to the **off-site inventory** systems (update off-site inventory) and the **off-site transportation** systems (update transportation status).
18 **Product supply batch** arrives the construction site and is put into the **on-site inventory**.	19 Records each arrived **product supply batch** quantity and sends information to the **on-site inventory** systems (update inventory)
20 **Construction worker** takes materials from inventory.	21 Records **material consume batch** quantity, and sends information to the **on-site inventory** systems (update inventory) and the **on-site transportation** systems (update transportation status).

** Conceptual classes are in bold*

In this use case, there are three essential tasks which influent logistics status:

3. **QuantityTake-off**: is to work out a model-based Quantity of Materials which supports the division-component project level of periodic measurement;
4. **UnitConversion**: is to get sufficient information from supplier and work out a model-based Quantity of Products, to avoid an excessive Just-in-Case strategy;
5. **Delivery**: is to balance the batch amount of product supply (off-site) and material consumption (on-site) and keep both off-site and on-site inventory safe and economical.

The QuantityTake-off process to generate a Quantity of Material is a model-based process i.e. ConstructionComponent and MaterialItem contain their own quantity information, rather than adding material attributes to a list of QTO (i.e. list-based BOM). As discussed before, the list-based BOM applies an enterprise level of periodic measurement and it is insufficient to a logistics planning. The model-based Quantity of Materials is explained as following:

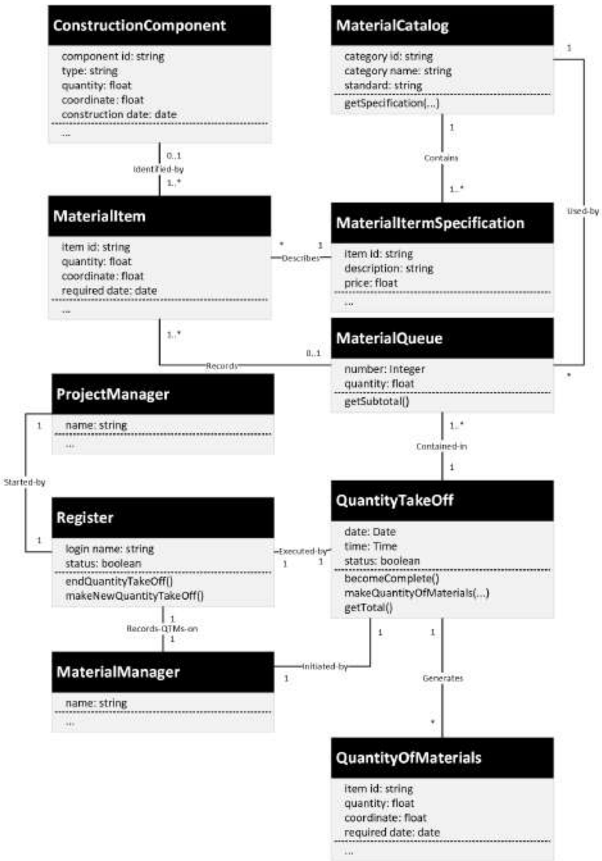

Figure 4. Domain model of QuantityTake-off

Besides Quantity of Materials, there is another important document: Quantity of Products, which is treated as an essential conjunction of the on- and off-site logistics at the planning stage. This Quantity of Products is a concentrated reflection of the off-site information from both sides. To work out a Quantity of Products, the Quantity of Materials and production specification are needed as the fundamental and a UnitConversion method is applied as following:

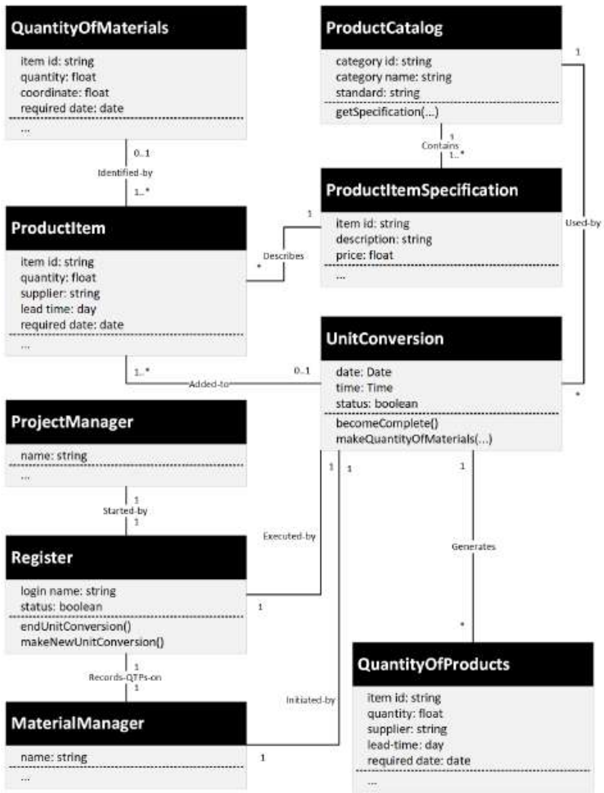

Figure 5. Domain model of UnitConversion

After Quantity of Materials and Quantity of Products both worked out, specific MaterialConsumeBatch and ProductSupplyBatch are taken into account. To design an optimized ProductSupplyBatch is not a simple task, because the on and off-site production, transportation and inventory data should be collected and a series of policies should be considered e.g. PricingPolicy and InventoryPolicy, as shown in Figure 6:

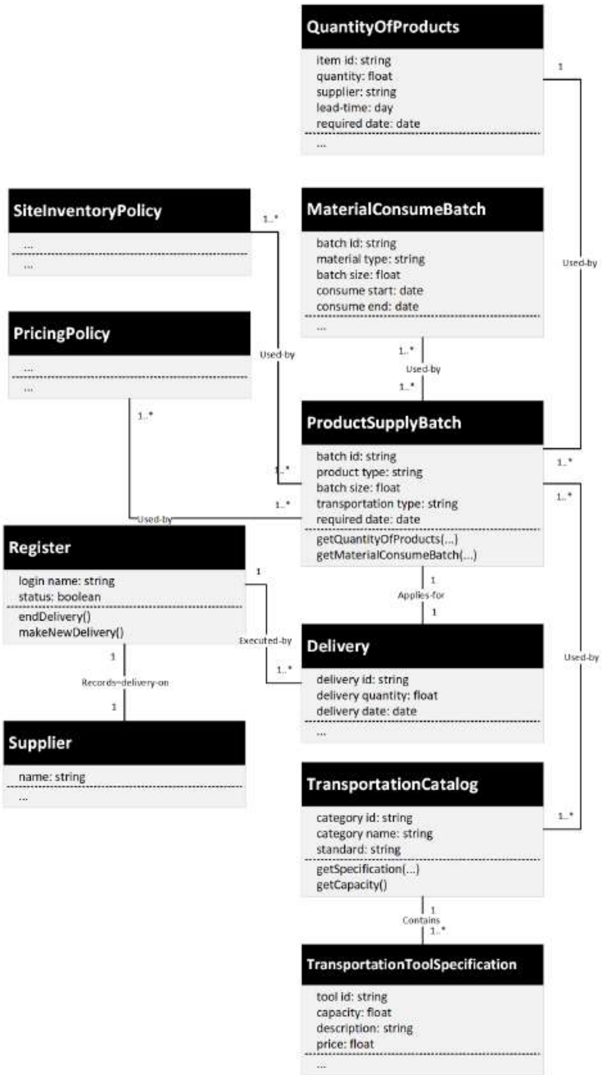

Figure 6. Domain model of Delivery

These three essential tasks of QuantityTake-off, UnitConversion and Delivery in this use case are essential to overcome the incompatibility in the periodic measurement, solve the mismatch of the quantity of material supply and consumption and further to develop more detailed on- and off-site logistics planning.

7 Conclusion

The aim of this paper is to explain existing problems in the construction logistics planning and initiate an exploration towards a digital logistics planning with a underlying concept of the on- and off-site material flow. This paper first introduced the material flow and analyzed the basic status of the physical presences of a certain type of material from the on-site to off-site domains. Then an object-oriented definition of logistics element with a start from predefined BIM element was discussed. Finally, a use case of Logistics Quantity Take-off with three essential tasks of QuantityTake-off, UnitConversion and Deliver was explained.

However, the logistics element definition and use case at this stage are not complete, there are several aspects need to improve, for example, logistics requirements in element definition should be specified and the method of UnitConversion should be designed in detail. Further, a new pattern of the logistics planning and management is not only to reflect and control the material change to make a project succeed, but also to rethink the construction industry itself and its own production theory.

Abstract -

Construction sites are continuously changing environments where construction workers have to adapt to dynamic situations while executing their work tasks safely and efficiently. Simultaneously, they are surrounded by heavy construction machinery and massive crane loads which they have to be aware of at any time. Frequent interruptions may often lead to a loss in productivity and also causes hazardous conditions or even incidents, injuries or fatalities. Tracking workers' paths on site can be used to approach these issues. Recorded tracks can be used to identify close calls of inexperienced or distracted workers. To date, pedestrian workers may participate in customized trainings in order to overcome individual deficits. Machine operators can be assisted to mitigate hazardous situations by warning them from construction workers approaching their machines.

Since surveillance cameras are already existent on most construction sites, a video-based detection and tracking system can be implemented at low costs. Relying on video streams, the detection of workers becomes similar to pedestrian detection. Some effort has already been made to elaborate those methods to the needs of construction worker detection. However, in contrast to the frontal view supposed in most pedestrian detection approaches, cameras on construction sites commonly provide oblique or bird's-eye view perspectives. This complicates the detection task as most body parts of a worker are occluded. Hence, we evaluate the applicability of pedestrian detection approaches in terms of the camera settings at hand. Ensuing, we propose a concept for the detection and tracking of construction workers which allows to improve the productivity and safety on construction sites.

Keywords -

Cascaded Classifier, Detection, Monitoring, Productivity, Safety, Tracking.

1 Introduction

Construction sites constitute highly complex, dynamic environments. Often, workers execute their working routines in collaboration with heavy machinery operating in their own workspace. For example, excavators and other construction vehicles cross the paths of construction workers and cranes lift massive loads over their heads. A variety of hazardous situations may arise from that such as incidents involving material and equipment or injuries and fatalities happening to workers or persons standing nearby. Hence, construction workers have to be trained to be sensitized for potential hazards. Hazardous situations such as close calls can directly be identified from the workers' actual paths across the construction site. Recording these could facilitate the identification of the necessity of further trainings as well as the customization of trainings with respect to the workers' deficits.

Concurrently, machine operators should be assisted in recognizing potential hazards involving workers in advance so that accidents can be avoided. Augmenting their field of view with the positions and walking path trajectories of workers as sketched in Figure 1 could further improve the safety on site as it enables operators to perceive distracted workers even if they are laboring in blind spots. Warning machine operators of such hazards could mitigate such situations which otherwise could end fatal.

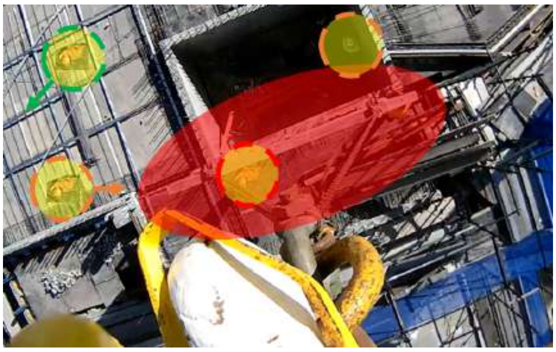

Figure 1. Augmented field of view of a crane operator. Yellow circles represent detected construction workers color-coded according to their level of hazard. Green highlighted workers are in sufficient distance to the hazard zone of the crane's load (red ellipsoid) and are predicted to walk away from it. Workers are marked orange if they approach the hazard zone or already stand near to it. Workers exposed to the hazard are marked red.

The obtainment of the construction workers' trajectories in construction-related areas of a site and in the surrounding of machinery, thus, allows to significantly decrease safety issues. Further application areas may also benefit from this, such as checking workers for wearing appropriate safety equipment, site access control systems, or even the improvement of productivity. A reasonable tracking of workers during their working routines tackles multiple issues on site and is already in the scope of research. Depending on the surrounding, common approaches rely on different radio signal emitters like radio-frequency identification (RFID), ultra-wideband (UWB), and global navigation satellite system (GNSS) tags. These are attached to the gear of each construction worker which involves high costs [1] and causes discomfort [2]. In contrast, a camera based tracking of workers on construction sites provides a cost-saving and less obtrusive approach.

Relying on video streams, the task becomes similar to pedestrian detection which is a well researched topic today. There are already approaches adapting methods of this field for construction worker detection. Nevertheless, crucial differences between the application areas have to be taken into account. Due to the actual scope of application in advanced driver assistance systems, pedestrian detection approaches commonly assume a frontal view. In contrast, surveillance cameras on construction sites as well as cameras for crane operator assistance are usually mounted in heights to existing structures resulting in bird's-eye view perspectives recording the workers sometimes even over far distances. This complicates detection since most parts of the bodies are occluded by the workers' heads and shoulders or physical obstructions. Therefore, we evaluate previous pedestrian detection approaches with respect to their applicability in bird's-eye view images. Based on this research objective, we propose a conceptual system which improves over previously made approaches tracking construction workers for safety and productivity issues. For this purpose, we apply a background subtraction method which identifies regions of interest in the camera image. A cascaded classifier investigates these regions and detects construction workers. In order to track the detected workers through multiple camera frames, we apply Kalman filtering.

The remainder of this paper is structured as follows: in Section 2, we motivate our work by surveys and studies concerning safety and productivity issues. We investigate previously made approaches of pedestrian detection in Section 3 and discuss these with regard to the limitations in the video data in the field of construction monitoring. Based on the findings, a conceptual system for tracking construction workers on sites is proposed (see Sec. 4). Finally, we discuss the results and conclude on our concept in Section 5.

2 Motivation

High rates of injuries and fatalities in construction are often explained by its complex, dynamic, and continuously changing work environment. Whereas cranes play a central role in construction operations, federal labor statistics in many countries relate about 15-25% of all fatal construction workplace accidents to too close proximity of pedestrian workers to construction equipment or hazardous materials [3]. Struck by moving parts of crane equipment or hit by falling objects are some of the most frequent causes of crane-related construction accidents [4]. Their outcome is often fatal [5], which distinguishes crane-related accidents from the majority of other construction accidents where the outcomes are minor (e. g., cut in finger).

Cranes come typically in numerous configurations to fit unique sites [6]. Cranes carrying loads over, into, and/or around workers' environment add yet another dimension of risk to an already complex workspace. Though safe crane design, several on-board safety devices and operational procedures exist, large problems remain to operate them safely. Research studies state:

- About 16% of all construction fatalities relate to cranes [7]
- 33% of all construction casualties and permanent disabilities relate to cranes [8]
- 87% of crane-related deaths occur among workers and do not involve operators [9]
- Few in the transient construction workforce have operating or rigging experience [5]
- Little information about the causal factors or environments leading to the accidents or close call events is known [10]

Few safety statistics from around the world exist that explain the problem in detail. The Center for Construction Research and Training analyzed data collected by the U.S. Bureau of Labor Statistics in the years 1992-2006 [11]. In this time period, 632 crane-related deaths were identified which occurred in 610 crane incidents. These numbers equal to an average of 42 crane-related deaths per year. Whereas mobile or truck cranes (at least 71%) were the main types of cranes that have been associated with crane-related fatalities, tower cranes (5%), floating or barge cranes and overhead cranes, and other/unspecified cranes are the other crane types (24%). Of the total 632 crane-related deaths, 157 (25%) were caused by overhead power line electrocutions, 132 (21%) deaths were associated with struck by crane loads, 89 (14%) involved crane collapses, 78 (12%) involved a construction worker being struck by a (i.e. falling) crane boom/jibs, 56 (9%) included falls from cranes/crane baskets/crane loads, 47 (7%) were struck by crane or crane parts, 30 (5%) caught-in between, and 43 (7%) deaths were from other causes. The activities immediately preceding the workers' deaths related to deaths from struck by crane loads (132 between 1992-206) were: 32% of the workers were not involved with the crane, 32% loaded/unloaded, 15% performed other crane-related work, 14% were flagging/directing/guiding, and 7% operated the crane. The majority of the workers belonged to laborers (191 deaths), while the others trades were heavy equipment operators (101), supervisors/managers/administrative (86), ironworkers (42), mechanics (41) and other trades (171).

In their recommendation to prevent crane accidents from happening in the future, CPWR recommends the following actions to take: crane operators should be certified; crane riggers and signalpersons should be adequately trained; crane inspectors should be qualified; cranes should be inspected; only qualified and competent persons should assemble, modify or disassemble a crane; cranes should not be allowed to pass over street traffic; and more thorough investigations and immediate follow-ups should be performed. Despite the poor safety performance of cranes in construction and several recommendations that are already part of many construction safety leaders' best practices, no proactive approach has been taken towards detecting and resolving the identified crane-related hazards [12]. For example, when a crane load swings over an active worker environment, pedestrian workers and crane operator should be warned of the risk of falling objects or being struck-by.

In Germany, construction occupational safety and health is embodied in and shaped by numerous laws, regulations and ordinances with a view to ensuring the safety and health of construction workers in the workplace. Technical Occupational Safety and Health includes all areas that affect the safety of workers at work. The Safety and Health at Work Act (ArbSchG) regulates the underlying occupational safety and health duties of the employer, the duties and rights of workers, and the monitoring of occupational safety and health in accordance with this Act. In the control hierarchy (a) technical, (b) organizational, and (c) personal measures are typically embedded in an organization's safety culture. These respectively and whenever possible, (a) avoid hazards in the first place by replacing hazardous work practices with safer ones and separate workers from hazardous workspaces, (b) limit the exposure time to hazards, and (c) provide personal protective equipment (PPE) and instruct personnel [13]. Again, existing regulations, rules or best practices on safety in construction do not envision proactive solutions other than education, training, and enforcement. For example, by means of using technology, pedestrian workers and operators could be automatically warned in real-time from nearby or approaching crane loads. However, such technology does not exist today [14].

3 Detection Methods

The safety of construction workers on site can be improved by focusing on their working behavior. By tracking their paths across the site, hazardous situations like close calls can be identified. Additionally, operators can be warned from potentially distracted workers approaching their machines too closely. For tracking workers on construction sites different technologies have already been applied. Most prominent are radio signal emitters like RFID, UWB, and GPS tags which are attached to the gear of the construction workers. Besides the imposed costs for equipping each worker on the site [1], theses tags are perceived to be obtrusive, resulting in discomfort accompanied by a decrease in motivation [2]. Video-based techniques overcome these deficiencies and allow for a uniform method of detecting and tracking workers all over the site. As nowadays cameras are ubiquitous and not primarily meant to control workers, they can be considered to be less obtrusive. Moreover, by making use of already existent surveillance cameras only few cameras have to be additionally installed, keeping new investments and maintenance costs low.

Identifying workers in video streams is similar to pedestrian detection. By now, this is a well understood field of research in the computer vision area which already provides a variety of satisfying methods. Especially the automotive industry continuously advances the current methodology. Due to the usual application area in advanced driver assistance systems, approaches in this field assume frontal images of pedestrians. Some approaches already adapt those methods to construction worker detection [15, 16]. Referring to this, Park and Brilakis [16] propose a two-parted detection approach. They learn shape features using a support vector machine (SVM) to identify people in frontal view images. Using color features these detections are further processed by a k-nearest neighbor (k-NN) classifier to detect construction workers by their safety vests. On construction sites, however, frontal view images are merely an exceptional case. Surveillance cameras are usually mounted to high posts, scaffolds, or on nearby building facades or roofs. In particular, for assisting crane operators at lifts, cameras have to be mounted to the jib or at least high on the crane tower. Detection and tracking of workers on construction sites, thus, have to be done in bird's-eye view images. This complicates the detection task as the workers' bodies are barely visible as can be seen in Figure 2. For this reason, identifying construction workers on site requires a robust detector which yields reasonable results despite sparse indications for the presence of a worker caused by the challenging perspective.

Figure 2. Construction workers recorded by a surveillance camera mounted 15 m above ground.

In comprehensive surveys Dollár et al. [17] and Benenson et al. [18] summarize the state-of-the-art pedestrian detection algorithms and evaluate their performance. Benenson et al. propose to categorize the approaches into deformable part-based models (DPM), deep learning, and decision forests.

DPM Approaches based on DPM subdivide an object into a star-structured part-based model consisting of a root object and multiple parts attached to it [19]. According to this, a latent SVM can be trained using a pyramid of histograms of oriented gradients (HOG) features in order to classify pedestrians by detecting their body parts [20, 21]. Advancing the part-based model towards a multi-resolution structure improves detection results [22]. Nevertheless, in our case the view is generally narrowed to the heads and shoulders of pedestrian construction workers wearing personal protective equipment (PPE). Approaches relying on the detection of silhouettes and body parts, consequently, are ineligible in this context.

Deep Learning Deep learning comprises approaches using large artificial neural networks. These can be used for object detection by extracting features from the image data. Sermanet et al. [23] apply a convolutional neural network which learns relevant features from the training data. Albeit the network yields fair results on similar data sets, it fails on generalization. Up to now, it has not been shown that deep learning approaches can be used to learn sufficient image features [18]. For other deep learning approaches [24, 25] features have to be predefined manually. It is doubtful if such heavy techniques are necessary to evaluate manually selected features. Furthermore, the latter approaches again pursue the part-based idea which is not applicable for bird's-eye view images. Since the results obtained by deep learning on pedestrian detection tasks are yet at the same level with DPM and decision forests, advantages of deep learning are still questionable [18]. Hence, simpler methods should be preferred instead.

Decision Forests Decision forests are ensembles of decision trees in which the nodes represent weak classifiers. Samples are classified by passing through the trees. Viola and Jones [26] proposed an approach using AdaBoost to train a pruned decision tree with Haar features as weak classifiers. Originally developed for face detection, they showed that it is also applicable to pedestrian detection [27]. Bourdev and Brandt [28] improved the method by promoting the confidence of each evaluated weak classifiers through the tree. Coupled with a generalized feature approach, Dollár et al. [29] showed that this method outperforms previous pedestrian detectors. This indicates that the detection results of decision forests improve with the development of features. By now, other pedestrian detectors achieve a similar detection quality compared to decision forests. Nevertheless, boosted decision trees usually outperform monolithic classifiers like SVM on most detection tasks [30]. Furthermore, boosting automatically selects the most suitable set of features from a given pool. This overcomes the need for evaluating features manually as it is commonly unclear which features qualify best for a certain task.

Whereas Benenson et al. mainly categorize the approaches by their machine learning algorithms, Dollár et al. focus on the sets of features. They found that gradient-based features like HOG [31] are most prominent. Besides this, shape features [32, 33] and motion features [27] are frequently used. While HOG feature approaches perform best in comparison to other single feature settings, even better detection results can be achieved when combined with multiple features providing complementary information. Accordingly, combining Haar-like features, shapelets, shape context, and HOG features outperforms any single feature approach [34]. In their study, Dollár et al. [29] focus on the choice of features and propose a framework to efficiently compute multiple features based on integral channels.

4 Concept

We evaluated previously made pedestrian detection approaches regarding the requirements and general conditions of construction workers detection in bird's-eye view images. In the following, we develop a concept for tracking construction workers on site considering the insights gained in Section 3. Figure 3 depicts the conceptual system in total.

According to the findings in Section 3, methods relying on DPM are not applicable for our purpose as the perspective does not allow for the detection of body parts. Also deep learning is not preferable in this context since it could not be shown that deep neural networks are advantageous over other approaches. In contrast, decision forests prove to be well suited for construction worker detection in bird's-eye view images.

For our conceptual worker tracking system, we propose a single classifier approach using a decision tree as this highly improves the speed over the two-parted detection system by Park and Brilakis [16]. We decide for the soft cascaded approach proposed by Bourdev and Brandt since its detection results exceed those of the Viola-Jones detector. Additionally, its likewise pruned cascading layout further improves the speed of classification by rejecting negative samples early in the cascade. Hereby, the entire cascade has to be processed for positive samples only; for negative samples only few image feature are evaluated before rejection. This eases real-time processing on video data. Moreover, since it is unknown which image features qualify for this task, boosting automatically selects the optimal set of features for our purpose. Accordingly, a manual selection as in the approach of Park and Brilakis [16] is not required.

We exchange the originally proposed thresholded Haar features by integral channel features. This further improves the detector as various image feature types can be efficiently computed using integral channels, and the combination of multiple feature types advances the detection quality over single feature approaches. Similar to Park and Brilakis [16], our concept relies on the identification of shape and color in order to detect construction workers. Since features responding to contours yield reasonable results on pedestrian detection, we draw on adjacent second-order integral channel features on grayscale images. These are equivalent to Haar features which act as edge detectors and, thus, indicate shape information. Apart from contours, construction workers are commonly characterized by their PPE including their helmets and safety vests. Thus, color features may improve detection by incorporating the prominent colors of these items. Color histograms can be efficiently computed by applying first-order integral channel features to quantified versions of each color channel separately. For both feature types, illumination has to be taken into account as it affects the features' responses. Grayscale images can be variance normalized to minimize the influence of different lighting conditions. In case of color histograms, the color space has to be chosen properly. In Figure 4 we compare RGB and HSV color spaces with respect to safety vests in different illumination. As can be seen, color histograms over red, green, and blue channels significantly change when altering the lighting conditions. As brightness is implicitly encoded in each channel of this color space, varying the illumination conditions directly affects the color information of these three color channels. Contrarily, in the HSV color space hue and saturation channels are invariant to illumination since brightness is explicitly encoded in the value channel so that only hue and saturation represent color information. Color spaces like HSL or YUV should also be considered as these offer equivalent channel characteristics.

Instead of scanning the entire image for construction workers we favor background subtraction beforehand. By identifying areas of motion within each video frame, classification can be limited to regions of interest. Albeit the speed of the soft cascaded classifier allows to scan images in real-time, restricting the scope of the classifier may significantly reduce false positive detection. Areas of motion can be identified by frame differencing. Assuming the previous video frame as background, subtracting it from the current frame reveals changes which imply movement (see Fig. 5). By thresholding the results, its sensitivity can be controlled:

$$|I_{t-1}(x, y) - I_t(x, y)| > \tau$$

where $I_{t-1}(x, y)$ and $I_t(x, y)$ denote the previous and current video frames and τ is the threshold.

The quality of the results highly depend on the choice of the threshold τ. Furthermore, image noise and fast illumination changes may be interpreted as motion. For a higher robustness we advance to learn a more complex background model. By averaging the background over multiple frames [35] a background model emerges which is insensitive to momentary changes between few frames.

In order to predict the paths of construction workers, the detected workers have to be tracked throughout the video frames. For this, we suggest the application of Kalman filtering to the detections. Given position and velocity data of a detected construction worker, the Kalman filter predicts its future state ongoing. Subsequent measurements of position and velocity are fed into the Kalman filter to reduce the uncertainty of the predictions. This approach also supports the detector as it provides further regions of interest in which construction workers may be detected even if they are standing still.

5 Conclusion

On construction sites, workers are exposed to a variety of hazards. Construction machines cross their paths and loads are lifted over their heads. This often results in close calls or even accidents. Thus, construction workers have

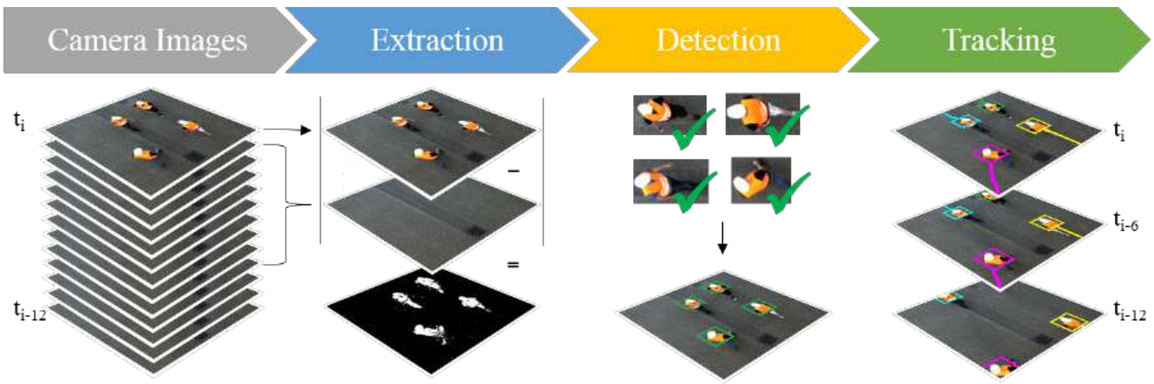

Figure 3. Conceptual system for tracking construction workers on site in bird's-eye view images. Initially a foreground extraction of the incoming camera images is made via background subtraction averaging the background based on a certain number of previous frames. Construction workers are, then, detected in the foreground by means of edge and color feature. Using a Kalman filter, these detections are tracked in the camera frames over time.

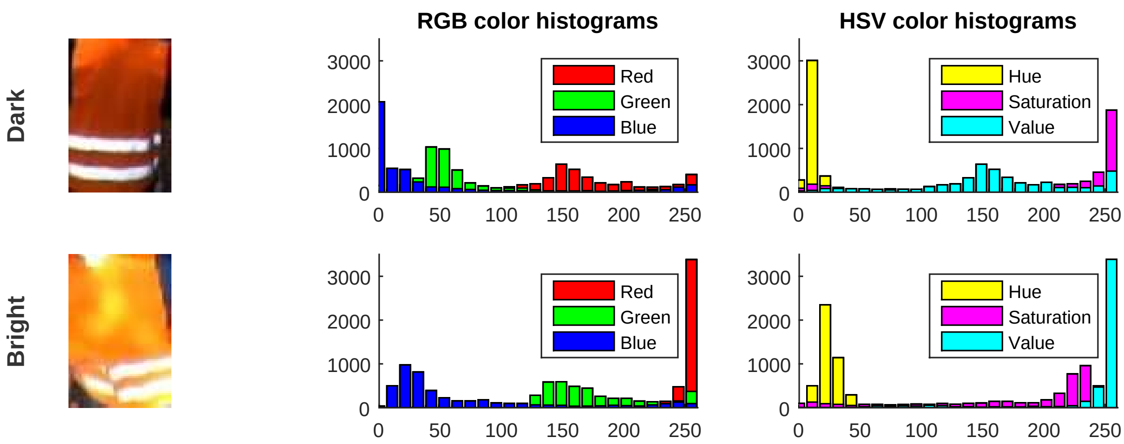

Figure 4. Comparison of histograms in different color spaces with respect to a safety vest (first column) in dark (first row) and bright (second row) illumination. In the RGB color space (second column) high variation occurs in the peak positions of each channels. On the contrary, hue and saturation channels of the HSV color space (third column) are significantly more robust to illumination changes.

Figure 5. Frame differencing applied to two consecutive frames showing a construction worker with a threshold τ of 40. White areas in the resulting binary image indicate areas with motion.

to be trained individually in order to sensitize them for potential hazards. Tracking workers during their working routines in construction-relevant areas on sites may improve the customization of the trainings since these can be adjusted to individual deficits. Furthermore, the tracking of workers can be used to avoid accidents involving heavy machinery by assisting machine operators and providing position and walking path information. The optimal for communicating such valuable and potentially life-saving information has yet to be found for applications in construction.

A video-based tracking system offers a cost-efficient and uniform alternative compared to conventional tag-based methods. Although detecting construction workers is similar to pedestrian detection, the perspective of high mounted cameras complicates the task. Thus, we investigated common pedestrian detection approaches with respect to the applicability for construction worker detection in bird's-eye view images. We discussed detectors of different categories and found that decision forests qualify best. Using a multi-feature approach enhances common edge feature approaches with complementing information which further improves detection. For this reason, we prefer to apply a soft cascaded classifier in our conceptual tracking system. As weak classifiers, we propose edge features and color histograms of the integral channel feature approach. Background subtraction is used to focus the classifier on regions of interest and to reduce false positive detections. In order to track detected workers and to predict their future walking paths, Kalman filtering can be applied.

Abstract –
Thermal cameras are widely used in the fatigue analysis of mechanical structures using the thermoelastic effect. Nevertheless, such analysis is hampered due to blurry images resulting from the motion of structure-under-test. To address the issue this paper presents a system that utilizes robotic vision and predictive control. The system comprises of a thermal camera, a vision camera, a RobotEye, and a fiducial detection system. A marker is attached to a thermal target in order to estimate its position and orientation using the proposed detection system. To predict the future position of the thermal moving object, a Kalman filter is used. Finally, the Model Predictive Control (MPC) approach is applied to generate commands for the robot to follow the target. Results of the tracking by MPC are included in this paper along with the performance evaluation of the whole system. The evaluation clearly shows the improvement in the tracking performance of the development for thermal structural analysis.

1 Introduction

Kelvin's Law has laid the scientific foundation on which the mechanical stress measurements can be derived from the temperature measurements [1]; and the formation of the Thermoelastic Stress Analysis (TSA) system has further taken shape alongside with the emergence of the suitable modern thermal camera where it can be used to remotely measure the stress distribution of a structure under load [2].

The effective use of TSA for full-field stress measurement, structural fatigue detection and crack propagation have since extended its prognostic capabilities to the construction industry, where TSA has been used to inspect and measure the usage stress load of aging infrastructures such as steel bridges, railway tracks, power poles, pipelines, heavy industrial equipment and vehicles [3], [4]. Even though full-field TSA measurement can be remotely conducted for large civil engineering structures, it would often demand for expensive optical setup and the resources required.

