1. Auflage 2018

Umschlaggestaltung: Jochen Teizer, Bochum

Introduction

This publication is the Proceedings of the 35th International Symposium on Automation and Robotics in Construction (ISARC). The symposium which had 490 attendees was held in the Maritim proArte and at the Technische Universität in Berlin, Germany during 20-25 July 2018. The Proceedings include an illustrated review of the program (in German language, previously published in BAUINGENIEUR), the names of organizations and persons who contributed to the technical program, and the 174 technical papers from 36 countries authored for this international meeting.

The manuscripts were presented during 29 sessions, among them: safety and health, information modeling, advanced sensing and imaging technologies, automation, robotics, control systems, intelligent computing on data processing, internet of things, 3D printing, emergency response, construction management, infrastructure and tunneling, augmented and virtual reality, data visualization, unmanned aerial vehicles, education, and ergonomics.

Please note: All ISARC proceedings since 1984 are available at no cost at http://www.iaarc.org.

We are very grateful for the support of so many. Thank you!

Dr. Jochen Teizer, Ruhr-Universität Bochum (General Chair, ISARC and Hackathon)

Dr. Markus König, Ruhr-Universität Bochum (Co-Chair, ISARC)

Dr. Timo Hartmann, Technische Universität Berlin (Co-Chair, Hackathon)

ISARC 2018: Internationale Konferenz und Hackathon zur Automatisierung und Robotik im Bauwesen

J. Teizer

1 Einleitung

Die „International Association for Automation and Robotics in Cosntruction" (kurz IAARC: www.iaarc.org) ist das weltweit führende Netzwerk von anerkannten Fachleuten aus der Wissenschaft und Industrie zur Entwicklung und Anwendung von Automatisierung und Robotik im Bauwesen. Seit 1984 bietet IAARC das jährlich stattfindende „Internationale Symposium on Automation and Robotics in Construction" (ISARC) an. ISARC bietet Führungskräften und Anwendern aus Verbänden, bauausführenden oder beratenden Unternehmungen, Technologie- und Softwarefirmen, Architektur- und Planungsbüros, Hochschulen und Universitäten eine außergewöhnliche Lern- und Austauschmöglichkeit, um Innovation in Prozessen und Technologieanwendungen in allen Projektlebenszyklusphasen voranzutreiben.

Nach 20 Jahren wurde wieder einmal Deutschland mit Berlin als Austragungsort der 35. ISARC-Veranstaltung gewählt. Vom 20. bis 25. Juli 2018 kamen insgesamt 490 internationale Teilnehmer aus 36 Nationen zusammen (**Bild 1**). Darunter befanden sich neben Professoren, Doktoranden und Studenten auch 120 Vertreter aus Politik und Bauwirtschaft. Es wurden aktuelle Forschungsergebnisse und praxisrelevante Innovationen vorgestellt.

Den Auftakt machte ein dreitägiger Hackathon mit mehr als 190 Teilnehmern, die in 27 Teams zusammen mit Industriepartnern Prototypen als digitale Lösungen entwickelten. Die Spannbreite der vorgestellten Themen reichte von der Integration von IoT-Systemen über intelligentes parametrisches Design, Anwendung von Virtual und Augmented Reality bis hin zum 3D-Druck.

Organisiert wurde die Konferenz von Dr. Jochen Teizer und Prof. Dr. Markus König vom Lehrstuhl für Informatik im Bauwesen der Ruhr-Universität Bochum sowie Prof. Dr. Timo Hartmann vom Institut für Systemtechnik der Technischen Universität Berlin. Unter der Schirmherrschaft des Bundesministeriums für Verkehr und digitale Infrastruktur und des Hauptverbands der Deutschen Bauindustrie e. V. unterstützen zahlreiche Sponsoren das Programm der ISARC 2018, darunter die Deutsche Forschungsgemeinschaft (DFG), weitere Bausoftwareunternehmen, Planungsfirmen und Technologie- und Systemintegratoren. Baufirmen ermöglichten als Teil des Rahmenprogramms zwei Baustellenbesichtigungen in Berlin, auf denen aktuellen Trends der Digitalisierung des Bauwesens, unter anderem BIM auf der Baustelle, praxisnah vorgestellt wurden (**Bild 2**).

Im Folgenden werden einzelne Veranstaltungshöhepunkte während der ISARC 2018 im Detail erläutert.

2 IAARC

In der Geschichte der IAARC wurden einige wichtige Entwicklungen vorangetrieben, die mittlerweile in der Baupraxis eingesetzt werden. So wurden bereits vor der Jahrtausendwende beispielsweise die Themen Building Information Modeling (BIM), 3D-Druck, Radio Frequency Identification (RFID) für Materialtracking und Robotik als industrielles Bauverfahren maßgeblich von Forschern und Entwicklern der IAARC beeinflusst. Das IAARC Board of Directors (BoD) ist daher für die strategische Ausrichtung der IAARC-Organisation verantwortlich. Ausgewählte internationale Vertreter aus der Wissenschaft, Technologieentwicklung und Baupraxis nehmen daran teil, um unter anderem die strategischen Ziele in der Automation und Robotik des Bauwesens zu definieren und zu koordinieren. Dieses Jahr konnte auch eine Delegation der Vereinigten Arabischen Emirate (VAE) und des Schwedischen Bauverbands begrüßt werden (**Bild 3**).

Dr. Abdullah Bin Mohammed Belhaif Al Nuaimi (Minister für Infrastrukturentwicklung), in Anwesenheit des VAE-Botschafters für Deutschland Ali Abdulla Al Ahmed, erklärte wie wichtig Innovation im Bauwesen sei. Der Minister machte in seiner Eröffnungsrede sowie während verschiedener Diskussionen mit den Teilnehmern sehr deutlich, dass die Automatisierung und insbesondere die Robotik das Arbeiten auf der Baustelle und auch in den Ingenieurbüros in Zukunft grundlegend verändern wird.

Auch der Schwedische Bauverband, vertreten durch Führungspersönlichkeiten mehrerer Bauorganisationen, pflichtete bei, dass Wissenschaftler/innen, Unternehmen und Anwender viel enger miteinander kooperieren müssten, um vorhandene Innovationspotentiale rascher in der Praxis zu implementieren. Nur so bleibe die europäische Bauindustrie wettbewerbsfähig.

3 Intl. AEC/FM Hackathon

Erstmals fand begleitend zur ISARC ein internationaler Hackathon statt. Es kamen 190 Entwickler, Studierende, Nachwuchswissenschaftler und junge Berufstätige aus Start-ups, Universitäten und Bauindustrie zusammen, um gemeinsam Software- und Hardware-Lösungen zu bestehenden Problemen der Bauindustrie zu konzipieren, prototypisch umzusetzen und testweise zu erproben. Das Programm des Hackathons richtete sich vor allem an jüngere Teilnehmer, deren Unternehmergeist geweckt oder gestärkt werden soll. Innerhalb von drei Tagen konnten so innovative Ideen gemeinsam mit Firmen umgesetzt werden und berufliche Perspektiven im Bauwesen eröffnet werden (**Bild 4**).

Bild 5. Präsentationen der 27 Hackathon-Teams vor der internationalen Expertenjury

Bild 6. Ein striktes Zeitlimit (max. 5 min) betont die Problemstellung, den Lösungsansatz, die Ergebnisse und die Wirtschaftlichkeit jedes Hackathon-Themas.

Bild 7. Robotergestütztes 3D-Drucken

Bild 8. 490 internationale Teilnehmer an der ISARC 2018 in Berlin

Nach der Teilnahme an halbtägigen Workshops zu den Themen Building Information Modeling (BIM), Big Data Mining, Remote Sensing, Internet of Things (IoT) und Augmented and Virtual Reality (AR/VR) bildeten sich 27 Teams welche unterstützt durch die Expertise internationaler Mentoren an einzelnen, selbstdefinierten Problemstellungen der Bauindustrie arbeiteten. Innerhalb von zwei Tagen wurden beachtliche Erfolge erzielt und anschließend die herausragenden Teams anhand der Bewertung einer internationalen Jury mit insgesamt sieben Preisen ausgezeichnet (**Bild 5** und **Bild 6**).
Unter den teilnehmenden Teams fanden sich anspruchsvolle Themen in der AR/VR, BIM-basierter Takt- und Steuerungsplanung, Robotik zur Herstellung von Straßenmarkierungen, Verkehrsflusssimulation zur Unfallanalyse, Modularisierung, Arbeits- und Gesundheitsschutz, intelligente Sensoren für Baustoffe und automatisierten Fertigung von Bauteilen (**Bild 7**).

4 ISARC 2018

Das Programm der ISARC 2018 umfasste 168 hochwertige Beiträge aus der Wissenschaft und der Industrie zur Digitalisierung des Bauwesens, unter anderem der Bauplanung, des technologieunterstützten Lean Construction, der sensorbasierten Datenerfassung (z. B. Verortung durch RFID/LoRa, GNSS, Laser Scanning, Drohnen), der computergestützten Datenauswertung (Big Data Mining), der erweiterten und virtuellen Realitäten (AR/VR) in der Aus- und Weiterbildung von Fachkräften bei Wartung, Montage, und Monitoring der Prozessabläufe, der Bauwerkinformationsmodellierung (BIM), der Baumaschinen- und Baugeräteautomation, der Modularisierung und Vorfertigung (u. a. Roboteranwendungen und 3D-Druck als neue Bauverfahren), der Internet der Dinge (IoT) (u. a., Cloud-Entwicklungen und mobile Endgeräte für den Einsatz auf Baustellen), sowie zahlreiche weitere interessante und aktuelle Themenfelder um Bauprojekte zuverlässiger planen, abwickeln und

Bild 9. Keynote von Dr. Ilka May zum Thema Gamification in der Bauindustrie

betreiben zu können (**Bild 8**). Auch das Schaffen nationaler und internationaler BIM-Standards zur digitalen Projektzusammenarbeit unter Verwendung von offen Schnittstellen (z. B. IFC: Industry Foundation Classes – ein offener Standard im Bauwesen zum Datenaustausch von Gebäudemodellen) war ein Thema der ISARC 2018 und dem internationalem AEC/FM Hackathon in Berlin.
Zwei Keynote-Präsentationen, gehalten durch Dr. Ilka May und Prof. Frédéric Bosché, verdeutlichten eindrucksvoll den Einsatz von Technologien der Computerspielentwicklung und der virtuellen Realität in Bauprojekten (**Bild 9**).
Die nächste ISARC 2019 findet vom 21. bis 24.Mai 2019 in Banff, Kanada statt (www.isarc2019.org). Vorrangige Themen der ISARC 2019 werden Modularisierung, Vorfertigung, Automatisierung und Robotik sein.

Unter http://www.iaarc.org/ sind alle ISARC Conference Proceedings seit 1984 abrufbar. Dort sind insgesamt mehr als 6 000 wissenschaftliche Publikationen frei verfügbar.

Abstract –

Tracking and monitoring resources in construction is of great interest to an industry that is in the continuous pursuit of reducing waste. Real-time location sensing technology like Global Navigation Satellite Systems (GNSS) and/or in combination with Radio Frequency Identification (RFID) have already been introduced in commercial applications to report the position of valuable construction resources such as equipment or materials. While several other communication protocols exist, unfortunately little is known about the performance and applications of LoRa (Long Range), a wireless data communication technology for very-long-range transmissions up to several kilometers at low power consumption. This paper first introduces the need for such technology and then explains the integration of LoRa in an Internet of Things (IoT) network, which enables to connect, collect, and exchange data for construction applications. The novel focus of this study is the evaluation and testing of LoRa in realistic construction work environments. The experiences made with the developed LoRa-technology are in particular useful for demonstrating the applicability of LoRa in the construction logistics and lean management sectors.

Keywords –

Building Information Model (BIM), construction resources, Global Navigation Satellite System (GNSS), Internet of Things (IoT), logistics, Long Range (LoRa), Radio Frequency Identification (RFID), tracking and monitoring, Ultra Wideband (UWB).

1 Introduction

Today's construction sites in Europe have become more international due to laws in the European Union (EU) that call for competitive tenders for most of the public works. A bundle of evaluation requirements exist; some examples are: (a) company experience (i.e., previous work, years in business, geographic territory, previous customers), (b) organizational structure (i.e., management processes, operational procedures, hiring and training programs, turnover), (c) quality performance, (d) safety records, (e) senior management experience, (f) current projects, and (g) financial strength. These and more influence the selection of a qualified contractor. While owners, financing lenders, and insurance agencies demand lowest possible risk in any of the aforementioned criteria, little focus has been set on measuring a contractor's ability to track and monitor its operation aside from running its business.

Another motivation for conducting this study originates from research on lean construction. Results on monitoring shell and interior construction show that waste times of 19 % are directly avoidable [1]. Some of the most wasteful activities observed in this study are reported as unnecessary ways and handling of material (10%), searching for equipment (6 %), and waiting for equipment (3 %). The same study sees further potential for the optimization of construction operations: an additional 16% of the total working time could be saved by reducing manual transport (9 %), information gathering and delivery (4 %), and clearing and rearrangement (3 %). Multiple other research studies, some of them using advanced technologies, found similar potential savings once construction site operations follow lean principles, i.e., optimizing the usage and disposition of construction machines, reducing material search times and idle times of equipment [2].

Fortunately, in recent years leading contracting organizations have been starting the adoption of technology that assists in some of the time-consuming and vulnerable tasks of performing the daily management of operations at their construction sites. One of such tasks, as highlighted originally in research by [3-5], is tracking and monitoring construction materials and equipment. Grau et al. [5], for example, called for a reduction in wasted work time for unnecessary ways and waiting and non-optimal disposition of equipment or materials. Their study demonstrated an 8:1 return on the investment and an overall 4.2% productivity gain once intelligent material tracking is applied.

While monetary benefits such as the expected gains from productivity improvements are often the main driver for a change in the existing construction business processes and operational practices, availability and retention of qualified workforce is yet another major issue that has to receive more attention in many contracting organizations [6]. Construction workforce at all levels has typically different backgrounds, e.g., education, experience, skills, and language. Measuring the impact of applying novel technology into practice and how well it potentially benefits or is eventually disliked by the workforce has yet to be explored in greater detail.

For the above mentioned reasons, namely leveraging technology for construction site operations monitoring and adoption by its workforce, this study investigates a novel communication protocol called LoRa (Long Range). The following sections of this paper are structured as follows: first a brief introducing on the shortcomings of existing tracking and monitoring technologies in construction is presented. The sections thereafter explain the developed LoRa-approach by measuring the location error, checking the reliability, testing the usability, and evaluating the practical benefits for implementation in construction operations. A discussion on the remaining limitations and an outlook for future work conclude this paper.

2 Background

While a vast body in the construction-related literature exists on location tracking and status monitoring, the scope of this review focuses on the use cases for the Internet of Things (IoT) and technologies as they relate to construction material and equipment location tracking and monitoring.

2.1 Internet of Things (IoT) in construction

The Internet of Things (IoT) stands for the digital mapping of the physical world and the ability to monitor and manage real things in the digital sphere [7]. With the IoT, data gathering by sensors and processing digitally via the cloud, for example, can be performed in a much faster and less complex way than real world objects and processes. This enables acceleration and optimization by data-driven decisions of many construction systems and businesses.

Already available in the IoT is the digital information from build-in sensors, computers and personal devices like smartphones. In a next step additional distributed sensors, for example installed on construction materials and equipment, complement this set of data. The data transfer of such assets is typically wireless without requiring human-to-human or human-to-computer interaction. The data is also collected on clouds for easy access and for further evaluation.

Decision criteria for wireless distributed sensors are typically the cost of hardware and use, usability, reliability, robustness, and lifetime. For any successful innovation in construction, these factors have to be fitted to specific needs in an organization's use cases.

Since the operation of many construction sites is still very complex and dynamic, much of it would benefit from wireless distributed sensor applications, in particular as they relate to location tracking and monitoring. Often named use cases (bold boxes) and some of their positive influences (grey boxes) thereof for location sensing are shown in an overview in Figure 1.