Since the structure is continuously under loading motion, with the thermal camera fixed looking at a region of interest, the resultant motion blur would stop TSA from being useful. To account for the resultant shift of pixels in the thermal images, the thermal camera can directly be mounted onto the structure under test; unfortunately, this approach has not always been practically or physically feasible. Thus specific attempts have often been made to compensate for this motion blur under each individual experimental setup; Wong & Ryall first presented a single axial loading, video-processing motion compensation technique [5], yet the search for an elegant and effective motion compensation method is still ongoing.

Attempts to visually track a moving structure with camera mounted on motion platforms such as a servo controlled pan-tilt mechanism, active gimbal devices and 6-DoF robotic systems etc. are some of the tactics that have been widely explored and developed [6]. Nevertheless, due to the demand on complex multidimensional loading dynamics, and due to nonlinear dynamics such as backlash and friction, tracking performance of such system degrades when it comes to random motion.

In order to tackle this problem, researchers from Defence Science and Technology Group have put forward a unique solution by having a stationary camera with a pointing mechanism to track moving structure. A major advantage of this technique is in having the stationary thermal camera staring at a low-mass pointing mirror, which undergoes a small angular motion to track an external structure's motion. This is where the complementary Ocular Robotics' RobotEye innovative optical pointing technology has made this solution practically possible [7].

This paper presents the solution proposed by Defence Science and Technology Group, where the high speed visual feedback is used to enable the optical pointing sensor to track the structural motion via a defined target, whilst at the same time it allows thermal camera to take long exposure, stable, un-blurred images of the region in the vicinity of this defined target.

This solution comprises of a RobotEye, the state-of-the-art pointing technology which has been developed and commercialized by Ocular Robotics Limited [7], a high-speed vision camera, a marker detection system [8], and a thermal camera embedded within the optical pointing system to capture the view where the eye is pointing. The pointing technology uses mirror-based technology [9], which significantly reduces the inertia of the sensor in comparison to the pan-tilt system. A fiducial marker is attached to the target, where its position is calculated using the marker detection system, as explained in [8]. Included also is the design of a predictive tracking controller based on the Model Predictive Control (MPC) for the optical pointing sensor's head motion. Since the robot is connected to a computer network, its tracking performance is affected by delays. Nevertheless, owing to the MPC, the control system for the actuator can generate control signals even in the presence of the unexpected delays.

Furthermore, this study canvasses a transformational idea that aptly fits to the advancement of modern day robotics and inspection technology, where our proposed solution here can be retrofitted onto a suitable autonomous vehicle platform to deliver a low, cost-effective in-situ structural health prognostic monitoring and management system. We envisage the potential benefits of having large infrastructures such as bridges, high speed rail tracks, pipelines and wind turbines inspected using such TSA autonomous systems, where the collected structural health information can be used to facilitate sound engineering analyses and decisions, and thus avoiding any surprise failures.

This paper is arranged in following sections. Details about the RobotEye technology and the proposed system are presented in Section 2, followed by the MPC for the robot's head motion in Section 3. Results are presented in Section 4. Finally, this paper concludes with a conclusion and recommendation for future works.

2 RobotEye Technology

The sensing technology used in this paper has a specific advantage in cutting-edge precision and responsiveness: it can be applied to enhance the dynamic control of LiDAR sensors for 3D mapping, navigation and automation, through to simultaneously tracking multiple dynamically moving objects even when mounted on a moving platform itself. In addition, the technology can be integrated with various types of sensors including vision, thermal and hyper-spectral, adding an extra dimension to sensing with these technologies [8].

2.1 Variables representing gazing direction

Orientation of the RobotEye pointing device or its the gazing direction can be described by two variables namely azimuth (ψ) and elevation (θ) as shown in Figure 1. The azimuth angle represents the rotation of the head about the vertical axis as depicted in the figure. Similarly, the elevation angle represents the angle made by the viewing direction with respect to the horizontal plane.

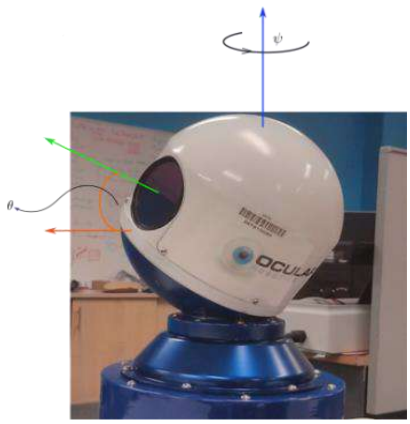

Figure 1: Variables representing robot eye head motion

2.2 Thermal target tracking

The advantage of light weight design makes the RobotEye technology a prefered choice in tracking applications. The laboratory set-up for this application consists of a high-speed vision camera, a RobotEye, a circular patches marker, and a thermal camera.

In the thermal target tracking system, the target is placed at the center of a fiducial marker which is within the field-of-view of the vision camera. The marker consists of circular patches. Details on the marker design and the detection algorithm are provided in [9]. The thermal camera is embedded inside the pointing sensor, thus, it captures the view where the RobotEye is pointing. This system has a huge implication in the fatigue analysis of mechanical structures which are under constant motion. As mentioned previously, fatigue analyses of such moving structures are adversly affected due to the blurry images captured by static cameras.

2.3 System Configuration

Coordinate systems assigned to the RobotEye optical sensor pointing device and the vision camera for tracking are shown in Figure 2. The reference frames for the vision camera and the RobotEye are represented by O_V and O_R, respectively. Similarly, the R_V^R is the rotational matrix that represents the orientation of the pointing device with respect to the vision camera reference frame. Consider an observation of the target position with respect to the vision camera be represented as p_V^t . Then, the observation can be represented with respect to the RobotEye reference frame as

$$p_R^t = R_V^R p_R^t + p_R^V, \tag{1}$$

where p_R^t is the position of target and p_V^t is the location of vision camera with respect to the pointing device.

As presented in Section 2.1, gazing direction for the RobotEye optical pointing sensor is represented by azimuth ψ and elevation θ angles which are in the spherical coordinate system. Therefore, for the representation of the thermal target as the gazing direction from the RobotEye, conversion from Cartesian to spherical coordinates should be applied as

$$\begin{aligned} \psi &= \tan^{-1}\frac{y}{x} \\ \theta &= \tan^{-1}\left(\frac{\sqrt{y^2+x^2}}{z}\right), \end{aligned} \tag{2}$$

where $p_R^t = [x\ y\ z]$.

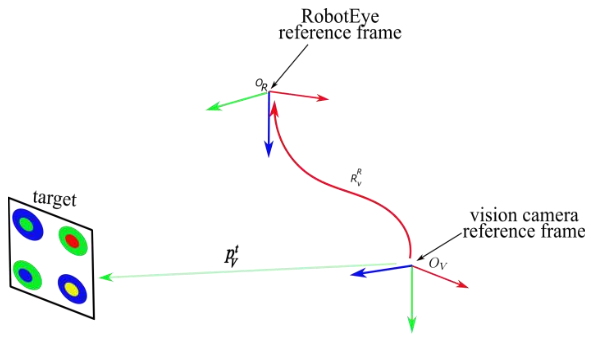

Figure 2. Arrangement of RobotEye and vision camera

2.4 Control architecture for thermal tracking

The system architecture for the proposed system comprising of a RobotEye, vision camera, and thermal camera is shown in Figure 3. In the system, the position and orientation of the target is estimated from the frames captured by vision camera which utilizes the circular marker detection algorithm [9].

After estimating the position of the thermal target with respect to the vision camera, it is calculated with respect to the pointing device in the azimuth and elevation space using equations (1) and (2). The conversion requires the extrinsic parameters such as R_V^T and p_R^V . After that, a prediction algorithm based on Kalman filter is utilised to predict its future trajectory. The filter uses a constant velocity model to represent the target motion. The model is represented as:

$$\begin{aligned} \hat{\boldsymbol{x}}[n+1] &= A_0\hat{\boldsymbol{x}}[n] \\ \hat{\boldsymbol{y}}[n] &= C_0\hat{\boldsymbol{x}}[n], \end{aligned} \tag{3}$$

where $\hat{\boldsymbol{x}} = [\psi\ \theta\ \dot{\psi}\ \dot{\theta}\ ]^{\mathrm{T}} \in \mathbb{R}^4, \hat{\boldsymbol{y}} = [\psi\ \theta\ ]^{\mathrm{T}} \in \mathbb{R}^2$,

$$A_0 = \begin{bmatrix} 1 & 0 & T & 0 \\ 0 & 1 & 0 & T \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix},$$

$$C_0 = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \end{bmatrix},$$

and T is the sample period.

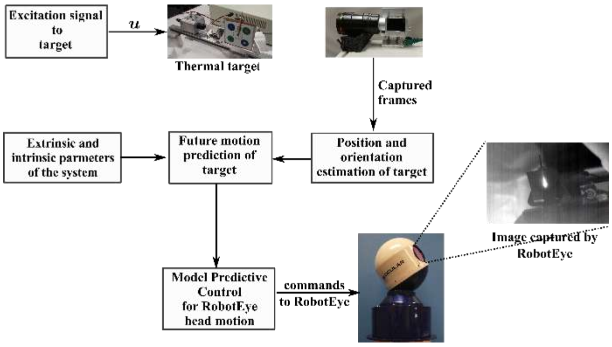

Figure 3. System architecture.

The predicted trajectory is then fed to a model predictive controller (MPC) which generates commands for the RobotEye drive controller. Here, the objective of MPC is to compensate for the lags in the system, which are introduced through various sources such as sensing and network delays, in order to improve the overall performance of the system. Modelling and Control System Design

2.5 Modelling

For the representation of the motion dynamics of the RobotEye sensor head, we have considered the state-space model in discrete-time as

$$\begin{aligned} \boldsymbol{x}[n+1] &= A\boldsymbol{x}[n] + B\boldsymbol{u}[n] \\ \boldsymbol{y}[n] &= C\boldsymbol{x}[n], \end{aligned} \tag{4}$$

where $\boldsymbol{x} \in \mathbb{R}^n$, $\boldsymbol{u} \in \mathbb{R}^m$, $\boldsymbol{y} \in \mathbb{R}^p$ are, respectively, the states, inputs and outputs of the system. In the case of the pointing actuator $\boldsymbol{y} = [\psi\ \theta]^{\mathrm{T}} \in \mathbb{R}^2$ and $\boldsymbol{u} = [\psi_{cmd}\ \theta_{cmd}]^{\mathrm{T}}$, where ψ_{cmd} and θ_{cmd} represent the command inputs to the system.

2.6 System Identification

For the identification of the system's parameter of equation (4), we measured the angles and inputs through the application programming interface (API) provided by the RobotEye. Then, we applied a standard identification algorithm such as N4SID in the framework provided by Matlab. Figure 4 shows the validation results of the identified method, which clearly indicate that the responses from the identified model is similar to that of the actual system. For instance, the similarity of responses in elevation and azimuth angles are, respectively, 95.4% and 94.39%. System matrices of the identified model are obtained as

$$A = \begin{bmatrix} -0.4141 & 288.6 & -848.2 & 54.97 \\ -75.28 & -40.89 & -495.1 & -127 \\ 757.5 & 43.73 & -546.4 & -80.56 \\ 75.16 & 48.69 & -210.6 & -13.13 \end{bmatrix},$$

$$B = \begin{bmatrix} -96.69 & -82.96 \\ -42.41 & -45.76 \\ -108.7 & -92.47 \\ -28.4 & -24.58 \end{bmatrix},$$

and

$$C = \begin{bmatrix} -9.633 & -9.392 & -8.936 & 72.69 \\ 19.64 & -11.09 & 7.066 & -98.29 \end{bmatrix}.$$

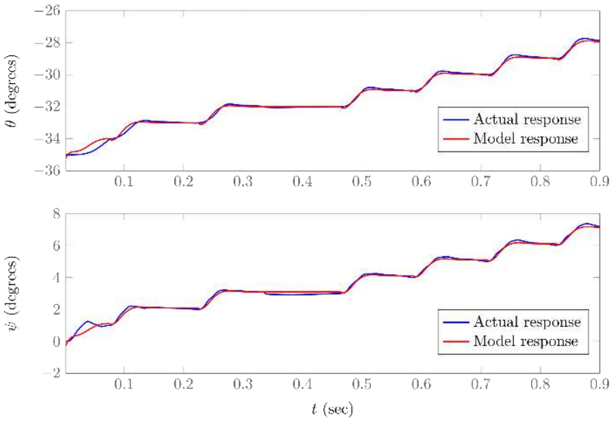

Figure 4. Validation of the identified model.

3 Model Predictive Control (MPC)

In order to apply the predictive control, we utilized the MPC in tracking the output reference signal. The problem is formulated as

$$\min \left\{ \begin{array}{c} \frac{1}{2}\sum_{i=1}^{N}\{(\boldsymbol{y}_i - \boldsymbol{r}_i)^{\mathrm{T}}\boldsymbol{Q}_y(\boldsymbol{y}_i - \boldsymbol{r}_i) + \boldsymbol{u}_i{}^{\mathrm{T}}\boldsymbol{Q}_u\boldsymbol{u}_i\} \\ +(\boldsymbol{y}_N - \boldsymbol{r}_N)^{\mathrm{T}}\boldsymbol{Q}_N(\boldsymbol{y}_N - \boldsymbol{r}_N) \end{array} \right\} \quad (5)$$

$$\text{subject to: } \begin{cases} \boldsymbol{u}_{min} \le \boldsymbol{u} \le \boldsymbol{u}_{max} \\ \boldsymbol{x}_{i+1} = A\boldsymbol{x}_i + B\boldsymbol{u}_i \\ \boldsymbol{y}_i = C\boldsymbol{x}_i, \end{cases}$$

where $\boldsymbol{y}_i = \boldsymbol{y}[n+i]$ is the i^{th} future output of the system, $\boldsymbol{u}_i = \boldsymbol{u}[n+i]$ is the i^{th} future input to the system, $\boldsymbol{r}_i$ is the i^{th} future reference, N is the prediction horizon, A is the system matrix, and B is the input matrix.

The cost function $V(\boldsymbol{U})$ can also be represented as

$$\begin{aligned} V(\boldsymbol{U}) \;=\; & (\boldsymbol{y}_0 - \boldsymbol{r}_0)^{\mathrm{T}}\boldsymbol{Q}_0(\boldsymbol{y}_0 - \boldsymbol{r}_0) \\ & +(\boldsymbol{Y} - \boldsymbol{R})^{\mathrm{T}}\bar{\boldsymbol{Q}}_y(\boldsymbol{Y} - \boldsymbol{R}) \\ & \boldsymbol{U}^{\mathrm{T}}\bar{\boldsymbol{Q}}_u\boldsymbol{U}, \end{aligned} \quad (6)$$

where

$$\boldsymbol{Y} = \begin{bmatrix} \boldsymbol{y}_1 \\ \boldsymbol{y}_2 \\ \vdots \\ \boldsymbol{y}_N \end{bmatrix}, \quad \boldsymbol{X} = \begin{bmatrix} \boldsymbol{u}_0 \\ \boldsymbol{u}_1 \\ \vdots \\ \boldsymbol{u}_{N-1} \end{bmatrix},$$

and

$$\boldsymbol{R} = \begin{bmatrix} \boldsymbol{r}_1 \\ \boldsymbol{r}_2 \\ \vdots \\ \boldsymbol{r}_N \end{bmatrix}.$$

With the system dynamics obtained and by using forward substitution, one can formulate the optimization problem as:

$$\begin{array}{l} \text{minimize } V(\boldsymbol{U}) = \boldsymbol{U}^{\mathrm{T}}\bar{H}\boldsymbol{U} + \bar{F}^{\mathrm{T}}\boldsymbol{U} \\ \text{subject to: } E\boldsymbol{U} \le \boldsymbol{\delta} \end{array}, \quad (7)$$

where

$$\bar{H} = \bar{S}^{\mathrm{T}}\bar{Q}\bar{S} + \boldsymbol{R},$$
$$\bar{F}^{\mathrm{T}} = 2\boldsymbol{x}_0\bar{T}\bar{Q}\bar{S} - \boldsymbol{R}^{\mathrm{T}}\bar{Q}\bar{S},$$

$$\bar{E} = \begin{bmatrix} I \\ -I \\ \bar{S} \\ -\bar{S} \end{bmatrix},$$

and,

$$\boldsymbol{\delta} = \begin{bmatrix} \triangle\, \boldsymbol{U}_{max} \\ -\triangle\, \boldsymbol{U}_{min} \\ \boldsymbol{Y}_{max} - \bar{T}\boldsymbol{x_0} \\ -\boldsymbol{Y}_{min} + \bar{T}\boldsymbol{x_0} \end{bmatrix}.$$

Now, this problem can be solved using the available QP solver [10].

4 Tracking results

4.1 Simulation

Figure 5 shows the results of the MPC controller for the sinusoidal reference signal. From the figure it is clear that the controller is able to track the reference signal. Similarly, from the plots of error signals, as presented in Figure 6, it is clear that the error in the Azimuth space is less than 0.03 degrees, compared to 0.01 degrees in case of the elevation angle.

The tracking performance can also be evaluated in terms of the performance index, e.g. Integral Square Error (ISE) which is defined as:

$$ISE = \sum_{i=1}^{M} e^2 [n]. \quad (7)$$

The ISE errors for Azimuth and Elevation angles are 0.34937 and 0.017448 degree^2, respectively.

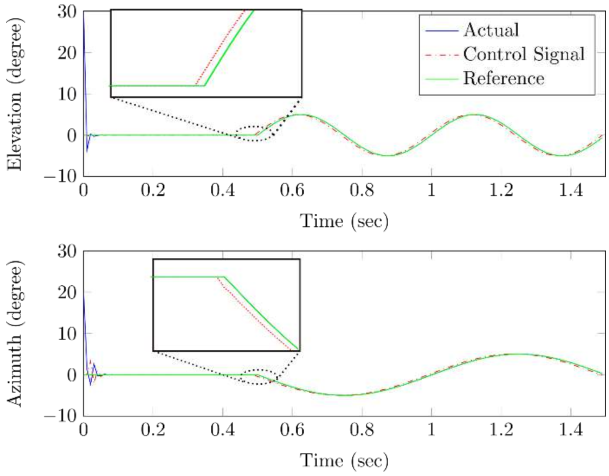

Figure 5. Plot of the angles along with command and actual values

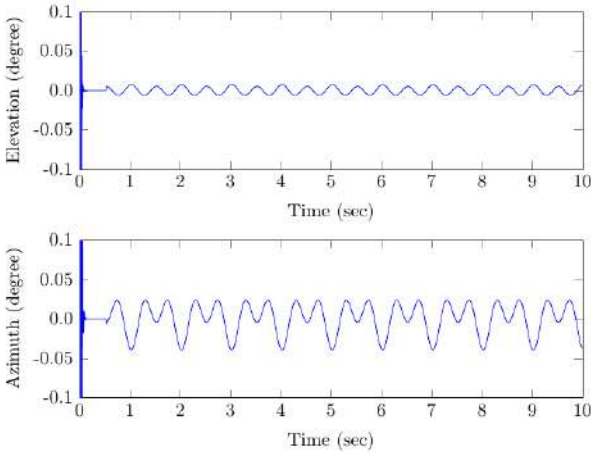

Figure 6. Plot of errors in Azimuth and Elevation angles

4.2 Real time tracking results

For the real-time testing, the MPC based predictive control algorithm was applied to a RobotEye with the specifications provided in Table 1. The block diagram for the experiment is provided in the Figure 7.

In the experiment, sinusoidal signals were provided as the reference signals. The frequencies of the reference signals were 1 Hz and 2 Hz for azimuth and elevation angles, respectively. To send the angular commands and receive the measurements we used the proprietary application programming interface.

The tracking errors during the experiment are shown in Figure 8. The error is less than 0.2 degrees for elevation and 0.1 degrees for the azimuth angle. Similarly, ISE errors for the azimuth and elevation angles are 3.947 and 33.73 degree^2, respectively.

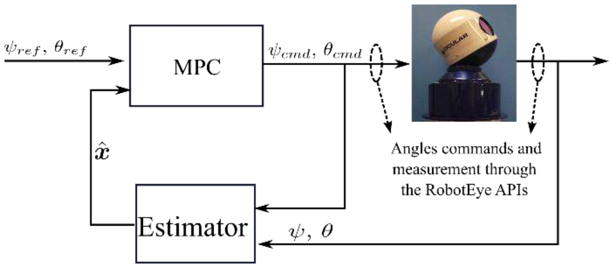

Figure 7: Real time experiment for MPC.

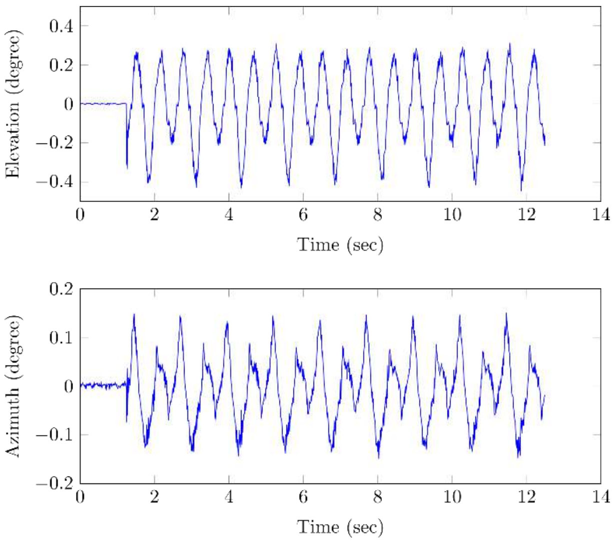

Figure 8. Tracking errors in azimuth and elevation angles in real experiment.

4.3 Performance evaluation for thermal target tracking

In this section, we evaluate performance of the proposed system described above and compare the performance with and without predictive control. The experimental setup for the evaluation of the system is presented in the Figure 9 with the specifications of all the components in Table 1.

The figure also shows the target consisting of the circular patched marker with a heat source at the centre of the marker. The heat source was used to detect the target in the thermal camera.

In this real time application, there is no direct way of evaluating the tracking performance of the system. However, as mentioned previously, the thermal camera is embedded inside the optical pointing device, to capture the view where it is directed to. Therefore, the thermal targets are detected via images taken by thermal and vision cameras, and then compared for evaluation.

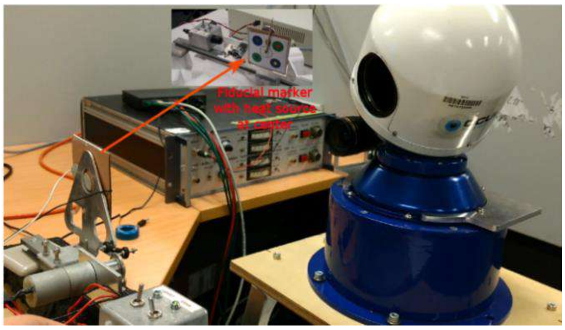

Figure 9: Experimental setup for tracking system.

The calculation of target pixels in the vision camera is obvious because the circular fiducial marker is attached with the target. However, the calculation of the target pixels in the thermal images is not straight forward. Therefore, a thresholding process is applied in every image, followed by a blob detection algorithm. The purpose of the blob detection algorithm is to detect hot spot on the image which is the location of the target.

Table 1: Parameters of the system.

	Parameter	Values
Vision camera	Focal length	16mm
	Resolution	658×492
	Frame Rate	100 fps
Thermal camera	Focal length	19mm
	Resolution	640×512
	Frame Rate	30fps
RobotEye	Model no	RELW 50
	Aperture diameter	50mm

After the calculation of target points in both vision and thermal camera, one can evaluate the target tracking performance of the RobotEye by comparing standard deviations of the target pixels in x and y-axis. Nevertheless, this approach does not give the clear indication of the performance. For example, if the variance of the target pixels in the vision camera is along y-axis but the variance of the pixels in the thermal camera is along x-axis then by comparing the above mentioned parameters does not represent the performance. In such situation, to better evaluate the tracking performance, the principal component analysis (PCA) of the target points can be applied. An example of the PCA of the target points is presented in Figure 10, wherein it is clear that the major axis and the minor axis of the PCA represents the direction of maximum and minimum variations of the target points. By using the principal component analysis, the following parameters:

- Maximum eigenvalues of the PCA of target pixels
- Minimum eigenvalues of the PCA of target pixels

are calculated for evaluation. It should be noted that in this system small variations of the target points in thermal cameras signifies better performance.

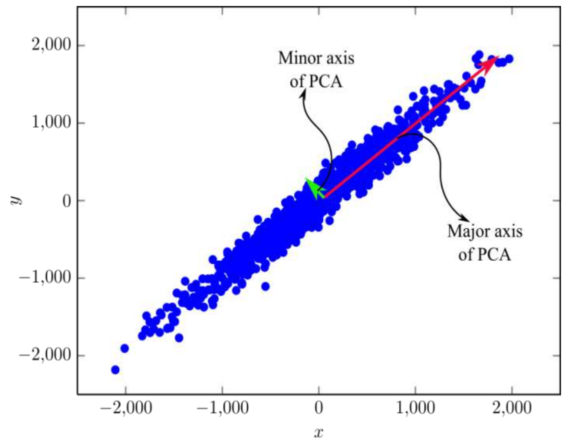

Figure 10. An example of the PCA of target points showing major and minor axis.

From the calculation of the above mentioned parameters, ratios of the parameters are obtained. Table 2 shows the summaries of the performance evaluations. From the table, it can be observed that there are improvements in all parameters. For instance, in terms of ratio of maximum eigenvalues there is the improvement by 74 percent. Similarly, in the case of the ratio of standard deviation in x-axis the improvement is about 42 percent.

Table 2: Summaries of the performance of the thermal tracking system with and without MPC.

	Without MPC	With MPC	% improvement
Ratio of maximum eigenvalues of PCA (thermal/vision)	0.0001	0.00002	74
Ratio of minimum eigenvalues of PCA (thermal/vision)	1.2213	0.8455	30
Ratio of standard deviation in X-axis (thermal/vision)	0.0101	0.005	42
Ratio of standard deviation (thermal/vision)	1.00659	0.8153	19

5 Conclusion

In this paper, we have presented a thermal target tracking system using RobotEye technology. The hardware comprises of the RobotEye optical pointing device, a thermal camera and a vision camera. Furthermore, the proposed system consists of an estimator for the target orientation and position with a Kalman filter using the application program interface for modeling and a Model Predictive Controller for command generation. In addition, a fiducial marker consisting of circular patches is attached to the target. The objective of the fiducial marker is to estimate the position of marker from the images taken from the vision camera. After the estimation of the target position, its future position is predicted using a Kalman filter, and a predictive control is then applied to generate command for the RobotEye. Experiments have been conducted and the tracking performance was evaluated for the system. The improvements of up to 74 percent is observed with the predictive control compared to the non MPC control case.

Abstract –

Due to the increasing growth of labor cost, academics and practitioners in this field have focused on finding ways to improve work productivity. Many previous studies have indicated that mental status has a deep influence on productivity. However, the relationship among work productivity, psychological state, and physical status has not been explored in the field of architecture, engineering, and construction (ACE).

As an initial exploration, this paper proposes a system to analyze how the psychological and physical status of construction workers influence their productivity. In this exploration, smart bands are adopted to measure the physical status of the bricklayers, STAI is used to collect the psychological data, and the time taken by construction workers to complete a unit of work (i.e., wall building) is recorded to reflect work productivity. Analysis on the correlations of the three dimensions (work productivity, psychological state, and physical status) was conducted. The initial experiment was conducted in Chongqing, China, from May 1st to May 3rd, 2018. The results show that bricklayers are in a relatively low level of anxiety, and that anxiety and heart rate levels are positively correlated with work productivity.

The wearable device-based system facilitates the real-time monitoring of construction workers' psychological and physical status. In turn, such information can help in planning their working schedules to enable them to work more efficiently.

Status monitor; Work productivity; Wearable devices

1 Introduction

Previous studies have suggested that mental health and psychological state are closely related to work productivity [1, 2]. Issah reported the association between mental health and emotional function with work productivity impairment, proving that the state of being nervous and depressed can result in lower work productivity [3]. Bubonya suggested that poor mental health can cause “emotional issues,” which may diminish the work productivity [4]. Bonnie studied the association between work productivity and depression, fatigue, and anxiety, and found that presenteeism is associated with increasing fatigue, depression, and anxiety [5]. Therefore, studying the relationship between mental state and work efficiency is necessary.

In the field of office work and manufacturing, researchers who tested the psychological state of workers recommended some solutions to achieve the goal of improving work productivity. Through an empirical study done in Australia, Bubonya proposed initiatives to reduce job stress and these offer the most potential to improve productivity [6]. Hillebrandt reported that psychological stress has a great impact on productivity. Setting some interventions can help increase job satisfaction, reduce adrenalin levels, and increase performance efficiency of workers in business [7]. Liff conducted a research in Northwest England and concluded that the productivity of women workers in the food factory industry can be affected by their mental status, which in turn, can reduce the overall work pressure and uplift work productivity [8]. All the studies above illustrate that, whether in the office or in the manufacturing industry, focusing on physical or mental states can avoid productivity inefficiency and lead to productivity improvement.

Due to the rapid growth of labor cost, increasing worker efficiency and reducing labor costs have become serious challenges in the architecture, engineering, and construction (AEC) field. Haas et al. presented for a prototype of a simple, low-cost, sensing solution for automatically monitoring undesirable movements and patterns of motion to help reduce Construction Work-related Musculoskeletal Disorders and help the workers work in a more efficient and safe way [9]. Gatti et al. propose that assessing physical strain in construction workforce is the first step for improving Safety and productivity management [10]. Lill use a simulation modelling to optimize the labour management strategies, and decrease the mismatch between required and available skilled labour and to discuss the consequences of ignoring the interests of craftsmen [11].

Unfortunately, few studies focus on how psychological and physical status influence work productivity. To fulfill this research gap, the current paper purpose a wearable device-based system to explore the relationship among work productivity, psychological state, and physical status.

The main problems and corresponding solutions in this paper are as stated below.

- For the measurement of psychological state, STAI questionnaire was used to reflect workers' mental status.
- For the measurement of physical status, the smart band was adopted to record workers' physical status.
- For the measurement of work productivity, the time spent by workers to complete a unit of work was measured.
- For the analyses of the three dimensions, regressive analysis was used to find the correlation

2 Research Method

This research proposes the use of a novel type of measurement (smart band) to monitor the physical data reflecting the mental status of the workers. Doing so can help us determine the relationship between mental status and work productivity. An initial experiment was done based on the logical framework of the experiment shown in Figure 1.

2.1 Psychological data collection

In this research, we collected psychological data, specifically data on state anxiety and trait anxiety. Trait anxiety is a relatively stable behavioral tendency of each individual, whereas state anxiety mainly indicates perceived risk or stimulation, producing brief emotional states, including individual tension, worry, anxiety, obsession, and euphoria of the autonomic nervous system.

Such data can be collected via a traditional but classic approach: by using the State-Trait Anxiety Inventory (STAI). First introduced in 1970 [12], this test has been proven to be effective in testing anxiety by many past studies, especially those in the medical field [13, 14]. This questionnaire is divided into two parts: one that tests trait anxiety and another that tests state anxiety. The test of trait anxiety mainly asks about how one person feels at the moment, whereas the test of state anxiety asks about how one feels in general. Each part has 20 items, and takes about 10 minutes to complete. These tests are answered on the basis of a scale with scores of 1 to 4 (1 - "not at all," 2 - "somewhat," 3 - "moderately so," and 4 - "very much so." It can reflex the emotion including tension, apprehension, and nervousness.

Table 1. Questionnaire of testing trait anxiety

Table 2. Questionnaire of testing state anxiety

Items	Options
I lack self-confidence	1 2 3 4
I am a steady person	1 2 3 4
……	

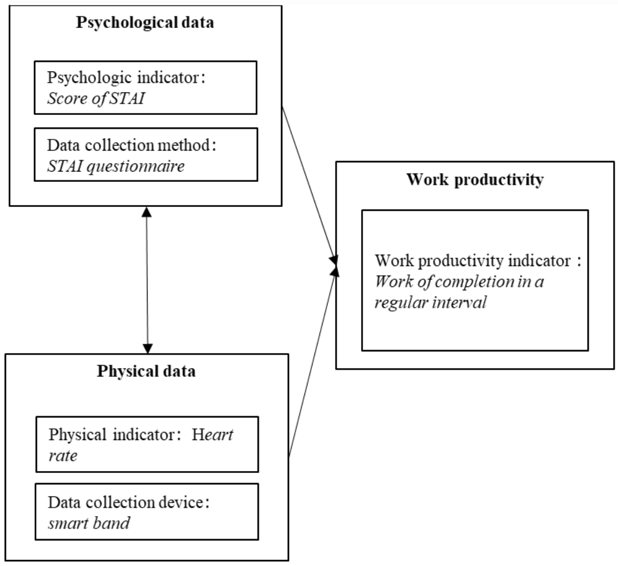

Figure 1. The logic framework of this study

2.2 Physical data collection

To collect the physical data, which can provide a real-time status of the jobsite workers, the physical indicators were selected. In the previous study, heart rate, ECG, electrodermal response, skin temperature, calorie, number of steps taken, and respiratory rhythm were used (Table 3). In this exploratory study, to make the study

Table 3. Questionnaire of testing state anxiety

Reference	[15]	[16]	[17]	[18]	[19]	[20]	[21]	[22]	[23]

Calorie				✓					
Movement steps				✓				✓	
Breathing rhythm			✓						

feasible and credible, we used heart rate, which is the most frequently used indicator.

The smart band was used to measure the two indicators. It has the following three main advantages compared with traditional physical status measurements.

First, the smart band is wireless and easy to wear. Wearable devices usually appear in the form of a bracelet, vest, glasses, and helmet. It can be worn like regular clothing or an accessory to allow movement without restrictions. In contrast, traditional monitoring instruments generally require the subjects to stay in a fixed location. Also, the smart band can provide real-time. monitoring. With such sensors as the heart-rate monitor, barometer, and angular velocity trans embedded, it offers the opportunities to detect human activities in real time.

Another thing which cannot be ignored, that the smart band is a practical and non-expensive option. In fact, some construction workers recognize the benefits of using a smart band [24], such as wearing it while working.

2.3 Work productivity measurement

Investigating work efficiency or productivity is the main study objective of this research. As ours is an exploratory study, we can easily calculate work efficiency or productivity by recording the time spent by each worked in completing a unit of work (i.e., wall building). In future works, however, this indicator should also consider accuracy and the quality of the final product.

3 Experiment and data collection

3.1 Selection of the experiment site and subjects

This experiment was conducted at the Dazhulin project located in Chongqing, China, as shown in Figure 2. This project, undertaken by Chongqing Wantai Construction Co., Ltd., is a frame-shear wall structure with a construction height of 123 m.

Figure 2. The experiment site

The subjects consisted of three bricklayers working on the 22nd floor. Their task was to build the walls, and this required them to pick up bricks, apply the mortar, climb numerous stairs, and so on. This type of work is very common in the field of construction. In past studies, researchers have proven that workers performing this kind of work are suitable subjects for the monitoring of real-time data on their physical and psychological state. For example, Chen designed an experiment, which included climbing a ladder, selecting a screw and installing the screw to test the physical and psychological state of the workers [25]. This kind of work is similar to what the bricklayers in the current study do in terms of complexity.

3.2 Experiment process

The experiment was carried out in the following procedures:

First, the subjects were numbered and asked to fill out the T-test in the STAI questionnaire.

Then, to collect their physical data, the subjects were required to wear the smart band daily. They should put it on in the morning when they start to work and take it off after work. The heart rate was measured every 1 minute.

During a regular interval (once every 2.5 hours), they were asked have a rest and fill in the S-test in the STAI questionnaire. The quantity of wall structure they completed was then identified.

Their behaviours, including talking with co-workers, and changes in the external environment, such as the project manager's inspection, were also recorded.

(a) (b)

Figure 3. The testees is filling out the STAI questionnaire (a) and working while wearing the smart band (b)

3.3 Experimental data collection

Since it is an exploratory study, the experiment had just been conducted for 3 days in March, 2018. The physical data was collected by using Millet bracelet. As a result, 1 time/minute*60*10 minute/day/people*3 people*3 days = 5400 data sample of their heart rate were collected (table 4).

As for the psychological status (including S-test and T-test) and work productivity data，4 times / day / people ∗ 3 days ∗ 3 people = 36 data samples were collected.

Table 4. A part of the original data (worker B; day 1; 6:30-9:00）

90	73	68	80	83	76	71	74	86	80
S-test score =22; work productivity=2.08m^3									

4 Data analysis and results

The experiment collected 5400 physical data and 36 sets of psychological and work productivity data. From these, several findings can be concluded.

All the subjects scored below 30 in T-test, indicating relatively low levels of anxiety and stress. The three subjects scored 22, 25, and 28, respectively. Compared with other occupations, for example, undergraduate student, the level of anxiety is significantly lower. Through the observation during the experiment, this result may have been due to the following reasons:

The most likely reason is.that the level of security at the construction site improves and the perceived risk is reduced, so construction worker feel more safe and the anxiety(stress) level decrease correspondingly.

The rise in wages may be the second reason for this phenomenon. The high wage make construction workers more satisfied with their lives.

The third reason this that the repeatability of the job makes them extremely confident in their ability to finish the work, thus reducing anxiety and annoyance

We can also observe that the score in the S-test (state anxiety index) is positively related with work productivity (Figure 4).

The findings indicate that workers work more efficiently when they feel relatively high levels of stress and anxiety. This is because the initial anxiety level of the bricklayers is very low given that the perceived stress is not enough. When the workers were supervised or criticized by the foreman, they felt more stressed and uncomfortable, which then increased their S-test scores

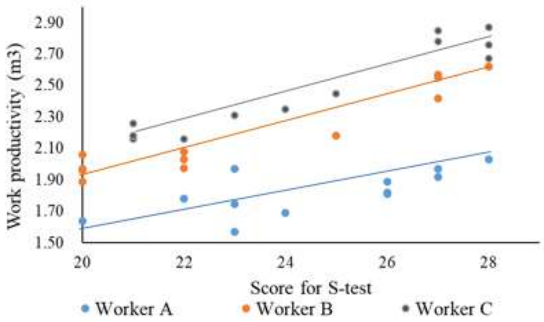

Figure 4. The correlation of work productivity and state anxiety index

and prompted them to work more efficiently. Another common situation is that workers talked to their workmates frequently, and such communication made them feel relaxed. As a result, their state anxiety index decreased, and their work productivity decreases correspondingly.

It can also be conclude that heart rate is positively correlated with state anxiety index and work efficiency

When bricklayers work efficiently, the peak values of their heart rates tend to be higher, and the standard deviation (SD) is also larger. A rapid heartbeat indicates the performance of efficient work (Figure 5).

The increase of heart rate during high work productivity can be explained from two perspectives. On the one hand, the amount of exercise increased, and on the other hand, relatively high degrees of mental stress and anxiety pushed them do better work.

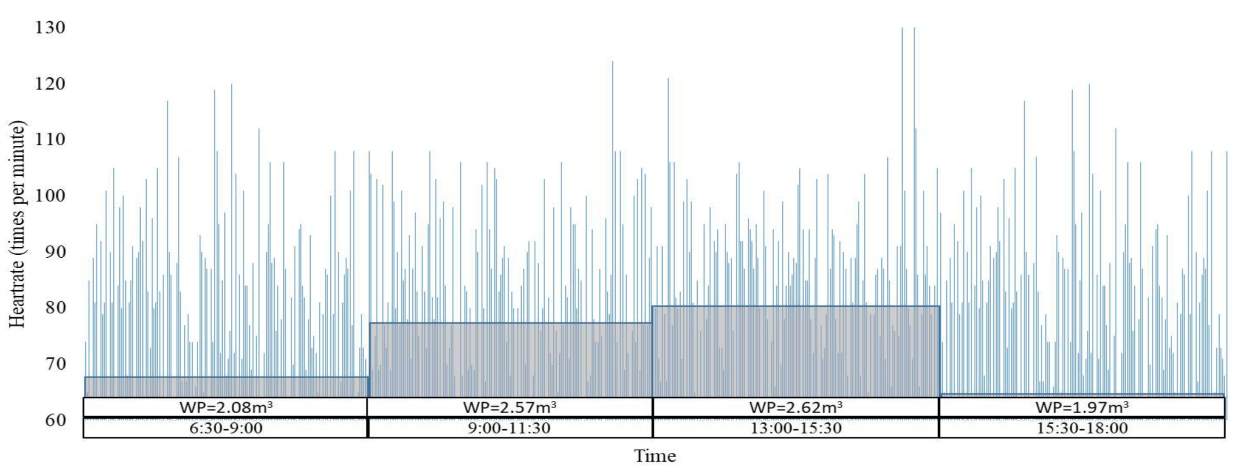

Figure 5. The relationship between work productivity and workers' real-time heart rate

5 Conclusion

This paper established a wearable-device based system that helped stakeholders understand the psychological and physical state of the construction workers in real time. Based on the experimental data, the following results can be concluded.

1. Bricklayers show a relatively low level of anxiety and stress.
2. State anxiety index is positively related with work productivity.
3. Heart rate was positively correlated with state anxiety index and work efficiency.

Though the real-time data, and the relationship among work productivity, psychological state, and physical status, the work productivity of construction workers can be predicted.

The significance of this research is that it provides an available approach to monitor construction workers' physical status and psychological state to predict their work productivity. A reasonable arrangement construction workers' working schedules can help improve their work efficiency.

***Abstract*— This work aims to show the importance of the different components that are immersed in lower limb prostheses, either at the Transtibial or Trasnfemoral level. this type of mechanisms substitutes a normal function of the human being as it is the function of the march. With the implementation of this research we intend to help design and build elements that allow us through good practices to generate different levels of well-being for patients with this condition. By having our own and local technologies we can manufacture components at low costs and with a high level of durability; the designs and prototypes are presented in the Center of Design and Metrology - SENA Capital District that has the Orthopedic technology school. Whose specific purpose is to train Technologists in Development and Adaptation of Prostheses and Orthoses.**

Keywords— Knee, prosthesis, transtibial, trasnfemoral, electromyography.

I. Introduction

Mobility in the human being is one of its most relevant factors within quality of life; absence or deficiency in mobility generates the marching functions to be compromised [1], in a mild or severe manner, depending on the injury for each patient. To our end, we will focus on analyzing and studying the different parameters affecting march in patients with amputated lower limbs, whether transtibial or trasnfemoral. These are the two cases of lower limb amputation with the greatest quantity of cases worldwide [2].

Through this research, we have achieved several proper and local advances from the Centro de Diseño y Metrología del SENA - (Colombia) Center for Design and Metrology SENA, in order to aid the improvement of some march conditions of a patient with this condition. Several devices have been designed, starting with the making of a dynamic foot in carbon fiber [3]. On the other hand, we have developed an electro-mechanic ankle component with a control system based on electromyographic signals from the residual limb of the patient [4]. Moving forward in the path of our research and increasing the degree of complexity as well as the level of amputation of the patient, we have proposed the design and manufacture of a mechanic polycentric knee, which, attached to the mechanical foot currently under testing, will enable us to work with patients whose amputation level is transfemoral at any level, whether proximal or medial. The knee design is given in design criteria compliant with the need of each patient and their personal mobility and physical configuration [5]. At the mechanical and functional aspects, we intend focusing our investigation on a polycentric knee which enables activity to a passive patient of 30-45 year old, 75 to 90 kg of weight, and 1,70 to 1,90m of height, with a moderately varied level of physical activity.

On the other hand, the prosthetic component under development intends to diminish the manufacturing cost of these elements, since it will incorporate low-weight, low-cost raw materials to make a component with great quality, low cost and light weight [6]. All of the previous us addressed to performing mandatory structural tests in accordance with ISO 10328, and thus obtaining a component with the highest quality standards.

II. General analysis of prosthetics

It is the multidisciplinary work of engineers, ortesists, prosthetist and some users along with a process of brainstorm, design thinking and possible empiric-analytical statements, that resulted in the design and construction of prototypes of some prosthetic components which were then assembled to solve the specific case of a user with transtibial lower limb amputation.

Digital modeling through the use of simulators enables a systemic methodology of correlation between the components and post-construction reality. This process leads to a functional model between structure and dynamics for effort analysis, movement axis, torque and other motor and mechanical factors required by the device.

Consequently, and based on available technologies at the creative lab of the formation center, participants carried out the first construction phase, through the use of 3D printing technology of polylactic acid polymers. This material allows design adjustment bearing in mind physical aspects to be corrected, such as the restriction of transmission rounds and displacement mechanical bumps. The product was then assessed by health professionals from the formation center, who provided technical certification to take the design to the next stage, which corresponds to functional prototyping in workshops dedicated to carbon fiber mechanizing and laminating.

On the other hand, some aspects were growing in importance along the development of the project, leading to subjects such as compact design, component miniaturization, efficiency, ergonomic and aesthetic factors which enable the improvement of visual perception. These challenges are deemed by users as highly important during the moment of adaptation of this type of components [7]. Because of this, it was necessary to include laminating and thermoforming technologies for high-hardness plastics, which enable cosmesis and improvement of all aspects considered in patient feedback to officially declare the product as completed.
Ethically speaking, it is required that, after validation, and for implementation there are good use practices, through a user manual containing a general vision of the component. For this reason, the user manual was constructed, as suggested by the International Classification of Functioning, Disability and Health (CIF).

Full articulation assembling

General assembly of prosthetics through the manufacture of each of the pieces occurred modularly, followed by the final assembly, which, according to the tolerance degree included in manufacture blueprints, occurred easily in all components.

Each of the pieces was manufactured bearing in mind three parameters; first, follow-up on specified planimetrics (fig. 1 a), where the level of tolerance, material and disposition of each piece provided a clear goal in the construction of the model.
Another of the parameters was modeling of each of the pieces using the software MasterCam V7, which used previous geometry from SolidWorks to provide the same model in coordinate points (fig. 1 b), so the four-axis lathe performs the mechanization process on the material selected.
Lastly, validation of each of the pieces was carried out individually and as a whole. This process occurred under the principle of modeling by Finite Element Method (FEM) with both, a specific static analysis of each piece individually, as well as a dynamic analysis of the whole set [8] (fig. 2 a and b). For this type of element, and given that it will be present on a human body, it is necessary to follow a thorough protocol in both piece analysis and structuration, as well as the consequent articulation controller [9].

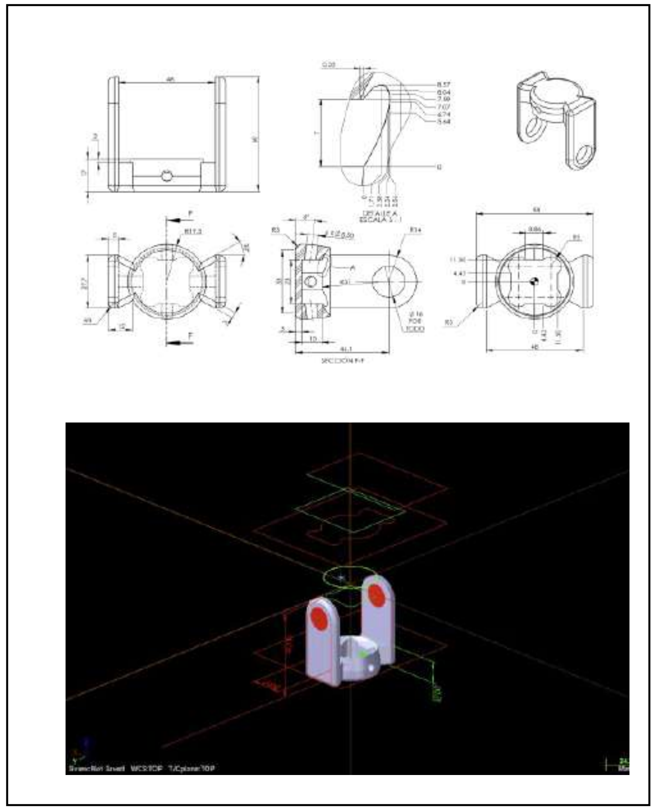

Fig. 1 a) Follow-up on proposed planimetrics. b) Design and parametrization in MasterCam V7.

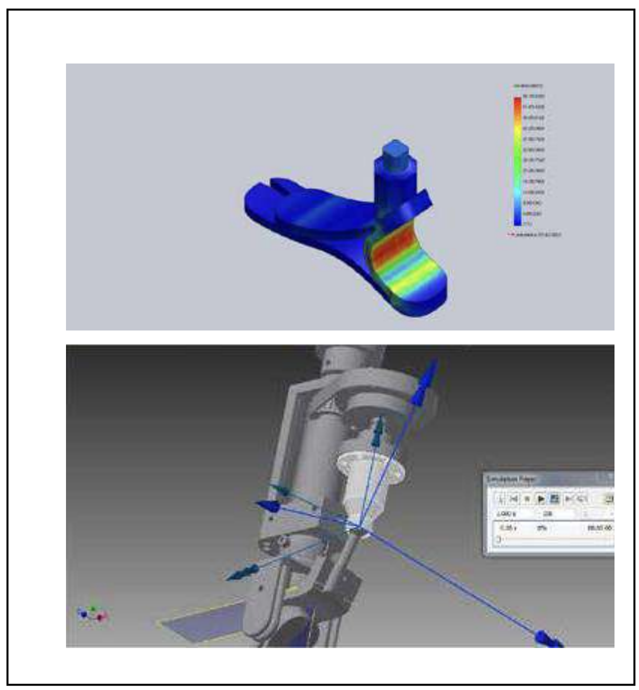

Fig. 2 a) Static analysis in SolidWorks. b) Dynamic analysis in SolidWorks.

For the specific case of foot manufacturing by carbon fiber modeling, the first step consisted on performing the molds for casting of fiber mixed with acrylic resin. In future papers we will clearly discuss how variation on the percentage of carbon fiber and resin changes the structural and resistance conditions of the final pieces. At the moment, a research group is building test specimens of the material used, in order to submit them to structural analysis by deformation and shavings, according to a lower-limb prosthetic.

Fig. 3 Design and manufacture of molds for carbon fiber casting.

The general assembly of the articulation was developed successfully with minor adjustments to distances in the perforations for screws. General and final assembly in dialuminium and carbon fiber was as follows:

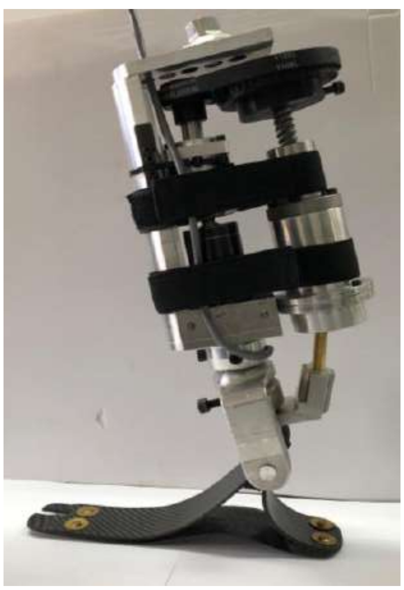

Fig. 4 Sagittal view of the prototype.

Fig. 5 Frontal view of the prototype.

This model clearly adjusts to the design parameters stated, and complies with the functional and mobility characteristics proposed for the patient object of study.

Future papers will focus on several fronts:

- Dynamic analysis of the articulation in the walk lab.
- Mechanic and structural analysis of materials used.
- Construction and adaptation of polycentric knee for each of the components designed.
- Transmission and gear mechanism.

III. Analysis and results by electromyography acquisition signal

Nature is filled with signals which are mostly classified and described through mathematical equations, which in turn pose a measurement variable. The human body is not without these qualities; there is a number of internal actions which enable movement. However, when follow-up on these parameters is required, other factors come into play to achieve the conversion to digital variables. The implementation of measurement and posterior control systems on an prothesis generates the need to transform body variables into analog; in other words, from variables in time to digital variables with only two logical states.

In the generation of the Project, it is born in mind that articulatory movements are not described on one individual axis, but rather, depending on the articulation under analysis, can have up to 6 degrees of liberty. This means that they require the implementation of a data acquisition system which separates variables in such a way that multiple systems can be developed for each degree of liberty; however, for this prototype we initially took as a reference 1 degree of liberty, more specifically, angular movement on axis Y, between +15 and -15 gradians.

Acquisition on the body is presented in two different ways, reading the movement of the muscle located in the higher section of the ankle, so that after training, the patient becomes able to move the limb only with muscular movements. The second manner consists on reading degrees of inclination of one part of the body directly linked to ankle movement during walk [10]. In this case, reading corresponds to the installation of a translator, which converts physical variables of the body (angular movement) into electric variables. Thus, it is possible for an electronic device to acquire movement data.

It is possible to measure the data from electric variables thanks to the wide spectrum of embedded devices, which enable us to manipulate data and make decisions regarding mechanical actuators [11]. Acquisition took place using Arduino Galileo, an embedded, printed, programmable card, with a high data processing velocity which uses a reading variable to generate a means for decision making on movement of the actuator.

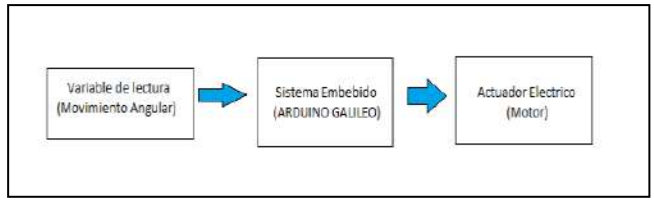

Figura 6. System of conversion of the signal taken by the body and sent to an electric actuator.

Digital posts and digital analogic converters enable the input of several external variables within a programmable logic. However, one of the great shortcomings in these devices is the watt power of the outlets, which is the reason that communication between the programmable device and the electric actuator occurs through an engine driver, which enables sending control signals to high-consumption engines through low-power signals generated by the imbedded system. Thus, it is possible to generate movement on an electric actuator from the acquisition of data from the body.

Regarding the implementation of the electric actuator, it was selected according to sole requirements. Although it is true that electrical induction engines do not have enough torque to generate the movement [8] of the ankle when lifting an average of 150 Kg, the adjustment was achieved using a 12-volt brushless engine and a reducing box with a ratio of 11 to 1, assuming that electric power consumption between the actuator and the driver are appropriate so the sole does not suffer. Thus, the functioning of the actuator is guaranteed without generating high consumption or damage to the acquisition card.

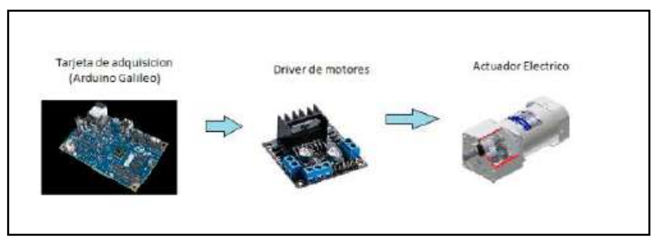

Figura 7. System of conversion of signal taken by the body and sent to an electric actuator.

The assembly of the various devices gives as a result the implementation of a system which allows control on the angular movement of the electric actuator [12], as shown in the figure.

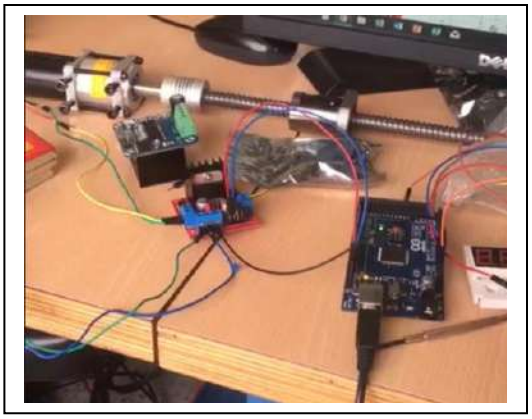

Figura 8. Real engine driver system and embedded system for actuator control.

In an electrically controlled system, when physical design parameters are modified, controller parameters are directly and proportionally affected as well. Therefore, it was necessary to establish the whole system with the electric actuator for final control analysis.

Figure 9. Functional model of the sole with the electric actuator attached.

Data acquisition, as well as the design of a functional sole which simulates assisted ankle movement, enables the generation of a system complying with the three fundamental stages: data acquisition, data processing and actuator movement, and lead to the following result:

Figura 10. Implemented Control System.

The current prototype has already been depurated and is now in feedback phase by the subjects of the study. This means that the initial goal was achieved in that we generated local components which somehow aid in the normal walk function.

IV. Conclusions

- The transmission mechanism must be rather well adjusted and synchronized, as it depends on two precision pulleys, which, if transmitted the improper force and required torque, could produce energy loss in transmission, which is translated into energetic costs and fatigue of the pieces composing the prototype.
- Piece mechanization requires a high degree of skills, since the various components present complex geometries, which make mechanization tiresome, leading to multiple setup of each piece.
- The control system of the mechanism or controller requires a high filtering stage, since stray signals present in the sensors prevent the mechanism to react as expected, transferring the uncertainty level to the patient.
- The controller, by being the brain of the component, cannot, under any circumstance, be present in slow cards or control strategies, since performance and success on the simulation of the various stage of walk depend on it.
- Due to patent registration at the Superintendencia de Industria y Comercio of the Republic of Colombia, it was necessary to avoid detail in this article; it was also necessary to place visual protecting bands around the prototype to avoid explicit divulgation which impedes proper registration of components.
- Due to mechanization and production time, it was necessary to implement the controller system in printed material initially, but not on the mechanized material. However, for tests with patients, the implementation is necessary on rigid 7075 dialuminium and carbon fiber, which resists the weight and activity level of the subjects of this study.

Abstract – Amongst increasing innovations in frontier engineering sciences, the advancements in Robotic and Autonomous Systems (RAS) has brought about a new horizon in construction applications. There is evidence of the increasing interest in RAS technologies in the civil construction sector being reflected in construction efforts of many military forces. In particular, Army or ground-based forces are frequently called upon to conduct construction tasks as part of military operations, tasks which could be partially or fully aided by the employment of RAS technologies. Along with recent advances in the Internet of Things (IoT) and cyber-physical system infrastructure, it is essential to examine the current maturity, technical feasibility, and affordability, as well as the challenges and future directions of the adoption and application of RAS to military construction. This paper presents a comprehensive survey and provides a contemporary and industry-independent overview on the state-of-the-art of earthmoving construction automation used in defence, spanning current world's best practice through to that which is predicted over the coming years.

Keywords – Construction automation; Earthmoving; Defence; Robotic and Autonomous Systems.

1 Introduction

Construction automation represents the field of research and development focused on improving construction processes by applying the principles of industrial automation [1-3]. Among general construction processes, there have been resurgent interests in the automation of earthmoving equipment such as wheel loaders and bulldozers. New thinking is occurring within a framework of modelling of control, planning and artificial intelligence with the use of sensing and information technologies [4,5] in combination with the frameworks for understanding robotic and autonomous systems (RAS) as applied to construction automation [6]. To this end, a great deal of research and development has been devoted to raising the level of autonomy of construction plant, in both civilian and military domains, to improve their efficiency, productivity, quality and reliability [7].

Robotic and autonomous systems tailored for the military call upon the ability to integrate sensors, vision imaging, actuators, end-effector manipulation, computer control and human interface for operations in unstructured, difficult and hazardous conditions. Army construction tasks for enhancing force protection include such earthmoving tasks as filling of protective barriers (HESCO baskets), building dirt bunding structures, as well as anti-tank ditches and trenching. For such tasks a variety of heavy construction machinery such as excavators, bulldozers, wheel loaders, graders and articulated dump trucks etc. have been customised to meet the special requirements of the military.

With the demand on combat engineering capability to provide greater force protection with more rapid rates of construction, there is an increasing requirement for the transformation of combat engineering construction plant into more autonomous systems. Studies in this field therefore have recently received much research interest. In [8,9], surveys of RAS used in military applications have been conducted with discussion on Unmanned Ground Vehicles (UGV) and air/sea-based robotic vehicles. However, the focus therein was mainly on combat and logistic operations rather than construction. Given the rapid developments in military construction automation with the use of high-mobility ground-based platforms, human-machine and machine-machine interfaces, teleoperation and control systems, data transmission systems, perception and manipulation capabilities [10], the survey presented in this paper aims to provide an overview and analysis on the state-of-the-art of earthmoving construction automation used for Army applications. This survey will cover construction tasks and corresponding platforms in alignment with defence applications. Platforms of interest include excavators, bulldozers and wheel loaders in tele-operated, shared-control, semi-autonomous, or autonomous modes of operation.

Most earthmoving tasks with their array of platforms and equipment are cooperatively coordinated within construction operations. On one hand, recent developments in networked robotics and the integration of IoT within intelligent digital infrastructure [11,12], could afford task coordination efficiency benefits to such construction operations. On the other hand, with digitally connected systems there also arises the inherent cyber risk compared to the traditional ones.

2 RAS in Ground-Based Construction – A Review

The application of RAS to typical platforms such as excavators, bulldozers and wheel loaders is evaluated through studies in teleoperation and autonomous operations [13] on the basis of the technology readiness level (TRL) framework [14] of 9 levels, from basic research (TRL 1) to operational deployment (TRL 9).

2.1 Excavator

2.1.1 Remote Control and Teleoperation

In remote control and teleoperation, a key challenge is to develop a reliable human-machine interaction model and real-time data feedback. One of the earliest studies in this direction was conducted in the early 1990’s by Burks *et al*. [15] in a study funded by the U.S. Army with the aim to find principles for the teleoperation of excavators to retrieve unexploded ordnance and radioactive waste (TRL1-2). At the subsystem development level (TRL 3-6), various studies have been conducted to develop models and prototypes for tele-operated excavators. In 1995, Ohmori and Mano introduced the concept of master-subordinate-slave tele-earthwork system, which replaced a human operator using a teleoperation system known as RoboQ [16]. Yokoi *et al*. (2003) developed a master-slave system which used a humanoid robot to operate and control a backhoe [17]. Teleoperation involving tele-grasping sensory perception, which is based on a master-slave teleoperation concept of a grapple-attached mini excavator, has been carried out by a group of researchers in Gifu University, Japan [18]. The proposed control system significantly improved the slow grasping of a soft object by improving the sense of grasping through the application of force feedback [19]. Such control requires the use of pressure and displacement sensors to be attached to the mini excavator. The research was verified by simulation and experiments confirmed the validity of the control system. Later, Yusof *et al*. (2012) conducted studies on operator sensitivity to various modalities, where the perception of the operator for each type of feedback was evaluated by using common 2D, 3D and virtual visual feedback [20]. Precision grasping was also tested by utilising auditory feedback, along with force feedback [21]. Kim *et al*. (2008) proposed an interesting study of controlling an excavator using the movement of the human arm [22] while Sasaki and Kawashima (2008) developed a remote controlled pneumatic robotic system, which can replace a human operator [23]. The benefit of the remote controlled operations conducted at local construction sites has been quantified by the increase in work efficiency of more than 50% compared to the direct operation of the excavator. The same concept was studied by using a teleoperated electro-hydraulic actuator, equipped with a 2.4 GHz remotely controlled system [24].

At the level of Integrated Pilot System Demonstrated (TRL 7-8), teleoperation of excavators has been tested in Japan for events involving post volcanic and earthquake disaster recovery [25], which was a milestone for application of RAS to a large-scale unmanned construction operation of post disaster recovery works.

2.1.2 Autonomous Excavation

Studies in autonomous excavation started in 1986 at CMU in which a prototype named Robotic Excavator (REX) was developed [26]. REX combined integrated sensing, modelling, planning, simulation, and action specifically to unearth buried utility piping at TRL 1-2. Human interfaces to REX included a joystick, keyboard and animated display, while a rugged hydraulic arm was appended to a four-link backhoe for actuation. Since then, a large number of studies have been conducted addressing various aspects of autonomous excavation. Excavator kinematics and dynamics can be analysed and derived by assigning coordinate systems to the manipulator configuration of boom, arm and bucket, and applying the Newton-Euler formula to the local coordinate frame for each link in succession as a free body [27]. In [28], full kinematic and dynamic models of the excavator arm represented as a planar manipulator with three degrees of freedom (boom, arm and bucket) are derived using the Lagrangian formulation. A virtual model for excavators was developed for an earthworks site, whose terrain geometry is continuously updated as excavation and earth-moving continue until completion, is used to study the interaction between the excavator and its surrounding environment [29]. In a recent work [30], the operation function is modelled through analysis of deterministic processes and trajectories of the relieving tool.

At the TRL 3-6 level, a number of studies focused on general control techniques for autonomous excavators. In [31], Bradley *et al*. (1989) discussed the developments necessary to operate a simple backhoe arm. Experimental studies were presented in [32] on mechanics of planetary excavation. In [33], the control of an intelligent excavator for autonomous digging in difficult ground was conducted on a mini excavator. Malaguti (1994) [34] proposed a decentralised variable structure control of joints, including the actuator dynamics, and considered the possibility to adapt the control dynamics on the system disturbs. In [35], the force and position control problem was addressed for electrohydraulic systems of a robotic excavator. The idea of controlling the force and position relationship was proposed by Ha *et al*. (2000) in terms of impedance control for a hydraulically actuated robotic excavator [36]. The control technique being implemented on a Komatsu 1.5-tonne excavator, demonstrated that the proposed control technique could provide robust performance when employed in autonomous excavation mode with soil contact considerations. The impedance control method was further developed by Tazafoli *et al*. [37]. Recently, partial automated blade control has been studied in [38] to control one of the excavator’s work cylinders while the machine operator controls the rest of non-automated work cylinders. A Time-Delay Control with Switching Action (TDCSA) using an integral sliding surface was proposed for the control of a 21-tonne robotic excavator [39], whereby analysis and experiments showed that using an integral sliding surface for the switching action of TDCSA was better than using a Proportional Derivative-type sliding surface. The proposed controller was applied to the linear motion of the entire excavator at the same speed level as that of a skilful human operator. In [40], the Time-Varying Sliding Mode Controller (TVSMC) combined with a fuzzy algorithm has been used for an unmanned excavator system. The computer control system [41] was implemented on a 1.5 tonne 3-link (boom, arm and bucket) excavator. Developments in high-level control have been studied for task level execution such as positioning, path planning and disturbance mitigation. In [42], Matsuike *et al*. (1996) developed an excavation control system, as a supporting system for large-depth excavation, in which the excavator was exactly positioned with the error being less than 30-50 mm. A control architecture was developed in [43] for autonomous execution of some typical excavation tasks in construction. Using the same platform, Maeda [44] dealt with disturbances arising from a material removal process by proposing the Iterative Learning Control (ILC) with a PD-type learning function as a predictive controller, to achieve a desired cut profile with non-monotonic transients which converged faster by learning disturbances directly from command discrepancies.