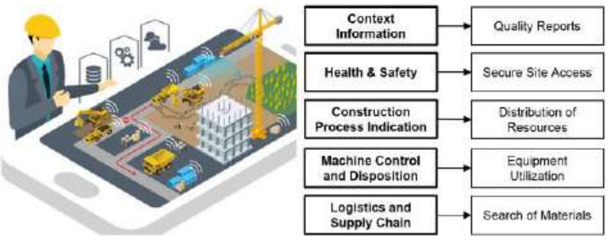

Figure 1: Typical construction uses cases and outcomes of distributed sensing [courtesy of Robert Bosch GmbH]

2.2 Location tracking and monitoring

Several ways exist to measure, communicate, and use positioning data. We define the term *location tracking* for the continuous gathering and transmission of a resource's (material or equipment) positioning data over time, while we speak of monitoring in terms of the simultaneous processing of the data to yield information which is then used in specific construction applications, such as resource location or resource status monitoring.

There are several dedicated systems for determining geolocation and time information. One of the most popular ones are grouped under the umbrella of *Global Navigation Satellite Systems (GNSS)*: GPS, GLONASS, Galileo, or BeiDou. These consist of satellites that continuously transmit data about their current position and time. On earth, a receiver monitors multiple satellites (a minimum of 4 of any GNSS) and logs the precise position in a high resolution time interval [8]. Clock calibration data and correction data is stored in the almanac (an internal database).

While the use of GNSS in *professional surveying applications* such as performed in earthwork activities (i.e. automated machine guidance) requires very high precision, many outdoor construction applications focus on *location awareness applications* that demand lower precision (typically within the meter range) [4-5, 9-11]. In both scenarios, the largest errors in GNSS positioning are attributable to the atmosphere such as distortions caused by the ionosphere (i.e. signal delays caused in space), troposphere like bad weather (i.e., cloud coverage), or multipath in dense work environments (i.e., reflections or obstructions from nearby high-rises).

Correcting such errors is expensive and often requires additional technologies. For example, telematics solutions for construction equipment are typically based on GNSS receivers for localization sensing. They use cellular networks for sending the data to a database where it is further processed. Although a GNSS receiver with current data in its almanac can acquire satellite signals more quickly (which helps determining the position faster), several minutes are generally needed to initialize the signal reception. This requires the receiver to be turned on (thus consuming power) and works only outdoors with a clear view (i.e., line-of-sight) of the sky. Alternative methods to get a faster GNSS-fix exist. A-GPS, for example, get their almanacs and approximate position from network stations (BTS, NodeB, eNodeB) based on GSM or LTE technology. It is therefore generally cost-prohibitive for tracking applications that would require to equip large numbers of items. Although their form factors (i.e., dimensions) have decreased in size over time, these reasons ask for alternative technologies.

A second technology closely related to this study and already applied in construction operations is called *Radio Frequency Identification (RFID)*. RFID solutions allow tracking, but require a tag located on the desired object. There are active, semi-active/passive and passive RFID tags consisting of scanners or antennas that read them [4-5, 12-13]. Depending on the type of RFID, the read range of the antenna can be from centimeters (passive tags) to several dozen or hundreds of meters (active tags) [14]. The advantage of passive RFID technology is that no internal power source is needed on the tags. These tags can be small in size, inexpensive once fabricated in large numbers, and attached to almost every type of material (even metal) [15].

Since RFID often transmits just the tag's identification number over shorter distances, no additional data like its precise positioning coordinates are available. A user demanding the terrestrial geolocation of construction assets in a large laydown yard, for example, thus has to combine RFID tags and antennas with a mobile GNSS receiver on a ground-based vehicle [5] or an unmanned aerial vehicle (UAV) [16]. Further software technology for data processing and visualization or managing of the timestamped geolocation information is also needed. As explained, the costs for implementation, use, and maintenance add up quickly (i.e., requiring also a licensed person for safely operating a UAV).

Other communication protocols based on radio frequency, including Near Field Communication (NFC) and Bluetooth Low Energy (BLE) for mobile applications, offer – as outlined in research – shortcomings. Imprecise and short read range limit their application in location tracking [17]. To name a few additional communication protocols that have been applied to or tested in construction are Zig-Bee, Z-Wave, Wi-fi, and Ultrawideband [18-19]. Although they were applied in specific scenarios perhaps relevant to construction, for example wireless personal area networks (WPANs) for high data transfer rates in home automation and communication, some of their distinct limitations are: high power consumption, additional signal sensing infrastructure requirements (e.g., number of nodes), low security standards, and limited range.

An alternative approach for location tracking are mobile radio standards. The Global System for Mobile Communications (GSM), for example, was first deployed in Finland in 1991 for fully digitalized mobile networks [20]. More recent distributed sensor-IoT solutions in smart city applications use unlicensed ISM bands (Industrial, Scientific, and Medical Radio Bands). They work in ranges of some kilometers and with very low bandwidths, so called Low Power Wide Area Networks (LPWAN). Most common LPWAN networks are Sigfox and LoRa. Both are a special design of autarkic distributed sensors with very low power consumption and cost of use. The main difference to LoRa is that SigFox is a network provider and any sensor devices to be used with SigFox has to be integrated within the SigFox network. LoRa is an alliance with more bandwidth than Sigfox and allows to build or use an existing LoRa network.

2.3 Introduction to Long Range (LoRa)

LoRa is filling a gap in wireless communications (Figure 2). Public LoRa-networks are currently being deployed all around the globe [21]. Just like mobile phones in a mobile phone network, LPWAN devices will be able to operate in public LoRa networks [22]. Private gateways will supplement public networks in the transition period.

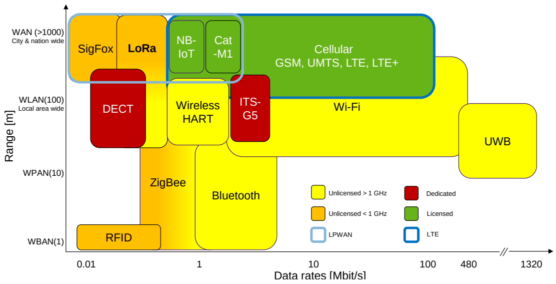

Figure 2: LoRa filling a gap for wireless communications

LoRa is specialized for the requirements of the IoT. LoRa offers secure bi-directional communication, localization, and mobility of services without the needs of static and complex installations. The open non-profit association called the LoRa Alliance has set itself the objective to standardize LPWAN to enable the IoT to guarantee interoperability in one open global standard. LoRa typically has a star-of-stars-topology. As shown in Figure 3, the end-devices (LoRaWAN slaves) communicate via LoRaWAN with the gateways that are within reach. A gateway serves as a transparent bridge by using a network connection (e.g., realized via GSM) to send the received data to a network server or vice-versa.

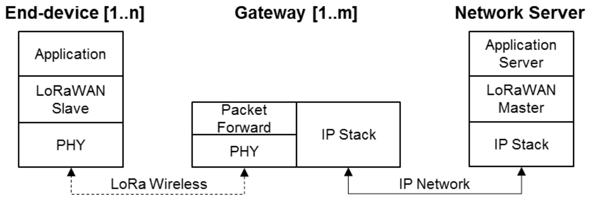

Figure 3: Communication in a LoRaWAN network (modified, after [21])

The communication between the gateway and end-device depends on data rates and frequency channels [23]. LoRaWAN data rates reach somewhere from 0.3 kbit/s to up to 50 kbits/s. However, because of the regulated restrictions on the 868 MHz frequency, only a maximum broadcasting time of 2% of the run time is permitted. At first look this restriction might limit many useful applications for LoRa in construction. However, the maximum throughput and probability of successful transmissions enable the tracking of thousands of objects.

Another increasingly important topic is security. LoRaWAN offers a multi-layer encryption for protecting sensitive data [24]. Regulations are Network Level Security and Unique Network Key (EUI64). A Unique Application Key (EUI64) provides security at the application level, and Device-specific button (EUI128). The encryption is particularly helpful once public wide area networks replace the local gateways on a construction site. Depending on a use case, sensors equipped with a LoRa end-device can transmit messages and receive acknowledgements or responses by listening to the network. This happens after sending requests on fixed intervals or in an always-on mode. The more power consuming is the always-on mode. The always-on mode, however, reduces the latency for time critical purposes, such as applications in infrastructure health monitoring. Optimized power consumption results in a battery life of many years. Theoretically, this enables LoRa sensors and devices to send and receive information even when located indoor or underground [23].

3 LoRa architecture

Many practical applications exist for LoRa in construction. Examples of much needed use cases in construction that can be solved are: locating and dispositioning assets, tracing off-site construction and checking-in inbound deliveries, finding of implements and tools, organizing fleets and cooperatives, monitoring machinery, geo-fence alerting, managing inventory and optimizing workflows, shock or temperature monitoring, maintenance or theft alerting, counting operation hours, and billing and providing evidence of back-office services. These examples in mind led to the design of a suitable LoRa-IoT architecture. The result is shown in Figure 4. While only providing low data rates, the main advantage of using GSM/LTE is the outdoor distance coverage. It makes it attractive for use in the proposed wide area field test. For sending the sensor data incl. the received position data from a built-in GNSS receiver the 300 ms latency of the LoRa is more than sufficient. The technology, incl. the LoRa device called thereafter TRACI, was later tested in realistic working environments common for construction.

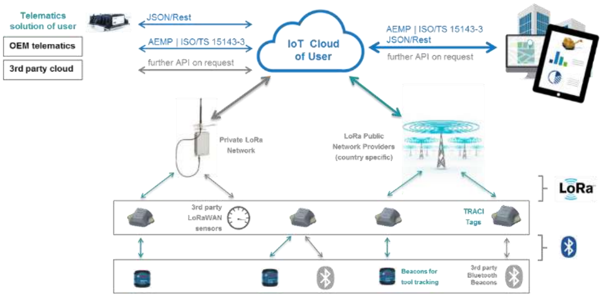

Figure 4: The LoRa architecture [image courtesy of Robert Bosch GmbH]

A TRACI tag with its integrated sensor stack delivers the following data, among other data:

- Network: LoRa - EU868 - Europe 863-870MHz
- Radios: Bluetooth 4.2 / passive NFC
- 3-axis accelerometer (+/- 2g 1mg; +/- 4g 2mg; +/- 8g 4mg; +/- 16g 8mg; fmax 2kHz),
- 3-axis magnetic field (3-axis, (+/- 1300µT 0.3µT),
- GNSS (ublox module) sensors
- Size and weight: 0,11 x 0,082 x 0,038m; 0.17 kg

4 Case study application and results

4.1 Geolocating

The position of the TRACI tag it determined through use of an embedded GNSS module. It has been found from interviews with leading construction organizations, that many use cases in construction require a position accuracy of less than 10 m which current Time Difference of Arrival (TDOA) methods for LoRa currently cannot deliver. Position accuracies of smaller than 200 m for LoRa TDoA can only be achieved with a high density of LoRa base stations (at least 3 gateways).

While this may serve some construction applications, like theft protection of expensive equipment, achieving lower error rates with denser networks would substantially increase the overall implementation and operational cost [22]. This is why TRACI needs a build-in and low-cost GNSS module and its performance must be tested.

The GNSS hardware (as explained before) used in this study achieved a *Center Error Probable 50%* (CEP50) of 2.3 meters (Figure 5). This result is based on a 24 hour measurement duration with 86,400 values. In the measurements performed for Figure 6 the use of GLONASS and Galileo, as additional satellite systems to GPS, did not lead to a measurable improvement in the position accuracy of the TRACI tag. Additional observations from tests with the developed LoRa device in a laboratory environment included:

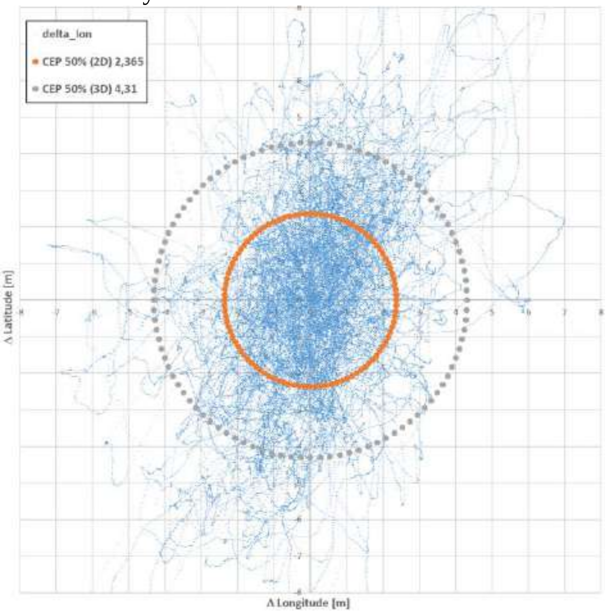

Figure 5: CEP50 for TRACI device (GPS only)

- Higher position accuracy comes at cost of battery life time. Figure 6 shows that a CEP50 increase from 2 to 3 meters can - in some cases - reduce the GPS-fix time from 100 seconds to below 20 seconds. Taking into consideration that TRACI's GPS-module consumes around 50 mA when active, reducing the CEP50 requirement can improve the battery life time of such sensors significantly.
- Due to the constraints of the limited bandwidth of LoRa, the sensor data is processed in the device itself with use case specific firmware. Sensor data is aggregated and processed in the application layer of the software. Doing so enables the transformation or gathering of (a) acceleration data or magnetic field data into operating hours of machines, and (b) strength of electric current or spatial orientation of the device itself. The aggregated data is then transmitted via LoRa to a cloud backend in compliance with the ISM-band duty cycle. From the cloud the data is shared via a JSON/REST API that allows stakeholders to add further value and build applications for different use cases.

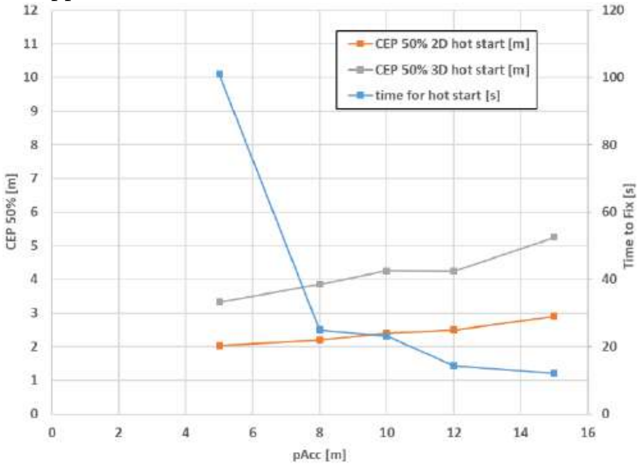

Figure 6: GPS fixe time over position accuracy (pAcc) for different CEP50

4.2 Equipment monitoring

The objective of the first field implementation of the TRACI tag was to automatically monitor a tower crane's operating time. Measurements were performed on a Wolff flat-top crane on a building construction site with a total number of 9 cranes. Usually, the TRACI tag measures operation hours based on vibration. The goal of this measurement, however, was to determine whether the acceleration signal of the motor of the main winch could derive the operation information. In case the acceleration signal is not strong enough, operation hours can also be counted with the help of its embedded 3-axis magnetic field sensor. For this reason, the feasibility of using the magnetic field signal of the motor was also assessed during the measurement (Figure 7). The gathering of the acceleration as well as the electromagnetic field data of the motor of the main winch (Figure 7, left image) resulted in data (Figure 8).