Interactions between construction tools and the soil represent highly-non-linear and dynamic processes [45]. There are two strategies to the problem of time varying soil-tool interaction forces: (i) to treat it as a disturbance and design a suitable controller for compensation, or (ii) to design an efficient soil-tool interaction model which can accurately model the dynamics of excavation in real time. One of the main challenges in designing an efficient, robust, adaptive controller for the excavator, emanate from the machine-environment interaction dynamics as the largest contributor of time-varying forces in the system. Complex rheological models capable of computing accurately soil behaviour require a large amount of computational time and hence are infeasible for a real-time dynamic controller [46]. To this end, some recent models have been proposed to predict soil-tool interaction sufficiently well. A 3D semi-infinite soil medium is often replaced by a non-coupled discrete rheological model, independent of its structural elements [47].

As the soil parameters required for accurate modelling are difficult to obtain experimentally, efficient methods must be used for soil parameter estimation [48]. A fuzzy system was proposed, using no information on soil conditions, and solutions offered were claimed to be sub-optimal [49]. Different tool-soil interaction models exist, e.g. the Finite Earthmoving Equation (FEE) model and its modifications [50], and the Linear Lumped Model [51], which is computationally more effective than the FEE. After all, soil behaviour by its nature is complex and the variation of some parameters can greatly alter the soil conditions. Sensors can therefore provide information to compensate for such variations and controllers should be able to handle such disturbances, a detailed survey of which can be found in [52].

Towards full-scale autonomous excavation at TRL level 7-8, a pioneer system was demonstrated by Stenz *et al.* (1999) [53]. The system is the first fully autonomous loading system for excavators being capable of loading trucks with soft material at the speed of an expert human operator. In another study, Yahya (2008) proposed the concept of parameter identification, as a key requirement in the field of automated control of unmanned excavators [54]. An automated excavating prototype was developed in [55] for excavating ditches for drainage. This system was composed of two sub-systems, an automatic surface finishing system and a laser guide system for excavating ditches up to 8 km in length. A vision-based control system for a tracked mobile robot such as an excavator was developed in [56], including several controllers that can be collaboratively operated to move the mobile platform from a starting position to a target location. A prototype of a autonomous hydraulic excavator was introduced to improve the basic technologies of construction machinery such as hydraulic shovels [57], which was also able to complete the autonomous loading of a crawler dump truck. More recently, a prototype system based on a Volvo EW 180B excavator has been reported as part of the autonomous excavator project THOR (Terraforming Heavy Outdoor Robot) with the goal of developing a construction machine which performs landscaping on a construction site without an operator [58].

2.2 Bulldozer

2.2.1 Principles and Subsystems

At TRL 1-2, pioneering work on autonomous bulldozers started several decades ago, as was the case for excavators. Muro (1988) introduced an automatically controlled system for maximising productivity of a dozer running on soft terrain [59], whereby a microcomputer was used to obtain information of terrain properties and vehicle states so that based on that information, optimum drawbar-pull and slip ratios could be computed during digging. Since then, various studies have been conducted, focussed on different research topics such as modelling and control, position and pose estimation, machine-soil interaction, navigation, teleoperation, simulation and real world applications.

At TRL 3-5, Olsen and Bone [60] investigated the modelling of a robotic bulldozing operation for the purpose of autonomous control. Later, in [61], the bulldozer's workflow was modelled using an adaptive neural network to simulate and predict the dependence of the resistive strain of gauge bogie displacement on the dig depth and trolley speed dynamically. The force acting on the blade was first modelled and a model-based adaptive control strategy was then proposed for controlling the blade. The control of the dozer blade could be addressed using fuzzy theory for the semi-automatic control of a real-world bulldozer [62]. Meanwhile, a control strategy for hybrid engines of tracked bulldozers was also addressed in [63], based on a multi-objective design optimisation of the engine control parameters to minimise fuel consumption.

In the soil cutting and pushing process, the dozer blade experiences soil resistance owing to friction, cohesion and adhesion between the blade and soil, and the soil and ground [64]. The forces acting on the blade vary in a complicated manner that may deteriorate the performance of the bulldozer. The resistance or draft force problem has been tackled either empirically [65] or using numerical methods [66], whereby a cohesive bond force model was introduced in which the microscopic behaviour of the cohesive force was evaluated against macroscopic shear failure characteristics. The dynamic behaviour has also been taken into account by considering velocity and acceleration in the model [67]. Numerical studies were conducted with the finite element method for soil mechanics and the failure zone using various models including constitutive equations of soil failure [68] and an elasto-plastic constitutive model [69]. In simulation and navigation, analyses of the driving system of a crawler bulldozer were carried out with two types of pavement, clay and hard, taking into account the driving force. The results provided a reference for improving the performance of the crawler bulldozer drive system [70]. Recently, a guidance system for the bulldozer has been developed using sensor fusion. The integration of an Inertial Measurement Unit (IMU) with two Real Time Kinematic (RTK) global positioning systems (GPS) allowed accurate estimation of the pose and position of the bulldozer blade, providing feedback to the navigation system [71]. Experiments on a full-scale bulldozer were implemented to validate the approach.

2.2.2 Integrated Pilot Systems

At TRL 7-8, a group of 20 prototype bulldozer robots were built to develop autonomous and cooperative capabilities [72], using tank-like treads driven by two independent actuators, and equipped with a scoop which can be lifted up and down and tilted back and forth. They also have a one degree-of-freedom head which constantly rotates with various sensors mounted onboard. Experiments were performed on an artificial lunar surface and the results were promising for various planetary tasks. Apart from space programs, autonomous bulldozers have been developed for surveillance, mining and construction. In [73], Moteki *et al*. have adapted the unmanned construction system technology to build semi-autonomous bulldozers for operations in a disaster situation. More recently, ASI Robotics Inc. has developed a system of robotic hardware components that allow users to control a vehicle in both modes, manual and autonomous modes. The system consists of NAV™ (the onboard computer and communications system), Vantage® (obstacle detection and avoidance features), and Mobius™ (command and control software) [74]. Together, these components form a universal automation solution for vehicles of different geometries, sizes, and applications.

2.3 Loader

Autonomous loaders are considered as an integrated system of hydraulic, mechanical and electronic subsystems. Being widely used at construction sites, these machines have received much research interest to continuously improve their performance and autonomy level. At TRL 1-2, since 1990's, the study on control and planning of frond-end loaders has become active [75]. By using a microcomputer, the computer controller is capable of positioning the linkage in either Cartesian or angular coordinate motion with the ability to store and recall trajectories. Since then, a number of studies have been conducted on model loaders, which are essential for improving their performance and autonomy level to TRL 3-4. Worley and Saponara (2008) presented a simplified dynamic model of a wheel-type loader to accelerate the structural design and analysis of the boom and bucket linkage subsystems [76]. The lateral dynamics of skid-steering high-speed tracked vehicles were presented, with a nonlinear track terrain model derived from classical terra-mechanics [77]. Recently, both kinematic and dynamic models of a skid-steered robot were identified via a learning process based on the Extended Kalman Filter and an efficient neural network formulation [78]. In terms of machine control, an automated digging control system (ADCS) for a wheel loader was developed using a behaviour-based control structure combined with fuzzy logic, and implemented on a Caterpillar 980G wheel loader [79]. A closed-loop digital velocity control was successfully implemented for those objectives with the results validated by experiments on a large Caterpillar 990 wheel loader, as reported in [80]. In another approach, an H-infinity based robust control design combined with feedback linearization was presented for an automatic bucket levelling mechanism wherein robustness of the controller design was validated in simulation by using a complete nonlinear model of the wheel loader [81].

At SRL levels 7-8 for integrated systems, Volvo Construction Equipment, developed a prototype of a fully autonomous haulage truck and wheel loader, and demonstrated it in 2016 [82]. Most recently, a fully autonomous track loader has been developed and tested in the field by Built Robotics Inc. taking advantage of the significant advances in self-driving car technologies. The developed software and sensor suite can transform off-the-shelf loaders and excavators into robotic platforms that can undertake earthmoving tasks with precision, and for hours without a break [83].

3 Earthmoving Construction Automation in Military Applications

3.1 EOD and landmine detection

One of the earliest RAS used in military applications was reported in 1992 [15] for the Small Emplacement Excavator (SEE), a ruggedized military vehicle with backhoe and front loader used by the U.S. Army for explosive ordnance disposal (EOD), combat engineering, and general utility excavation activities. Its features include teleoperated driving, a telerobotic backhoe with four degrees-of-freedom, and a teleoperated front loader with two degrees-of-freedom on the bucket. In [84], a terrain scanning robot can autonomously manipulate a typical handheld detector for remote sensing of buried landmines using map building and path planning implemented in real-time software. A commercial Modular Robotic Control System (MRCS) was first integrated onto a Nemesis HD Robotic Platform for the tasks of ground clearance and landmine detection Wetzel *et al*. (2006) [85]. It was then installed on the 924G Bucket Loader, shown in Fig. 1, for various construction operations including excavating, digging, lifting/loading, stripping, levelling, and stockpiling.

Another commercial-off-the-self robotic kit, the Appliqué Robotics Kit (ARK), was also designed to allow the modification of existing plant to remote controllable with the minimal modification of the host vehicle or its electro-hydraulic system. In [86], the ARK was installed on a front end loader/backhoe used for excavation of small emplacements, material handling, and general construction tasks as shown in Fig. 2. Experimental results showed that this RAS technology was suitable for operational use and supported hasty route clearance operations for the military. These unmanned ground vehicles can also be used for other purposes such as surveillance; remote monitoring; engineering and military policing tasks; and chemical, biological, radiological, and nuclear (CBRN) defence.

Fig. 1: MRCS installed on the 924G Bucket Loader [85].

Fig. 2: An Army loader/backhoe installed with ARK [86].

3.2 Earthwork for military purposes

Earthwork operations have been used for centuries as part of military defensive operations. This could be in the form of moats, foxholes, or bunkers to protect equipment and personnel. It is not difficult to organize such work as it does not involve technology and can be performed with rudimentary equipment. A more permanent form of earthwork may have facing materials on the parapet that makes up the higher part of the earthen embankment. This could be constructed with stones, sandbags, wood, or any other material. Such protection requires additional time and is rarely a form adapted in actual battle conditions. Other forms of military earthwork include moats, which are often built around inhabited areas and filled with water to slow down the enemy. Modern day warfare uses the same method to create tank trenches, quite often for miles to slow down an armoured column assault.

A *Forward Operating Base* (FOB) is a secured forward military position, commonly a military base that is used to support tactical operations. A FOB may or may not contain an airfield, hospital, or other facilities. The base may be used for an extended period of time. FOBs are traditionally supported by Main Operating Bases that are required to provide backup support to them. A FOB also improves reaction time at the local level rather than having all troops in the Main Operating Base. In its most basic form, a FOB consists of a ring of barbed wire around a position with a fortified entry control point. More advanced FOBs include an assembly of earthen dams, concrete barriers, gates, watchtowers, bunkers and other force protection infrastructure. They are often built from special retaining or shoring walls called bastions for defence. Figure 3 shows construction of a HESCO bastion by US Marine Corps with the help of an excavator [87], for a FOB in Afghanistan's Delaram District.

Fig. 3: Building Delaram FOB [87]

A common example of military earthwork is to put in place a *barrier* between the force and the enemy for force protection. The basic form of any such earthwork operation is a mound of earth or embankment rising above the general ground level. This embankment is formed from earth that is excavated in the same locale, thus simultaneously creating a ditch. The ditch adds to the height and depth available for protection. A *foxhole* is the simplest form of military earthwork normally dug in position by a soldier who will use it for self-protection in battle. A section of soldiers may connect up their individual foxholes to form a continuous trench that can be used to facilitate the supply of ammunition and allow communication ferrying with commanders.

The *HESCO bastion* is a modern gabion primarily used for military fortification. It is made up of a collapsible wire mesh basket and a heavy-duty geo-fabric liner. They are used as a semi-permanent blast wall against explosions or small-arms fire and used for FOB wall constructions as in Figure 3. One of the best features of HESCO is its ease in setting up. Flat pack and concertinaed HESCO can be pulled off a truck and erected quickly. With a front-end loader or excavator used to fill the baskets with dirt, sand or gravel, a wall can be built within hours and is much quicker than sand bagging.

Antitank ditches are constructed to strengthen prepared defensive positions. As they are costly in time and effort to construct, much is gained if the excavation can be made by means of cratering charges. An antitank ditch must be wide enough to stop an enemy tank, and it may be improved by placing a log hurdle on the enemy side and the spoil on the friendly side. Forming such ditches can be improved by digging the friendly side nearly vertical. Antitank ditches are usually triangular, rectangular, or trapezoidal in cross section and have a low parapet on the defender's side. Their dimensions vary and they are often reveted or contain water. Figure 4 shows a British Army Terrier combat vehicle employed for trench digging. Manufactured by BAE, it has drive-by-wire and teleoperation capability, equipped with a remotely controllable hydraulic front bucket and excavating arm. It is used remotely by operators for clearing routes, creating cover, digging anti-tank ditches and trenches under harsh conditions [88].

Fig. 4: Teleoperated trench digging [88].

3.3 Military use of RAS on earthmoving platforms.

The application of RAS is becoming more widely used on legacy earth moving plant within the military. Autonomous land vehicles have been developed for navigation, reconnaissance, surveillance, and target acquisition. Recently, the US Army has tested the autonomous vehicle technology in its fleet of logistical vehicles. The leader follower technique in robotic formation was used to form a convoy of trucks equipped with a laser-based sensor (LIDAR) used for maintaining the distance clearance. Figure 5 shows a test scenario to demonstrate the concept of V2I (Vehicle To Infrastructure) that allows for a formation of one manned truck leading seven driverless connected vehicles [89].

Fig. 5: The US Army is testing a "leader-follower" system that will employ up to 8 convoy vehicles [89].

For military use, bulldozer blades can be optionally fitted to platforms including, such as artillery tractors of Type 73 or M8 Tractor. Dozer blades can also be mounted on main battle tanks, where it can be used to clear antitank obstacles, mines, and dig improvised shelters. Combat applications for dozer blades include clearing battlefield obstacles and preparing fire positions. Bulldozers employed for combat engineering roles are often fitted with armour to protect the driver from small arms fire and debris, enabling bulldozers to operate in combat zones. The Israeli Army Engineering Corps have also completed an extensive project to equip unmanned bulldozers with autonomous capabilities, as shown in Fig. 6, to carry out specialized tasks for earth moving, clearing terrain obstacles, opening routes and detonating explosive charges [90]. Front end loaders are also commonly used in military applications for constructing and removing road blocks and building bases and fortifications.

Fig. 6: Robotic bulldozer used by Israel Defence Forces [90].

4 Construction Automation – A Projection Regarding Military Applications

Since the last decade of the 20th century, there has emerged increasing research evidence for the viability of RAS in autonomous construction tasks including the more challenging problem of autonomous excavation [91, 92]. The enabling technologies arising from the research and development into RAS for automating construction tasks using platforms such as excavators, dozers and loaders have become much more mature and better integrated, providing a foundation for the next stage of growth in off-the-shelf products. In addition, embracing the recent advances in manufacturing with Industrie 4.0 [93], cloud computing, cyber-physical systems and IoT, tomorrow's technologies for construction automation can be foreseen in the improvement of construction site efficiency with a plethora of technologies, systems, data and services.

Looking ahead at the use of RAS in construction, Kendall Jones, the Editor-in-Chief of the ConstructConnect blog [94], emphasises efficiency and accuracy, envisaging an automated construction site in the future that will have a fleet of dozers, graders, and excavators undertaking site works without any operators behind the cabin controls, and some without cabins.

During the Second World War, when the U.S. and Germany started to develop Unmanned Air Vehicles (UAVs), military robotics has made tremendous progress. As increasing evidence of defence interest in autonomous systems, in 2001 the US Congress mandated that, "By 2010, one third of the operational deep-strike force aircraft fleet are unmanned, and by 2015, one-third of the operational ground combat vehicles are unmanned"[1]. Unmanned Ground Vehicles (UGVs) are becoming more engaged in a variety of missions including Explosive Ordnance Disposal (EOD), combat engineering, reconnaissance, and civil works. RAS, including ground, aerial, underwater, amphibious vehicles [95], anti-munition systems, armed robots, cyber-attack and defence systems are anticipated to become a central piece of military operations in the years ahead.

According to Randall Steeb, a senior scientist at Rand Corporation, commented that the US Army's Future Combat Systems (FCS) program emphasised the use of autonomous, armed cooperative robots [96]. While eventually cancelled, the FCS program was further evidence of a growing interest in military application of autonomous systems. Cooperation of unmanned platforms with humans and inhabited machines in construction has been gaining interest in the RAS community. In parallel with this is the widening use of the military concept of teaming of unmanned vehicles [13]. For example, the flexible leader-follower formation of skid-steered tracked vehicles towing polar sleds has been studied with a developed dynamic model and a proposed control architecture. The results have shown that the follower tractor maintains the flexible formation but keeps its payload stable while the leader experiences large oscillations of its drawbar arm indicating potential payload instability [97]. In this context, efficient and adaptive RAS, along with artificial intelligence techniques and ubiquitous communication networks can effectively support the cooperation to meet the expectations of ever changing operational environments and recover from disturbances.

In construction and infrastructure, the emerging field of IoT is directly applicable to the technologies for interconnected systems, consisting of several communication layers, such as in the driverless vehicle technologies, or in advanced manufacturing. IoT is a paradigm that considers the pervasive presence of a variety of objects possessing digital intelligence in an environment. These make themselves recognizable and can behave intelligently by making context related decisions thanks to information aggregation and sharing with other objects.

Teaming of different platforms in military construction will find its root in the development of methodologies and techniques for interconnected systems [98] and the application of intelligence science, data science and IoT or cyber-physical systems [99]. In the military domain, IoT finds direct applications in such operations that are often conducted in a complex,

[1] Section 220(a) (2) of the Floyd D. Spence National Defense Authorization Act for Fiscal Year 2001 (as enacted into law by Public Law 106–398; 114 Statute 1654A–38).

multidimensional, highly dynamic and disruptive environment, e.g. a FOB, where commanders have to accurately and promptly assess the situation, to gather all possible information sources to obtain the most complete and relevant picture in order to make decisions [100]. Scenarios for use of IoT in warfare conditions may include its applications to support tactical reconnaissance, smart FOBs that incorporate IoT technologies in force protection at bases as well as maritime and littoral environments, health and personnel monitoring, and equipment maintenance. The technical challenges will rest with reliability and dependability, especially when IoT becomes mission critical; actuation of IoT devices, especially with real-time requirements; power for their tactical deployment; architectural aspects of military IoT infrastructure including security, information, and communication architectures; and interoperability and integration of disparate technologies.

5 Conclusion

We have comprehensively surveyed the use of RAS in earthmoving construction machinery with applications to the land force. Typical automated platforms such as excavators, bulldozers and front-end loaders are reviewed with regard to modeling, low and high levels of control, their system architecture, sensing and navigation, tool-soil interactions, simulation and experiments from laboratory set-ups to full-scale field tests, in remotely controlled, teleoperated, semi-autonomous and autonomous modes of operation. The developments of RAS for these platforms have been perused from several decades till the present day and, this survey has provided an overview of these in terms of their technology maturity and systems readiness. These developments range from basic research through to operationally employed systems.

Acknowledgements

Support received from the Land Division, Defence Science and Technology Group of the Australian Government and the UTS Distinguished Visiting Scholar scheme is gratefully acknowledged. The authors would like to thank Prof. Miroslaw Skibniewski and Mr Stephen Baker for fruitful discussion and improvements during the preparation of this survey.

Abstract –

Four-dimensional (4D) Building Information Modelling (BIM) has been credited with improving construction planning procedures. The integration of 3D model with schedule information has enabled the effective detection of design and planning flaws in many construction projects. Due to the lack of research on using 4D BIM in Turnaround Maintenance (TAM) projects, this paper firstly introduces a novel framework of applying 4D BIM to improve TAM process planning and execution. Then, a real TAM project was selected to validate the effectiveness and efficiency of the proposed framework. Finally, benefits such as time and cost reduction, and safety improvement are calculated and explained.

Keywords –

BIM; Turnaround Maintenance; Planning

1 Introduction

Turnaround maintenance (TAM), as a periodic comprehensive programme which contributes significantly to the long-term stability and continuous production availability of the oil and gas plants, is one of the most important maintenance strategies to minimise the risk of production losses [1]. TAM project is known for its complexity due to the involvement of massive man powers and financial resources during its planning and operation [2-4]. It is reported that a major TAM can potentially cause an annual productivity loss of 2-3% [5]. The peculiarities of high labor intensity and capital concentration make TAM project a time-sensitive project that any delay or inefficiency can lead to catastrophic failure.

Traditional project management techniques, such as Critical Path Method (CPM)/ Program Evaluation Review Technique (PERT), are commonly applied to manage TAM projects. However, these methods are believed to be inadequate to accommodate the complexity of TAM projects.

Building Information Modelling (BIM) is emerging as a method of creating, sharing, exchanging and managing the information throughout project life cycle among all stakeholders [6, 7]. A Four-dimensional (4D) BIM model results from the linking of 3D model to the fourth dimension of time [8]. In the 4D model, the temporal and spatial aspects of the project are inextricably linked, as they are during the actual construction process [9]. In project shaping stage, 4D BIM is useful in communicating and validating construction plans and processes, while during construction phase, they are helpful in identifying errors in the logic of the schedule, potential time-space conflicts, and accessibility issues [10, 11].

In recent years, 4D BIM has been largely implemented on building and infrastructure projects, and proven its capabilities in planning simulation and optimisation [12-16]. However, there is a lack of 4D BIM studies in TAM projects. Therefore, it is worthwhile to investigate the capabilities of 4D BIM in improving TAM planning and execution. This paper firstly introduces a novel framework of applying 4D BIM to improve TAM process planning and execution. Then, a real TAM project was selected to validate the effectiveness and efficiency of the proposed framework. Finally, benefits such as time and cost reduction, and safety improvement are calculated and explained.

2 Framework of Applying 4D BIM to Improve TAM Planning and Execution

This section describes a 4D BIM framework for improving TAM planning and execution (as shown in Figure 1). In the left part, a typical TAM project structure is developed which consists of six levels of details based on the functional logic [5, 17]. The first level is defined based on a TAM project unit, which explains the project scope, cost, planning, governance, key performance indicators, health, safety, environment and quality, and emergency response. For a major shutdown, a TAM project will contain jobs conducted in two or more independent trains. Therefore, a major TAM campaign is always divided into several sub-campaigns. Given a train-related sub-campaign, the third level classifies the jobs into a number of sub-sub-campaigns according to the plant unit, such as Compressor or Turbine. The fourth level further divides the related jobs within a sub-sub-campaign into different work orders according to the system unit, such as Piping, Mechanical, and electrical systems. The last two levels detail the work order into batch and activity units respectively. For instance, for a given work order of a spool removal, there are a number of elbows need to be uninstalled, in addition, detailed process for uninstalling a specific elbow also needs to be explained.

According to the TAM project structure, four levels of the 4D BIM simulation are developed including Plant, System, Batch, and Activity level (as shown in the right side of Figure 1). For a given level, the 4D BIM simulation is developed based on the corresponding level-of-detail 3D model and schedule. Each of them is explained in detail in the following sub-sections.

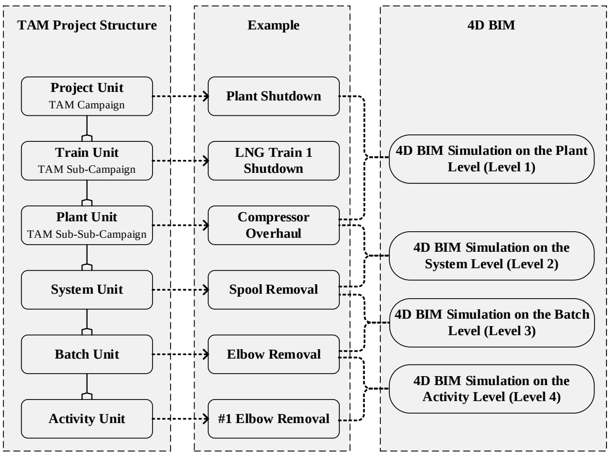

Figure 1: Framework of Applying 4D BIM to Improve TAM Planning and Execution

2.1 4D BIM Simulation on the Plant Level

The main objective of this level of 4D BIM simulation is to effectively engage core teams (i.e. Operations, maintenance & Integrity, and Turnaround Lead) to review the project scope. If the scope does not align with the initial plan, additional works, such as revising plans, need to be conducted before proceeding to the next stage. Therefore, the reviewing process is very critical to the turnaround success.

4D BIM modelling and simulation on this level is developed based on the 3D Plant Model and TAM milestone plan. In order to accelerate the agreement establishment among plant operation, maintenance, and turnaround teams, the 3D Plant Model should have all the main 3D objects (i.e. Compressor, Turbine, or Heat Exchanger) that defined within the project scope, and their functional location information. In addition, a general plant site model including site layout information should be also incorporated into the 3D Plant Model. The TAM milestone plan should lay out the key checkpoints and delivery dates for the planning cycle and form the basis for forecasting planning resources.

The plant-level 4D BIM simulation should be developed ten to twelve months before starting the field execution. For small turnaround projects with no major material lead times, the completion data of this simulation can be 6-8 months before actual starting.

2.2 4D BIM Simulation on the System Level

The main objective of this level of 4D BIM simulation is to engage teams of Planning, Work Pack Development, Engineering, and Procurement to: (1) communicate and review terms of reference, discuss initial risks, functional requirements, likely resources and establish delivery strategy; and (2) review initial scope against turnaround acceptance criterial, prioritise tasks and establish initial work list.

4D BIM modelling and simulation on this level is developed based on the 3D System Model and TAM work development plan. In order to efficiently review and confirm initial work list and initial preparations plan, the 3D System Model should include: (1) all the connected components (i.e. Spools and steel structures) of the instruments that plan to be replaced; and (2) major construction equipment, such as mobile cranes, that plan to be used to perform lifting tasks. The TAM work development plan should include: (1) an integrated plan (schedule, equipment and resources); (2) preliminary critical path schedule; (3) updated preliminary work list; and (4) critical lift plans.

The system-level 4D BIM simulation should be completed six to eight months prior to the shutdown of the plant or equipment.

2.3 4D BIM Simulation on the Batch Level

The main objective of this level of 4D BIM simulation is to engage external contractors and/or out-of-plant personnel to evaluate the critical path, and come up with alternative execution methods to shorten the project duration. Reviews of maintainability, reliability, and constructability are the main focus at this stage.

4D BIM modelling and simulation on this level is developed based on the 3D Batch Model and TAM detailed plan. In order to efficiently finalise the work list, the 3D Batch Model should include: (1) supported structures such as steel platforms and scaffolds; and (2) safety signs and tags such as frame signs, swing stand signs, and barricading. The TAM detail plan should include critical and sub-critical activities, lifting plans, mobile equipment requirements, detailed shop loading plans, and what-if scenarios.

The batch-level 4D BIM simulation should be completed three to five months prior to the turnaround.

2.4 4D BIM Simulation on the Activity Level

The main objective of this level of 4D BIM simulation is to ensure that all parties understand the work to be done and the sequence and details of the shutting-down process together with preparation for entry.

4D BIM modelling and simulation on this level is developed based on the 3D Activity Model and TAM execution plan. In order to efficiently (1) train operations, maintenance, and contractor personnel and (2) review environmental and safety requirements, the 3D Activity Model should include: (1) temporary facilities such as temporary offices, stores, tool houses; (2) functional equipment such as lighting tower, gas detector, and hydrostatic test unit; and (3) virtual avatar. The TAM execution plan should include: (1) shutdown and unit clean out sequences, (2) start-up plan; and (3) detailed execution sequences.

The activity-level 4D BIM simulation should be completed two weeks to two months prior to the turnaround.

3 Case study

The case study was conducted based on a major plant turnaround project that consists of LNG Train 5 and Fractionation Train 1. The key activities involved in this turnaround include: (1) Turbine major inspection; (2) Statutory vessel inspections; (3) Compressor blade carrier change-out; (4) Bearing and seal inspections; (5) Tray modifications; (6) Molecular sieve bed change-out; (7) Mercury guard bed change-out; and (8) Valve overhauls, upgrades and replacements.

3.1 3D Model Development

The selected gas plant was built more than 30 years ago. There is a lack of a 3D model that can be used to create a 4D simulation. Fortunately, the laser scanning technology is becoming mature enough, and is affordable for current industry. There are lots of automated methods that have been developed for transforming point cloud data into 3D model [18]. However, in this case study, the 3D model was created manually by engineers in order to assure the modelling accuracy. The underlying reasons are twofold: (1) Most of the existing algorithms developed for automatically transforming point cloud data into 3D model, are focused on building industry. When applying them in gas plant domain, the average accuracy of the transforming process is not acceptable. (2) The scope of this TAM project is small, only covering the Compressor-related area, thus both time and cost spent for creating the 3D model are affordable. Figure 2 shows the point cloud data, and Figure 3 shows the converted 3D model.

Figure 2: 3D Point Cloud Model

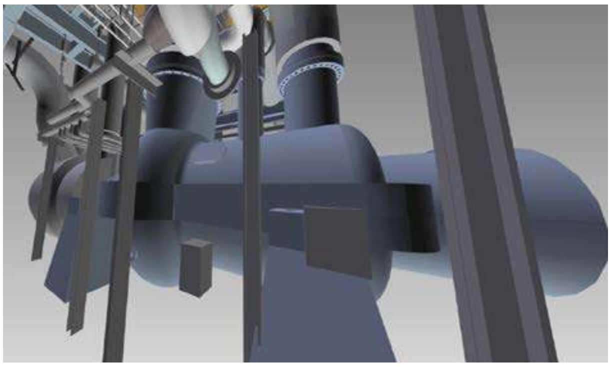

Figure 3: Converted 3D Model

3.2 4D BIM Simulation Implementation

In this case study, the four levels of 4D BIM simulation defined in Section 2 were developed as the project progresses. The aim of the 4D BIM simulation on the plant level is to help decision-makers to efficiently gain a better understanding of project scope and critical works. Figure 4 shows the 4D BIM simulation on the plant level which visualises the major activities defined within the project scope.

The simulation was created by the TAM core team and presented to the project steering committee for guidance. Through the simulation, the steering committee had gained a better understanding of

- The thirteen major maintenance happened in LNG train 5, such as: gas turbine overhaul of *5KT1410* and *5KT1430*, process compressor overhaul of

5K1410, *5K1420*, *5K1430* and *5K1450*, statutory inspections of 43 vessels, and *5C1410* tray modifications; and

- The nine major maintenance happened in LNG train 4 and Frac-3, such as: thirty control valve installations, three exchanger installation, product exchange of 4C2501, and compressor overhaul of *4K4401* and *4K4403*.

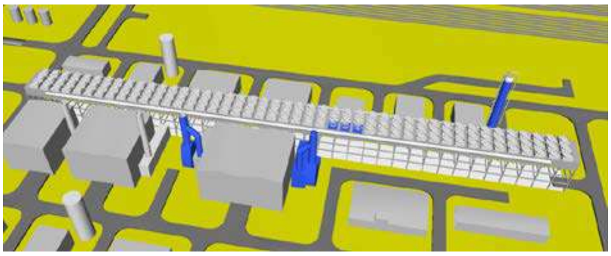

Figure 4: Screenshot of the 4D BIM Simulation on the Plant Level

In addition, one critical workscope and three sub-critical workscopes were also determined in terms of their durations and dependences. The *5K1410* compressor overhaul was the critical one and it would take 20 days to complete. The sub-critical workscopes includes: *5KT1430* turbine overhaul (24 days), *5KT1430* turbine overhaul (25.5 days), and *5C1410* internal tray modification (13 days).

Figure 5 shows the 4D BIM simulation on the system level which not only visualises the sequence of the main activities, but also evaluates the constructability and efficiency of the lifting and access plans created by the TAM execution team.

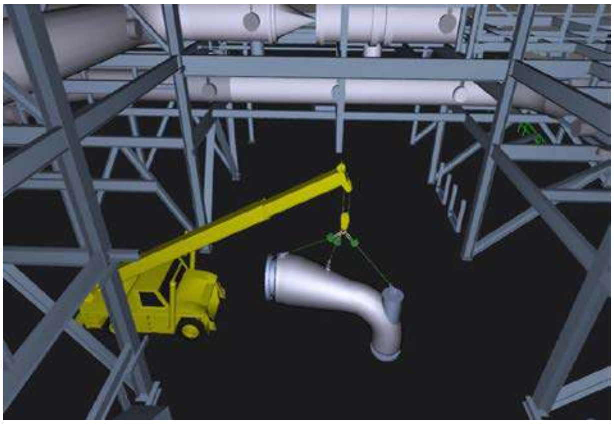

Figure 5: Screenshot of the 4D BIM Simulation on the System Level

Take LNG Train 5 as an example, the original lifting plan contains six mobile cranes. The working location and lifting capacity of each crane are shown in Figure 6a. According to the simulation result, seventeen major conflicts were identified between the planned construction sequence and the original lifting plan. For instance, Crane 2 was occupied by two main activities simultaneously during 9:30-10:18 on the 11th September 2015, and Crane 4 was occupied by two main activities simultaneously during 6:45-7:51 on the 18th September 2015. If these conflicts were not solved successfully before field execution, there would be fifty hours schedule delay and more than two hundred man-hours waste. These numbers were estimated by the TAM core team.

In order to solve the seventeen lifting conflicts, the TAM core team went through these conflicts one by one, and found that fourteen of them were related to the Crane 2 and 3. Therefore, they decided to add another crane located between Crane 2 and 3 to share the lifting load. The other three lifting conflicts were related to the Crane 4. Instead of adding a new crane, the TAM core team decided to enlarge the lifting capacity of Crane 5 from 20 tonnage to 50 tonnage so that it can share the lifting load of Crane 4. In addition, the working locations of Crane 4 and 5 were also adjusted to assure the lifting efficiency. Figure 6b illustrates the revised lifting plan for LNG Train 5.

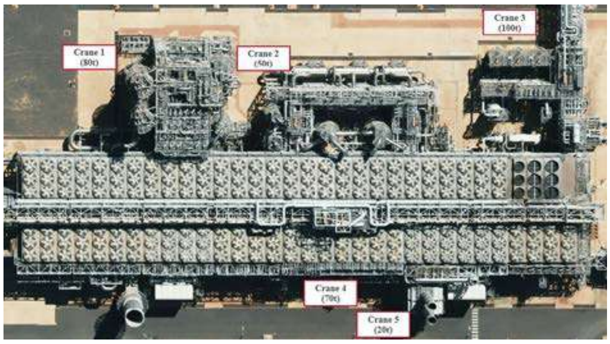

Figure 6a: The Original Lifting Plan for LNG Train 5

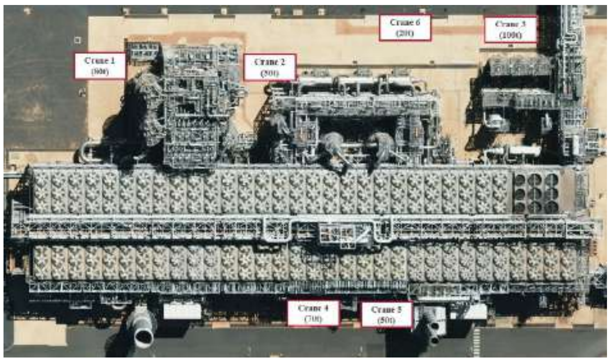

Figure 6b: The Revised Lifting Plan for LNG Train 5

The 4D BIM simulation on the batch level was developed by the TAM execution team, which visualises the sequence of all the activities involved including temporary jobs such as scaffold erection and dismantling (as shown in Figure 7). In order to improve site productivity and better focus on critical activities from stopping to restarting production, operations and maintenance teams were engaged at this stage to identify potential constructability issues and duration reduction opportunities. A cloud BIM platform (as shown in Figure 8) was also developed to allow people from other shutdown projects but has similar working experience to easily access this simulation and comment their ideas remotely.

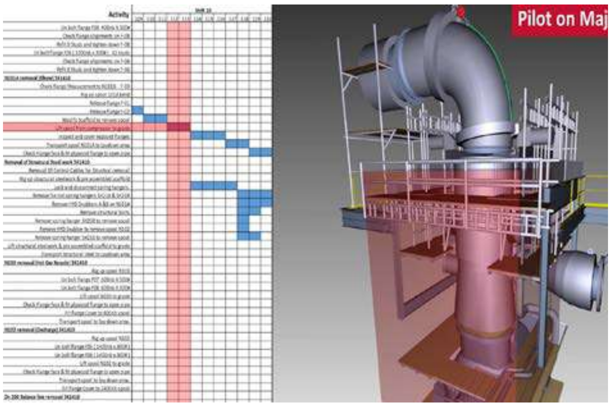

Figure 7: Screenshot of 4D BIM Simulation on the Batch Level

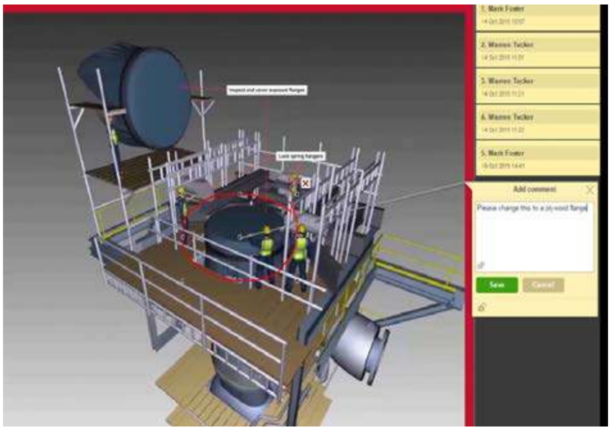

Figure 8: A Cloud BIM Collaboration Platform for Constructability Review

Figure 9 summarises the issues identified at this stage. A total of 104 issues were found by the TAM internal and external teams. These issues were further classified into eight categories, i.e. issues of Crane, Equipment & tools, Safety, Material, Work space, Permit, Activity Sequence, and Work front access. Incorrect activity sequence was the top one issue which accounted for 27% of the total issues. For instance, “This handrail is only installed once the steelwork has been removed”, “The scaffold should be modified first before removing the spool N101A”, “Remove spring hanger SH216 first before removing the spool”. Incorrect permit was the second most serious issues which accounted for 22%. TAM work requires extensive permits for every shift to ensure each work is performed safely. The plant engineering and operation teams contributed significantly on identifying these permit issues. For instance, they found that six activities were lack of appropriate permits, and another seventeen permits were incomplete and needed further development. Sixteen safety issues (i.e. 15%) and thirteen crane operation issues (i.e. 13%) were also detected through the Cloud BIM Collaboration Platform. The other three types of issues are work space (10%), work front access (9%), and equipment & tools (4%), respectively.

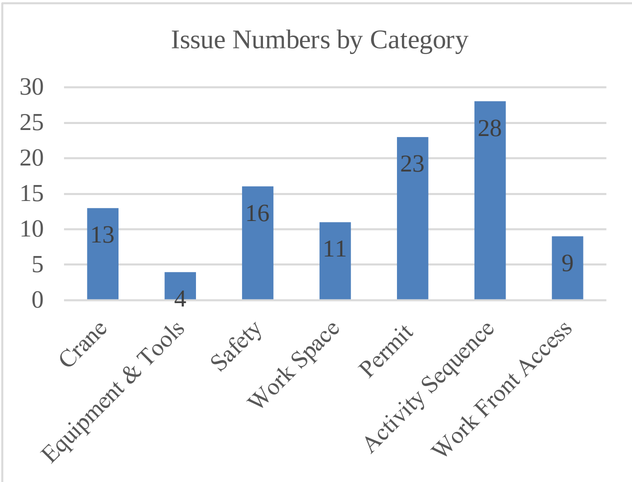

Figure 9: Issue Numbers by Category

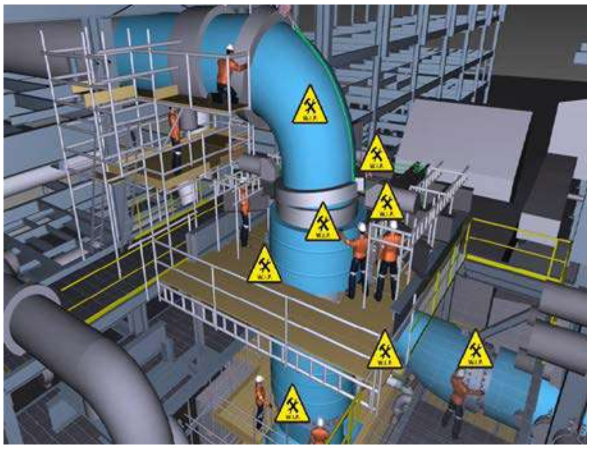

Figure 10: Screenshot of the 4D BIM Simulation on the Activity Level

Figure 10 illustrates the 4D BIM simulation on the activity level which takes account of maintenance work crews. At the peak, there are nearly 1000 people on site which creates a complex logistical task. In order to streamline the construction site work flow, locations and walking paths of each work crew were shown during the simulation, especially during those working periods that contain massive concurrent activities. Rigging plans were also visualised including shackles, turnbuckles, and slings being used.

4 Time and Cost Reduction Analysis

A quantitative analysis of the time and cost reduction is difficult because it should predict what would happen if the issues that detected by 4D BIM simulation are not resolved. Instead of directly calculating each issue effect, a previous equivalent TAM project that conducted two years ago was selected as a benchmark to measure the time and cost savings. The raw execution data of the selected case were extracted from the Document Retrieval Integrated Management System (DRIMS) (i.e. a type of corporate document management system) and SAP (i.e. an enterprise resource planning system).

Figure 11 illustrates the maintenance duration reduction. The left column with red colour indicates the actual duration of the valve replacement, i.e. 14 days. The planning of the current TAM project started from the previous one, and after the first two levels of 4D BIM simulation (i.e. Plant level and System level), the initial expected duration was adjusted to 13.5 days. Before the field execution, the TAM team set the project target duration to 12 days based on the results of the 4D BIM simulation on Batch and Activity levels. According to the final project report, this project was completed within 11.6 days.

Based on a rough comparison, the field execution work was finished 0.4 day (i.e. 9.6 hours) before the target schedule and 1.9 days ahead of the initial plan. When compared with the previous equivalent one, a total of 2.4 days were saved. Excellent results were also achieved on the health and safety front, such as: 50% reduction in minor first aid cases, no environmental incidents, no medical treatment incidents, and no high potential incidents.

For cost reduction analysis, considering the inflation and the changing prices for instruments procurement and equipment leasing, it is meaningless to compare the actual cost of the two TAM projects. Figure 12 illustrates the project cost estimated at three different stages: initial stage, pre-execution stage, and completion stage, respectively. The initial budget (i.e. AUD$ 24.1 million) was estimated based on the initial work list and estimated duration. The budget before field execution (i.e. AUD$20 million) was calculated based on the final confirmed construction schedule and resource plans. The actual cost for this TAM project was AUD$ 19 million according to the project completion report.

A total of AUD$ 4.1 million was saved when comparing the actual cost with the initial budget. Specifically, AUD$ 4.1 million cost reduction was achieved during the project planning phase while another AUD$ 1 million was achieved during the project execution phase.

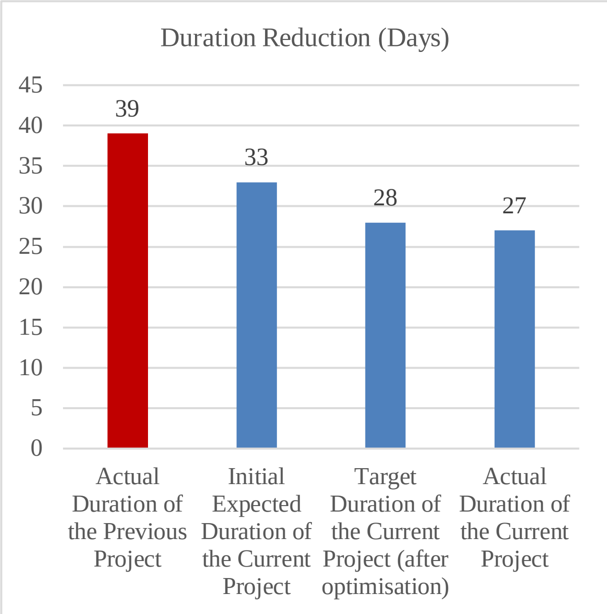

Figure 11: Duration reduction

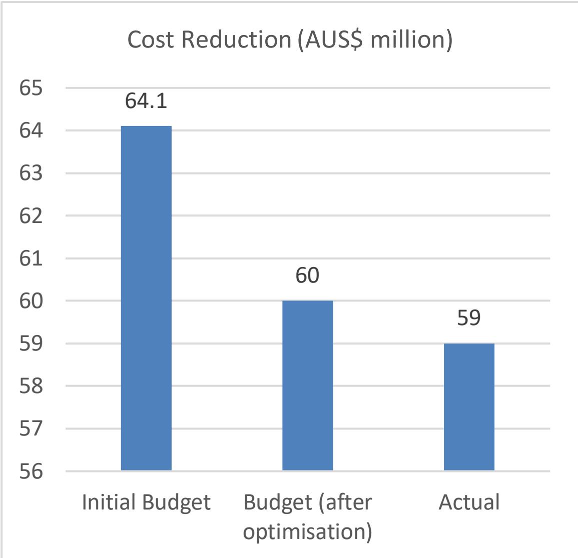

Figure 12: Cost reduction

5 Conclusions and Future Works

In this paper, a 4D BIM framework is developed for improving TAM process efficiency, which encompasses four different levels of BIM simulation, i.e. Plant, System, Batch, and Activity level. A real TAM project was selected to evaluate the effectiveness and efficiency of the proposed 4D BIM approach in waste elimination and time and cost reduction. The results show that: (1) the TAM project starts on time and finishes 0.4 day (i.e. 9.6 hours) before the target schedule and 2.4 days ahead of the original schedule; and (2) A total of AUD$ 4.1 million has been saved when comparing the actual cost with the initial budget. In the future, automated progress monitoring of planned activities will be investigated. Advanced technologies such as Ultra-Wideband [19], Photogrammetry [20], Laser Scanning [21], and Internet of Things [22] will be reviewed and tested in a plant turnaround environment for site maintenance activity tracking.

Abstract

The number of cities that are implementing sustainable transportation programs has been recently on the rise. Reliance in large urban areas is on the use of public transportation systems such as busses and rapid transit lines (heavy rail) to act as the main mode of public transport in multi-modal transport systems. It should be noted however that operations of rapid transit lines are associated with heavy noise levels. When it comes to addressing the issue of noise pollution from rail lines, it is important to consider the design factors that affect the levels of noise disruption impacting the surrounding population. An important design factor that plays a significant role in determining the overall noise levels that propagate from the rail lines to the noise-sensitive residential zones is the choice of the rail route. As a result, careful consideration of the location of the stops of a rapid transit line is an important issue to address when attempting to curtail the noise pollution of rail operations. This paper proposes a novel mathematical formulation, based on a Binary Integer Programming model, to optimise the locations of stops for a typical rail line construction project. The focus in the proposed model is on minimising the total noise pollution levels associated with the operations of the transit line, given that noise is an important social and environmental factor that impacts the sustainability of the project. A case study is presented at the end to demonstrate the applicability of the proposed model.

Station Location Optimisation; Noise Pollution; Sustainable Rail Design, Binary Integer Programming; Location Theory

1 Introduction

Sustainable practice in the construction industry is based on balancing social, environmental and economic aspects when designing and planning projects. Designing sustainable infrastructure projects requires careful consideration of the resulting environmental impacts associated with the operation of the project [1]. One of the nuisances reported during and after infrastructure construction works is that related to noise pollution. The issue of noise pollution during the construction process can be handled through measures that target the noise source (i.e. noise dampeners installed at machines), noise receivers (noise insulation in wall buildings, or noise transmittance path (use of noise barriers around the construction site [2–4]. Once the rail line starts to operate then the issue of noise is harder to handle; as a result, enhanced decision making at the initial design stage requires a better understanding of factors that impact noise propagation when the rail line is operated.

Noise from rail tracks is a result of many elements, the most prominent of which is the impact between the wheels of the rolling stock and rough rail surface [5]. Other causes of noise from a rail system are the consequence of sharp turns of the vehicle due to large rail track [6], or the crossing of a vehicle over dipped weld within the track [2]. It is also important to note that there are certain factors which can exacerbate noise levels, and which need to be accounted for when assessing noise generated by a railway system; this includes the turbulent boundary created around the train and the Doppler Effect induced by high speed trains passing a particular point [7].

Noise pollution resulting from rail line operations is reported to be associated with a number of health ailments. Exposure to rail noise during the night leads to sleep disturbances [8]. This in turn creates stress, triggering the sympathetic and endocrine system, and causing a change to blood pressure and heart rate in individuals [9]. There are studies that indicate a link between sleep quality depreciation and railway noise [10]. Others report that lower cognitive performance results following nocturnal railway noise exposure [11]. The cardiovascular system in sleeping subjects was also observed to be impacted by nocturnal railway noise [12]. In some instances, when compared to well documented noise from highways, annoyance of railway noise was found to be similar if not worse [13]. What the majority of studies agree on is the fact that noise disturbance from rail lines is present and requires practical regulatory policies for it to be tackled [3]. Factors that play into the perception of noise are wide and varied; some are even due to socio-cultural traits of a particular region [14]. An imperative factor discussed by [15] that is a strong determinant of noise annoyance reception is the distance between the receiving end to the railways. In addition, train timetable and schedule are thought to have a direct association on the level of noise generated from the rail lines [16]. Even though there are various studies that examine the location of rail stations in the literature [17] and its impact on land value [18,19], their focus has not been on minimising noise pollution from rails when it comes to the location of the stations.

It is thus essential to target more effective measures when addressing the issue of noise pollution of rail lines during the initial design phase. This paper attempts to achieve this through introducing a novel mathematical optimisation model for locating stations of a rapid transit line such that noise pollution is minimised.

2 Problem Description

The problem of locating a transit line or network is concerned with maximising riders' accessibility while minimising rail line construction costs at the same time [20–23]. Accessibility of a transit line is modelled in two ways: in one of the approaches stations are positioned in a manner that ensures maximal service coverage to demand points surrounding the assigned transport corridor. This problem is known in the literature as the maximal coverage shortest path problem [24]. Another approach is to locate the stations so that total travel distance between demand regions and the nearest station located on a line is minimised; in this case the problem is known as the median shortest path problem [25].

For the majority of the work available in the literature the focus has been mainly on objective functions that concern the system's patrons or operators. Little attention has been directed towards modelling the impact that the design of the proposed rail line is likely to cause on the neighboring population in terms of noise.

The problem examined in this paper is concerned with the location of the stations forming the rapid transit line. In order to find optimal locations for the network line, the problem is formulated to minimise the total noise levels reaching receiver points; these receiver points represent surrounding residential zones.

2.1 Measuring Noise Levels in Rail Lines

To assess the effect of rail noise exposure at residential buildings surrounding the rail system, some studies adopt the equivalent noise level assessed over a 24 hour period measure; this is calculated from the sound exposure levels and number of different train types [13]. It is, however, reported in the guidelines published by Environmental Protection Agency (EPA) in Australia that the continuous equivalent noise level (L_{Aeq}) measured over a certain period corresponding to daytime, night-time or the noisiest one hour duration, should be deployed [26].

When it comes to noise estimation from rail-lines, a number of steps needs to be followed. These are based on guidelines published by both EPA and the Department of Transportation [26,27]. The steps are summarised as follows. First, the railway needs to be divided into segments. For each segment, the number of receiver points that will be impacted by the noise need to be mapped. The angle of view of the receivers with respect to each track segment is then calculated.

The second step involves calculating the reference noise level (SEL) for each train that will be operating on tracks. The baseline SEL at a reference of 25m from the train (i.e noise source) is obtained from train manufactures. The baseline SEL will then need to be corrected to account for the number of vehicles in the train. A track correction also needs to be applied to account for the type of tracks and the associated ballast laid.

The third step involves accounting for the distance propagation impact. This will be determined based on the location of the reception point with respect to the tracks. The height of the track below/above the reception point needs to be considered. Ground propagation and air absorption are corrected for. The presence of any barriers around the tracks, separating the track line from the reception points, will also need to be considered in the distance propagation measure. The angle of view from the tracks with respect to the receiver points is also considered in the noise propagation calculations.

The fourth step involves consideration of noise reflection effects due to façade of the reception points (assuming the receiver is a building).

In the fifth step, the SEL is converted into the equivalent continuous noise measure $L_{Aeq,T}$ over the duration of the assessment ($T = 6$ hours usually for nighttime and T = 18 hours for daytime) using the following equations, **Eq. (1) – Eq. (2)**:

$$L_{Aeq,6} = SEL + 10\log_{10} Q_{night} \quad (1)$$

$$L_{Aeq,18h} = SEL - 48.1\log_{10} Q_{day} \quad (2)$$

where Q_{night} and Q_{night} represent the total number of trains predicted to pass the receiving points during the night and day time respectively. The unit of measurement for the equivalent noise level is the A-weighted decibel (dB(A)).

2.2 Mathematical Model

The mathematical optimisation model proposed is a Binary Integer Programming (BIP) model that attempts to find the most suitable rail line configurations associated with the least noise pollution, as measured at the surrounding population. The objective function and constraints formulated to address the problem are described next

2.2.1 Notation

The notation adopted in the proposed model is presented in **Table 1.**

Table 1 Notation Set

Notation	Description
O	Set of potential origin stations
D	Set of potential destination stations
$k \in O \cup D \subseteq K$	Set of all potential stations
$r \in R$	Set of noise-sensitive receivers
P	Maximum number of stations on a transit line
N_{kr}	Noise levels resulting at receiver point $r \in R$ due to train passing potential station $k \in K$
z_k	Binary variable, which equals 1 if station k is selected, and 0 otherwise
x_{ik}	Binary variable, which equals 1 if potential stations i and k are connected, and zero otherwise

2.2.2 Objective function

The objective function captures the maximum noise disruption that is caused at each potential station location and is formulated as shown in **Eq. (3)**:

$$\text{minimise} \quad \sum_{k \in K} \max_{r \in R}\{N_{kr}\} z_k \quad (3)$$

In particular, the final equivalent continuous noise measure is mapped onto the noise parameter N_{kr} (i.e. $L_{Aeq,6} \rightarrow N_{kr}$).

2.2.3 Constraint Type 1: Origin & Destination Stations

The start and end of the transit line is determined by the choice of the origin and destination stations. **Eq. (4)** is defined to locate an origin station, while **Eq. (5)** defines the location of a destination station

$$\sum_{k \in O} z_k = 1 \quad (4)$$

$$\sum_{k \in D} z_k = 1 \quad (5)$$

2.2.4 Constraint Type 2: Connectivity

There needs to be a constraint defined to ensure that all selected stations are connected. Two types of equations are formulated: one is for stations that are either the origin or destination station, where these require to be connected to 1 other station. In particular, **Eq. (6)** is formulated for connecting the chosen origin station with another interim station on the line. **Eq. (7)** on the other hand is defined to link the chosen destination stations with other interim stations on the line.

The second type of connectivity constraints is associated with interim stations (not origin or destination stations), given that these require to be connected to 2 other stations. This is achieved through **Eq. (8)**

$$x_{ij} = z_i z_j \quad \forall i \in O, \forall j \in K / O \cup D \quad (6)$$

$$x_{ij} = z_i z_j \quad \forall i \in K / O \cup D, \forall j \in D \quad (7)$$

$$\sum_{i<k} x_{ik} + \sum_{j>k} x_{kj} = 2z_k \quad \forall k \in K \setminus O \cup D \tag{8}$$

2.2.5 Constraint Type 3: Sub-tour elimination constraints

Only a single continuous tour, representing the route of the rapid transit, is to be produced as the final solution, as opposed to two or more disjoint sub-tours. The algorithm is prevented from creating sub-tours by introducing **Eq. (9)** in the model:

$$\sum_{j \in K} \sum_{\substack{i \in K \\ i \neq j}} x_{ij} \leq |S| - 1 \tag{9}$$

2.2.6 Domain of variables

The domain of the variables used in the model is given in **Eq. (10) – Eq. (11)**:

$$z_i \in \{0,1\} \quad \forall i \in K \tag{10}$$

$$x_{ij} \in \{0,1\} \quad \forall i, j \in K : i < j \tag{11}$$

3 Case Study and Discussion

In order to display the applicability of the model, a realistic case study is examined. The case study, a simplified representation of a future rail project to take place in Doha, Qatar, comprises a single track railway. For the purpose of this study, only 1 type of train is assumed to traverse the rails. The section of the train to be designed is assumed to be a straight line segment. Average speed of the train across the rail way system is set at 150 km/h. A total of 179 train passes are assumed during the day, while the number drops to 17 passes during the night. The area between the track and the reception point is assumed to be flat. The region under consideration, with residential areas, and potential station locations, is highlighted in **Fig. 1**. In particular, the potential station locations for the origin and destination nodes of the rapid transit line to be constructed are highlighted by the circulated zones in **Fig. 1**. **Table 2** displays the noise analysis conducted at each residential node.

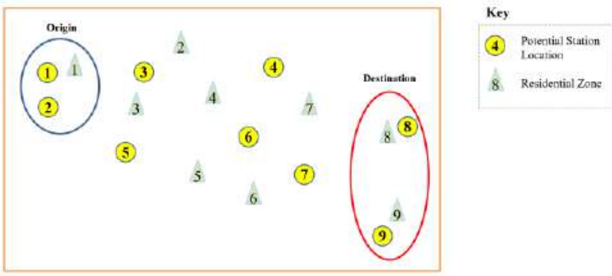

Fig. 1 Case study representation

The model is programmed in GAMS [28] and solved using CPLEX [29], on a desktop computer running on Microsoft Windows 10 operating system, with Intel core i7 processor at 3.4 GHz and 16GB of RAM. The computation time was recorded at 73 seconds, for the algorithm to reach an optimal solution with 0% optimality gap. The solution produced is given as follows:

2 → 5 →6 →7→9

where the origin of the rapid transit line starts at Node 2, and the destination node is at Node 9. The average noise pollution of the overall proposed rail line route is assessed to be around 68 dB (A).

Table 2 Noise level in dB (A) at each station

Residential Nodes $r \in R$	$(N_{1r}, \cdots, N_{9r})$
1	(91,83,63,43,51,47,34,20,20)
2	(64,62,91,80,72,71,55,42,20)
3	(71,72,93,73,101,61,53,42,20)
4	(51,53,73,84,65,96,78,61,45)
5	(40,56,61,43,82,94,81,64,53)
6	(31,43,45,52,65,82,92,66,51)
7	(23,32,51,74,54,81,91,64,55)
8	(20,20,32,53,45,55,71,101,83)
9	(20,20,33,41,43,62,81,92,103)

The solution yielded by the proposed model is contrasted with an approach that is based on selecting the route with the least overall cost; this can be achieved by minimising the travel distance and number of stations respectively. The results are displayed in **Table 3**. It is clear that some sort of trade-off exists between the two contrasted models. The mimimum noise model produces a solution that is 22% less noise intensive than that of the minimum construction cost model. The cost of construction associated with the minimum cost model is however 39% higher. It is important to note that this is only case specific and there can be instances where the solution that minimises the noise pollution due to the operations of the rail line is also the one that minimises the construction cost. What the test highlights however is the need to consider the trade-off between other factors impacting the design of rapid transit lines in urban regions.

Table 3 Noise level in dB (A) at each station

Model	Average Noise Level (dB(A))	Monetary Cost ($ AUD)
Minimum Noise Model	68	123,909
Minimum Construction Cost Model	87	75,444

4 Conclusion

In this study a novel mathematical optimisation model was presented, based on a binary integer programming approach, to minimise the noise pollution associated with the operation of an urban rapid transit line. The model optimises the locations of stations making up the rail line, through forming a continuous link between the selected stations, while minimising the noise levels measured at receiving points along the track. The proposed model can therefore act as a decision support tool to rail line designers at the initial planning phases of the project in order to reflect considerations for the sustainability of the rail track.

In order to test the applicability of the model, a realistic case example was examined. In addition, the solution yielded by the proposed model was also contrasted against one that was based on minimising the construction cost of the rail line. Results revealed that a drop of 22% can be achieved if noise is optimised, as opposed to construction cost. The solution produced by the cost minimisation model however yielded a track that was 39% cheaper. A trade-off was therefore realized between the two models for the case study considered.

The proposed model is formulated for new rail lines proposed in an urban region. With slight modification, the model can also be adopted to account for incorporation of one or more stations to an existing line. Future work will be focusing on developing a multi-objective optimisation model that accounts for social, environmental and economic aspects of rail line route design.

Abstract –

In this study, we investigated the effects of immersive vs. non-immersive virtual environment (VE) platforms (i.e., head mounted display (HMD) vs. laptop PC) on compliance with pro-environmental behaviors. We performed a detailed analysis of the effects of these VE platforms on other variables, such as task performance, sense of presence, and simulator sickness. We also explored the factors, such as participants' gender and immersive tendency that could have influenced the effects of VE platforms. In a between subject design, 100 participants were randomly assigned to interact with either a desktop or an HMD. The results showed no significant effects of VE platforms on compliance with pro-environmental requests, task performance, and sense of presence. However, the HMD elicited higher simulator sickness compared to the desktop display. In addition, we demonstrated there was a strong relationship between participants' immersive tendency and the presence that they experienced. Our findings provide empirical evidence capable of helping researchers select an appropriate VE platform when investigating the influence of behavioral interventions aim to promote sustainable behaviors.

Keywords –

Virtual environments; pro-environmental behavior; immersion; presence; simulator sickness; compliance

1 Introduction

To study occupant behavior in general and occupants' interactions with buildings, many studies used immersive virtual environments to collect occupant-related data [1-3]. For example, Heydarian et al. used immersive virtual environments to collect data on occupants' lighting-related behaviors and preference. They used the data to investigate the design alternatives aiming to meet occupants lighting preferences while increasing building's energy efficiency [2]. Saeidi et al. investigated the effectiveness of IVEs to be used as a tool to collect data on occupant behavior. They suggested that IVEs can be more valuable tools if they are used during the design stage of the building to define the main drivers of occupants' lighting behaviors in buildings [4]. Virtual environments (VEs) are also increasingly used for scientifically studying the effects of communication in different persuasive contexts (e.g., health, advertising, and education) on human behavior by enhancing the experimental designs in a controlled manner [5-7]. However, the VE systems that have been used across different studies vary in their dimensions specifically in their level of immersion, the degree to which a system can "deliver an extensive, inclusive, surrounding, and vivid illusion of virtual environment to a user [8]." Immersion is one of the main factors required to enable the users to perceive all aspects of the space to create lifelike impression [9]. Choice of an appropriate system for a specific application impacts the effectiveness of VEs [10]. VEs are mostly characterized based on their platforms (e.g., desktop/laptop PC, head mounted display (HMD), etc.). However, there is no guideline leading us to the selection of an appropriate platform. One of the main considerations in the selection of appropriate VE platform is the level of immersion, which is often linked to the sense of presence and simulator sickness (motion sickness experienced during an interaction with a VE) experienced by users of those environments. "Presence is defined as the subjective experience of being in one place or environment, even when one is physically situated in another [11]."

Studies have used different VE platforms varying from a simple desktop/laptop computer with standard monitors to more immersive environments like HMD, in which users wear the computer display on their head to be immersed, and later to a fully immersive environment, like Cave Automatic Virtual Environment (CAVE), in which users move around in a room where they are completely surrounded with computer projected displays.

Each platform has different characteristics and user interfaces. Selection of the VE platform could impact the behavioral responses of participants engaging with the VEs [5]. However, it is relatively unclear whether the level of immersion, sense of presence, and simulator sickness experienced through different VE platforms influence user performance and behavior. Often, the effects of VE platforms on performance and behavior appear to be overshadowed by other factors, such as task context and user characteristics (e.g., age, gender, and previous experience with VEs) [12,13].

Several studies have been completed to investigate this issue and compared various platforms with each other in different contexts. In this study, we investigated the influence of VE platforms on measuring compliance with pro-environmental requests. We compared a non-immersive VE (i.e., laptop PC) with an immersive VE platform (i.e., HMD). To explore the factors that could influence the effects of VE platforms, we conducted an experiment, in which we investigated the effects of sense of presence and simulator sickness on user experience while interacting with different VE platforms: a laptop computer with a standard monitor and a laptop computer with a head mounted display system (laptop PC vs. HMD) and the effects of these factors on compliance with pro-environmental requests and task performance. In addition, we examined other factors, including users' gender, immersive tendency, and previous experience with VEs that could impact the effects of VE platforms on compliance. Immersive tendency refers to individual differences in the proclivity to become immersed in a simulation and previous experience with VE, like playing video games, can influence the immersive tendency [11].

2 Background

A common assumption about virtual environments is that increased immersion is associated with higher experienced presence and it results in enhanced task performance and behavior change. However, research shows that there are conflicting views on whether the level of immersion impacts the user's experienced presence, performance, and behavior. For example, Gorini et al. [14] tested the effects of a VE platform (immersive vs. non-immersive) and narrative context (emotional vs. non-emotional) on the users' experienced presence. Their results suggested that both immersion and context have a significant role in generating an effective VR experience as they contribute to increasing the feeling of presence from different aspects. In another study, Grassi et al. [15] investigated the effects of different platforms (mobile phone, desktop PC, and HMD) as well as emotional context (amusement, sadness, fear, and neutral) on the sense of presence and the results showed that platform type did not impact the sense of presence while the emotional context did impact the sense of presence.

User characteristics (e.g., gender, immersive tendency, and previous experience with VEs) can also influence sense of presence. Sense of presence and performance in VEs is likely to increase when user is familiar with the VEs and has higher immersive tendency. However, other studies found no relationship between sense of presence and immersive tendency and VE experience. A study conducted by Nowak et al. [16], investigating causes and consequences of presence in the context of violent video games, showed that user's characteristics (previous game experience and gender) can predict presence. In another study, Schuemie et al. [17] exposed participants to a virtual environment for phobia treatment and they found no correlation between sense of presence and gender or experience with VEs. These findings suggest that a user's sense of presence in a VE might not be influenced only by the characteristics of the VR platform; but also by context of the task performed and the characteristics of the individual user (e.g., gender and previous experience with VEs) [18].

A review of the relationship between the level of immersion and performance in VEs revealed that a positive relationship exists between the level of immersion and behavioral responses and performance. For example, Kim et al. [5] investigated whether different VE platforms (desktop PC, HMD, and CAVE) induce different patterns of emotional responses in contexts including high- and low-stress tasks. The results of their study suggested that immersive virtual environments (either an HMD or fully immersive VE platform) were more effective than a standard desktop PC in eliciting emotional arousal.