Figure 7: Implementation of Lora-tags on tower crane motors (i.e., raise/lower, move in/outwards, turn)

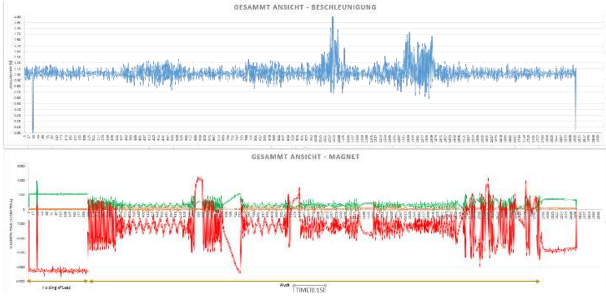

Figure 8: Typical machine data when accelerating the crane block: electromagnetic data shows the tower crane's activity (0 equals no crane activity)

From the large data set that was recorded, a snapshot of 190 seconds will be explored to highlight some of the findings. The motor's magnetic field signal shown in Figure 9 shows a measurement that was recorded while the crane performed several hoists (lifting and lowering) with a load of 1,700 kg at different speeds. Findings from the observation were:

- While further measurements with lighter loads did not lead to significantly different signals, loads had little influence on the magnetic field measured with the sensor.
- Acceleration measurements of the crane structure during idle time showed that the signal noise from wind and other external influences lead to vibrations on the crane with an amplitude of around 0.2 g absolute.
- The acceleration signal in Figure 8 shows, that the acceleration in most working conditions does not exceed the normal structural idle noise on the crane. Hence, the acceleration signal is not sufficient to reliably deliver the operating hours of the motor and subsequently the crane.
- The acceleration peaks at the beginning and end of the measurements are due to changes in the measurement range of the sensor and are not caused by the crane itself.
- The magnetic field components, represented by the three lines (red, green, and orange) show a strong signal which can be used for evaluation the working hours of the motor.
- The sampling rate in the data visualization tool used led to aliasing effects, which become obvious in a distorted and non-continuous signal behavior. The actual oscillation of the magnetic field does happen at a higher frequency than displayed. However, the amplitude of the signal shown in Figure 8 and the sampling rate of the sensor itself do allow for a precise determination of the actual operation hours of the motor, based on the magnetic field change only.
- Furthermore, the oscillation when working can be discriminated from the electrical holding of the load without mechanical breaks, which can be seen in Figure 8 in the first section of the measurement. Being able to differentiate between the two active modes of the motor leads to a more precise evaluation of the actual work happening.

These findings led to a more detailed investigation of the crane's activity. As shown in Figure 9, on one particular work day (24 hours), the crane was in operation a total of 7 hours and 6 minutes. For reasons of better visualization, the observation time was grouped into 40-min intervals. By analyzing the TRACI data only, the crane showed activity (bars in green color) in the intervals 22-26, 38, and 40-56. Within the intervals of activity, TRACI reported that the utilization of the crane varied (as shown by the percentage values). At all other times, TRACI reported no operation of the crane (red bars). The crane's utilization reported by TRACI was compared using the multi-moment-analysis (triple M) method [25]. The thin line (black) in Figure 9 indicates the results of a knowledgeable person briefly observing the crane at repeating, but specific time intervals. As can be seen, the manual not always overlaps with the automated data. On this particular day, this person did not record any crane activity in 6 while deviating in 4 other intervals for more than 30% from the results of the automatically recorded data. While these error show one disadvantage of the manual multi-moment-analysis method, data analysis and reporting can be delayed as well.

Figure 9. Crane use vs. idle time

The overall utilization of the crane given a 10 hour work shift over a 4 work day period can be assessed as the following.

- Day 1: 318 min or 53% of 600 min.
- Day 2: 287 min or 48%.
- Day 3: 314 min or 52%.
- Day 4: 284 min or 47%.

As a result, about half of the work time during the 4 days that crane was not utilized. An experienced manual note taker further assessed productive vs. wasteful activities of the time when the crane was in action on the first and last observation days. While these manually observed data points may not be compared with data from TRACI, the note taker reported productive work execution in:

- Day 1: 53.8% of 318 min.
- Day 2: 52.3% of 287 min.
- Day 3: 52.6% of 314 min.
- Day 4: 50.9% of 284 min.

This results in an overall productive utilization rate of the tower crane of about only 25%. While this data is not representative for other work days on this particular construction site, it may hint towards a larger potential for crane use optimization. This case study ended with some additional reasoning how automatically-generated crane data and its analysis might enhance its operation:

- The idle times of a crane can be recognized and subsequently optimized. Proper equipment resource allocation, such as crane availability to the competing work crews on the ground, can significantly impact a project's construction schedule, and in particular in high-rise construction where hoist times are often critical [26].
- The automatic recording and processing of crane data could be used, among other noteworthy examples, in (a) billing a subcontractor's crane use time, (b) recording the overall crane operating hours for resource leveling among all subcontractors, (c) alerting and calling for preventative maintenance tasks, and (d) overall progress monitoring of site activities based on historical estimates or real-time data.

5 Conclusions and Outlook

The construction industry is currently experiencing a change towards digitalization. Building information models (BIM), Internet of Things (IoT), mobile or smart wearable devices have become buzzwords for construction applications intended to follow lean principles. IoT for construction yet has to fully implement simultaneous data gathering, analysis and visualization. While a multitude of sensors exist to collect data, Local Range (LoRa) fills a gap in existing data communication protocols. This study has shown in an independent case study of how a novel IoT-LoRa architecture and its developed technology might be applied in construction. The study leveraged LoRa-tags in combination with magnetic field sensors on a tower crane for monitoring its activity. The results show that the technology exceeded the human capacity for the recording and the analysis of the plentiful of data that is available in construction. Future research though has to carefully evaluate the reliability of any of these technology in daily work practices (perhaps at much larger operation scale) as well as its impact on human workers. Further work may therefore focus on exploring human-technology interfaces and the richness of new information that is generated once it is applied to information models [27]. Once envisioned in applications for intelligent decision making tools, in particular as they relate to construction site logistics applications, much of the existing problems, such as uninformed decision making or unawareness of project or resource status, might be solved.

Abstract –
The resource efficiency and labor productivity in the construction industry are still viewed critically. Concrete 3D-printing processes have the potential to significantly improve both factors. Currently, research activities in this field are growing rapidly worldwide, thus similar advances and market developments can be expected, as have already occurred in other sectors of the stationary industry. The TU Dresden relies on the development of the CONPrint3D® (Concrete ON-site 3D-Printing). It specifically relies on: established machine technology, the production of fully filled concrete structures, sustainable concrete formulations with a maximum grain size of up to 16 mm and the use directly on the construction site. In contrast to small-scale 3D-printing processes, the data processing chain for large-format 3D-printing with concrete still has considerable deficits. In order to depict the complex solidification properties of the building concrete, computer simulations are indispensable as a basis for the development of an optimized printing strategy. In this paper, investigations on the strategic process optimization of concrete printing using the method CONPrint3D® are presented. First, the relevant boundary conditions of concrete 3D-printing are described. Subsequently, calculation methods of the trajectory planning are presented.

Keywords –
3D-printing; Concrete; Optimization; Simulation; Continuous path control

1 Introduction

The concrete installation directly on the construction site is very labor-intensive and time-consuming. The costs of formwork accounts for a high proportion of the shell costs, at around 25 % to 35 %, and the construction period is largely determined by the formwork. [1] As a result, the development of a construction method without any formwork, which uses continuous 3D concrete printing, can yield great savings. In other industries, such as medical or aerospace industries, 3D printing technology has developed rapidly in recent years and is now being used not only for prototyping, but also increasingly for the manufacturing of marketable components.

Experts agree that the use of 3D printing technology in construction offers both significant economic potential and new architectural design. Economic considerations for CONPrint3D® resulted in cost savings of around 25 % and four to six times shorter execution times compared to conventional masonry construction. [2]

Compared to the stationary industry, the boundary conditions are completely different for computer-aided manufacturing in the construction industry. Changing environmental conditions (such as site location, subsoil characteristics or environmental impacts) makes it difficult to introduce automated production methods on site. The increasing digitization and establishment of new planning methods, such as Building Information Modelling (BIM), can ease the introduction of automated processes on construction sites. A BIM model already contains all the data necessary to control the machine technology. The BIM data only has to be prepared for an optimized construction process and converted into data formats which are readable for the machine.

The key process in data preparation is the "slicing" of the 3D model. The term means the division of the 3D object into two-dimensional layers having a defined layer height. While slicing the structure, important input parameters are defined for the printing process, such as the printing paths, printing speeds or the material discharge quantity. Subsequently, a machine control code, usually in the form of a G-code, is outputted. The optimization of the printing strategies is extremely relevant to ensure the efficiency of the process. The construction process is usually computer simulated before printing.

This paper discusses the 3D concrete printer as a robotic platform based on CONPrint3D®. In the 2nd section, the concept is presented. In the 3rd section, design requirements are described. In the 4rd section calculation methods of the trajectory planning are presented. The 5th section gives a small outlook.

2 CONPrint3D® Concept

Since 2014, an interdisciplinary team at TU Dresden has been researching the development of an innovative concrete construction process. Based on the principle of extrusion, load-bearing building structures are to be continuously produced by 3D shaping fresh concrete. Figure 1 shows the main components of CONPrint3D®.

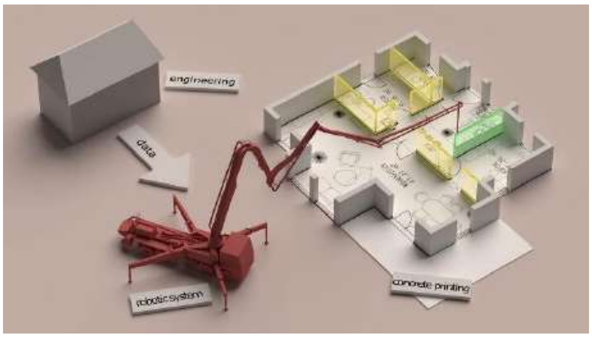

Fig. 1: Essential components of the concrete 3D printing process CONPrint3D®

As a mechanical platform, a modified truck-mounted concrete pump is used. Additional control technology and a newly developed print head ensure the continuous extrusion of the concrete and the geometrical precision on the construction site. The basis of the control process is a BIM-based planning. The necessary control data in the form of geometric data and material data are extracted from a 3D building model, then processed and transferred to the modified concrete pump. This allows the direct implementation of a previously created concreting plan in the machine control for automated movement. At the end of the geometrically precise distribution boom, the fresh concrete from the print head is laid out layer by layer with lateral shaping elements (see Figures 2,3). This

Fig. 2: Geometrically precise installation of the concrete by modified truck-mounted concrete pump

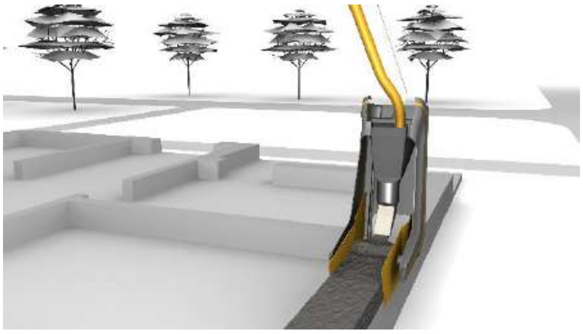

Fig. 3: Extrusion-based installation of fresh concrete using a newly developed print head

is how the building is constructed using the layering principle.

The research activities are clearly different from other global development work. The basic principles of the CONPrint3D® process are:

1. The execution takes place directly on the construction site (in-situ concrete construction).
2. The machine base represents a construction machine established on the market: the truck-mounted concrete pump.
3. Concretes with a maximum grain size of aggregates of up to 16 mm are used for the process.
4. Monolithic, fully filled concrete structures are created.

The research team of the TU Dresden consists of three institutes. The Chair of Construction Machinery handles the mechanical implementation. The Institute of Building Materials develops the special concrete technology. The economic implementation on the construction site and the productivity of the application as well as an optimized data management are ensured by the Institute for Construction Management.

Within a theoretical study, the feasibility of all three areas was initially ensured. Within laboratory tests on a scale of 1: 5 (see Figures 4 and 5), suitable concrete

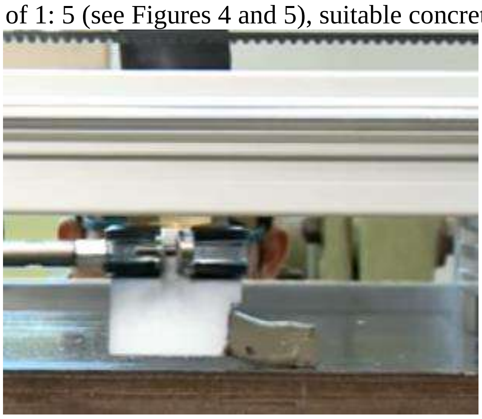

Fig. 4: Concrete technological extrusion trials on a scale of 1: 5

Fig. 5: Printed concrete components for the investigation of the layer composite

recipes were developed, decisive strength values determined and the layer composite investigated. More detailed results are included in further contributions of the research team [2, 3, 4, 5, 6].

In a primary development step, CONPrint3D® aims to produce unreinforced concrete structures. The integration of reinforcement elements and other materials (eg. TGA installations, plaster or thermal insulation) is planned only in the long-term development. First of all, CONPrint3D® focuses on producing unreinforced walls directly on the construction site in order to replace traditional masonry and drywall construction. Thus, the main field of application of CONPrint3D® is in residential construction.

3 Design requirements

In the literature, Additive Manufacturing (AM) methods are often referred as 2½-D methods. The layers are generated in the x-y plane, the so-called printing plane. The layer thickness is usually constant. This creates the third dimension in the z-direction only by the superimposition of the individual layers. [7]

CONPrint3D® is characterized by the fact that the wall cross-sections are completely filled with concrete by a driving movement. In addition, sharp-edged 90° corners are to be generated. In other research activities, smaller concrete strands are printed resulting in round corners with small radii. The different methodological approaches are compared in figure 6.

In order to produce wall connections with CONPrint3D® in a force-fitting manner, conventional solutions already exist in masonry construction, which can be transferred. Accordingly, there are fundamentally three ways to produce force-fitting wall connections:

- Constructive gearing by alternating layer arrangement,
- Surrounding of the walls to be connected,
- Connection by stainless steel flat anchor systems.

Fig. 6 left: Approach of CONPrint3D®
right: Extrusion of smaller concrete strands with round corners and subsequent concrete filling [8]

The examination of the geometric requirements reveals that three different categories of wall connections can be distinguished:

- Corner joints,
- T-connections,
- Intersections.

In this article, the constructive execution of corners is to be considered more closely. The non-positive wall connection should be made by constructive gearing. Table 1 describes the printing structure of force-fitting corners.

Wall connection	Layer 1, 3, 5, …	Layer 2, 4, 6, …
Corner		
Table 1: Printing-strategy to produce a force-fitting corner

In order to produce a force-fitting corner connection by constructive gearing, two different printing paths are required, which repeat alternately over the entire wall height. In contrast to other global research activities, which track strands pressure, only one printing path is to be developed, thereby followed in every layer.

In order to create a wall corner connection with the given geometry of the CONPrint3D® printhead (see Figure 7), certain movements must be considered. This is illustrated in figure 8.

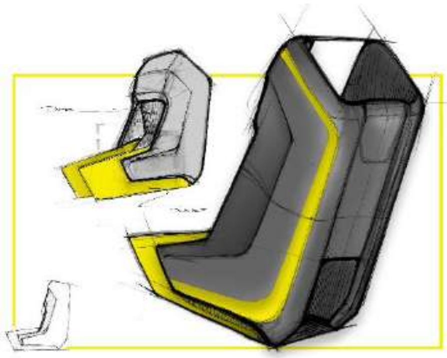

Fig. 7: Design of the printhead [3]

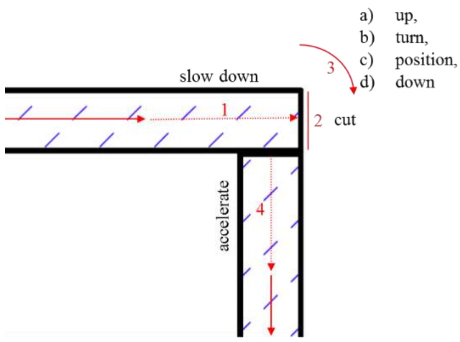

Fig. 8: Movement of the printhead at a corner

In the area of the recesses (door and windows) no material is discharged. The soffit is realized by a) decelerating, b) Cutting off the concrete, c) Driving without material discharge, or d) accelerating with material discharge. Above the windows, a prefabricated lintel is inserted similarly to the masonry construction. The layer height depends on the nozzle opening and the printing materials. With CONPrint3D®, layer heights of 5.0 cm can be reliably achieved.

4 Planning the Trajectories of the Printer

The task to develop the trajectories of the end effector motion of a manipulator is reduced to describing a sequence of motions in the plane X_P, Y_P parallel to the plane X_0, Y_0 of the robot coordinate system. The Z_P coordinate does not change within one stacking cycle, and then increases by an amount Δh, corresponding to the thickness of the stacked layer.

Figures 9 and 10 show examples of floor plans for different monolithic objects. As can be seen from the diagrams in figures 9 and 10, the trajectories of motion are either a set of rectangles or circles. When constructing the static frame of an apartment house (see Figure 9), it is necessary to formulate an array of coordinates of points on the basis of the building plan and to determine the sequence of traversal of rectilinear sections.