Simulator sickness might also influence user's experience of VEs. For example, Kim et al. [5] investigated the effects of different VE platforms (desktop, HMD, and CAVE) on simulator sickness while completing stressful tasks. The results showed that HMD induced significantly more simulator sickness than the CAVE and the desktop.

In summary, the level of immersion in different VE platforms could influence the sense of presence and simulator sickness symptoms and might also impact user behavior and performance. However, these effects might be mediated by the context of the task and user characteristics.

Previous studies mostly focused on performance measures in contexts that involve navigation or visualization and behavioral responses in psychological settings. Less has been done to investigate behavioral responses in social contexts, in which people interact with each other to influence each other's behaviors and attitudes. In this study, we investigated whether different VE platforms with different levels of immersion elicit different behavioral responses to persuasive pro-environmental requests.

3 Present study

We conducted an experiment to examine the compliance with persuasive pro-environmental requests and performance, using an office related task across two representative VE platforms, which varied in their level of immersion but used the same technology to interact with the environment (an Xbox controller). As the VE platform with lower level of immersion, we used a standard laptop. As the VE platform with higher level of immersion, we used Oculus DK2 Head-Mounted Display to provide an immersive environment, in which a positional tracker would track the participants' head and neck movements (Figure 1). The virtual environment represented a single occupancy office space and was identical in both the desktop and HMD conditions.

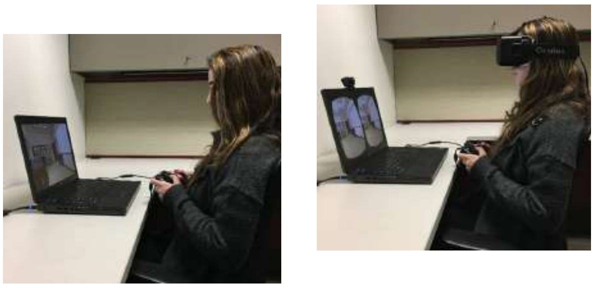

Figure 1 – Different VE platforms: laptop display (left); HMD (right)

We investigated the following dependent variables: (a) compliance with the pro-environmental request, (b) task performance, (c) presence, and (d) simulator sickness. Considering that research shows contradictory findings regarding the influence of the level of immersion as a characteristic of VE platforms on the sense of presence, behavior change, and performance, and these effects have not been investigated before in social contexts that aim to influence behavior, we could not hypothesize whether different VE platforms would generate different levels of presence or influence the compliance with the persuasive pro-environmental requests or task performance in the context of our study. Therefore, we investigated the following questions: (1) Do different VE platforms (desktop vs. HMD) influence the compliance with pro-environmental requests? (2) Do different VE platforms (desktop vs. HMD) influence the presence experienced by the participants during the experiment? (3) Do different VE platforms (desktop vs. HMD) influence the performance on the assigned task (reading a passage and answering some questions about it)? Considering that user characteristics can be another factor that influence the sense of presence, we also investigated the following questions: (4) Do different VE platforms influence the simulator sickness participants experienced while interacting with the environment? and 5) Do participants' characteristics (immersive tendency, previous VE experience, and gender) influence the presence that they experienced during the experiment? We also investigated the interaction between the sense of presence and effects of VE platform type on compliance with pro-environmental behaviors, as well as the task performance. The same for the interaction between simulator sickness and effects of VE platform type on compliance with the pro-environmental behavior and task performance.

3.1 Design

Pro-environmental requests included contents requesting participants to change the light level and temperature setpoint using the principles of reciprocation, which is a social influence method. A female avatar, representing the building manager, delivered the request since the adopted social influence method and delivery style were found to be among the most effective ones [19,20]. Participants were randomly assigned to one of the two experimental groups: laptop group, in which participants interacted with VE using a standard laptop without an HMD, and the HMD group, in which participants were immersed in a VE using an HMD. The only difference between these two groups was the platforms used for interacting with the VE.

3.2 Virtual Office Environment

The model was first generated in Revit© and then exported to 3D Max© to add materials, furniture, texture, lighting, reflection, and shadows in order to make it look more photo realistic. Then it was imported to Unity© game engine to program interactive options, such as opening/closing windows and turning on/off lights (Figure 2).

Figure 2 – Virtual Office

3.3 Procedure

As the first step of the experiment, participants were asked to complete a questionnaire covering general questions, including their age, gender, immersive tendency and previous experience with VE, and simulator sickness symptoms.

The Immersive Tendency Questionnaire (ITQ) was developed by Witmer and Singer [11] to measure the tendency or capabilities of individuals to be involved or immersed in a virtual environment. Simulator Sickness Questionnaire (SSQ) was developed by Kennedy et al [21] to measure the level of simulator sickness symptoms in a VE system. Prior to the main VE task, participants underwent training to become familiar with the virtual environments in which we showed them how to work with VE platforms and different settings in the virtual environment.

After the training session, we explained the experiment procedure to the participants. The procedure was as following: participants had to sit on a chair in an office and perform a very common office related activity: reading a document (two passages in this study). They were asked to read the passages very carefully as they had to answer comprehension questions about them. During the experiment, a female avatar representing the building manager would communicate with them (Figure 3).

Figure 3 – Pro-environmental requests delivered to the participant in the VE

Participants were told to pay attention to the requests carefully, as they would be asked what the requests were at the end of the experiment. However, it was noted that it was completely up to the participants whether to comply or not with the requests, and that they had to act as they would in their own offices. While participants were reading the passages, a request was delivered to them (30 seconds after starting the task). Two different pro-environmental requests were delivered to each participant: (1) “if I open the blinds for you to have natural light, would you please dim or turn off the artificial lights?”; and (2) “if I open the window for you to have a breeze and fresh air, would you please increase the temperature setting on the thermostat?”

The default lighting setting in the office room was the artificial lights on while the blind was closed and the default temperature setpoint was 73˚F. If the participants chose to comply with the pro-environmental request, they had to go to the light switch and lower the level of lights or turn them off while the blind was open. Likewise, if the participants chose to comply with the other pro-environmental request, they had to go to thermostat and increase the temperature setpoint. We observed the participants’ compliance with the requests in the assigned conditions (laptop vs. HMD). In addition, we assessed the participants’ performance by measuring the time that they spent on reading each passage and their reading comprehension (number of correctly answered questions).

After completing the virtual part of the experiment, the participants completed the post-experiment questionnaires. The first questionnaire assessed how participant’s values and attitudes resembled the environmentalists’ values and attitudes. The second questionnaire assessed the participants’ environmental setpoint preferences: preferences for lighting sources (daylighting vs. artificial lighting), lighting levels (amount of lighting), and temperature setpoint. As the last set of questionnaires, the participants completed two questionnaires investigating their sense of presence in the VEs: the Witmer and Singer Presence Questionnaire (PQ) [11] which measures the degree of presence and engagement that individuals experience in a virtual environment and the Slater, Usoh and Steed Presence Questionnaire [22], which focused mainly on psychological and behavioral response to immersion and involvement. Finally, participants completed the Simulator Sickness Questionnaire (SSQ). The participants had also completed the SSQ in the pre-experiment session so that their pre- and post-test scores could be compared to identify simulator sickness caused by interacting with VEs. The entire experiment took about 40 minutes.

4 Results

The results presented here are based on 100 participants (66 females and 34 males) recruited through the USC psychology subject pool who received course credits for their participation.

In order to analyze the data, we compared the compliance and other dependent measures including presence, task performance, and simulator sickness between the two types of VE platforms. We also investigated the effects of other factors, such as participants’ characteristics (i.e., gender and immersive tendency), on the dependent measures.

To examine the effect of the VE platforms on compliance with pro-environmental requests, we conducted an independent sample T-test (laptop PC vs. HMD) on the number of times participants chose to comply with the pro-environmental requests. There were no significant differences in the number of times that participants complied with the request in the laptop PC ($M = 1.30$, $SD = .81$) and HMD ($M = 1.20$, $SD = .83$)

conditions: t(98) = .61 , p = .54. These results suggested that the level of immersion does not influence the participants' decision regarding compliance with the pro-environmental request. We also checked the possible factors that might have impacted the compliance including participants' preferred source of lighting, preferred lighting level and temperature setpoint, and identification with environmentalists. Using linear regression analysis, the results showed no main effects of these factors on compliance: preferred source of lighting (β = -.05, p = .61), preferred lighting level (β = -.04, p = .67), preferred temperature setpoint (β= .01, p = .89), and identification with environmentalists (β = -.11, p = .26).

We also investigated the influence of VE platforms on task performance. As a measure of task performance, we computed the average time to read the passages in two different conditions (laptop PC vs. HMD). Using an independent sample T-test, the results showed that there were no significant differences in the average time that the participants spent reading the passages in the laptop PC (M = 57.97, SD = 15.63) and HMD (M = 60.04, SD = 17.86) conditions: t(98) = .53 , p = .25. In addition, we measured participants' reading comprehension by computing the number of correct answers to the questions that were asked about the passages. The results showed no significant difference in participants' reading comprehension in the laptop PC (M = 7.76, SD = 1.33) and HMD (M = 7.58, SD = 1.37) conditions: t(98) = .81, p = .51, suggesting that participants performed in the same way in both conditions.

We examined the sense of presence using the two presence questionnaires. Investigating the effects of VE platforms on presence using the questionnaire developed by Witmer and Singer, conducting independent sample T-test, the results showed no significant difference in the sense of presence experienced in the laptop PC (M = 89.10, SD = 15.25) and HMD (M = 91.90, SD = 18.22) conditions: t(98) = -.83 , p = .41. In analyzing the data from the Slater-Usoh- Steed Presence Questionnaire, using linear regression analysis, the results showed no significant difference in sense of presence experienced by different VE platforms: β= .14, p = .15.

Next, we investigated the interaction between the VE platforms and sense of presence (using the Witmer and Singer's questionnaire) by linear regression analysis. The results showed no interaction between the laptop PC (0) vs. HMD (1) dummy-coded variable and sense of presence measuring compliance (β = -.40, p = .56) and performance, both average time completion (β = .21, p = .75) and reading comprehension (β = .18, p = .79). The same results were observed for Slater-Usoh- Steed Presence Questionnaire: no interaction between VE platform and sense of presence measuring compliance (β = -.51, p = .15) and performance, both average time completion (β= .24, p = .51) and reading comprehension (β= -.29, p = .41).

Results of a mixed ANOVA on participants' simulator sickness symptoms before and after exposure to VE as well as within subjects effect and platform type and between subjects effects revealed significant interaction effects for simulator sickness (pre vs. post participation) and VE platform type (F(1, 98) = 8.24, p = .005). Accordingly, we conducted independent samples T-tests to examine the effect of VE platform type on participants' level of simulator sickness both before and after the experiment. The results showed no significant differences in the participants' level of simulator sickness before the experiment in both laptop PC (M = 154.32, SD =149.63) and HMD (M = 166.81, SD = 187.44) conditions: t(98) = -.37 , p = .71. However, there was a significant difference when comparing the participants' levels of simulator sickness after the experiment, such that participants experienced greater motion sickness in the HMD condition (M = 1073.89, SD = 276.56) than the laptop PC condition (M = 974.76, SD =198.59), t(98) = -2.06 , p = .04. We also investigated the interaction effects of VE platform type and simulator sickness on compliance and performance. The results of analysis showed that the interaction of VE platform type and simulator sickness did not have any significant effects on compliance with pro-environmental requests (β = -.12, p = .81) and performance, both average reading time (β = -.84, p = .1) and reading comprehension (β = -.29, p = .56).

We used the immersive tendency questionnaire to investigate if participants' characteristics influenced the sense of presence they experienced in VEs. We also tested the two experimental groups to ensure that there was not failure of random assignment (i.e., there were no significant differences between conditions in participants' levels of immersive tendency). Using independent sample T-tests, the results showed no significant differences between participants immersive tendency in the laptop PC (M = 67.62, SD = 10.54) and HMD (M = 69.76, SD = 11.40) conditions: t(98) = -.97 , p = .33.

Next, we examined if the participants' immersive tendency influenced the presence they experienced in the VE, as well as their performance and compliance with the pro-environmental requests using linear regression and correlation analyses. We used the presence data collected by the Witmer and Singer's presence questionnaire as this presence questionnaire as well as the immersive tendency questionnaire were both developed by Witmer and Singer. The results showed significant effects of immersive tendency on the sense of presence, meaning that participants with higher level of immersive tendency experienced higher sense of presence (β = .26, p = .01). A person, who is more likely to become immersed in a VE, will experience a greater sense of presence while interacting with a VE. These results suggested that participants, who had the ability to get deeply involved in an activity or a stimulus, such as books or movies showing a tendency to maintain focus on that activity, were more likely to experience higher presence in the virtual environment; participants' tendency to play video games was not an effective factor causing sense of presence.

The effects of immersive tendency on the sense of presence were independent of the platform type and no significant interaction effects were found for platform type and immersive tendency (β = .5, p = .38). No significant effects were found for immersive tendency on compliance with pro-environmental request (β = .09, p = .66) and performance: average time (β = .08, p = .45) and reading comprehension (β = -.06, p = .52). Also no significant effects were found for the interaction of platform type and immersive tendency on the compliance with pro-environmental request (β = -.30, p = .66) and performance, both average time (β = -.53, p = .43) and reading comprehension (β = -.94, p = .16).

In addition, we used regression analyses to examine whether the participants' gender had any effects on compliance, presence, and performance or moderated impacts of VE platforms. There were no interaction effects of gender and VE platforms on compliance, presence, and performance (Table 1).

Table 1 – Gender main effects and interaction effects with VE platforms on compliance, presence, and performance

Dependent Measure	Between Subject Measure	Beta	t
Compliance	Gender (Interaction with platform type)	.20	.32
Presence (Witmer and Singer)		-.20	.33
Presence (Slater-Usoh- Steed)		-.06	.76
Performance (Average Reading Time)		-.01	.97
Performance (Reading Comprehension)		.20	.31

5 Discussion and Conclusions

Overall, the results of this study showed no significant differences in the participants' sense of presence and performance while interacting with two different VE platforms that varied in their level of immersion. In addition, there was no significant difference in participants' compliance rates in the laptop PC and HMD conditions. We also investigated the relationship between the occurrence of simulator sickness symptoms and VE platforms, compliance, and task performance. Results of our study showed HMD-based VE induced a higher level of simulator sickness. These results suggest that studies designed with the aim of minimizing simulator sickness symptoms may take advantage of using a laptop PC over an HMD [5].

We also found no relationship between participants' gender and their sense of presence, behavior and performance. In addition, we found no relationship between participants' immersive tendency and their behavior and performance. On the other hand, the results showed that there was a strong relationship between participants' immersive tendency and the presence they experienced. The participants with higher immersive tendency experienced higher sense of presence, however, these effects were independent of the type of VE platforms. We also found that individuals' tendency to become involved in situations and maintain focus on current activities can predict the presence that they experience in the VE and their previous gaming experience is not an influential factor.

This study provides findings about possible benefits and limitations of using immersive and non-immersive VE systems in a study examining the effectiveness of persuasive requests. However, there are limitations. For example, we only used two kinds of VE platforms. Although a laptop and a HMD are appropriate representations of non-immersive and immersive VE technologies, different types of VE platforms (e.g., fully immersive virtual environments like CAVE) can be addressed in future studies to continue to characterize the effects of these different VE systems on user behaviors. We plan to conduct future studies investigating the advantages and disadvantages of using different VE platforms in research on behavior change replicating and extending the findings using other behavioral contexts in buildings, such as security and comfort. Our study can also guide similar studies by comparing the effectiveness of different VE platforms and by investigating the potential factors that impact the effectiveness of these platforms.

Abstract –

Construction workers are commonly subjected to ergonomic risks due to awkward postures and/or excessive manual material handling. Accurate ergonomic assessment will facilitate ergonomic risk identification and the subsequent mitigation. Traditional assessment methods such as visual observation and on-body sensors rely on subjective judgement and are intrusive in nature. To cope up with the limitations of the existing technologies, a computer vision and smart insole-based joint-level ergonomic workload calculation methodology is proposed for construction workers. Accordingly, this method could provide an objective and detailed ergonomic assessment for various construction tasks. Firstly, construction workers' skeleton data is extracted using a smartphone camera with an advanced deep learning algorithm. Secondly, smart insoles are used to quantify the plantar pressures while the worker performs a construction activity. Finally, the gathered data is fed to an inverse dynamic model in order to calculate the joint torques and workloads. The aforementioned approach was tested with experiments comprising simulations of material handling, plastering and rebar. The results reveal that the developed methodology has the potential to provide detailed and accurate ergonomic assessment. Overall, this research contributes to the knowledge of occupational safety and health in construction management by providing a novel approach to assess the risk factors of work-related musculoskeletal disorders (WMSDs).

Construction worker; Occupational health and safety; Deep learning; Machine learning

1 Introduction

Workplace safety and health is an important issue in construction industry around the globe. One of the main reasons is the highly physical demanding nature of the construction tasks [1]. Repetitive and prolonged working could increase the possibility of fatigue, which in turn could result in decrease in attention and accidents in worst case scenarios [2]. In addition, fatigue might decrease construction workers productivity [3] and develop work-related musculoskeletal disorders (WMSDs) [4]. Considering the significant negative influences of physically demanding workload on construction workers, it is important to provide precise workload assessments for its mitigation. Manual observation is frequently used to estimate construction workers' physical workload based on workers' postures and external loads. However, due to the subjectivity of the observed data and inability to quantify the loads, the assessments appear to be not accurate enough. Additionally, it entails increased requirement of safety management staff on the construction sites. To get more objective and precise quantification of workload, biomechanical measurement devices were introduced to facilitate workload analysis [1]. Although these studies have proven the concept, they are intrusive in nature, requiring multiple sensors to be attached to the body of construction workers. As such, on-body sensors are uncomfortable to wear and could easily instigate irritation.

Considering the limitations of the aforementioned methodologies, this research proposes a blend of computer vision technology and smart insoles for workload assessment of the construction workers. The proposed methodology could provide a novel non-intrusive method to quantify the workload. First, a computer vision-based 3D motion capture algorithm is developed that could model the motion of various body parts while performing construction tasks using a RGB camera. Second, smart insoles equipped with multiple pressure sensors are used to capture workers' plantar pressure distribution. These pressure sensors would register the plantar pressure due to self-weight of the construction workers and other forces while carrying load, operating tools and performing related activities. Together with the 3D joint-model data from the developed motion capture algorithm and pressure data from the insoles, inverse dynamic modelling will be applied to calculate the joint-level torques. Subsequently, these torques will be used to calculate workload and plan ergonomic risks` mitigation strategies.

2 Literature Review

The purpose of this review is to provide an understanding of the previous research in this area as well as providing a rationale for the choice of workload assessment and data collection methods used in the present study. We begin with a review of the definitions and influences of workloads; three workload assessment methods, including self-report, observation and biomechanical analysis, are then reviewed and compared; this is followed by a discussion of the behaviour data collection methods used previously in the construction context.

2.1 Definition of Physical Workload

Workload refers to all of the factors that constitute a challenge which a worker has to surpass in order to perform a task, including physical workload and mental workload [5]. This research focuses on physical workload because: 1) physical workload has been proven to be one of the major risk factors of acute trauma injury and cumulative musculoskeletal disorders [6]; 2) it is more practical to provide a relatively objective and quantitative assessment of physical workload. It should be noted that physical workload can be assessed in two different ways namely biomechanical load and cardiovascular load [7]. Biomechanical load measures the workload as a set of torques applied on a human body resulting from the task which he performs, while cardiovascular workload is defined by the physiological changes in the human body as a response to an external task (e.g. heart rate, breathing frequency, core temperature). Biomechanical workload can be measured with non-intrusive methods such as observation and non-contact sensors (e.g. cameras). Besides, biomechanical load has more clear relation with external load and work postures [8]. Therefore, this research assesses physical workload from the biomechanical perspective.

2.2 Previous Workload Assessment Methods

The self-report-based workload assessment method focuses on workers' subjective ergonomic feelings and self-assessment on physical discomfort. For example, NASA-TLX (Task Load Index) scores workload from six aspects such as mental demand and frustration [9]. Borg RPE scale (Borg Rating of Perceived Exertion Scale) was developed to describe perceived work load [10]. Questionnaires and interviews are the main data collection approaches in these methods, making data collection time- and effort- consuming.

Observation-based methods are another kind of widely-used methods. Many workload assessment methods have been developed based on visual assessment of the work being performed and response of the worker to that work (e.g. work posture, external load, repetitive and duration). These methods include but are not limited to OCRA (Occupational Repetitive Actions, RULA (Rapid Upper Limb Assessment), and REBA (Rapid Entire Body Assessment). Although these methods are easy to use and can provide a rough workload assessment, they are prone to subjectivity and requires dedicated safety personnel. Additionally, these methods focus on different aspects of workload constructions (i.e. some of them do not consider work repetition). As a result, assessing the same workload with different methods may lead to different results [11].

Biomechanical analysis has also been applied in various cases to provide workload assessment. [12] applied biomechanical methods to explore the relation between work posture and workload during insertion of pin connectors. [13] determined low back pain risks with biomechanical analysis. Biomechanical methods have also been successfully applied in construction industries to facilitate determination of work-rest schedule using simulations [14].

Theoretically, biomechanics analysis can be applied to all parts of body while examining any work task [11]. Since biomechanical analysis require precise information of orientation of various body parts and their movements, traditional observation-based methods cannot be used. Traditionally, an integrated system of multiple cameras has been used for this purpose under laboratory conditions. As such, this approach could be used for actual construction sites where deployment of such system is not feasible [15,16]. Accordingly, researchers have adopted various other technologies to bridge this gap which are discussed in the following section.

2.3 Automatic Data Collection Methods for Workload Assessment

Posture data and biomechanical data are the data foundations of biomechanical analysis. This section reviewed and compared current posture and external load data collection methods.

2.3.1 Automatic Posture Data Collection

One of the widely-used motion capture sensor system is inertial measurement unit (IMU). If attached to key joints, IMU sensors are able to capture the location and acceleration of the joints, and the human body motion data can thus be retrieved [17]. The main disadvantage is the intrusiveness. IMU sensors are required to be tied tightly to human body, but from the view of application, workers may reject wearing sensors so tightly. Such sensors are feasible for short-period track but may instigate irritation if used for long-time [18,19].

With the development of computer vision, various video-based methods are proposed to collect worker's posture data. Compared with sensors, cameras are less intrusive and inexpensive. Several previous studies have applied vision-based methods in construction management, for example, RGBD sensors have been used to recognize workers action [20], whereas depth cameras have been used to capture worker joint angles [21]. The study also found that although depth camera is an efficient tool to collect posture data for ergonomic/biomechanical evaluation but is not appropriate for construction sites because it cannot work under direct sunlight and requires the subject to be in near vicinity. Other researchers extracted posture information based on RGB pictures from ordinary cameras. For example, [14] proposed computer vision-based framework to identify construction activities from 2D image sequences. [17] used ordinary cameras to capture worker's posture. However, the major limitation of these methods is that they can only provide 2D postures of construction workers, which cannot support 3D biomechanical analysis of construction workers.

A recent progress in computer vision shed lights on video-based joint level biomechanical assessment. A newly developed computer vision algorithm can estimate 3D human skeleton from 2D video frames, making it possible to collect joint angles just based on videos [22]. By combining the state-of-art computer vision algorithm, this research aims at developing an accurate, real-time, and non-intrusive ergonomic assessment method which is suitable for both indoor and outdoor environments.

2.3.2 Automatic External Load Data Collection

Most of previous methods didn't quantify the external loads and performed ergonomic assessments solely using posture related data. Insole-shaped plantar pressure sensor is an efficient tool to collect external load data, which can quantify the ground reaction forces from both feet non-intrusively [23]. Recently, [24] demonstrated the potential of applying smart insole to collect construction workers' plantar pressure in working status without interfering normal construction activities. Similarly, this research has used smart insoles to continuously collect the ground reaction forces for the calculation of external loads in order to perform biomechanical analysis. By combining computer vision-based posture data and smart insoles-based external workload,

This research provides an automatic workload assessment measurement methodology. Such method could provide relatively accurate and objective workload assessment for construction workers as compared to previously on-site adopted methods, which will help the managers to better understand the ergonomic risks and provide data foundation for ergonomic improvements.

3 Methodology

Figure 1 depicts the flowchart of the proposed construction worker's workload evaluation method. The first row in Figure 1 represents the input data, including anthropology information (age, gender, weight and height), RGB video from smart phone camera and plantar pressure data from plantar-shaped pressure sensors. Then joint capacity was calculated based on joint capacity prediction equation. 3D skeletons consisting of the xyz coordinates of key joints are generated from the RGB video frames based on a computer vision algorithm. External loads are calculated based on plantar data. Next, the 3D skeleton data and the external load data are used to calculate joint torques with biomechanical analysis. Finally, the workload is assessed by comparing the joint torques and joint capacity.

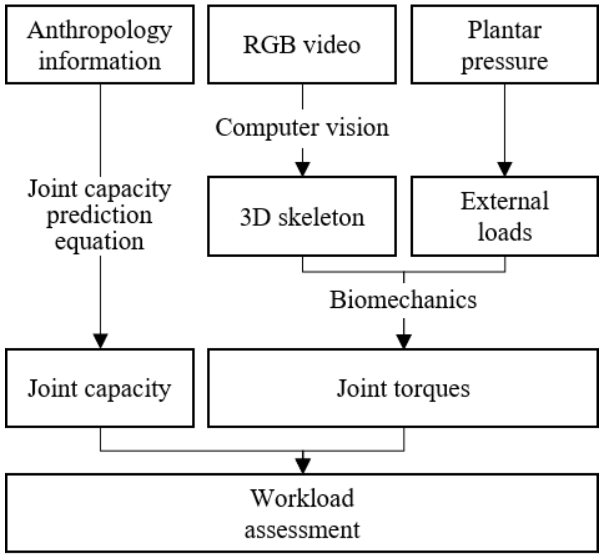

Figure 1. The outline of the automatic workload assessment method

3.1 3D Pose Capture from 3D Images

The workflow of the 3D pose estimator is shown in Figure 2. First, RGB images are collected from construction video clips. A deep learning architecture, named hourglass network (Newell et al., 2016) is trained to estimate the 2D coordinates of joints. Then the joint length ratio constrains are used to estimate the 3D coordinates of the various body joints [22].

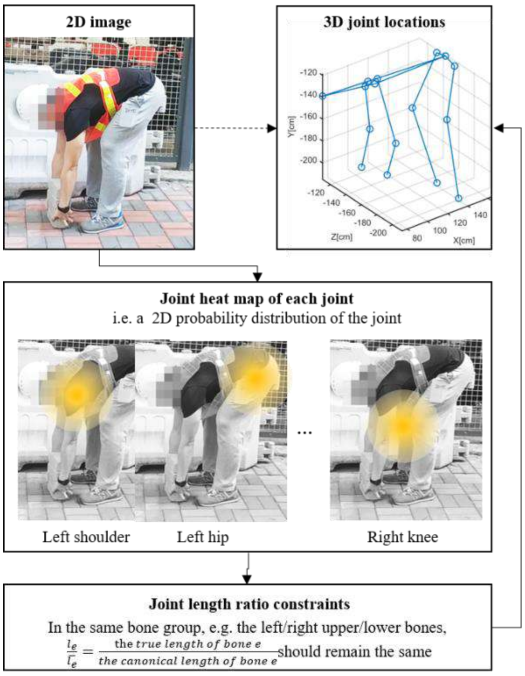

Figure 2. The framework of 3D pose estimator

3.2 Automatic External Load Assessment

A novel insole with plantar pressure sensors, named Moticon, is used to measure the total ground reaction force generated during the work task. This includes the worker's self-weight and external burden, as shown in Figure 3. The insole can be used in virtually any shoe. The commercial available smart insoles can transfer data wirelessly through ANT radio service. The size of external loads can thus be calculated by subtracting worker`s self-weight from the total reaction force generated. It is important to note that for most of the construction tasks, the external loads are usually applied at hands, resulting from the tools or equipment which a worker uses to perform the task.

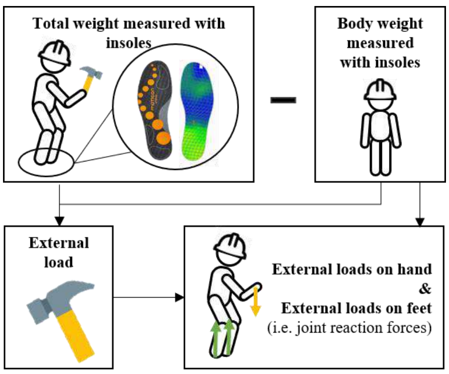

Figure 3. The calculation of external loads with smart insoles

3.3 Biomechanical Analysis

Inspired by biomechanics, this research simplifies the human body as a lever system, and then utilizes mechanics principles to analyse the internal load of each joint. The inputs of inverse dynamic model include: 1) a muscle-skeleton model, which simulates the muscles, tendons and skeletons with a lever system connected with hinges and dampers; 2) a motion file containing the time series of three-dimensional coordinates of the joints in muscle-skeletal model; and 3) external load data including the size and direction of ground reaction forces on both feet and the external loads on both hands. Based on the above data, the inverse dynamics model can be written as Equation (1).

$$M(p)\ddot{\boldsymbol{p}} + \boldsymbol{C}(\dot{\boldsymbol{p}}, \ddot{\boldsymbol{p}}) + \boldsymbol{G}(\boldsymbol{p}) = \boldsymbol{\tau} \tag{1}$$

where $\boldsymbol{p}, \dot{\boldsymbol{p}}, \ddot{\boldsymbol{p}} \in \boldsymbol{R}^N$ are the vectors of joint positions, velocities and accelerations, respectively ; N is the number of the degrees of freedom; $M(p) \in \boldsymbol{R}^{N\times N}$ refers to the mass of different body parts; $\boldsymbol{C}(\boldsymbol{p}, \dot{\boldsymbol{p}}) \in \boldsymbol{R}^N$ is the vector of centrifugal forces; $\boldsymbol{G}(\boldsymbol{p}) \in \boldsymbol{R}^N$ is the vector of gravitation forces; and $\boldsymbol{\tau} \in \boldsymbol{R}^N$ is the vector of generalized forces. 3DSSPP (Michigan University), a human body motion simulation software was used here to solve Eq.1.

3.4 Workload Analysis

The joint capacity in this paper is defined as Maximal isometric strength (MVIC) of each individual. MVIC can predicted with anthropology information including age, gender, weight and height [26]. Then workload equals to the ratio of joint torque to the joint capacity.

4 Experiment

Three main construction activities, including material handling, rebar, and plastering, were conducted during the experiment, as shown in Figure 4. The subjects wore smart insoles to capture the self-weight and any external load. A smart phone camera fixed on a tripod recorded the whole process. At the same time, a set of IMU sensors tied to the subject's main joints also recorded the location of the joints. The IMU sensor has an accuracy of up to 1 degree [27]. Experiments were enacted in both indoor and outdoor environments to demonstrate the feasibility of the proposed method.

Figure 4. The example frames during material handling, plastering and rebar

4.1 Experiment Data

Table 1 provides the raw data. The video data frequency is 25 fps (frames per second). The IMU data frequency is 30 fps. The insole pressure data is 50 fps. The 3D joint coordinates, ground reaction forces, and hand loads were calculated and synchronized.

Table 1 The information of experiment data

Activity		Material handling	Plaster	Rebar	Total
Duration [sec.]		22	19	114	155
Video data	No. of frames	550	475	2853	3878
	No. of joints	16	16	16	-
IMU data	No. of frames	660	570	3424	4654
	No. of joints	13	13	13	-
Insole data	No. of frames	1100	950	5706	7756
	No. of sensors	26	26	26	-

4.1.1 Posture Data

The video clips were first separated to frames at the rate of 1 fps (frame per second). Then the 3D pose estimator was applied on each frame to get the 3D coordinates of each joint. Figure 5 provides an example of the frame during material handling. Given a picture (Figure 5(a)), the 3D posture estimator estimates the 3D coordinate of 16 key joints. Figure 5(b) visualizes the 3D pose estimation results.

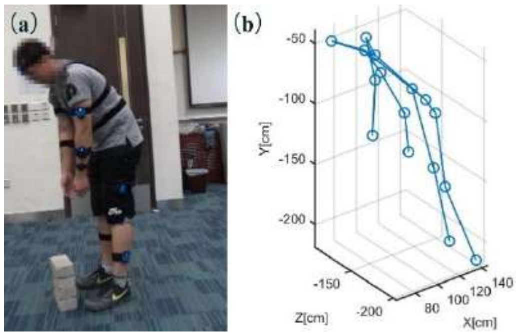

Figure 5. An example of the 3D pose estimation result

IMU sensors were used as the ground-truth to test the accuracy of the pose estimator. Figure 6 shows joint average of the estimation error of each frame. The results indicate that the average error of each joint was 4.10 cm.

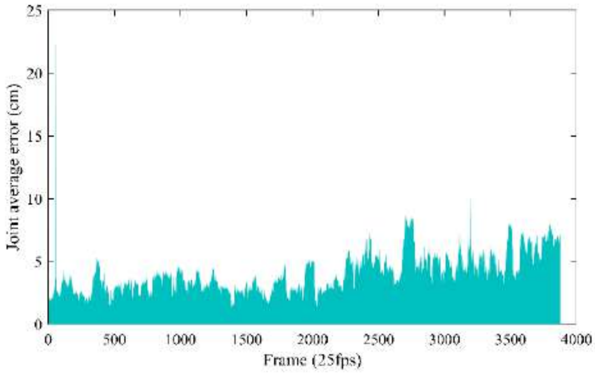

Figure 6. The error of 3D pose estimation

4.1.2 External Load Data

External load was estimated with the pressure data from the smart insoles. During the material handling experiment, the subjects were required to lift 0,1,2,3 or 4 bricks and hold them for 10 seconds. Each brick weights 2 kg, which equals to an external load of 19.6 N when g=9.8 m/s^2. The estimated external load resulting from the bricks was calculated as the difference between the ground reaction forces of consecutive liftings, as shown in Figure 7. The relative error is 5.99% by comparing the differences between the estimated external load and the ground truth external load.

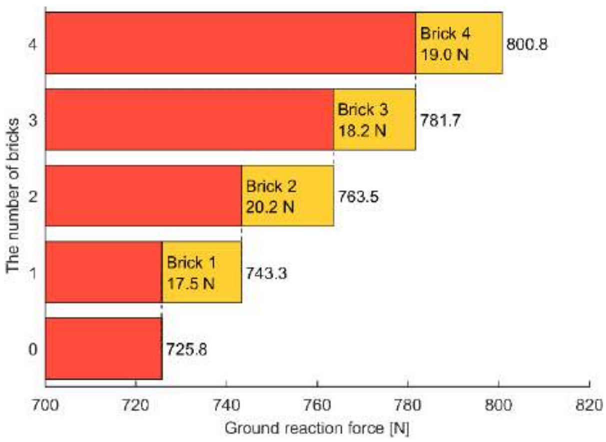

Figure 7. The measurements of external loads

4.2 Workload Assessment

Inverse dynamic modelling was applied to calculate the torque at each joint based on the posture data and ground reaction force data 3DSSPP was applied to facilitate the biomechanical calculations. The joint capacity was estimated according to the equations as suggested by The National Isometric Muscle Strength (NIMS) Database and the participant`s anthropometric information (age, gender, weight and height). Then, the workload was calculated as the percentage of maximum joint torque. Figure 8 delineates the joints` capacities, joints torques and resulting workload at each joint, which helps to assess the workload by illustrating the various body joints with different colors depending upon the workload percentage.

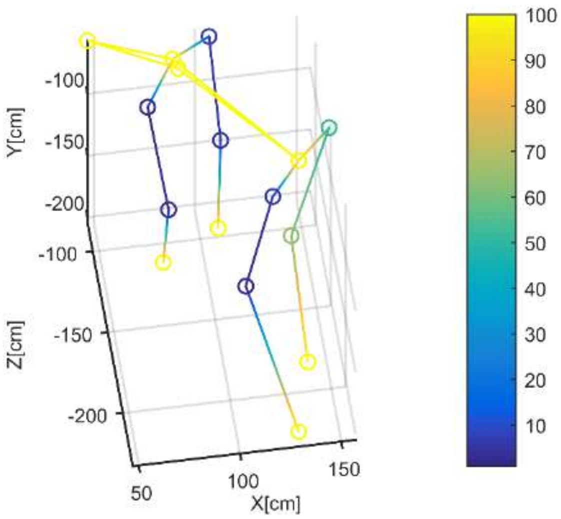

Figure 8. The visualization and calculation result of workload

Figure 9 shows the joint workload distributions during typical postures of the three construction activities involved. By comparing the join workloads of three construction activities, material handling was more likely to result in high joint workload than plaster and rebar. In all of the three activities, left hip and left knee had higher workload than other joints. The result suggested that the subject may need to reduce the workload of left legs by balancing the workload of both legs.

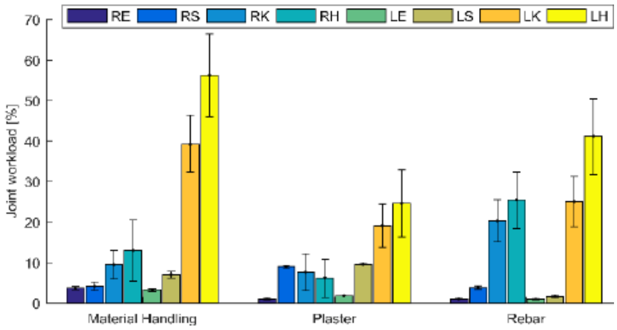

Figure 9. Joint workload assessment results

5 Discussion

Construction workers faced with high ergonomic risks, resulting in a negative influence on the workers' wellbeing and productivity. It is important, therefore, to assess the workers' ergonomic risk accurately. Observations, sensors, and depth cameras are three main posture data collecting methods, but are faced with challenges of low accuracy, uncomfortableness, and unsuitability to outdoor environments. This research intends to solve the issues by blending a video-based 3D pose estimation algorithm with smart insoles. The experiment results suggest that the method could 1) accurately collect construction workers posture and external load data, 2) automatically provide workload assessments without intrusiveness, 3) work well in both indoor and outdoor environments.

The methodology, however, has the following shortcomings and deserves further improvements.

First, the 3D motion estimation accuracy should be improved. Figure 10 provides two failure cases of the 3D posture estimation in an on-site experiment. The reason lies in visual obstacles. In Figure 10, the worker was squatting, and most of the body parts was invisible. The 3D pose estimation could be improved by adding more pictures with obstructions to the training dataset, so that the blocked body segment could be inferred.

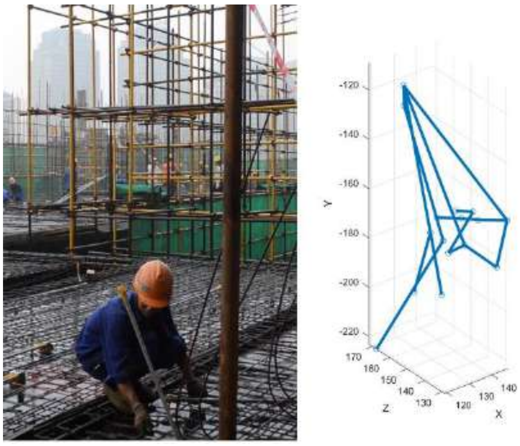

Figure 10. Failure examples of 3D pose estimation

Secondly, the current methodology can only be applied on frames containing only one worker. However, in most of the case, one supervision camera can record the activities of several workers. If the methodology could recognize all the workers within one frame, the efficiency could be increased a lot.

Thirdly, the pressure sensor data is not stable. Figure 11 shows the data from one sensor in the insole. It can be found that there exists sharp fluctuation in the first several frames. The reason might be workers' quick movements, which could lead to the unstable connections between pressure sensors and data receiver in the insole.

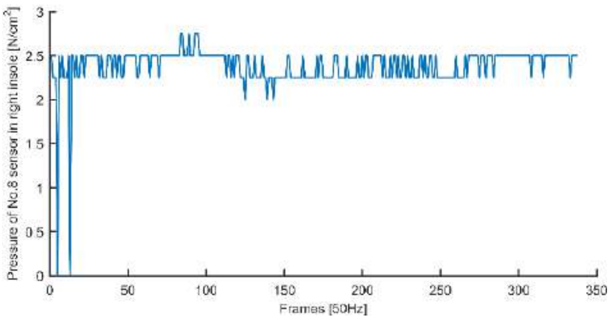

Figure 11. The data from one pressure sensor in the right insole

Finally, the methodology needs to be further demonstrated with real construction site data. Though the experiment demonstrates the feasibility of the methodology, the on-site experiment only records a ten-minute video for each worker. For data-based ergonomic improvement suggestions, it is necessary to take longer-period video records for more construction workers.

6 Conclusions

The research proposed a non-intrusive workload assessment approach for construction workers by merging computer vision, pressure sensors and biomechanics. The experiment results demonstrated the feasibility and accuracy of the approach. Development of such a system could equip the industry with a non-invasive tool for workload monitoring. Also, the approach provides detailed information about the posture and external load and associated patterns which could help understanding the relations between construction activities and workloads, which could serve as the data foundation for ergonomic improvements such as work-rest schedule and workstation design.

Abstract –

Path planning is crucial in constructability analysis and heavy construction equipment scheduling, particularly in industrial plants. The main purpose of construction equipment path planning is devising the shortest path between its initial and aimed location. This suggested path is supposed to be safe, and collision-free. The current planning practice, even in industrial projects whose sites are extremely congested, is manual based on the expert judgment. Thus, this sophisticated manual process is not only prone to errors, but also time-consuming. This research presents an automated path planning approach based on an obstacle avoidance technique in robotics to support the decision-making process. The proposed methodology finds the shortest path for the planar motion of any convex 2D object. It assumes continuous translational (i.e. X and Y directions) and discretized rotational motions for the object. Two case studies are also presented to illustrate and to validate the proposed methodology.

Construction Equipment; Collision-free Path Planning; Robotics; Automation in Construction

1 Introduction

Dams, bridges, roads, industrial plants, and other construction mega-projects heavily rely on the utilization of heavy construction equipment. Construction equipment planning and management is a sophisticated task due to its interrelationship with dynamic activities (i.e. workspace logistics, material delivery, and equipment allocation) [1]. Thus, improper planning and management of construction equipment would lead to unsafe, inefficient, and unproductive construction projects. Nevertheless, current construction equipment planning practice is manual and extremely depends on engineers' intuition, experience, and imagination and is proceeded by trial and error methods. Thus, this sophisticated manual process is not only prone to errors but also time-consuming. Additionally, complexity, uncertain nature and dynamic conditions of congested construction sites require frequent and short-term re-planning. Therefore, to maximize productivity, developing effective and flexible tools would be necessary to help engineers manage these pieces of equipment.

The movement of mobile construction equipment is one of the principal causes of fatalities on a construction site. A collision-free path for construction equipment can reduce the risk of worker injury and fatality [2]. Such a collision-free path can decrease the probability of workspace conflict, enhance construction equipment management, and increase the productivity of the construction process. As a result, path planning analysis plays a pivotal role in constructability analysis and heavy construction equipment scheduling, particularly in congested industrial plants.

This research aims to present an automated path planning approach based on an obstacle avoidance technique in robotics to support the decision-making process. The main purpose of construction equipment path planning is devising the shortest path between its initial and aimed location. This suggested path is supposed to be safe, and collision-free.

The sub-objectives of this research are as follows: (1) developing and enhancing a methodology for finding the shortest path for the planar motion of any convex 2D object.; (2) using the method to determine the shortest collision-free path on a construction site for mobile construction equipment; (3) providing a visualization tool in CAD environment in order to present and evaluate the results and the whole process. Planners should be able to evaluate the user-defined variables and the final output. This research proposed a computer program to meet these goals and provides engineers with a computational, visual, and interactive way of decision making support systems. The proposed method is validated by some pilot case studies to prove that it can provide a visually effective and efficient result.

2 Literature Review

An effective construction equipment planning and control includes (1) site planning, and (2) heavy construction equipment movement control [1]. A lot of studies conducted to make these processes more efficient and flexible particularly by using computer-based automated solutions. For example, type and location optimization [3], resource allocation optimization [4], path checking [5], activity analysis and control [6] concentrate scholars' attention in recent decades.

Path planning is a sub-process in robots' motion planning and aims to find a collision-free path between the initial and goal configuration of the robot. The construction equipment path planning problem is potentially interchangeable to the path planning problem of mobile robots. A fundamental study conceded by Lozano-Pérez [7] proposed a method called "configuration space (C-Space)" to solve 2D motion planning problems for 2D convex mobile robot objects. The pivotal idea of this method is to reduce the dimension of the moving object's shape into one single representing point and to augment the obstacles to configuration space obstacles (C-Obstacles). The most significant advantage of this idea is that dealing with the intersection of a point and a set of obstacles is easier than the intersection of the moving object and the set of obstacles. Figure 1 (A) demonstrates how to convert an obstacle to the corresponding C-Obstacle based on a rectangular moving object without considering the rotations. The central point of the moving object is chosen as the representing point (B), and the obstacle is grown by the shape of that, creating a new area (C-Obstacle) (C). After the creation of the C-Obstacle, the problem of finding a collision-free path for the moving object is equivalent to finding a path for the representing point avoiding the generated C-Obstacle (D). If the moving object rotates, the shape of the created C-Obstacle would be changed. Previous work on construction equipment path planning employs various algorithms to search the created C-Space. However, the main focus is on two main search categories: (1) discretized (node-based) search algorithms (i.e. Visibility Graph [8], Gridding plus A*, GA, Dijkstra's Algorithm [9]), (2) continues (sampling-based) search algorithms. (i.e. RRTs [10], [11], PRM [12]).

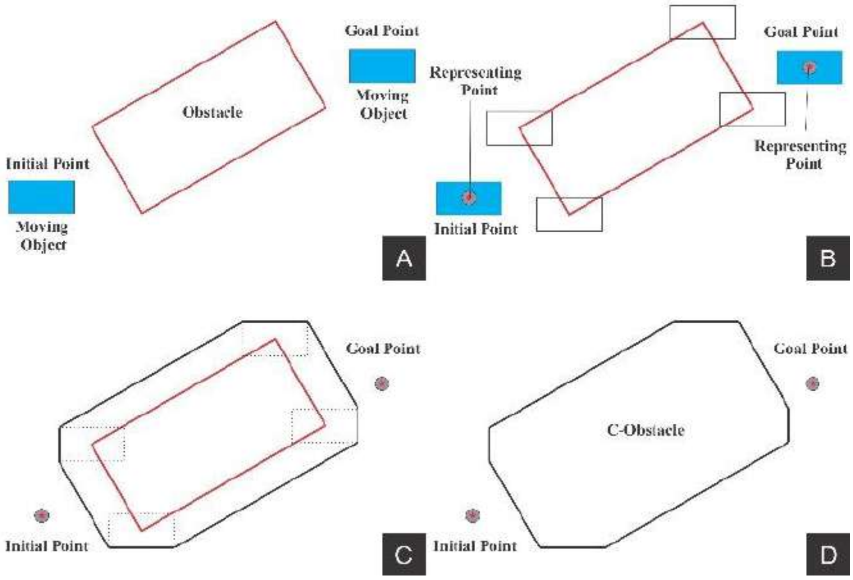

Figure 1- C-Space Generation Steps

3 Proposed Methodology

This research is based on the limitation enhancement of a research work done by Lei et al [13]. They neglected full discretization for rotation as the third degree of freedom for moving object. Mixed rotation-transition movement not only affects the optimality of the solution adversely, but also it restricts the developed system to 2D path planning. By exemption of this limit, this paper combined the robotic motion planning with the construction equipment path planning to reach a more flexible and developable methodology. Figure 2. Illustrates the proposed methodology which consists of several components. The system is developed in VisualBasic.Net employing MS Access database.

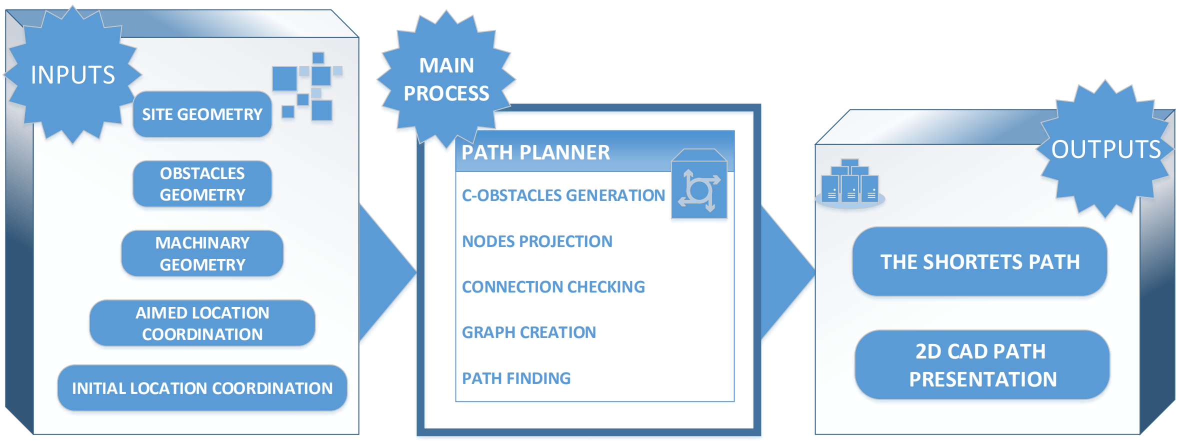

Figure 2- Proposed Methodology

3.1 C-Space Generation

As mentioned above, the shapes of the generated C-Obstacles would be changed as the moving object rotates. Therefore, the ideal modeling approach is to generate the C-Obstacles while considering the continuous rotation of the moving object. Nonetheless, in order to make the model computationally feasible and efficient, finite rotation steps are assumed. In this regard, for each rotation step of the moving object, the C-Obstacles are generated and kept on a separate corresponding rotational plane by their vertices. (Fig 3.) In this regard, it is needed to rotate the geometrical shape of the moving object by the 2D rotation matrix and proceed the augmentation process for each obstacle. Finding the shortest collision-free path for a convex 2D object through obstacles is now changed to finding the shortest collision-free path for the representing point through grown obstacles (C-Obstacles) between its initial and aimed location. Indeed, the moving object will avoid obstacles, if and only if the corresponding representing point is located out or on the perimeter of the C-obstacles.

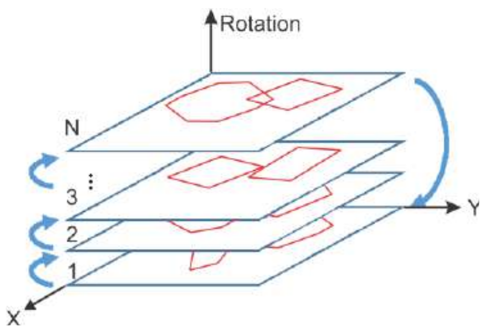

Figure 3- Discretized rotational planes in the generated C-Space

3.2 Corresponding Graph's Node Generation

Based on visibility graph, a collision-free path for a set of points and obstacles in the Euclidean plane is an array of feasible connections between the points (i.e. obstacles' vertices, start point, and aimed point) which starts from the initial point and ends to the aimed point. In fact, a visibility graph is a graph in which each node represents the representing point location, and each edge represents a visible connection between them. Two nodes will be connected, if and only if their connector segment does not have any intersects with any obstacles.

In order to implement this idea, it is necessary to introduce the nodes at the first stage. In this study, two types of nodes are introduced for each rotational plane: (1) Internal nodes; and (2) External nodes. Internal nodes initially consist of vertices of corresponding C-Obstacles for that rotation. Initial and aimed location of the representing point are two extra internal nodes which are added to their corresponding rotational planes. External nodes are introduced in this study to complete the full-discretized modeling of the moving object rotation. External nodes within any rotational planes are those nodes that are added from other rotational planes via continuous projection. The continues projection process proceeds in the negative and positive manner for clockwise and counter-clockwise rotation of the moving object for the amount of a single rotation step, respectively. During this process, each individual internal node within each rotational plane is projected to the next successive rotational plane negatively/positively. By so doing, the object ability to rotate around the representing point is investigated. For example, an internal node N(x,y) within plane j positively projected to plane j+1 and added to it as an external node N'(x,y), given that the projected node will not be placed inside of new plane's C-Obstacles. For the next step, N' would be projected to j+2. The positive projection will be continued unless projected nodes are placed inside the planes' C-Obstacles. In that case, the projected point will not add to that plane, and the positive projection process will be stopped for N(x,y). Right after that, N(x,y) will be negatively projected to plane j-1 to obtain N''(x,y). Similarly, the negative projection would be continued unless projected nodes were placed inside the planes' C-Obstacles.

make an inter-plane connection if they have the same coordination (i.e. X, Y). It is necessary to define a metric to assign a weight for any connections. In this work, the distance and length of motion is simply used. Finally, each connection and its weight treated as the corresponding weighted graph's edge.

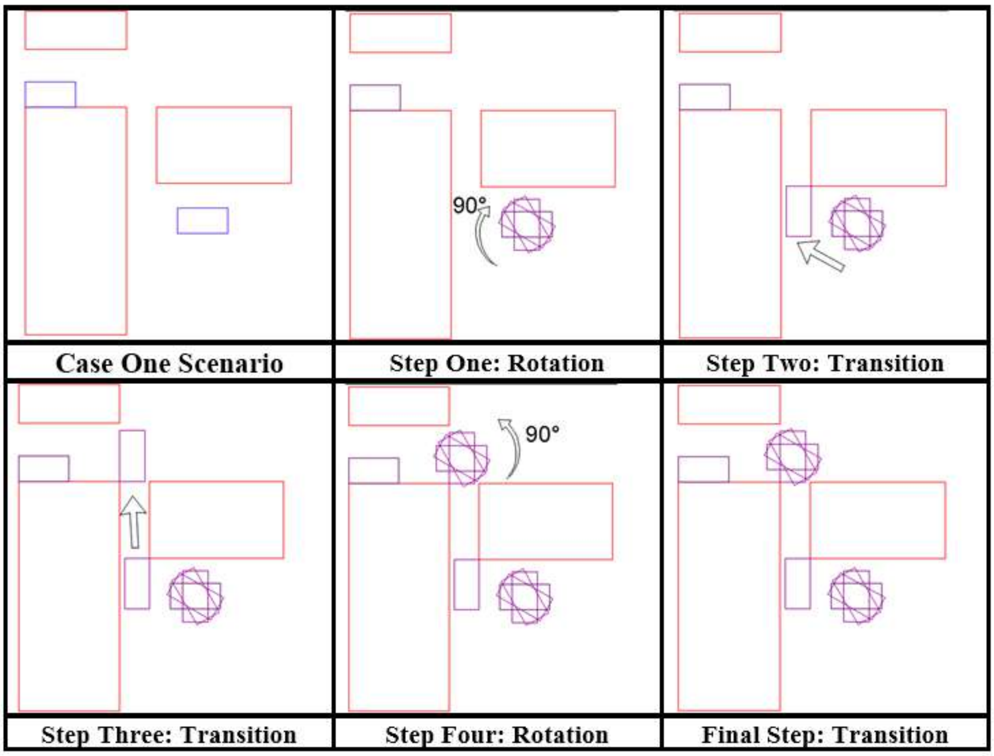

Figure 4- The shortest path in case one

3.3 Corresponding Graph's Edge Generation

When two nodes are connected, it implies that there is a feasible motion between the two positions represented by the nodes. This research proposed two types of connections between nodes: (1) in-plane connections; and (2) inter-plane connections. For instance, a connection between two nodes from the same rotational plane j represents that the moving object can transit without any rotations from one node to the other using a straight line; and a connection between two nodes from two successive rotational planes (e.g. j and j+1) implies the rotation of the moving object. This rotation is equal to one single rotation step.

Two nodes within the same rotational plane will be connected if the segment connector does not collide with the existing C-Obstacles. The connection for two nodes from successive layers is checked to guarantee that the rotation to the amount of a single rotation step will not collide with the existing obstacles. Hence, two nodes will

3.4 Path Finding

Dijkstra's algorithm is employed in this study to find the shortest path in the generated corresponding graph. The principal idea of Dijkstra's algorithm is to calculate the minimum cumulative weight of connections to reach any nodes such as the aimed node from the initial node in a weighted graph G= (V, E). [14]

4 Case study

4.1 Case One

Case one presents an illustrative example in which a moving object is supposed to move through three obstacles in five steps. (Figure 4) In each step the moving object is able to either transit or rotate, but there is no mixed movement for it. The proposed path is safe and collision-free.

4.2 Case two

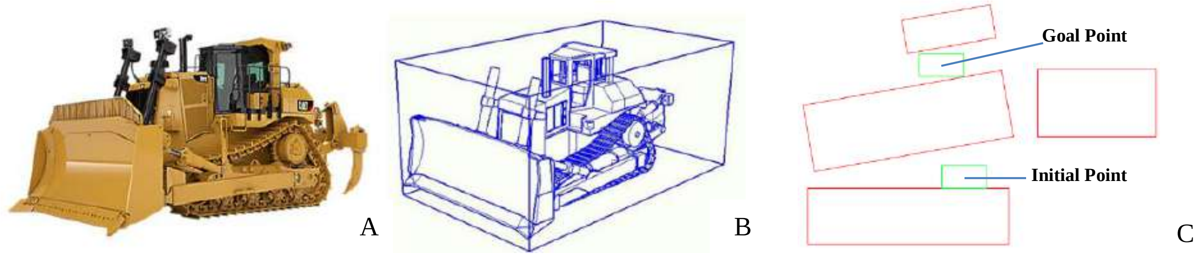

Figure 5- (A) CAT-D9 dozer; (B) Boundary box envelope; (C) A congested scenario

To apply the proposed methodology in finding the shortest collision-free path between initial and aimed location of construction equipment, it is needed to simplify that machinery to a 2D convex. Hence, a boundary envelope is used to guarantee that the mobile construction equipment will avoid obstacles. The boundary for a CAT-D9 dozer (Figure 5(A)) is shown in Figure 5(B); it is a box that completely encloses it. In other words, no points of the dozer will be placed outside of the boundary box.

Additionally, case two presents a more congested scenario with four obstacles (Figure 5(C)). In this case, a complex environment considered to challenge the proposed methodology. However, it is designed to be trackable for any individuals to easily validate the shortest path.

As shown in (Figure 6(A)) rotational planes and their C-obstacles are generated. Meanwhile, in-plan and inter-plane connections are made afterward (Figure 6(B)). The final result is shown in Figure 7 as below.

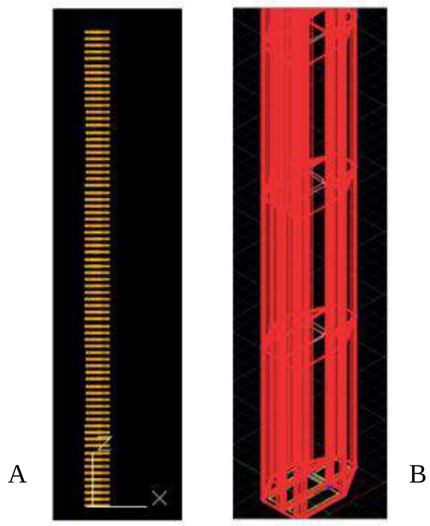

Figure 6- Case two; (A) Rotational Planes; (B) Connections and corresponding graph

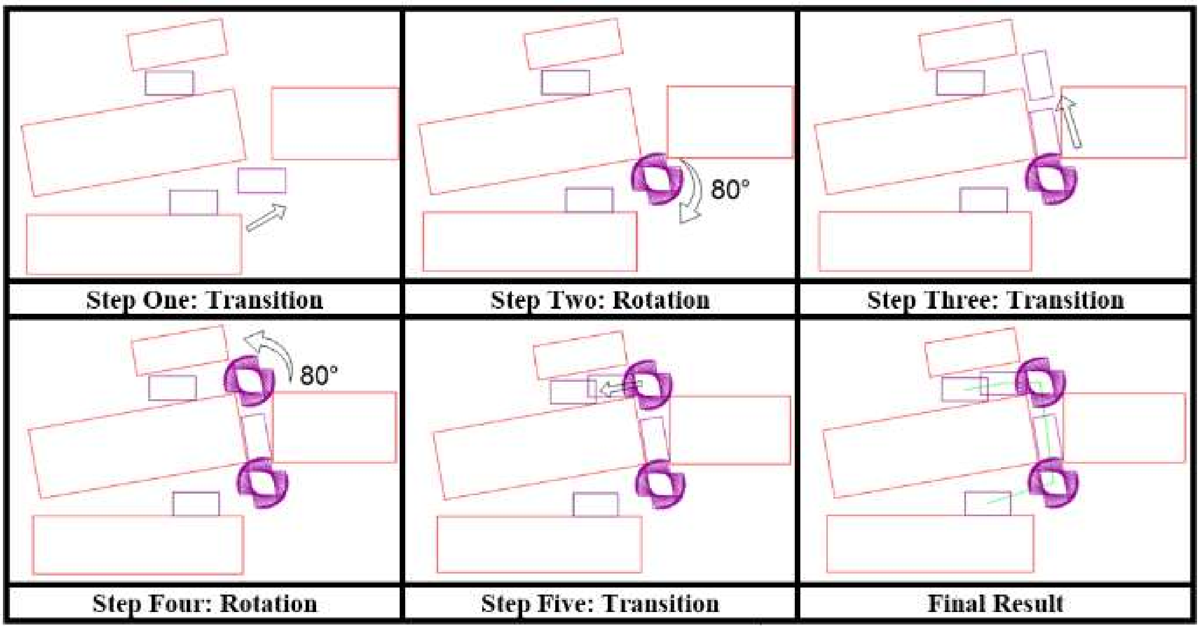

Figure 7- The shortest path in Case Two

5 Conclusion

Path planning is crucial in constructability analysis and heavy construction equipment scheduling, particularly in industrial plants. The main purpose of construction equipment path planning is devising the shortest path between its initial and aimed location. This suggested path is supposed to be safe, and collision-free. The current planning practice, even in industrial projects whose sites are extremely congested, is manual based on the expert judgment. Thus, this sophisticated manual process is not only prone to errors but also time-consuming. This study presents an automated path planning approach based on an obstacle avoidance technique in robotics to support the decision-making process. This research enhanced the limitation of the other scholars' efforts. However, the proposed system only considered the shortest path, but it can consider ease of operation, machinery movements, and other constraints in future studies. This research work will be further extended into heavy lift path planning of mobile cranes.

Abstract –

Many kinds of industrial projects involve the use of prefabricated modules built offsite, and installation on-site using mobile cranes. Due to their costly operation and safety concerns, utilization of such heavy lift mobile cranes requires a precise heavy lift planning. Traditional heavy lift path planning methods on congested industrial job sites are ineffective, time-consuming and non-precise in many cases, whereas computer-based simulation models and visualization can be a substantial improving tool. This paper provides a Virtual Reality (VR) environment in which the user can experience lifting process in an immerse virtual environment. Providing such a VR model not only facilitates planning for critical lifts (e.g. modules, heavy vessels), but also it provides a training environment to enhance safe climate prior to the actual lift. The developed VR model is implemented successfully on an actual construction site of a petrochemical plant on a modular basis in which heavy lift mobile cranes are employed.

Keywords –

Heavy Lift Planning; Virtual Reality (VR); Modular Construction; Automation in Construction; Mobile Crane

1 Introduction

Effective management and planning of resources are pivotal tasks in construction projects management. In recent decades, many industrial projects are constructed using industrialization/ prefabricated offsite construction methods, particularly modularization methods. Modules (e.g. pipe racks or vessels) are offsite prefabricated elements that assembled in module yards and shipped to the site for installation [1]. A set of modules constructs a larger structure. During the installation process, heavy mobile cranes are employed as the main lifting machinery. This heavy and large construction equipment is highly expensive and required precise planning and control due to safety concerns and the extensive impact on the project schedule. For example, the rental cost of a heavy lift mobile crane may reach $1,500 per hour [2]. Moreover, not only these resources force highly expenses (e.g. mobile crane rental cost, skilled crew, and mat cost) to a project, but also they are just available for a restricted period of time.

Proper use of these heavy mobile cranes can reduce costs and make the construction process faster. In contrast, inappropriate crane operation can lead to overruns, delays, and safety issues. Heavy lift path planning is one of the most significant elements in heavy mobile crane planning and management. Traditional heavy lift path planning methods on congested industrial job sites are ineffective, time-consuming and non-precise in many cases, whereas computer-based simulation and visualization can be considerable improving tools.

With tremendous development of graphical computer aid modeling and also novel interactive hardware, a definite opportunity is provided in architecture engineering and construction (AEC) industry to facilitate the training process and effective learning in virtual environments (i.e. virtual reality, augmented reality and mixed reality) through that. A lot of research has been done in this area, and scholars tried to examine the effectiveness of the application in the construction industry. Additionally, there are also many untapped opportunities in the construction planning process.

The objective of this research is to provide a Virtual Reality (VR) environment in which one can experience a simulated lifting process in an immerse virtual environment. Providing such a VR model not only facilitates planning for blind or critical lifts (e.g. modules, heavy vessels) but also provides a safe training environment prior to the actual lift. Moreover, using VR technology make it possible to provide useful extra information, and by so doing, operators, planners, and engineers will have the opportunity to obtain a common understanding and would be capable to cooperate to improve the plan.

2 Related Works

Throughout the recent decades, computers have played a significant role in construction. Scheduling and many other planning tasks are done with the support of computers. In the recent years, other applications have been also investigated particularly in construction operation visualization. Visualization aims to verify trustworthiness and to provide presentable insights about the modeled system. For instance, four-dimensional (4D) computer-supported design CAD technology presents a visualization of the advancement of construction by linking three-dimensional (3D) computer models of the project and construction schedules [3]. 4D models barely enable users to envision a construction schedule previously developed. However, they are not able to simulate the construction activities [4]. More recently, more pioneer computer-based technologies are employed to facilitate the visualization process. Immersive virtual technologies, such as VR technology, enable multiple design solutions to be evaluated digitally, which leads to a faster design process and more optimized end products. The first industrial use of VR was introduced when virtual prototypes started to be used in the design process. VR is a virtual prototyping technology that provides a three-dimensional scene that can be manipulated in real time and used collaboratively to explore and navigate the 3D model. By simulation of the construction process, VR makes users to get a better understanding and perception about the actual environment. As illustrated in Figure 1, there are many potential application areas for VR systems [5]. Various conducted research in the case of VR technology applications has confirmed that VR can bring vital value improvement and cost declines to the construction process [6].