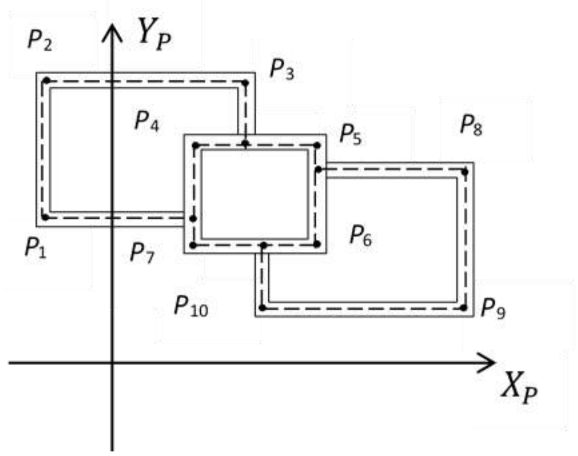

Fig. 9: Static frame of an apartment house and the trajectory of motion of the end effector

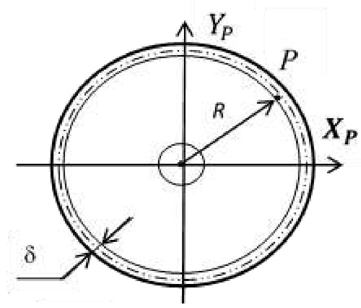

Fig. 10: Plan for a monolithic tower and the trajectory of motion of the end effector

Each section can be described by equations of the form:

- for sections parallel to the X-axis

$$X_0 \to P_{jS}(x_{jS}, y_{jS}), P_{jE}(x_{jE}, y_{jE})$$

$$y = y_{jS} V y_{jE} \to x_{jS} \le x \le x_{jE}; \quad (1)$$

- for sections parallel to the Y-axis

$$Y_0 \to P_{iS}(x_{jS}, y_{jS}), P_{iE}(x_{jE}, y_{jE})$$

$$x = x_{iS} V x_{iE} \to y_{iS} \le y \le y_{iE}. \quad (2)$$

When building tower-type structures, the printer is placed on a telescopic carrier platform in the center of the structure. Therefore, its trajectory is a circle (see Figure 10) of radius R_{0P} lying in the horizontal plane X_P, Y_P:

$$(x - \Delta x_{0P})^2 + (y - \Delta y_{0P})^2 = R_{0P}^2,$$

where $\Delta x_{0P}, \Delta y_{0P}$ – is the deviation of the load-bearing platform from the design axis of the erected structure. These parameters are automatically controlled by laser control systems and are entered into the robot control system. Planning of movements of robots is performed in generalized coordinates. This means that for each section of the trajectory of the nozzle, it is necessary to obtain a temporal law of variation of each generalized coordinate of the manipulator, which provides the required motion, i.e. it is necessary to formulate for each sector a vector

$$q(t) = [q_{1i}(t), q_{2i}(t), \dots, q_{ni}(t)],$$

where i is the number of the trajectory section and n is the number of degrees of freedom of the manipulator.

Solving the tasks of movement planning of the working body for manipulation robots with a nozzle on the final link is performed in the following sequence. In the general case, at the beginning of the task, it is necessary to formulate the laws of the change in the time of the position and orientation of the working member and the speed of its movement:

$$\begin{cases} tr_i(t) = [x_i(t), y_i(t), z_i(t)], \\ v_i(t) = \left[v_{xi}(t), v_{yi}(t), v_{zi}(t)\right], \\ \psi_i(t) = [\theta_i(t), \varphi_i(t), \beta_i(t)], \\ \omega_i(t) = \left[\omega_{\theta i}(t), \omega_{\varphi i}(t), \omega_{\psi i}(t)\right], \end{cases} \quad (3)$$

where $tr_i(t), v_i(t)$ – are the position and velocity vectors at the current time t when moving on the i-th section of the trajectory; $\psi_i(t), \omega_i(t)$– are the orientation and angular velocity vectors on the i-th section at time t.

The above equations can be directly used to obtain the temporal laws of variation of generalized coordinates. However, in most cases, this problem is unsolvable in explicit form. Another important use of equations (3) is the accuracy control of the result by means of the degrees of freedom. In the general case, any rectilinear portion of the trajectory of the grasping movement with uniform motion at a speed $v_i = \left[v_{vi}, v_{yi}, v_{zi}\right]$ can be described by the vector:

$$tr(t) = \begin{bmatrix} x_S + v_{xi}t \\ y_S + v_{yi}t \\ z_S + v_{zi}t \end{bmatrix} \to \begin{bmatrix} x_{Si} \le x_i \le x_{Ei} \\ y_{Si} \le y_i \le y_{Ei} \\ z_{Si} \le z_i \le z_{Ei} \end{bmatrix}, \quad (4)$$

where x_{Si}, y_{Si}, z_{Si} – are the coordinates of the starting point of the trajectory; x_{Ei}, y_{Ei}, z_{Ei} – are the coordinates of the trajectory end-points.

When planning the movements of concrete printers along rectilinear trajectories, the areas can be in the form of arcs of a circle. A characteristic feature of building robots is that the working planes are usually parallel to the planes X_0Y_0 (P_{XY}) (see Figure 11).

Consider the basic relations for the description of movements. When the robots operate in the plane parallel to the plane Z_0X_0, the motion along the arc of the circle is described by a system of equations of the form:

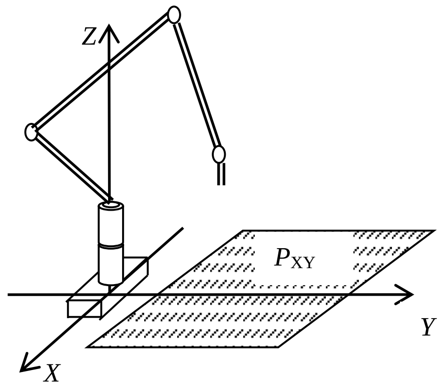

Fig. 11: Location of the working surface in the robot coordinate system

- option 1

$$\begin{cases} x = x_r + R\,\sin\omega t \\ y = y_r = const \\ z = z_r + R\cos\omega t \end{cases}; \begin{cases} v_x = \omega R\cos\omega t = v\cos\omega t \\ v_y = 0 \\ v_z = -\omega R\,\sin\omega t = v\,\sin\omega t \end{cases}$$

$$\to 0 \le \omega t \le \pi; \quad (5)$$

- option 2

$$\begin{cases} x = x_r + R\,\cos(\pi - \omega t) \\ y = y_r = const \\ z = z_r + R\sin\omega t \end{cases}; \begin{cases} v_x = v\,\sin\omega t \\ v_y = 0 \\ v_z = v\,\cos\omega t \end{cases};$$

$$\to 0 \le \omega t \le \pi; \quad (6)$$

where R – is the radius of the trajectory section; ω – is the angular velocity of motion; x_r, y_r, z_r – are the coordinates of the center of the circle. If the motion is carried out in the plane X_0Y_0, then it is described by a system of equations of the form:

- option 1

$$\begin{cases} x = x_r + R\,\sin\omega t \\ y = y_r + R\cos\omega t \\ z = z_r \end{cases}; \begin{cases} v_x = \omega R\cos\omega t \\ v_y = \omega R\,\sin\omega t; \\ v_z = 0 \end{cases}$$

$$\to 0 \le \omega t \le \pi; \quad (7)$$

- option 2

$$\begin{cases} x = x_r + R\,\cos(\pi - \omega t) \\ y = y_r + R\sin\omega t \\ z = z_r \end{cases}; \begin{cases} v_x = \omega R\sin\omega t = v\sin\omega t \\ v_y = \omega R\cos\omega t = v\cos\omega t \\ v_z = 0 \end{cases}$$

$$\to 0 \le \omega t \le \pi; \quad (8)$$

In many cases, when planning the movement of the manipulator after describing the trajectory of motion in the form (4), the length of the trajectory or the path of motion is determined. In the case of rectilinear sections, the coordinates of the boundary points are $P_S^{(i)}, P_E^{(i)}$:

$$l_{tr}^{(i)} = \sqrt{\left(x_E^{(i)} - x_S^{(i)}\right)^2 + \left(y_E^{(i)} - y_S^{(i)}\right)^2 + \left(z_E^{(i)} - z_S^{(i)}\right)^2} \quad (9)$$

where i – is the number of the section. For arcs of a circle lying in the plane X_0Y_0, based on the coordinates of the boundary points $P_S^{(i)}, P_E^{(i)}$ and the arc radius R, the length of the trajectory l_{tr} is calculated in accordance with the equation:

$$l_{tr}^{(j)} = \int_{x_S}^{x_E} \sqrt{1 + y(x)}\, dx \ \rightarrow \text{plane } X_0Y_0. \quad (10)$$

In the general case, when the trajectory section is curvilinear and described by the equation of a plane curve $f(x, y)$, then the trajectory length is calculated as an integral:

$$l_{tr} = \int_{x_S}^{x_E} \sqrt{1 + df(x)\,/dx}, \quad (11)$$

where $df(x)\,/dx$ – is a continuous derivative of a function on a section $x_S \leq x \leq x_E$. For a spatial curve given in parametric form

$$x = x(t), y = y(t), z = z(t) \rightarrow t_S \leq t \leq t_E,$$

the length of the trajectory is expressed by the formula:

$$l_{TR} = \int_{t_e}^{t_s} \sqrt{(x(t))^2 + (y(t))^2 + (z(t))^2} \quad (12)$$

The total length of the trajectory consisting of n sections is defined as the sum of the lengths of these sections:

$$L_{tr} = \sum_{e=1}^{n} l_e$$

Knowing the length of each section of the trajectory, and the technology-limited speed of their execution, the time of passage of each section and the whole trajectory as a whole is estimated preliminary:

$$T_{tr} = \sum_{e=1}^{n} t_e = \sum_{e=1}^{n} \frac{l_e}{v_e}$$

Having planned operations at the seizure level or tool, it is necessary to build a program for changing the generalized coordinates of the manipulator and at the same time to verify the practical feasibility of the planned movements on each section of the trajectory. When planning in Cartesian coordinates, on the basis of the dependences $tr(t)$, $v(t)$, the values of the generalized coordinates $q_i(nT)$ at discrete instants of time, as well as the velocities $\dot{q}(nT)$, which are used to form the control actions in the next control step are determined. However, this approach requires, at each step of the control, the solution of inverse kinematics problems and significant computer time, which does not always allow real-time operation of the control system. In this regard, when controlling the robot, it is recommended that the motion planning be performed in generalized coordinates. In this case, for each boundary and node points of the trajectory, on the basis of the solution of the inverse position problem, generalized coordinates characterizing the configuration of the mechanism at these points are determined. For each coordinate, the constraints and realization of movements are checked by the executive-level management system. Planning of movements in this case ends with the construction of functions $q_i(t) \rightarrow i = 0,1,2...,n$ with the necessary condition $q_i(t_j) = q_i^{(j)} (j = 0,1,...,m)$. In this case, the planning is carried out in real time and the controlled variables are directly generated.

The planned trajectory $q_i(t) \rightarrow t_S \leq t \leq t_E$ forms a continuous path of movement for the manipulator arm. Continuity and fluidity of the tool movement are mandatory requirements for the movement of the robot. When robotizing this operation, one needs carefully to plan not only the movement of the tool, but also its speed and acceleration of movement [9,10].

5 Summary and Outlook

Concrete 3D printing processes have high economic potential. Initial cost-effectiveness considerations for CONPrint3D® are likely to result in building cost savings of approximately 25 % and significant reductions in execution time compared to conventional construction methods. In the first part, the article dealt with the special features of CONPrint3D® and considerations on the motion profile of the printhead. In the second part, mathematical basics of the Trajectory Planning of the Printer were presented.

The path planning is carried out taking into account the restrictions on the continuity and smoothness of the trajectory and also in accordance with a given set of constraints on the position, speed and acceleration of the generalized coordinates at the reference points of the trajectory. When solving the problem of planning the trajectories of motion, sections of acceleration and braking of the printhead are provided. Planning of the trajectory is carried out in space and time, which ensures the passage of the printhead the nodal points of the working space at a given time period. The solution of the planning task is determined by the appointment of the robot, its kinematic characteristics, performed by the technological operation and the technical environment conditions.

In order to achieve the process-reliable construction site application, adapted 3D printing strategies have to be developed and implemented in a continuous digital process chain. Digital data preparation and processing is currently not ready for application. As part of the research project digiCON^2 (digital CONcrete CONstruction), an adapted data management system for CONPrint3D® is being developed (duration 01/2018 to 12/2019, funding provider: Federal Ministry of Education and Research). The aim of the international research project is to complete the digital process chain from BIM to machine-specific optimized G-Codes. At the Technical University of Dresden, research will continue to be carried out in order to achieve the goal of construction site application.

Abstract-

This article studies the development of a cyber-physical system for diagnosing and forecasting the technical condition of electric drives in robots used for construction. The structure of the cyber-physical system is described and the defect statistics for asynchronous drives submitted. Additionally, a critical analysis of existing diagnostic methods, the selection of the optimal set of diagnostic parameters and existing methods for measuring and analyzing the parameters used for the drives adopted in construction robots for is described. Herein, a method capable of distinguishing a faulty state from a load change based on wavelet transformation and neural networks (diagnosing the technical condition of robot drives) is proposed. Finally, we provide the simulation and experimental results of the proposed method.

Keywords –

Cyber-physical system, building robots, electric drives, diagnosing of technical conditions, forecasting, wavelet transformation, neural networks classification

1 Introduction

Increasing the requirements for reliability and efficiency of construction robots entails the need for constant monitoring of the technical condition of all actuators with further optimization of the operating mode of individual components and hence of all equipment as a whole. This can be achieved by using a technical condition monitoring system built into the robot's end-effectos, which continuously measures parameters with sensor system, analyzing the information obtained and determining the current technical condition, forecasting the development of defects, and optimizing the parameters of the object's operation mode. Implementation of this approach to improving the functioning efficiency of the equipment assumes the integration of computing resources into physical processes, i.e. application of cyber-physical systems [1]. In such systems, sensors, mechanical equipment and information systems are connected during all stages of the life cycle and interact with each other using standard Internet protocols in order to predict and adapt to changes in operating conditions and technical condition of the equipment. The structural scheme of the cyber-physical predicting diagnosing system of the construction robot is shown in Figure 1.

The cyber-physical prediction diagnosis system has five levels: connection, conversion, cloud, cognition and configuration [2].

At the "Connection" level, sensors are selected and installed, which can be designed for self-connection and self-monitoring of the state of the object.

At the "Conversion" level, data from devices with autonomous connection and sensors measure the characteristics of critical problems and methods for analyzing the information that will be used to determine possible selected malfunctions.

Storage and processing of large amounts of diagnostic information is carried out in cloud servers. This will allow the information flow and communication between the drives of various construction robots. Based on that, the optimization of the technological process starts taking into account the state of a separate actuating element.

At the "Cognition" level, the results of diagnosing and forecasting are determined, which are presented to users and transferred to the mathematical model of the object for further optimization of the object mode operation.

The application of the cyber-physical approach is to develop a diagnostic platform. The forecasting systems will significantly improve the reliability of the construction robots. Information links between the robots at the construction site through the Internet protocol will allow optimizing the entire construction process, depending on the technical condition of each drive of the executive equipment. This will maximize performance and minimize the likelihood of failure.

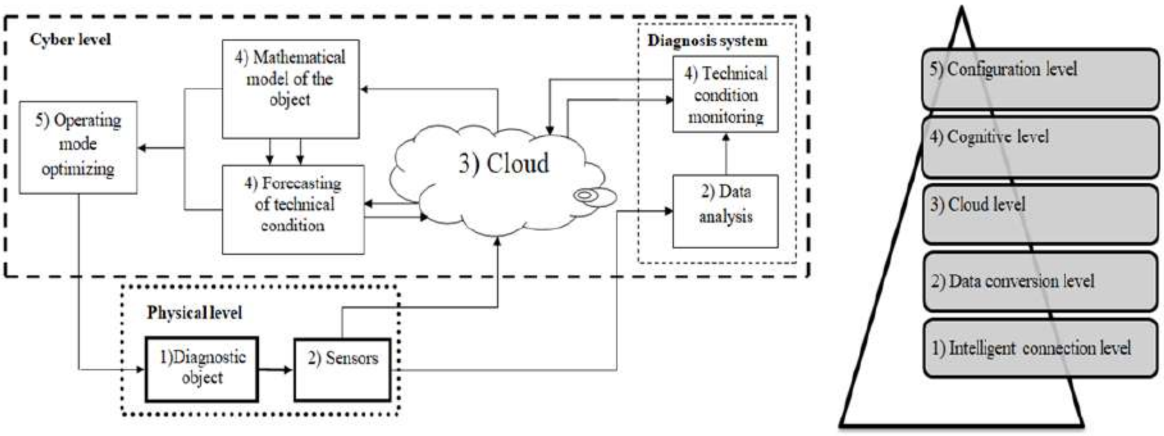

Figure 1. Cyber-physical system of the technical condition prediction diagnosis for electrical equipment

2 "Connection" level organization

The main component powering up the end-effectors of the robots is the electric drives of direct and alternating current (e.g. see Figure 2), which operate in a short-time mode and must have a high overload capacity and dust and waterproof design criteria known as IP standards.

The main type of drives used in construction robotics is a medium power asynchronous drive with a squirrel-cage rotor. The available statistics give the following data on the relative damage of the nodes of such engines (e.g. see Table 1) [3, 4].

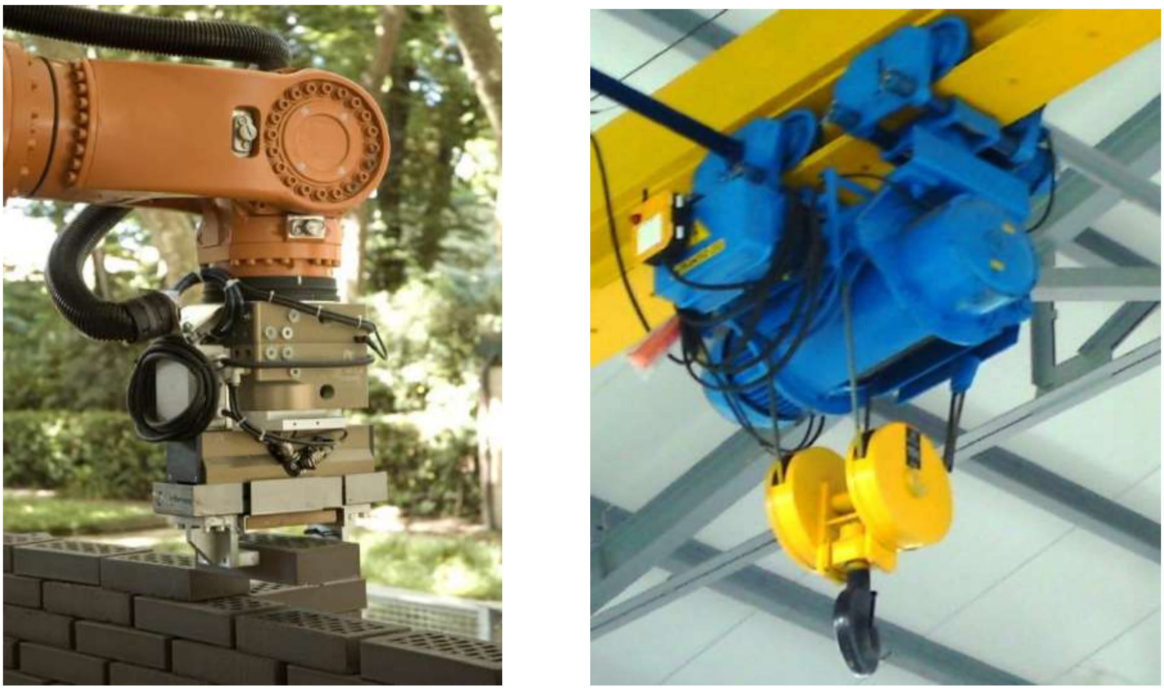

Figure 2. Electric drives in building robots

This figure shows that all engine failures of the aforementioned type are of mechanical or electrical origin. Thus, multi-parameters diagnostics methods are used that assume control of thermal, electrical and mechanical defects at the operating voltage [5]. In this case, the following applies:

- direct electrical control methods with galvanic connec-tion to the terminals of the motor leads (measurements or harmonics, or pulsations, or pulses of the supply current and voltage);
- methods of monitoring with the installation of sensors on the motor housing that fix electromagnetic or sound waves:

Table 1 Medium voltage motors typical defects

Fault	Percentage failure in operation
Discharge an sparking in current wire	40
Discharge and sparking in insulator. Heating of the terminal box	20
Insulation damage in stator winding	15
Sparking in magnet core. Heating of the defect zone	10
Heating of bearing	9
Discharge in cable insulation	4
Sparking in the squirrel cage	2

measurements of partial discharges, sound waves or capacitive currents to the ground while monitoring vibration;
- method of remote control: thermal imaging measurements of the temperature of the engine and bearing surfaces.

Joint use of these methods makes it possible to determine the technical state, but at the present time, the analysis of diagnostic information is currently done manually by troubleshooting experts, which is very not cost effective.

Hence, it is necessary to choose a list of diagnostic parameters that allow determining all possible classes of defects, having accepted sensitivity features over the changes in the values of structural parameters, minimum composition, accessibility for monitoring, measurement and software analysis without operator's involvement, cost and time effectiveness and sufficient degree of segregation when recognizing individual defects.

Construction robots operate in complex non-deterministic conditions with high alternating loads in conditions of high humidity and dust; their drives are often installed on a mobile base, which imposes significant requirements for the choice of methods and means of diagnosis such as:
- minimum composition of the measured parameters;
- the absence of complex bulky measuring equipment installed on the drive housing, which can affect the operation of process equipment;
- the ability to automatically analyze the measured parameters.

The most common diagnostic parameters for asynchronous drives are a partial discharge, supply and capacitive current, vibration and temperature [6]. A comparative analysis of the adequacy of methods based on the control of these parameters [7, 8], taking into account the limiting requirements, allows to make the following conclusions:
- the diagnostic of mechanical defects in medium power engines, instead of vibration analysis, harmonic analysis of motor feed currents (MCSA technology), harmonic analysis of capacitive currents to ground (CTG technology) can be used;
- as for the diagnostic of electrical defects, it is advisable to combine harmonic analysis of supply and capacitive currents in the ground circuit.

Analysis of the majority of electrical and mechanical faults of the asynchronous drive can be detected by monitoring the supply and capacitive current, which can be measured without the use of special sensors.

3 "Conversion" level organization

The analysis of current supply harmonics (MCSA-Technology) consists in the decomposition of the signal using Fourier transform and amplitude analysis at characteristic frequencies. Each fault has its own characteristic frequencies, including sub-harmonics, harmonics and intera-harmonics between the spectral lines of the reverse frequency - f_{rot}. For example, if there are harmonics of the reverse frequency (f_{rot}, $3f_{rot}$, $5f_{rot}$), there will be misalignment or no parallelism of the motor shafts and the mechanism. With several simultaneous defects of the shafting line, half and quarter harmonics appear ($¼f_{rot}$, $½f_{rot}$, f_{rot}, $1{,}5f_{rot}$). With the stator winding, the stator windings fob, $2f_{rot}$, $3f_{rot}$, etc.

The analysis of the harmonics of capacitive currents (CTG-Technology) studies the capacitive currents to ground. In the case of vibration, the capacities change with frequencies proportional to the vibration of the active part in the engine [9, 10], i.e. it is possible to determine the regularities of vibration phenomena in the engine itself, and therefore it exceeds the harmonic analysis of the currents feeding the motor in terms of information.

Schemes for diagnosing the engine when measured on the motor supply cable, i.e. characteristics of the motor feeding the network, is possible taking into consideration two conditional directions:
- the first direction is the low-frequency range representing the "mechanical defects": the informative characteristic of which are supply current spikes in the "power supply wires or motor leads", these defects can be detected by the harmonic analysis of the supply current (MCSA) during the galvanic analysis from the supply wire or input into the motor (e.g. see Figure 3, a).

- the second direction is for the circuit in the high-frequency range or "defects of the electric type": the informative characteristic of which is the voltage surges on the "motor power wires". These defects are fixed by the measurements of pulsations (voltage surges) on the motor power cables during galvanic analysis of capacitive currents from the motor to ground (CTG) (e.g. see Figure 3, b).

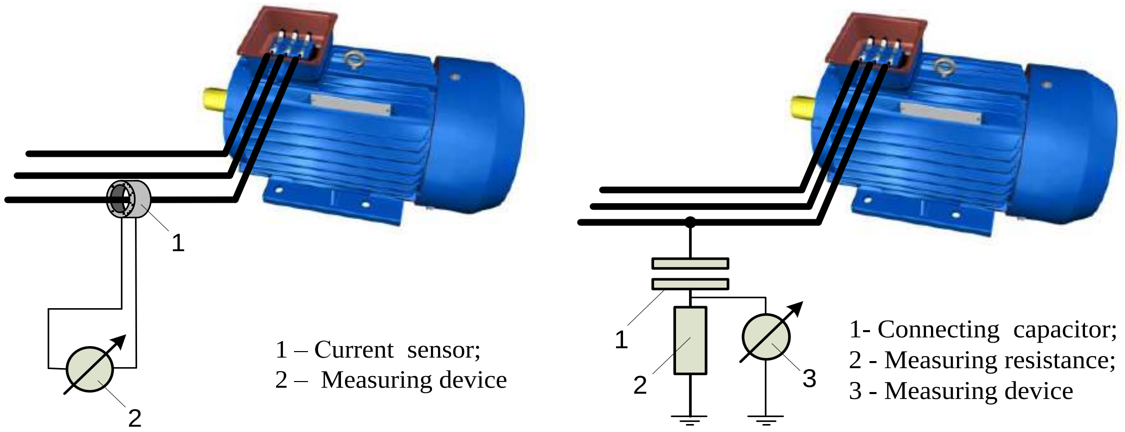

Figure 3. General scheme of galvanic connection for measurements and harmonic analysis of the current feeding the motor a) for the control of "mechanical defects" (MCSA-Technology), b) for the control of defects of "electric nature" (CTG-Technology).

4 Technical condition diagnosis method

At the present time the most popular method for current signals analyzing is Fourier transform, which has a number of disadvantages [11]. This method leads to the loss of valuable diagnostic information. In general, it is not suitable for use in the composition of the cyber-physical system.

An analogue of the Fourier expansion is the wavelet transformation is considered. It treats the signal as a two-dimensional sweep in time and frequency. The wavelet functions of the basis allow us to identify local signal features that cannot be detected using the traditional Fourier and Laplace transformations. The wavelet transformation of a signal is represented in the form of a generalized series or as Fourier integral over a system of basic functions [12]

$$\psi_{ab}(t) = 1/\sqrt{a}\,\psi((t-b)/a), \qquad (1)$$

constructed from the parent (original), the wavelet $\psi(t)$ possesses certain properties, due to the time shift operations b and the time scale change a. The factor $1/\sqrt{a}$ ensures that the norm of these functions is independent of the scaling number a. Small values of a correspond to small scales $\psi_{ab}(t)$, or high frequencies (ω~1/a), large parameters of a - to large scale $\psi_{ab}(t)$. The wavelet scale, as a unit of the time-frequency representation of the signals, is inversely proportional to the frequency (e.g. see Figure 4).

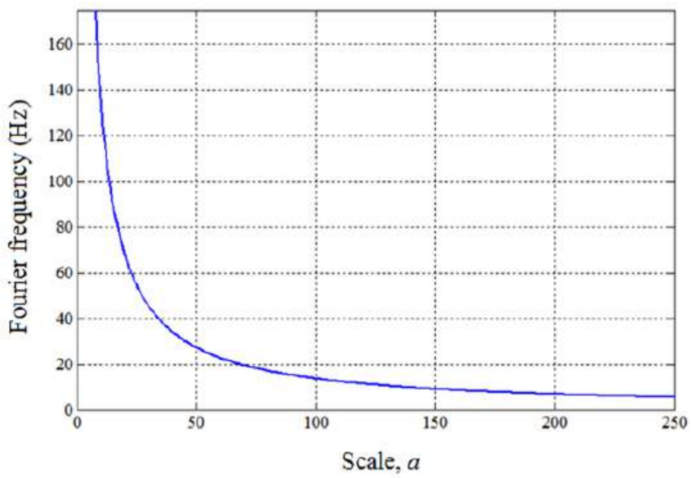

Figure 4. Correspondence of the Fourier frequency and the scale of the wavelet

To troubleshoot using wavelet transforms, it is necessary to recalculate the Fourier frequencies of the spectrum into the scale of the wavelet, according to the relationship in Fig. 5. The analysis of the signal at the received characteristic frequencies allows finding the object malfunctions. A large number of experiments conducted on DC and AC engines under various loading conditions made it possible to reveal the regularity illustrated in Figure 5.

The wavelet coefficients at the characteristic scales of the healthy and faulty motors significantly differ from each other. With a serviceable unloaded engine, they have minor oscillations at start-up, then the process is practically linearized. When a load occurs, the oscillatory process at the start of the engine is more pronounced, but then decreases with repetition at certain periodicity. While the process is stable, there is no significant increment in the amplitude of the oscillations with time (Fig. 5, a). The coefficients of the wavelet transformation of the faulty motor are much lower than the serviceable ones and have constant oscillations. This phenomena increases when the load appears (e.g. see Figure 5, b).

The plot of wavelet coefficients on an uncharacteristic scale for a faulty and faulty motor is identical (e.g. see Figure 5, c). The signal has a high density and small values of wavelet coefficients, while the signal is regular and completely repeated at a specified repetition rate. This regularity is valid for the current, voltage, and vibration for AC and DC drives.

The received five characteristic signals can be used to design the identification of the state of electric drives in the structure of the cyber-physical diagnostic systems based on an artificial intelligence approach.

To apply the obtained experimental information in cyber-physical diagnostic systems, it is necessary to develop a method for automatic signal analysis without the involvement of an expert. One of the methods for solving this problem is the development of a neural signal classification network [13]. As the initial data, the values of the wavelet coefficients are used on a characteristic scale uncharacteristic for the failure (e.g. see Figure 5). As an input, a matrix containing five lines of characteristic signals is given. The output of the network is the class of diagnosis: "1" - normal or "2" - defective.

To classify the technical state of an object, a neural network of direct signal transmission having the structure shown in Figure 6 is modeled.