Management of heavy construction equipment is a sophisticated task due to highly dynamic activities such as work-space logistics, material deliveries, and resource allocation. However, construction equipment management suffers from some deficiencies in different levels of site planning and their movements. Studies indicate that construction site planning highly depends on individuals' experiences, imaginations, and intuitions. Even though 4D visualization enhanced communications and mutual understanding of various stakeholders, there is no effective tool to analyze, evaluate, and anticipate ongoing challenges and future difficulties [7]. Furthermore, in modular industrial projects, heavy mobile cranes are employed for on-site module

Figure 1- Potential Applications of VR in Construction [5]

installation at their set locations. Efficient planning is essential to decrease errors, accidents, additional costs, and schedule delays [8]. An effective crane planning in these kinds of projects includes many tasks (i.e. crane type selection, crane location optimization, lift sequencing, lift path planning). Heavy lift path planning is a pivotal subtask in heavy lift planning. Many scholars proposed computer-based solutions to optimize or enhance the process by automation [8]–[10].

In order to increase the construction productivity, investigations are conducted to link these novel visualization technologies to crane planning and management. Some scholars employed the VR technology to provide a virtual environment to train cranes operators with neither dangers or expenses. For instance, overhead crane [11] and bridge crane [12] operator training systems based on virtual reality are discussed. Some other efforts are made to evaluate and enhance safety conditions in this regard [13]–[15]. However, authors have not found any specific investigation in the application of VR technology in heavy lift planning process of mobile cranes.

3 Development of VR-Based Heavy Lift Planning Simulator

The objective of our approach is to unify a virtual environment for different use cases in lift planning and execution of heavy lifts of prefabricated modules in industrial projects. Using an interactable virtual environment (VE) would enable users to have more profound experiences. Virtual reality (VR) is a mixture of digital processing, computer graphics, multimedia technology, sensor technology, and other computer-based information technologies. Thanks to VR technology, users are able to freely navigate any simulated 3D models in a VE.

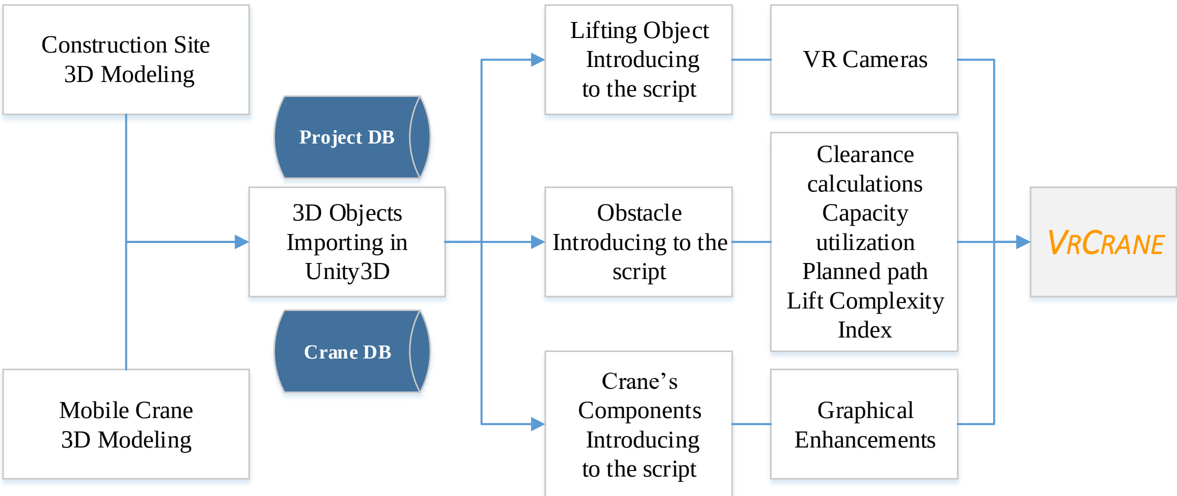

Figure 2 - VR-Crane Development System

Moreover, they would be capable to actively interact with the VE. Navigation is one of these interactions. Navigation includes the ability to move around and explore the simulated objects in a virtual environment. Similarly, interaction is the ability to control and affect the VE and also be affected by it. For example, the ability to move objects in a VE is an interaction between the user and the VE. The most significant advantage of VR models to other forms of VE such as personal computers (PC) displays is providing a lifelike three-dimensional and 360° experience via a wearable display-headset with a higher degree of virtual immersion.

In this research, a prominent VR headset, Oculus Rift is employed which consists of several parts. A head-mounted display (HMD), an Xbox Controller, and Oculus Rift Constellation sensor, an optical-based tracking system developed by Oculus VR, are the main parts of the VR device. The VR device needs to be supported by a high-performance graphical process unit (GPU). Thus, the user can experience a more realistic environment than simple 3D-glasses.

This paper presents the overall concepts of VrCrane, a VR simulator for heavy mobile cranes (see Fig 2). Authors proceeded five main steps in order to achieve a VR tool which facilitates the lift planning for heavy mobile cranes. In this regard, a 3D model of the selected crane and the construction site is required. It is possible to use BIM models or a raw 3D model and a manual database. Hence, a pilot BIM model of an industrial plant is employed which has both information and 3D model. Moreover, it is required to make users able to control mobile cranes' every possible degree of freedom. Therefore, Uinty3D as a handy and free game engine is used to simulate its every six degrees of freedom. These degrees of freedom are controlled by the Xbox controller (see Fig 3). Various types of virtual cameras equip the simulated model to make users experience the lifting operation as an operator, a signalman, or through other views which is easily possible in a virtual environment (i.e. bird view, plan view, dynamic view, etc.). Extra real-time calculations and information presentations (i.e. capacity usage percentage, clearance color-coding, risk evaluations, etc.) for virtual operators and others would increase the common understanding and facilitate the communication process among all decision makers and other key stakeholders (Fig 4). In addition, a life-like experience of a heavy lift would reveal the underlying challenges which were previously concealed during typical 2D lift planning.

4 Conclusions

By the development of virtual environments such as virtual reality, augmented reality and mixed reality in architecture engineering and construction (AEC) industry, it is an indisputable need for stakeholders and planners to use a better approach for their labor-intensive and error-prone activities particularly in heavy lift planning. Provided a virtual reality environment in which the user can experience lifting process in an immerse virtual environment not only facilitates planning for critical lifts (e.g. modules, heavy vessels) but also provides a training environment to enhance safe climate prior to the actual lift in a safe, fast, and low-priced manner.

Automation of the Execution of Monolithic Reinforced Ceilings

A. Więckowski

E-mail: awiecko@agh,edu.pl

Abstract

The development in numerical control, 3D technology, as well as new materials, have a great potential in respect of automatic construction, while at the same time they contribute to freeing people from hard physical labour, improve quality of performance, and minimise the volume of waste. Vertical components are erected automatically, while possible horizontal structures are engineered using prefabricated materials. The presented *stropotronic* technology, using automatic formwork that moves together with the robot embedding materials, was applied to construct monolithic reinforced ceilings. Owing to its high early strength (over 20 MPa just after 1.5 h from reaction with water), concrete using rapid setting calcium sulphoaluminate (CSA) cement assures self-supporting strength in a very short time. The robot continuously places reinforcement and extrudes concrete while moving together with the formwork perpendicularly to the ceiling span. Automatic formwork moves very slowly under the ceiling constructed to assure continuous support for the setting concrete at the width of approx. 1.5 m, namely until the slab becomes self-supportive across the span between supports. The example of a section of the ceiling with composite inserts (main bars of steel, distribution bars of glass fibre) presents the results of preliminary analysis of the applied CSA cement-based concrete, progress of works related to material embedding, and the conclusions.

Keywords –

automation in construction, production organization, JA-WA system, stropotronic, CSA cement

1 Introduction

Current automated construction systems using large-size 3D devices apply 'wet' technology with nozzles forming the material to build walls, whereas ceilings are assembled of prefabricated materials, [2, 3, 7, 11, 13, 22]. The *JA-WA* system (Polish: ***J**ednostronna **A**plikacja* – ***W**ędrującym **A**utomatem*) represents the technology of single-sided material application using mobile automatic devices, [14-16,18]. For construction of ceilings (Polish: *strop*), a prototype '*stropotronic*' technology is proposed. The method allows construction of monolithic concrete ceilings reinforced with rods directly at the buildings constructed, with automated control of the equipment, according to a predefined numerical algorithm.

By standard, monolithic ceilings are placed on a prepared formwork placed in the space, relying on temporary supports, or on the floor. After stabilization of the formwork and placement of reinforcement inserts, the concrete mix is usually transported from the central concrete plant, and pumped at the site to the place of embedding, levelled, and mechanically compacted using manually operated power tools or manually. Following the period of concrete curing, the formwork can be removed, usually after several days, sometimes even later.

In the proposed *stropotronic* technology, ceiling construction is entirely different, and the time for supporting the formed part of the slab with the formwork totals just about 1.5 hours. The equipment is controlled by the operator, involving automatic formwork placement and a robot using the system for component mixing and embedding, according to the following principle. With the progress of works, automatic formwork and a robot placing reinforcement and coatings to secure against water evaporation and preparing the concrete mix for extrusion, as well as forming the external layers of the ceiling section, move on the rail scaffolding supported on the ground.

Precise operation of automatic equipment, appropriately to the results of analyses of the existing conditions and the calculation algorithm, with simultaneous continuous monitoring and control of the works quality, permits the application of rapid setting CSA (calcium sulphoaluminate) cement that takes about 30 minutes to begin, and with rapid early strength build-up. As a result, the support of the fresh ceiling with mobile formwork is only required for a short time, until the fresh concrete achieves the necessary strength to guarantee self-supporting properties of the executed section of the structure.

CSA cement, as applied in *stropotronic,* is a mineral, hydraulic binder with rapid early strength build-up (e.g. over 30 MPa after 8 from reaction with water), small contraction, and high resistance to sulphates. Main CSA components include: anhydrous *calcium sulphoaluminate* ($4CaO\ 3Al_2O_3 \cdot SO_4$), dicalcium silicate ($2CaO \cdot SiO_2$), and gypsum ($CaSO_4 \cdot 2H_2O$). When CSA cement is mixed with water, a quick reaction occurs between the anhydrous *calcium sulphoaluminate*, gypsum, and i calcium hydroxide, involving dynamic heat generation and intense generation of ettringite, mineral that allows achieving high early strength, with full strength guaranteed by the manufacturer to be achieved after 3 - 7 days, [4, 5, 8-10, 21]. Due to immediate binding of such cement, it requires specialist (very efficient) execution.

2 *Stropotronic* technology for monolithic ceilings

The *stropotronic* kit includes:

- analytical algorithms for equipment control with monitoring of ambient conditions, [2, 14-16],
- the robot forming the ceiling, namely placing the reinforcement and protective coatings, as well as composing the components, and embedding the concrete mix,
- mobile formwork moving with the operating area, supporting the freshly made ceiling until it achieves self-supporting strength,
- scaffolding rail that supports the system equipment (mobile formwork and the robot) and transmitting load onto the ground, [14-16],
- intermediate material resource to assure logistic stock of materials to guarantee continuity of work, [12, 17, 19-20].

3 Analytical algorithms, robot forming the structure, and mobile formwork

During the works, appropriately to the changing conditions and rapid CSA cement-based concrete strength build-up, the control, monitoring, and quality control of the automatic mobile formwork, the robot embedding the materials, and the material stock are assured. Depending on the ambient thermal conditions and calculation results, the automatically controlled kit of equipment allows for real-time coordination, continuous preparation, and embedding of materials at strictly defined times, with the necessary production intensity. Keeping of the preparation and embedding times preconditions correct curing of the monolithic concrete structure, and the appropriate time of supporting the freshly made ceiling. Hence, the necessary efficiency of works execution and the equipment movement velocity are controlled.

According to Fig. 1, embedding kit A, executing ceiling 1, connected to mobile formwork B, continuously moves with the works section in direction 2.

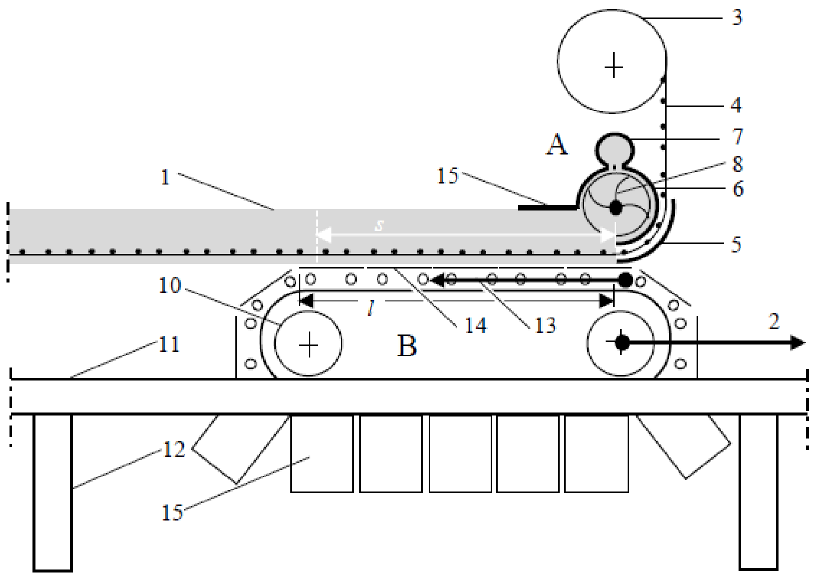

Figure 1. Diagram of the embedding kit - A and mobile formwork – B, description in the text

In the embedding kit A, the reinforcement mesh 4, unfolded from roll 3, for formed ceiling 1, is input between the front plate 5 and embedding kit casing 6. Concrete mix supplied with hose 7 is distributed across the ceiling span, extruded and compacted using carrier 8. Top plate 9 forms and smoothens outer surface of ceiling 1.

Mobile formwork B moves in direction 2 with the progress of the works, on wheels 10, on track 11, supported on supports 12. At the same time, particular formwork disks 14 move in the opposite direction 13. End parts of the formwork disks (over the tracks) are tilted. When the formwork plates move under, such end parts 15 on hinges tilt from the vertical, which allows for moving of formwork disks between the tracks and the supports.

The formwork supports freshly formed ceiling on section *l*, in the early period of (CSA cement-based) concrete curing for a time longer than until the fresh concrete achieves the parameters to guarantee its self-supporting properties in its entire cross-section at the span between the supports, as indicated below.

4 Properties of the applied CSA cement

During The first tests involving aluminous cement were conducted in the 1930's, including in France and in Poland by Stefan Bryła, [9, 10]. In 1966, in the USA, Alexander Klein proposed the application of calcium sulphoaluminate as the source of aluminium ions, and then patented the technology involving mixed Portland and expanding cements based on calcium sulphoaluminate, [1, 8-10,].

At present, CSA cement on calcium sulphoaluminates is manufactured with grades 42.5, 52.5, 62.5, 72.5, 82.5, and 92.5 (in this case, the values indicate compressive strength values achieved after 7 days). CSA cements stored in dry places in sealed packaging have the use by dates of 12 months. Major manufacturers of rapid setting cements are located in the USA and China. It is assumed that in the early period of CSA hydration, 80% ettringite is formed still before the hydration phase, and hence cement does not show strong expansion, and it can be classified as non-shrink cement. According to [19], after 28 days, in the conditions of very dry air, the contraction totals approx. 0.076 mm/m, while in the wet environment swelling of 0.2 mm/m occurs (acc. to ASTM C 845-96 [1], the limit for non-shrink cement totals up to 0.5 mm/m).

According to [4], CSA cement achieves compressive strength of f_{ck} = 20 MPa just one hour from its mixing with water, while after one day – 45 MPa, with full strength of 50 MPa, as guaranteed by the manufacturer, achieved after seven days. Later on, strength build-up occurs similarly as in Portland cements, and increases with time, totalling 62 MPa after 28 days. Further strength increase was investigated by Oreworld Cement Manufactured (OCM). As compared to compressive strength after 28 days, increase of 25% was recorded after one year, with further increase in strength of further 33% reported after five years [4].

Pursuant to the tests performed by the OCM, the proportions of tensile strength vs. compressive strength are similar as in Portland cements. Tensile strength after seven days totalled 4.1 MPa, with tensile strength at break of 5 MPa.

In order to achieve the intended strength parameters, CSA concrete preparation and laying must occur at outdoor temperature of from 7ºC to 32ºC (at lower temperatures, the setting process occurs at a much slower rate, while at higher temperatures, with additional hydration heat, ettringite may become decomposed). At the temperature of 20ºC, according to [4], setting occurs just after 15 minutes or up to several minutes later. With citric acid used as a retardant, the onset of setting time can be elongated by 15 minutes.

The onset of CSA cement setting, usually occurring after just several minutes, requires non-standard execution of the works. The setting and curing processes occur almost immediately after the addition of water, much quicker than in the case of Portland cements. In most frequent cases, when performing urgent and short-lasting repairs, concrete teams trained and equipped with the suggested equipment perform works according to the predefined works organisation. Concrete must not be vibrated after it has started to set, and the surface must be secured against evaporation. During the work, tools must be systematically cleaned, usually not less frequently than every 30 minutes. Standard pumps and pipelines must also be cleaned at similar time intervals.

5 Concrete Mix tests

At the laboratory of the Department of Geomechanics, Civil Engineering and Geotechnics of the AGH University of Science and Technology in Krakow, preliminary compressive strength tests f_c, were performed on concrete on CSA Rapid Set® cement, with setting onset of t_{pw} = 32 minutes. Concrete Mix was applied available in 25 kg bags, [8]. The water, dry mix, and ambient temperatures totalled 20ºC. With water/cement proportion of w/c = 0.5, the test involved three cubic samples each, with dimensions of 100 x 100 x 100 mm, in each of 9 concrete age times, counting from the time of mixing with water. The results of the compressive strength tests performed according to EN 12390-1 [5] (on walter+bai ag DB 3000 press with control module NS19) have been presented in Table 1.

Table 1 Strength values for Rapid Set® fresh concrete pursuant to tests and calculated according to equation (1)

Test of concrete aged t, h	1.5	2	3	4	8	24	48	72	168
Average strength from tests $f_{cm(t)}$, MPa	24.9	27.3	29.9	31.5	35.1	37.9	40.2	41.5	44.3
Characteristic strength values, acc. to (1) $f_{ck(t)}$, MPa	20.9	23.3	25.9	27,5	31.1	33.9	36,2	37,5	39.3

In the case of application of CSA cements, where fresh concrete in the ceiling needs to be immediately deprived of formwork, the *ja-wa* system requires information on the characteristic concrete compressive strength $f_{ck(t)}$ already at the age of $t \geq 1.5$ h.

When analysing the strength of samples tested (3 samples each, at 9 times, from 1.5 h up to 7 days; at the aforementioned laboratory of the Department of Geomechanics, Civil Engineering and Geotechnics of the AGH University of Science and Technology), major differences of the results, with standard deviation of s = 1.38, occurred for samples with concrete age of 8 h (from mixing the components with water). Average strength of three samples totalled $f_{cm(8)}$ = 35.1 MPa. *t*-Student was applied to check whether EN 1992:2008 Eurokod 2, [6], condition of 95 % samples in the lot achieving the characteristic strength, has been met. For sample strength of δ = 4 MPa lower than average $f_{cm(8h)}$, the value of test statistics $t_{obl} = (\delta/s)\sqrt{n-1}$, following substitution totals t_{obl} = 4.099 and is higher than *t*-Student distribution quantile of $t_{(0.95,\,2)}$ = 2.920. Therefore, the following was assumed that the characteristic concrete compressive strength $f_{ck(t)}$ at age t totals:

$$f_{ck(t)} = f_{cm(t)} - 4 \text{ MPa}, \quad \text{for } 1.5 \text{ h} \leq t \leq 168 \text{ h}, \tag{1}$$

$f_{cm(t)}$ - average concrete compressive strength at the age of t hours.

Table 1 present the results for fresh CSA-based concrete compressive strength determined in the tests, as well as calculated pursuant to equation (1).

According to Article [21], creep results of samples aged t_o = 1,5 h during the curing time of concrete CSA Rapid Set®, with the load of k_σ = 0,40, have indicated that deformations in creep-testing machines were lower than calculated according to EN 1992:2008 Eurokod 2, [6]. On day one, average sample deformation values in creep-testing machines totalled 0.74 deformation values calculated acc. to Eurocode 2, and the proportion decreased with time to 0.53 on the 7th day of the test.

6 The ceiling slab structure

It was assumed that the analysed ceiling slab is unfinished, free-supported at the edges, made of reinforced concrete. Main reinforcement is made of A-III ribbed steel, and distribution bars - of glass fibre composite rods. The solution allows rolling a long section of the prefabricated mesh (owing to its high elasticity and shape memory of the composite rods as distribution rods).

Three phases have been defined in the behaviour of the load-bearing structure. State I, or self-supporting ceiling slab (without an external load), state II – planned layers in the ceiling, and state III – corresponding to target behaviour of the load-bearing structure with full operational load.

6.1 State I – self-supporting ceiling slab

According to the tests, CSA-based concrete of age t = 1,5 h (from mixing with water) was characterised with strength $f_{cm(1.5)}$ = 24.9 MPa, cf. Table 1. After calculation acc. to equation (1), characteristic strength totalled $f_{ck(1.5)}$ = 20.9 MPa.

Pursuant to calculations according to EN 1992:2008 Eurocode 2 for unfinished slab, free-supported at the edges, with axial distance between supports of 3.3 m, thickness of 0.15 m, loaded with own weight q = 3.6 kN/m², for concrete C 16/20, with agglomerate of 0.8 cm, with cover of 1.5 cm (C_{dev} = 1.0 cm, C_{dur} = 0.0 cm), and reinforcement of A-IIIN grade ribbed steel (RB500), with calculated elasticity limit of f_{yd} = 435 MPa:

- reinforcement cross section area:

$$A_{s1I} = 2.01 \text{ cm}^2.$$

- bend deflection:

$$f_I = 0.07 \text{ cm}.$$

The following was assumed:

- main reinforcement φ = 0,8 cm, with spacing of 5 cm, and value A_{s1p} = 10.05 cm².

6.2 State II of planned layers in the ceiling

In the above conditions, pursuant to laboratory tests and calculations according to (1), it was assumed that CSA-based concrete with age t = 24 h has characteristic strength of $f_{ck(24)}$ = 33.9 MPa. For C 25/30 concrete grade, with constant load q = 5.1 kN/m²:

$$A_{s1II} = 2.01 \text{ cm}^2, \; f_{II} = 0.11 \text{ cm}.$$

Therefore, reinforcement as in section 6.1, namely φ = 8 mm, with spacing of 5 cm, and value A_{s1p} = 10.05 cm^2 , are bigger than required for state II.

6.3 State III of slab bearing strength with operational loads

In the conditions as in section 6.1, it was assumed that CSA-based concrete with age t = 168 h has characteristic strength of $f_{ck(168)}$ = 39.3 MPa. For C 30/37 concrete grade, with constant load of 5.6 kN/m^2 and variable load of 2.0 kN/m^2:

$$A_{s1\mathrm{III}} = 4.81\ \mathrm{cm}^2,\ f_{\mathrm{III}} = 1.00\ \mathrm{cm},$$

$$f_{\mathrm{I}} + f_{\mathrm{II}} + f_{\mathrm{III}} = 1.18\ \mathrm{cm} < f_{\max} = 1.32\ \mathrm{cm}.$$

Therefore, the applied reinforcement as in section 6.1, namely φ = 0.8 cm, with spacing of 5 cm, and value A_{s1p} = 10.05 cm^2, are bigger than required for state III with target load, and the final slab deflection is lower than permissible.

7 Time limits for concrete mix embedding

In the *stropotronic* technology, automatic mixing of components with water, and their direct transport and dynamic extrusion embedding (mechanical compacting of the concrete mix with pressure exerted by the carrier blades) occurs in one continuous production process. Any portion of the mix that has water added into it at a specific moment features two important process times to be noted. One, ‘the latest time’ after which no vibrations from the dynamic extrusion of fresh material embedded can affect the cement during its setting time, and the other, ‘the earliest time’ to assure that the time of supporting the freshly formed section of the ceiling has been long enough, and concrete age assures the necessary compressive strength and the structure can start functioning as a self-supporting structure from that time onwards.

7.1 The latest time of concrete mix embedding

According to the conditions of correct workmanship, after t_{pw} – onset of cement setting, the concrete mix must not be moved or exposed to vibrations, initiated here by the machine upon material compaction, as this might cause damage to the bonding crystals formed. Therefore, it must be assured that the formed mix is no longer exposed to vibrations transferred by the material laid from the added and mechanically compacted mix still before the onset of CSA cement setting. Because of intense attenuation occurring in the pressure-densified fresh mix in our solution, the vibration zone is small, and already at a small distance a, totalling up to a few cm from the surface of direct exposure to compacting machine blades, the harmful impact is limited.

Therefore, in reference to each portion of the mix, at a time shorter than until the onset of CSA cement setting, components must be mixed with water, transported, and embedded, with such a quantity of material added so that the operating zone of the machine is moved away to the distance a, in order to eliminate the negative impact of vibrations. This can be written as:

$$t_{pw} \geq t_m + t_{tw} + t_a \tag{2}$$

t_{pw} – time interval from mixing components with water until the onset of CSA cement setting time, t_{pw} = 32 minutes,

for concrete mix portion (mixed with water at time t) duration:

t_m – component mixing, t_m = 2 minutes,

t_{tw} – transport and extrusion (in the most unfavourable case, with mix transport to the most remote embedding location, namely at the section of 3 m) t_{tw} = 9 minutes,

t_a – construction of a ceiling section with length a = 8 cm, in minutes.

After transforming the equation (2) and substitution of values, the construction time of section a = 8 cm of the ceiling must meet the following condition: $t_a \leq 21$ min.

7.2 The earliest time of formwork removal

Automatic machine forms the ceiling section on consecutive mobile formwork discs that move underneath, continuously under the freshly placed concrete mix, cf. Fig. 1. Characteristic compressive strength $f_{ck(t)}$, as above, depends on age t – of the analysed portion of concrete. According to section 6.1, a slab of reinforced concrete automatically formed on formwork discs achieves self-support function in the span between the supports, namely state I, at the age of CSA-based concrete totalling t_{I}. Therefore, the earliest time of removing the formwork supporting the ceiling in the span between the supports corresponds to the age of concrete totalling t_{I}. When analysing the embedding process, one can write it as:

$$t_{\mathrm{I}} \geq t_m + t_s \tag{3}$$

t_{I} – age of concrete upon the ceiling slab becoming self-supportive (without an external load) in the span between supports – state I, t_{I} = 90 minutes,

t_m – as above, component mixing time (t_m = 2 minutes; here, during the mixing, the material is transported to the nearest place of embedding; hence, the time t_{tw} – transport and extrusion was omitted)

t_s – applicable period of supporting the ceiling slab in the span between the supports with mobile formwork, in minutes.

After transformation of equation (2), the applicable period of supporting a ceiling slab section in the span between the supports with the mobile formwork (corresponding to the earliest time of the ceiling becoming self-supportive in the span between the supports) can be specified with the equation:

$$t_s \geq t_{\mathrm{I}} - t_m. \qquad (4)$$

Due to the short time of component mixing t_m, the assumption is that $t_s \geq t_{\mathrm{I}}$.

7.3 Maximum speed of machine and mobile formwork movement

The automatic machine moves in the time t_s (namely period where concrete achieves the strength to assure self-supportive ceiling in the span between the supports) at the section with the length of:

$$s = vt_s \qquad (5)$$

v – ceiling construction speed, corresponding to the moving speed of the automatic machine, cm/min.

In order to meet the condition of ceiling support in the span between the supports for the applicable time interval t_s, it is required that l – the width of formwork discs supporting the curing concrete (cf. Fig. 1) is not lower than s – length of the ceiling section constructed in such time interval t_s, hence:

$$l \geq s. \qquad (6)$$

In equation (5), following the substitution for s and transformation, velocity v of machine movement when constructing the ceiling must meet the following condition:

$$v \leq l/t_s\,. \qquad (7)$$

In the case analysed, when freshly constructed ceiling is supported by formwork discs at the section l = 1.5 m, and with value t_s = 1.5 h, the moving speed of the machine is low, and totals $v \leq 1.0$ m/h (namely $v \leq 1.67$ cm/min).

Similarly, efficiency Q of embedding concrete mix in m^3/h can be calculated using the equation:

$$Q \leq hbv, \qquad (8)$$

h and b – respectively, thickness and width (span) of the ceiling section constructed, m.

In the case of a ceiling with slab thickness of h = 0.15 m, span b = 3.3 m and machine and formwork movement velocity as above, $v \leq 1$ m/h, concrete mix embedding efficiency totals $Q \leq 0.45$ m^3/h (namely 7.52 dcm^3/min).

8 Conclusion

The prototype *stropotronic* technology for construction of monolithic concrete ceilings with mesh reinforcement:

- envisages numerical control of an integrated sequence of machinery in charge of: intermediate material stock – dosing, mixing, and transport of components – placement of reinforcement and extrusion of the concrete mix – support of the formed structure during concrete curing for the required period of time;
- applies the system for material preparation and feed, including a robot embedding the reinforcement mesh of main steel rods and distribution rods of glass fibre, as well as concrete mix on rapid setting CSA cement, as well as simultaneously moving mobile formwork to support the constructed structure during concrete curing time, until the ceiling slab achieves self-supporting properties (across the span between the supports; after the formwork has been removed from the ceiling constructed, the self-supporting slab must not be exposed to external loads for 24 hours).

  Owing to numerical control, and as a result of precise operation of the robot embedding the materials, and mobile formwork, it is possible to apply the CSA (calcium sulphoaluminate) cement-based concrete which, after mixing with water, is characterised with:
- very short time to the onset of cement setting (approximately 0.2 to 0.5 h);
- next, immediate concrete hardening and rapid increment in its early strength, e.g. compressive strength f_{cm} – average test values were over 24 MPa, 37 MPa, and 44 MPa, respectively after 1.5 h, 24 h, and 168 h, while characteristic values $f_{ck(\mathrm{t})}$ calculated according to the proposed equations totalled, respectively 20.9 MPa, 33.9 MPa, and 39.3 MPa;
- ceiling slab made as above achieves state I of self-support (across the span between the supports) after 1.5 h, state II allowing for execution of planned layers in the ceiling – after 24 hours, while state III of complete load bearing capacity adjusted to target loads is achieved after 168 hours.

  According to the calculation algorithm, the conditions of timely works execution in respect of each concrete mix portion are continuously controlled in the aspect of:
- the latest embedding time,
- the earliest formwork removal time,
- through control of material preparation and embedding efficiency, as well as robot and mobile formwork moving speed.

Characteristics of *stropotronic* technology include:

- liberating people of hard physical labour, including the need to prepare labour-intensive formwork in difficult site conditions;
- adjustment of the equipment and progress of works to the properties of materials applied; here: rods of glass fibre and CSA cement;
- limited involvement of technical means, namely low weight and low capital intensity of the solution.

About the IAARC Community and Annual ISARC

The International Association on Automation and Robotics in Construction is the world's leading network of professionals and researchers in architecture, engineering, construction, and facility management (AEC/FM) who feel that the practice, education, and research of automation and robotics in construction have to transform in order to respond to the world's existing and future challenges. What historically has been organized by leading academics around the world has turned in 1990 to the world's leading International Organization for Automation and Robotics in Construction (IAARC).

By then a number of international symposia had already been convened and since 1984 the International Symposium on Automation and Robotics in Construction (ISARC) is IAARC's annual flagship event where both practitioners and researchers, industry and academic leaders meet. While ISARC has steadily grown over the past years it has always been presaging most of the innovations that have prominently emerged in the construction and infrastructure industries. Topics including 3D reality capture (i.e., laser scanning, drones), augmented/mixed/virtual reality (AR/MR/VR), artificial intelligence (AI), information modeling, 3D printed, automated heavy equipment, lean construction, supply chain management, prefabrication, and modularization have all been researched under the IAARC umbrella.

While the IAARC members come from all over the world, most are from the various industry and academic sectors in construction. Their common tie is to work together to drive innovation in safety, productivity, efficiency, and quality performances in an industry often pointed to lag behind others. The proclaimed goal of IAARC is to improve processes and people in the construction industry by advancing research and education on technology and innovative practices.

Even IAARC's open source intellectual property (IP) approach is innovative. Over 4,500 ISARC proceedings are all freely available on the IAARC website, with a new set added every year. Numerous innovations first researched within the IAARC community eventually emerged as commercial technologies, processes, and products, though in some cases it has taken decades. The recent uptake in interest of the AEC/FM community in transforming an entire industry through information and communication technologies (ICT) has considerably shortened the path of commercializing scientific research. Research-to-product (R2P) as well as rigorous prototype testing of integrated, practical, or operative solutions result in novel intellectual property (IP).

Other IAARC success stories involved innovative and forward thinking principles and methods like real-time automated material tracking, digital site layout planning, robotic platforms for automated assembly, human-machine interfaces, laser scanning for point cloud data acquisition and as-built modeling, internet-of-things (IoT), wearable sensing and actuation devices for safety and health monitoring, and many more. These are just a few of the topics that are presented at the annual ISARCs. Contributions of the most recent ISARC have proven that research and development on automation, robotic and digital technologies go hand-in-hand. They are about transforming the way we design, construct, or operate the built environment. It is therefore worth attending an ISARC where academic and industry leaders meet to bring much needed change to our industry! For more information, please visit http://www.iaarc.org.