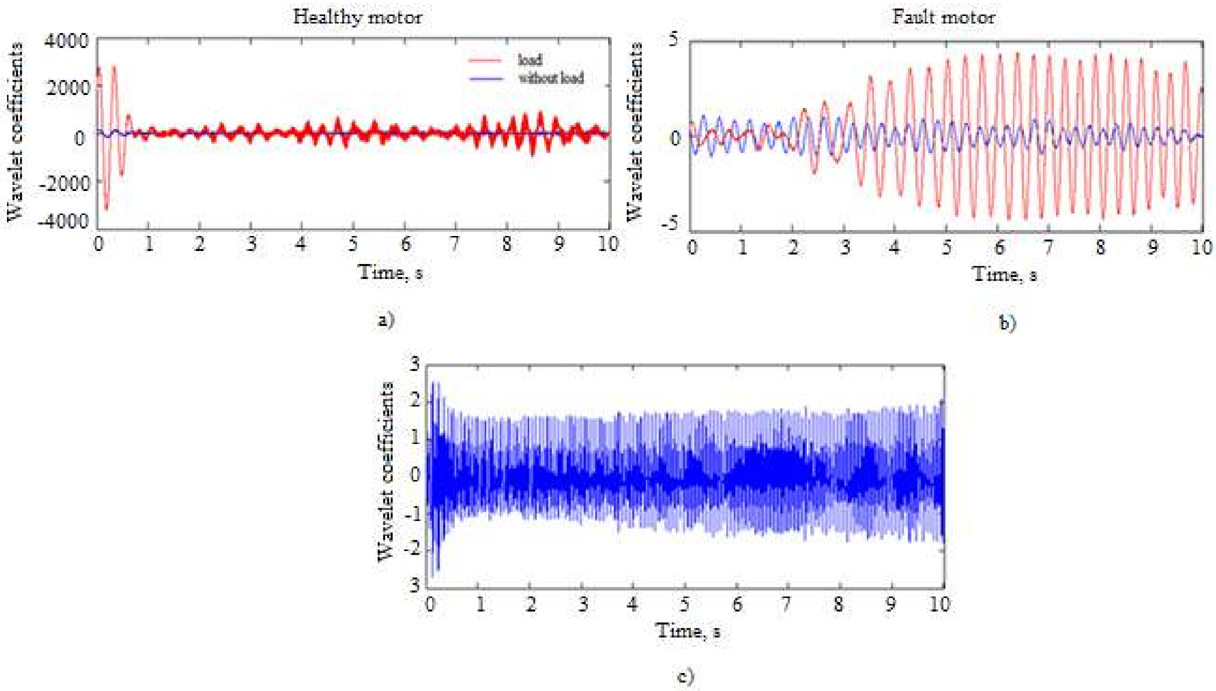

Figure 5. The wavelet current signal: (a) the characteristic scale of the serviceable engine, (b) the characteristic scale of the faulty engine, (c) the uncharacteristic scale of the faulty and faulty engines

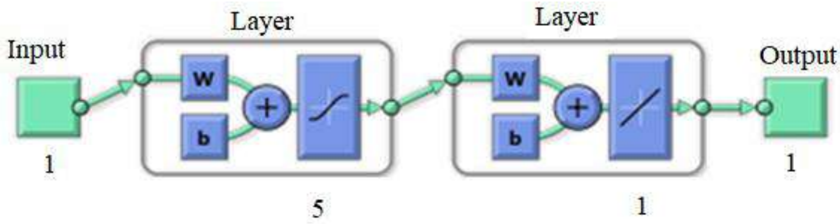

Figure 6. Structure of the neural network classification of the technical state of the electric drive

The network contains three layers: input, hidden and output layers. The hidden layer has five neurons with a tangential activation function while the output layer is a linear neuron. To train the neural network, the Levenberg-Marquardt algorithm [14] which is designed to optimize the parameters of nonlinear regression models is used. The network training and validation results are shown in Figure 7. The output of the neural network is a vector string containing the given technical state number "1" - normal, "2" defective. The size of the output vector is equal to the number of wavelet coefficients. Therefore, for the convenience of analysis, it is necessary to find the mean value and round it according to the rules of mathematics. As a result, you can evaluate the status of the diagnostic object.

To test the trained network, samples of the training set were randomly assigned to the input, and the network unmistakably assigned them to a given class. The status of the technical condition was checked during the diagnosis of the induction motor (e.g. see Figure 8). The analysis was performed on a faultless and faulty engine at various rotational speeds. To simulate a malfunction, an additional resistance was introduced into one of the phases of the stator winding, which is equivalent to closing the turns of the stator winding. This fault can be determined on the first three harmonics of the reverse frequency.

The wavelet coefficients of the supply current at these frequencies were fed into the trained neural network, which unmistakably classified the serviceable engine to class "1", and the faulty engine to class "2". An analysis of the other scales of both engines has shown that the state of the engine belongs to class "1". The received neural network therefore allows the determination of the technical state and the cause of the failure.

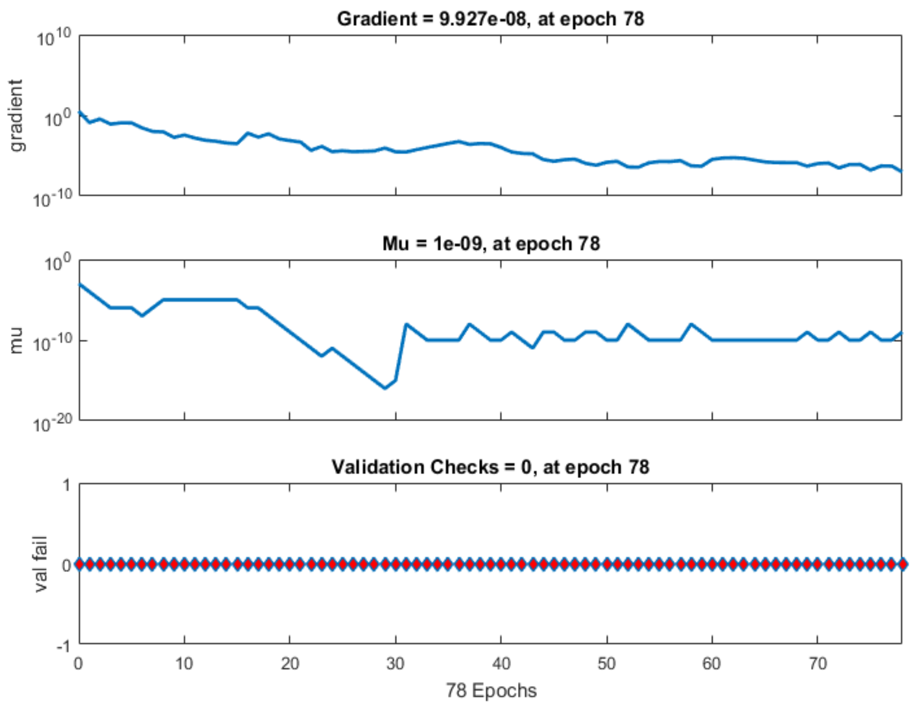

Figure 7. Learning outcomes of signal classification neural network

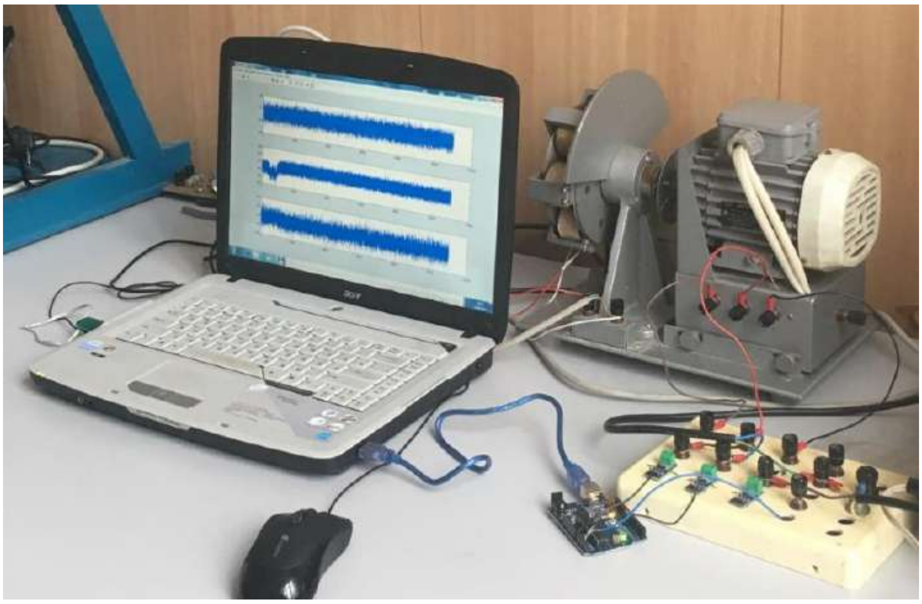

Figure 8. Experimental researches

A method for diagnosing electric drives of building robots has been obtained, which makes it possible, without using expensive measuring instruments, to determine their current state of failure, a malfunction from changing the operating mode. This will increase the efficiency of such robots and the quality of construction operations.

The performed efficiency analysis shows that the introduction of the proposed methods makes it possible to increase the productivity of the facility by 17-18%, the technical utilization factor by 14% and obtain an economic effect if the modernization costs do not exceed 20% of the cost of the facility.

5 Conclusion

In this paper, the design of a cyber-physical system for diagnosing and predicting the technical condition of electric drives of construction robots is presented. Furthermore, the structure of the cyber-physical system consisting of five levels is defined and the work of each system level is also described. The statistics of defectiveness of asynchronic drives were shown and their existing diagnostic methods considered.

The optimal set of diagnostic parameters for drives used in building robots was selected taking into account operating conditions. The existing methods for measuring and analyzing selected parameters have been described and a method for analyzing diagnostic parameters proposed. This method allowed the determination of the technical state of the robot drives under different load conditions of the drive. To implement this method, wavelet transformation and neural networks for the classification of signals were proposed. It was further established that any maternal wavelet may be used. Finally, the validity of the theoretical calculations and the adequacy of the model were confirmed by the large volume of experimental studies.

Abstract –

Efforts to integrate construction planning have thus far focused on the interoperability of models and computer applications. However, merely linking different models, e.g. design and schedule, while useful, necessarily restricts planners to an iterative improvement of plans. This research defines a single integrated mathematical model with singularity functions to directly represent the different aspects that need to be considered in planning construction projects, such as their design, schedule, budget, site layout, etc. This allows all relevant aspects to be taken into account simultaneously when optimizing the construction plan. The new model can be used to visualize different aspects of a project, allowing the planner to interact with the model and manipulate it. Examples are provided for the intuitive visualization of the time-space that building components, site objects and construction activities occupy, of the dynamic relations and buffers between objects and activities, and of the impact of changes in the plan.

Keywords –

Scheduling, Singularity Function, Site Layout, Cranes

1 Introduction

The efficient and safe planning and management of construction projects requires an integrated modeling of their different aspects (or 'dimensions'). Much effort, centering on applying Building Information Modeling (BIM), has consequently been made in the domain of integrated project modeling (e.g. [1], [2]). But as the following section will explain, currently available multi-dimensional models generally consist only of partially interlinked models. While this allows making certain manual and iterative improvements in the construction plan, it does not fully support its efficient optimization.

Therefore we propose that a truly integrated model of construction projects should be based upon a single mathematical model that is capable of representing all their relevant aspects. This would allow construction plans to be continuously modified and optimized according to evolving project objectives and constraints. These constraints (e.g. scope, time, cost, and resources) are typically interrelated, yet competing with each other. Also, effective means for an integrated visualization of these different aspects of a project should be developed to provide planners and managers with their complex information in a way that will be easily understood. It will also allow them to directly manipulate the model, in accordance with the dynamically changing conditions.

This paper presents such a mathematical model for integrated modeling of construction projects, which addresses different elements, e.g. building components, construction activities, and temporary site objects, and the dimensions of time, cost and spatial location. The paper also presents a novel framework for visualizing the model, using three-dimensional (3D) diagrams that can represent any chosen triplet of aspects of the project.

2 Literature Review

Visualization is an emerging area, riding on a rapid increase in ubiquitous computing capabilities and access devices. Tools equip their users with powerful ways to communicate with near and far participants, understand complex interactions of aspects, and support decision-making. A list of 17 'grand challenges' for visualization, information modeling, and simulation includes needs to provide 'formats and mediums suited for construction", "format and interoperability to enable data sharing", and "[g]enerating models that adapt to real-world changes", plus calls to stronger connect academia with industry [3, p. 2] Currently only partially interconnected models of the aforementioned vital aspects of construction projects are available, which allow merely an iterative process of limited improvement, but no truly efficient optimization.

Sorting the literature by dimensionality of its models illustrates the relevant rather diverse body of knowledge:

- 2D: Linking work with time, linear, repetitive, and location-based schedules [4] represent productivity explicitly, not just duration in network schedules. Focusing on finances instead of product, cash flow diagrams can track cost and payments over time to determine cumulative balances throughout the life of a project [5]. Analogously, resource use over time can be optimized for even workflow (leveling) [6] or shortest project duration (allocation). Some models allow handling multiple resource types [7];

- 3D: Three-dimensional space dominates existing commercial computer-aided design (CAD) tools, whose dimensions are spatial. Suitable coloration and iconography can give information of planned versus actual progress [8]. But 3D can also offer spatial-temporal views, e.g. work paths across sites at different times [9]. It can apply logic operators between site objects [10]. Extending the traditional criticality and float concepts gives spatial-temporal schedules [11]. Even more varied representations of any permutation of three aspects generates all existing diagram types, plus various new ones [12];
- 4D: Four-dimensional (4D) models are dominated by animating 3D CAD images as short videos, e.g. to plan site operations with an easy-to-understand way. Alternatively, selected view may be shown as slices of a 'space-time cube' [13]. The entire 4D realm is closely related to BIM applications [14];
- 5D: While five aspects, namely technical, schedule, cost, context, and financing, have been presented jointly [15], they unfortunately remained limited to mere spider charts, which simply plotted empirical assessments of megaprojects on a 0-to-100 scale;
- nD: Further expansion require shifting to a purely mathematical model, where complete graphics are no longer feasible, but all aspects can be contained in an *n*-dimensional vector space. Three aspects of interest could always be selected for visualization.

But a conceptual gap in the aforementioned spatial-temporal mathematical model remain is its lack of site objects. Refining it will create a comprehensive 3D tool as a foundation toward future generalization [12]. Two sequential objectives are established to support this goal:

1. Derive a mathematical model to handle any temporary site objects in spatial-temporal 3D space;
2. Create and validate a visualization of the cost of temporary site objects within spatial-cost 3D space.

3 Methodology

In this paper a mathematical model is presented. It can represent different aspects of a construction project, such as time, work, and cost, using singularity functions. It supports continuous modification and optimization of the construction plan by expressing physical elements:

- Building components and assemblies;
- Stationary and moving construction activities;
- Planned work spaces and the work paths within them, and required safety buffers around them;
- Temporary site objects: Cranes, stockpiles and their changing sizes, earthmoving equipment.

Elements are linked by Boolean operators of AND, OR, and XOR or the material implication (IF-THEN). Visualization as 3D diagrams will provides the planner with the complex information in a way that is easily understood to support manipulating the model directly.

3.1 Singularity Functions

Singularity functions were first used in structural engineering to calculate the effects of distributed loads at different sections of beams [16]. The term singularity indicates that the function behaves discontinuously at a point, but is defined for all values of the independent variable [17]. Managerial dimensions of construction engineering and management feature such independent-dependent variable pairs, e.g. work quantity and time (linear schedules), resource counts and time (resource leveling and allocation), and cost and time (cash flows). This implies that the underlying formulation of loads on beams can be swapped for such quantifiable aspects of projects, and indicates that the mathematics should work, as prior research has successfully shown [e.g. 6, 5, 12].

3.1.1 Point-Scalar Form

Equation 1 defines the basic term of any singularity functions within a two-dimensional coordinate system. Pointed brackets are a case distinction operator to select from two options: If the independent variable x is equal to or larger than the activation cutoff a, then brackets are treated like conventional round algebraic ones, else if x is smaller than a then the operator returns zero. Note that Equation 1 is right-continuous; Equation 2 provides an analogous left-continuous version. Changing strength s and exponent n generates customized behaviors of the function, whereby the former acts as a scalar to increase or decrease its magnitude and the latter steers its growth.

$$y(x) = s \cdot \langle x-a \rangle_{\mathrm{R}}^{n} = \begin{cases} 0 & if\ x < a \\ s \cdot (x-a)^n & if\ x \geq a \end{cases} \tag{1}$$

$$y(x) = s \cdot \langle x-a \rangle_{\mathrm{L}}^{n} = \begin{cases} 0 & if\ x \leq a \\ s \cdot (x-a)^n & if\ x > a \end{cases} \tag{2}$$

3.1.2 Point-Vector Form

Singularity functions can be extended to 3D [9, 10]. Vector $\boldsymbol{v}$ starts at point (x_{1S}, x_{2S}, z_S) to grows in direction (Δx_1, Δx_2, Δz) per Equation 3. An independent variable h_1 from 0 to 1 within the operator controls how $\boldsymbol{v}$ grows until it finishes at ($x_{1S} + \Delta x_1$, $x_{2S} + \Delta x_2$, $z_S + \Delta z$). Such a point-vector form can model any line segment from start to finish within a 3D space system. For spatial-temporal schedule modeling, the first two elements in the three coordinates (x_1, x_2, z) will represent its spatial dimension, while the third coordinate z denotes the time dimension.

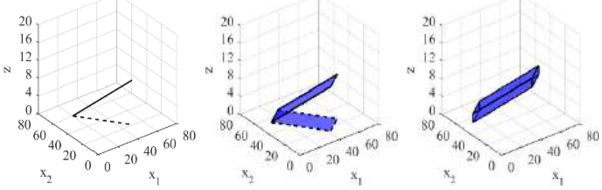
$$\mathbf{v}(h) = \begin{pmatrix} x_{1S} \\ x_{2S} \\ z_S \end{pmatrix}_{Start} + \begin{pmatrix} \Delta x_1 \\ \Delta x_2 \\ \Delta z \end{pmatrix} \cdot \left(\langle h_1 - 0 \rangle_R^1 - \langle h_1 - 1 \rangle_R^1 - \langle h_1 - 1 \rangle_L^0 \right) \tag{3}$$

3.2 Work Area Definition (Temporary Site Objects)

3.2.1 Earthmoving (Prism)

Many construction activities proceed linearly on a site, e.g. earthmoving or paving. Its equipment moves accordingly. The geometrical shape of that equipment in the 2D spatial plane is a rectangle, whose length is the moving distance (dashed line in Figure 1a) and width is a safety buffer for traveling equipment [10]. Adding the duration data for this earthmoving activity adds a slope in the 3D spatial-temporal coordinate system (solid area in Figure 1b) to the rectangle. Note that the projection of the sloped rectangular plane into the x_1-x_2 plane is the spatial work area of the equipment (dashed area in Figure 1b). Assume that a time buffer of 2 days must be maintained for an earthmoving activity. Then the sloped rectangular plane has a height of 2 days and expands the geometrical shape to a prismatic volume (Figure 1c).

The point-vector form of Equation 3 captures a start point plus an offset; only the offset part has a singularity function term. Applying this offset concept to a line will generate a rectangular plane, and offsetting it will create a prism [10]. The flowchart of Figure 2 defines a prism in 3D space mathematically with three offsets functions per Equation 4 (n = 1, 2, 3). Note that a term '+ $Offset_n$' is applied to all points in the geometrical shape *before* the term (i.e. start point, start line, and start plane). For Example 1, an earthmoving activity starts at (20, 60, 0) and moves to its finish position at (50, 20, 10) with a duration of 10 days. The spatial safety buffer is 10 m to each side (perpendicular to the moving direction). Time buffer is 2 days. Thus the inputs are: (x_{1S}, x_{2S}, z_S) = (20, 60, 0), $Offset_1$ = (30, -40, 10), $Offset_2$ = (8, 6, 0), and $Offset_3$ = (0, 0, 2), respectively, as Figure 1 shows.



(a) Line (b) Plane (c) Prism

Figure 1. Process to Generate Prism

1: Known variables
Start point (x_{1S}, x_{2S}, z_S) and $Offset_1$, $Offset_2$ and $Offset_3$

2: First offset generates line
Start point (x_{1S}, x_{2S}, z_S)
Finish point = start point + $Offset_1$

3: Second offset generates plane
Start line (shape from step 2)
Finish line = start line $\pm Offset_2$

4: Third offset generates prism
Start plane (shape from step 3)
Finish plane = start plane + $Offset_3$

Figure 2. Flowchart to Define Prism

$$Offset_n = h_{nS} \cdot \langle h_n - h_{nS} \rangle_R^0 + \begin{pmatrix} \Delta_{nx_1} \\ \Delta_{nx_2} \\ \Delta_{nz} \end{pmatrix} \cdot \left(\langle h_n - h_{nS} \rangle_R^1 - \langle h_n - h_{nF} \rangle_R^1 - \langle h_n - h_{nF} \rangle_L^0 \right) \tag{4}$$

3.2.2 Crane (Prism Sector)

The geometric shape of the work area of a crane is a cylinder in the 3D spatial-temporal coordinate system, whose mast is located at the center around which its jib rotates with a certain radius [18]. If a crane may only rotate within an angle on a construction site, e.g. to not swing over a sidewalk for safety reasons, then its work area is a prism sector in the 3D space. To define a sector per Figure 3, $Offset_2$ in the flowchart will be a rotation and mathematically expressed as a rotation matrix [17]. Equation 5 is the rotation function, where θ is the angle of rotation. Note that the singularity function term $\langle \theta - 0 \rangle^0_R \cdot \langle -\theta - (-2\pi) \rangle^0_R$ controls a range [0, 2π] of the angle. For Example 2, a crane mast is located at (70, 70, 0) and its jib radius is 60 m. The start position of the jib end point is (22, 34, 0) and the angle of rotation is $\pi/4$. The duration of the crane on the construction site is 10 days. Thus the inputs are: (x_{1S}, x_{2S}, z_S) = (70, 70, 0), $Offset_1$ = (-48, -36, 10), $Offset_2$ is the rotation matrix with θ is $\pi/4$, and $Offset_3$ = (0, 0, 10). Figures 4a-4c show how to generate the work area for this crane.

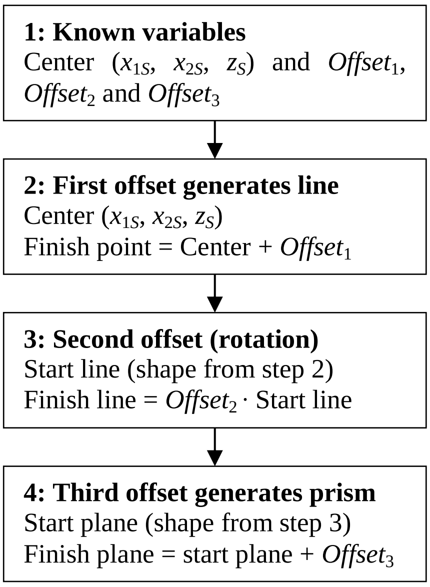


Figure 3. Flowchart to Define Sector

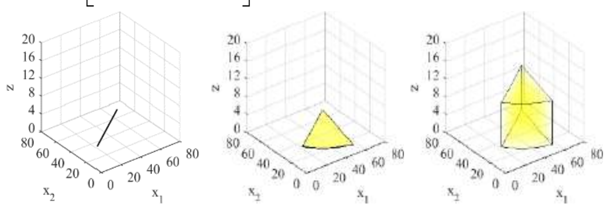
$$Offset_2 = R_z(\theta)\cdot\langle\theta-0\rangle_R^0\cdot\langle-\theta-(-2\pi)\rangle_R^0 \tag{5}$$

$$= \begin{bmatrix} \cos\theta & -\sin\theta & 0 \\ \sin\theta & \cos\theta & 0 \\ 0 & 0 & 1 \end{bmatrix}\cdot\langle\theta-0\rangle_R^0\cdot\langle-\theta-(-2\pi)\rangle_R^0$$



(a) Line (b) Sector (c) Prism

Figure 4. Process to Generate Sector

3.2.3 Material Stockpile (Cone)

Material waiting to be lifted by a crane is assumed to be a cone, so that the area of the material stockpile will decrease to zero. If an original pile with radius R will be exhausted in D days, then the radius Offset1 decreases from R to 0. Thus, the radius change rate Δr = R / D. Assuming that the pile is exhausted continuously, the offset in the time direction Offset3 for each layer of the pile at a time point also grows continuously. For this, the temporal dimension of Offset3 (Δz) has infinitesimal duration ε, and its integral is D ($\int_{z_S}^{z_F} \Delta z dz = D$).

Figure 5 shows the flowchart to define a cone. The difference between Figure 5 and Figure 3 is that there is an iteration loop for modeling a cone: If the radius $Offset_1$ is larger than zero and $\int_{z_S}^{z} \Delta z dz$ is smaller than D, then subtract the radius change rate Δr from the radius until the radius becomes zero (material exhausted) and $\int_{z_S}^{z} \Delta z dz$ is equal to D. For Example 3, the center of a pile is located at (40, 40, 0) with an initial radius of 20 m. The duration to exhaust the stockpile is 10 days. In the 3D spatial-temporal coordinate system this pile has a height (or duration) of 10 days. The radius change rate Δr is 2 meters / day. Thus the inputs are: (x_{1S}, x_{2S}, z_S) = (40, 40, 0), $Offset_1$ = (-20, 0, 0), $Offset_2$ is the rotation matrix with θ is 2π, and $Offset_3$ = (0, 0, ε). Figures 6a-6c shows how to create the work area of this pile.

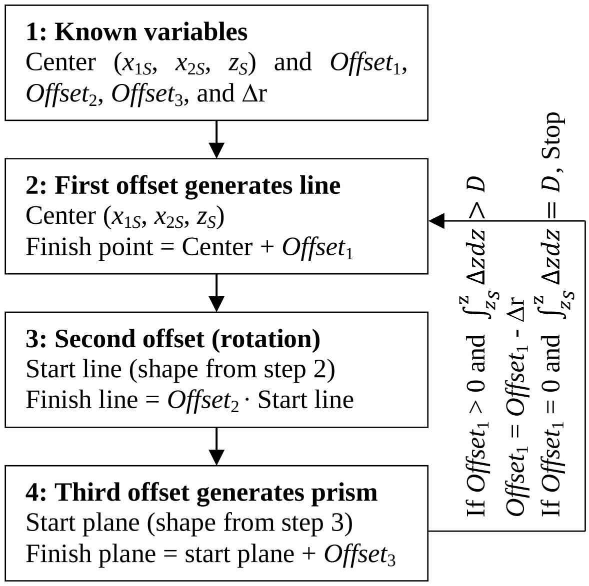


Figure 5. Flowchart to Define Cone

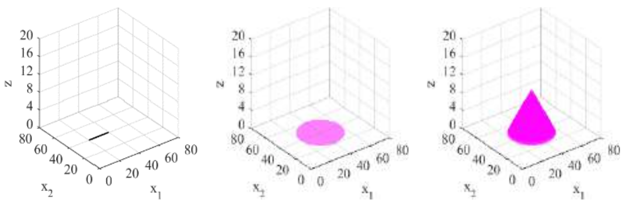

(a) Line (b) Circle (c) Cone

Figure 6. Process to Generate Cone

3.3 Spatial and Temporal Relations (Boolean)

Boolean relations can be used to define constraints between multiple temporary site objects in the spatial-temporal 3D space [10]. Four types are considered: Material implication IF-THEN, conjunction AND, disjunction OR, and exclusive disjunction XOR. The IF-THEN is only defined on the time dimension (i.e. two activities must occur sequentially – if the predecessor is finished, then a successor can start). The other three relations are used to define spatial-temporal constraints: Multiple temporary site objects must occur concurrently (AND); multiple temporary site objects can (but need not) occur concurrently (OR); or multiple temporary site objects must never occur concurrently (XOR). Boolean operations between two objects can be calculated with signals of these objects. Per Equation 6, the signal value of an object is 1 if a coordinate point is inside the work area of the object and 0 if it is outside. Rules for signal functions to conduct these four Boolean operations are summarized in Table 1. Boolean operations with signal functions are then multiplied with work areas functions to model temporary site objects and their relations in spatial-temporal 3D space. This fulfils Objective 1.

$$Signal(x_1, x_2, z) = \begin{cases} 0 & if \quad (x_1, x_2, z) \notin Object \\ 1 & if \quad (x_1, x_2, z) \in Object \end{cases} \tag{6}$$

Table 1. Boolean Operations and Signal Functions (adapted from [10])

Type	Rule A	Rule B	Rule result	Signal function
IF-THEN	1	1	1	N/A
	1	0	1	
	0	1	0	
AND	1	1	1	$Signal_A \times Signal_B$
	1	0	0	
	0	1	0	
OR	1	1	1	$Signal_A + Signal_B - Signal_A \times Signal_B$
	1	0	1	
	0	1	1	
XOR	1	1	0	$OR_{Signal} - AND_{Signal}$
	1	0	1	
	0	1	1	

3.4 Spatial-Cost Area Definition

In analogy to spatial-temporal work areas, spatial-cost can be modeled to visualize location and cost data, where the vertical axis is cost. This shows the total cost of different items on site and allows comparing options visually. To realize it in 3D, the assumption is: *Cost of a temporary site object is assumed as evenly distributed across its geometric shape of the spatial work area.*

The difference between a spatial-temporal work area and a spatial-cost area is that time grows continuously, whereas cost occurs discretely (e.g. daily, weekly, or once). For mathematical modeling, the temporary site object concept of Section 3.2 is used, but using the cost as the third dimension instead will return their functions for spatial-cost area, which is omitted here for brevity. From the general contractor's perspective, the shapes of spatial-cost areas of temporary site objects are:

1. Material: Cost occurs once when transporting it to the site. It is a cylinder with the height of its total cost;

2. Crane: Cost occurs periodically (e.g. weekly rental). Its shape are a multiple layers of a sector surface with the height of the cumulative total weekly cost;

3. Earthmoving: Cost gradually increases (daily). Its shape is a cuboid with a height of its total cost (or layers of a rectangular surface, whose number equals duration, with the height of the cumulative total cost for each day).

4. Indirect: Cost gradually increases (daily) and covers the whole project. Its shape is a solid with the height of its total cost (or layers of a whole site surface, for which the same rules will apply as for earthmoving).

Geometric shapes in 3D spatial-cost space are shown in the next section. Defining and visualizing cost data for temporary site objects fulfills Objective 2.

4 Application

The following example demonstrates how this new integrated model can analyze, visualize and improve the scheduling, cost and site layout planning of construction projects. In the example, two sequential activities (with a finish-to-start or IF-THEN relationship between them) are executed in a rectangular work area. Earthmoving equipment is used for Activity 1, whereas in Activity 2 a crane lifts material that is stored onsite. Consequently, AND relationships are defined between crane, material, and Activity 2. An XOR relationship is defined between the crane and Activity 1 to prevent safety hazards.

The model is applied to plan the activities so that their durations and costs are minimized. Two options will be compared. In Option 1, Activity 2 is carried out by one crew with a single crane. In Option 2, Activity 2 is carried out simultaneously by two crews with two cranes. The optimal option in terms of both duration and costs is identified by a least-cost scheduling approach, which reduces the duration of the activities in each option until their total cost has been minimized, without violating the previously described relationships.

Figure 7 shows temporal and spatial dimensions of activities and site objects in Option 1 with 3D time-space diagrams. In them, the locations of the objects on the site are indicated on the horizontal axes, whereas the duration of their presence on site is indicated on the vertical axis. This allows the user to easily change their location and/or timing while exploring options. Figure 8 analogously shows cost and spatial dimensions in the cost-space diagrams. In them the vertical axis indicates the cost of each object. This provides the user with an immediate understanding of cost implications of any change in the plan. Time-space diagrams and cost-space diagrams for Option 2 are shown in Figures 9 and 10.

The resultant site layout plan for Option 1 is shown in Figure 11, and its final schedule and costs in Tables 4 and 5. Figure 12 shows the site layout plan for Option 2. The final schedule and costs of this Option are shown in Tables 2 and 3. A comparison shows that Option 2 has a shorter duration (6 days versus to 9 for Option 1) and a lower cost ($305,000 compared to $327,500).

Table 5. Cost Data for Option 2

Item	Cost	Total cost
Manpower	2,000 per day (weeks 1-3)	90,000
Material	50,000 (week 3)	50,000
Crane	20,000 per week (weeks 3-6)	120,000
Indirect costs	1,500 per day (for entire project)	45,000
	Overall cost	305,000

5 Conclusions

This paper has presented a novel integrated model to plan construction projects. As has been demonstrated, it can be used to maximize the efficiency of both the site layout plan and the execution of the planned activities, without compromising the safety. Options can be easily modified and compared through the new diagram types.

5.1 Contributions

This paper has made the following contributions:

- A mathematical model has been presented that can represent different aspects of a project, (e.g. time, work, and cost), and its physical elements (e.g. building components, activities, work spaces, and temporary site objects);
- Boolean operators (AND, OR, and XOR or the material implication IF-THEN) can define the constraints between activities and site objects;
- Novel 3D diagrams provide planners with a visualization of complex information in a way that it can be easily understood and changed.

5.2 Recommendations for future research

Future research should expand the proposed model into a true multi-dimensional model of construction projects. Such *n*D model is envisioned to integrate and simultaneously handle multiple managerial dimensions like time, work, cost, resources, etc. Selections thereof could be visualized. The use of weighted constraints in addition to binary Boolean operators should also be inserted to enable representing not just hard constraints, but also ‘soft logic’ such as priorities and preferences of planners for their site layout based on their experience.

Supporting Post-Occupant Evaluation through Work Order Evaluation and Visualization in FM-BIM

C. Pin[a], C. Medina[a], and J.J. McArthur[a]

a Department of Architectural Science, Ryerson University, Canada

Abstract –

The application of BIM and data analytics in facility management is an area of growing interest and research. The ability to mine data from occupant complaints in real-time and visualize this at the building and building cluster scale provides new opportunities for facility managers to more effectively respond to occupant complaints and optimize the performance of the building. A project is currently underway at Ryerson University in collaboration with the facility management team to mine data from work orders and develop a comprehensive visualization strategy for FM-BIM integration. This paper presents the development of mapping and data visualization strategies to support the identification of priority areas and extraction of key occupant satisfaction trends. Key visualizations and BIM integration protocols from the campus deployment are presented and discussed to identify applicability of this data to support post-occupancy evaluation, limitations, and opportunities for further expansion and refinement.

Keywords –

Post-Occupant Evaluation, Work Order, BIM, Facility Management, Visualization, Operations & Maintenance

1 Introduction

People spend 80% of their lives indoors, where indoor environmental quality has significant effects on occupant comfort, productivity, and well-being. At the same time, buildings use approximately 40% of total energy globally, with the majority of this use – and associated cost - associated with day-to-day operations [1]. Within this context, Post-Occupancy Evaluations (POEs) are increasingly recognized as providing significant value to both increase occupant comfort and decrease energy and operations costs. Studies have found that buildings rarely perform as expected during occupancy, requiring intervention [2]. Despite this, POE is rarely effectively used in practice [3] and adoption rates remain low [4]. The motivation for this research is to develop strategies to support POE through the evaluation of already-collected data (work orders) to increase this adoption rate.

While there is little consensus regarding the definition of POE [4], several elements are commonly considered within the scope of such studies: indoor air quality (IAQ), indoor environmental (thermal, acoustic, visual & spatial) quality, space functionality, asset condition, cleanliness, aesthetics, sound privacy, workspace & building features, occupant behaviour, occupant health & safety, and user satisfaction/comfort [5-10]. User surveys are the most common source of information for POEs [5], and are often combined with in-situ measurements to contextualize user responses [3, 7].

The increasing adoption of Building Information Modelling (BIM) within the Facility Management (FM) context provides a significant opportunity to integrate a multitude of building information of value to POE studies. There have been several significant studies, for example [11-13] exploring the benefit of BIM within the FM context, and this body of research is well-summarized in recent literature reviews [14, 15]. A number of case studies [16-20] demonstrate the development of such models. Of specific relevance to this paper, Akcamete *et al.* [21] linked work order information with BIM in spaces to allow spatio-temporal analysis of maintenance history to support operations; this work focused primarily on maintenance costs and issue frequency but did not consider occupant experience directly. Motawa and Almarshad [22] developed a case-based reasoning system to create knowledge from work order information. Shoolestani *et al.* [6] developed SocioBIM to enable user comments and feedback on building condition and occupant concerns, which could be read by other users and the FM team. Gerrish *et al.* [23] integrated building management systems (BMS) with BIM to develop a dashboard but found unstructured data very difficult to integrate. To overcome this unstructured data issue, machine learning was used by Raghubar *et al.* [14] to automatically classify work orders by complaint type and map these to an FM-BIM using techniques developed by Khaja *et al.* [24].

Few studies have linked BIM with POE, notably the work of Göçer *et al.* [3, 9] who created a GIS and BIM-enabled platform to support bi-directional communication between FM teams and users and created a series of supporting BIM visualizations of POE survey results. This paper responds to existing research gap of POE integration within BIM [5] and presents strategies for leveraging maintenance work orders to enhance and complement POEs. An FM-BIM integration approach is integral to implementation, providing an information management framework and visualization capacity. A set of sample visualizations from a current case study demonstrates the application of these strategies.

2 Methodology

The development of the POE-BIM integration for the case study (a university campus) consisted of six steps: (1) documentation of POE information requirements; (2) review of work order content and alignment with POE inputs; (3) storyboarding of potential visualizations; (4) development of the necessary data structure to support FM-BIM integration; (5) data mapping; and (6) visualization creation.

When analyzed and organized correctly, work orders provide a large database that enables increasing evolution of Computer-aided FM (CAFM). Generally, previous research has described three approaches to POE: indicative, investigative, and diagnostic. A work order system that is intrinsically diagnostic and lends itself to supporting diagnostic POEs, has the potential to permit targeting of investigative POE toolkits in problem areas and provide justification for such future investment.

Work orders intrinsically provide strictly negative feedback as users are motivated by dissatisfaction to report issues. As a result, work orders must be understood as first indicating those areas where dissatisfaction exceeds a threshold for the user, thus only identifying priority areas; areas without significant issues will be indicated only by a lack of comment. Because of this nature of the input data, dissatisfaction was developed as the primary metric for such diagnostics.

Prior to defining a data structure for the POE information, the visualization concept was storyboarded to determine how this information could be most effectively integrated and presented for FM use. This strategy is central to user-centered design practice of Human-Machine Interfaces (HMIs) [25] to allow end-users to provide feedback on potential visualizations.

Once the information requirements and visualization concepts were developed, the supporting data structure was created to host the required information. Because all occupant-reported work orders are logged by room by the CAFM system, rooms were deemed the most appropriate hosts. Data mapping was achieved using Python coding in Dynamo, similar to the approach presented in previous studies [23, 24]. Visualizations were then developed using HMI design best practices from industry [26, 27] and academic literature [28, 29, 30]. The data source used for test deployment are the campus work orders from 07/2015 through 12/2017.

3 Work Order and POE Alignment

3.1 Information Required to Support POEs

The 'essence' of POE has been discussed using terms such as health, safety, security, functionality, cleanliness, asset condition, satisfaction, and comfort. The first three are best defined by the presence of alarms, incident reports, and security system information, which can all be integrated in an FM-BIM, but this is beyond the scope of this initial study. Acoustic, thermal, visual, and indoor air quality [5] define the indoor environmental quality (IEQ) of a space and address the latter two categories while reports of broken fixtures, furniture and equipment (FFE) and custodial and groundskeeping requests indicate compromised functionality and condition issues (covering both maintenance and cleanliness) of specific elements within the space.

3.2 Information Generated by Work Orders

A machine-learning enabled work order reporting system is being deployed that automatically classifies work order types [31] and prompts building occupants with follow-up questions during issue reporting. These questions, developed by the FM team, provide the necessary input to both enable engineers to quickly identify problem causes and deploy the necessary personnel to resolve the issue. A sample of these categories and associated questions is shown in Figure 1.

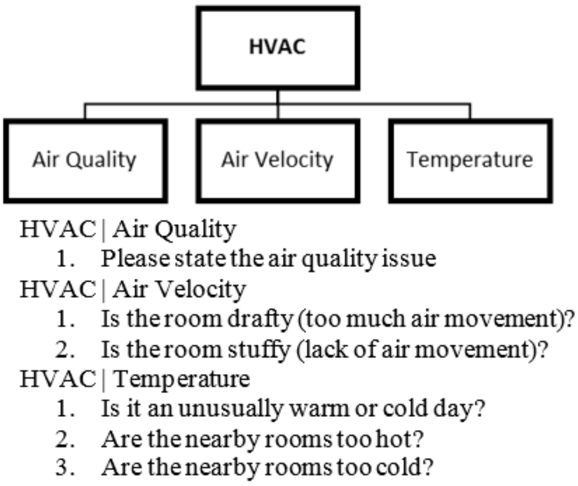

Figure 1. Work order classification structure and selected follow-up questions

This enhanced work order reporting system will allow a greater structure of information regarding occupant complaints to be obtained. Alignment with POE requirements is defined by six dissatisfaction subcategories: thermal, acoustic, IAQ, visual, condition, and functionality. These are presented alongside relevant work order categories and the information that can be gleaned from the enhanced system in Table 1. The sum of the dissatisfaction category scores is defined as the *Occupant Dissatisfaction* (OD), which serves as an overall metric and provides a basis for prioritization.

4 FM-BIM Integration

There are two key benefits to integrating POE diagnostic information into an FM-BIM. First, the multi-dimensional (nD) nature of BIM intrinsically supports data management and visualization necessary for spatio-temporal analysis of semantics. Second, complementary use cases executed in FM-BIMs such as space management, equipment characteristics and repair histories, and building automation system (controls and sensors) information, provide additional information on users, equipment, and measured space conditions, respectively, contextualizing complaints.

The FM-BIM integration consists of two key steps: pre-processing work orders to calculate dissatisfaction scores for each space over time, and mapping algorithms to integrate these score histories into the FM-BIM.

The pre-processing first uses a series of logical relationships based on the Table 1 alignment to assign a score of 1 (aligns) or 0 (does not align) for each dissatisfaction metric. Work orders are then sorted by metric. Since user complaints are reported by location, rooms are the most appropriate hosts for dissatisfaction data. Input arrays for the BIM are created such that each column includes data for the room while rows provide time series data in reverse chronological order. Each array is then saved as a comma-separated value (csv) file named for the metric type, e.g. thermal.csv. The monthly average based on two years of historical data is also calculated for each metric to provide a historical baseline for FM team reference and is saved as a separate baseline file.

FM-BIM mapping requires that a set of parameters for both monthly counts ({Thermal, Visual, IAQ, and Acoustic Dissatisfaction, Functionality, Condition} as integers), and baseline values ({same set} as numbers) to be created and mapped to rooms, levels, and buildings. Using a modification to the technique developed in [24], Dynamo is used to populate these parameters. For a given time selected, the appropriate row is identified and the mapping algorithm creates a vector of parameter values for each room. This data structure supports the integration of customized slider in the visualizations to permits navigation through time. The Dynamo script and code blocks (developed in Python) support this functionality and are presented in Figure 2.

Table 1. Work Order and POE Alignment

POE Category	POE Information Required	Work Order Category	Information generated by work order system
Acoustic Comfort	Type of Disturbance Disturbance Frequency	NOISE (all)	Description of noise Extent of complaint (spatial, temporal)
Thermal Comfort	Thermal Complaint, Draftiness	HVAC | Temperature HVAC | Air Velocity	Too hot or too cold Extent of complaint (spatial, temporal) Too much/not enough air movement
Indoor Air Quality (IAQ)	Air Quality, Freshness/Stuffiness	HVAC | Air Quality	Too much air movement (Drafty) Lack of air movement (Stuffy) Air quality description
	Olfactory Discomfort	ODOR (all)	Odor description, source (if known), Duration of complaint
Visual Comfort	Lighting Quality; Glare	LIGHTING (all) FFE | Coverings GRAFFITI	Lights burned out or flickering; Glare from non-functioning blinds or missing lens; Graffiti
Functionality	Broken Equipment	FFE | Fixture PLUMBING | Fixture	Details of broken or malfunctioning fixture(s) and equipment
Condition	Indications of spaces requiring cleaning, indications of wear, or poor asset condition	CUSTODIAL (all); PLUMBING | Leak; FFE | Paint	Reports of stains, graffiti, spills, etc. as well as leaks and other condition-related issues

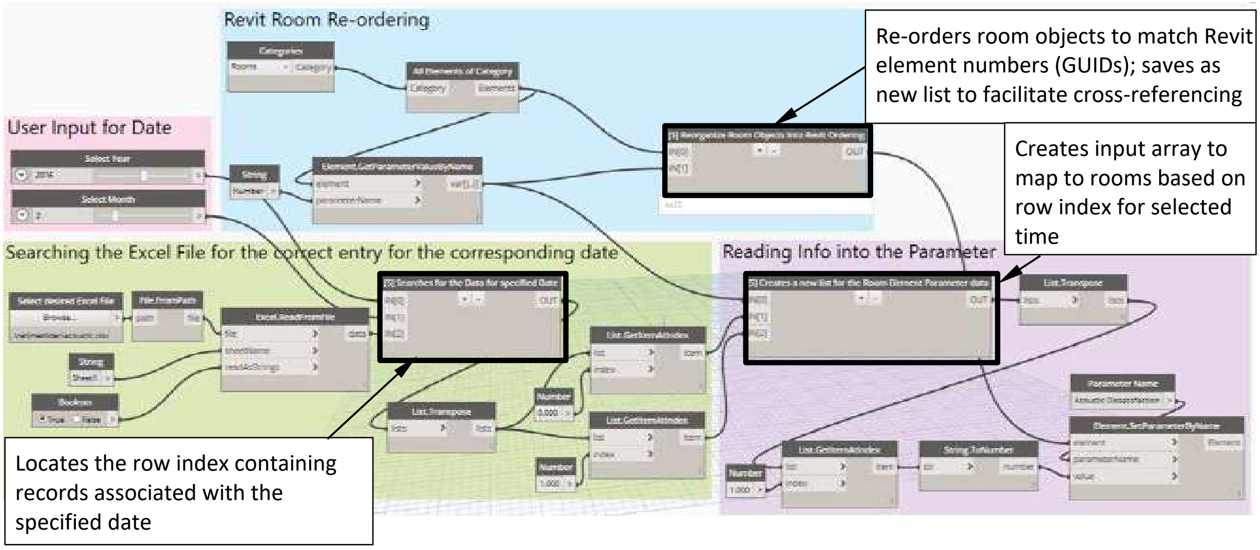

Figure 2. Dynamo script to execute time navigation and supporting code functions

5 Visualization Strategy

There has been significant research within the process control domain to developing effective human machine interfaces (HMIs). To develop the visualization strategy, HMI best practice from both academic literature [25, 29, 30] and industry guidelines [26, 27], including principles of user-centered design, were considered.

5.1 Priority Identification

In order to improve the AAG ability of CAFM systems, the proposed visualization strategy will incorporate a priority identification chart that will map, 1) worst buildings, 2) worst building levels, 3) number of open POE-related complaints for the selected time, and 4) top complaint data categories. The first two comparisons in the priority identification chart use OD (total complaints) metrics to develop these ranks, but individual dissatisfaction metrics can be selected using a toggle function.

5.2 Temporal Analysis

The dashboard will allow the user to select the desired timeframe to show OD and the associated category metrics for the area under consideration. By displaying the current (rolling window) value of these metrics along with average values from a three-year period as illustrated in Figure 3, it is readily apparent to the FM team whether the current frequency of complaints is (a) consistent (b) noticeably above, or (c) noticeably below historic values.

5.3 Spatial Analysis

Where full 3D geometry exists for FM-BIMs, 3D visualizations of the building(s) under consideration provide insight on potential causes. For example, a high window-to-wall ratio could explain significant thermal comfort issues within a particular space. Providing level totals for each of the POE dissatisfaction metrics allows the priority level(s) in a building to be identified quickly.

In all cases, 2D representation (floorplans), color-coded by semantic parameter (nD) data providing POE information are used as the primary navigation interface. Following published guidance [26, 29] a neutral (white) background is used for all floorplans and increasing color saturation – associated with each individual metric – indicates a higher dissatisfaction value.

5.4 Spatio-temporal Representation

Visualization of issue clustering in both space and time provides benefit to the FM team by simultaneously showing clusters of rooms with common issues as well as complaint clusters at individual points in time. The time navigation slider described previously permits near-real-time navigation of historical data. This functionality draws from a data consolidation and mapping architecture developed under a related project [32] to create the necessary time-series arrays for FM-BIM integration.

6 Case Study Implementation

The central theme of user-centered design is to actively engage the end-user, focusing on understanding their needs and priorities, and developing prototypes and mock-ups to gain input at each iteration [25], similar to the Agile [33] process used to develop the FM-BIM at the case study campus [34]. The following priorities were communicated by the Facility Engineers related to prioritization: (1) immediate identification of the most problematic areas; (2) visualization of clusters of issues within buildings and an understanding of these issues over time; and (3) the ability to differentiate between types of issues and their distributions. The support of root cause analysis of these complaints is a long-term goal but is beyond the scope of this study; at this time, this analysis is related to seasonal and other temporal effects.

To address the need to identify priority areas, a hierarchy of views [26] are required: 1) room, 2) level, 3) building, and 4) multi-building comparison (where applicable). Along the top of the screen is the navigation bar to indicate the current scale and permit navigation to other scales. A common conceptual layout is used for each scale. The HMI (Figures 3-5) displays the highest priority areas in the leftmost pane, with a visual of the worst areas based on *OD* (top left), tables listing the OD scores and top complaint types (middle left) and graph indicating breakdown by type of issue (bottom left). The top right pane indicate the current scores by dissatisfaction metric on a gradient metric where the center of the metric (grey) is the baseline value, increasing to red for higher scores and to green for lower scores. The bottom right quadrant shows the navigation through time and permits the user to select a value type (current value, total over range, average over range) and metric for the area selected using the time slider described previously and displays values for each subspace. Increasing color saturation and consistent colors indicate increasing metric scores [26]. At the building cluster level (Fig 3), this is a map showing each building total.

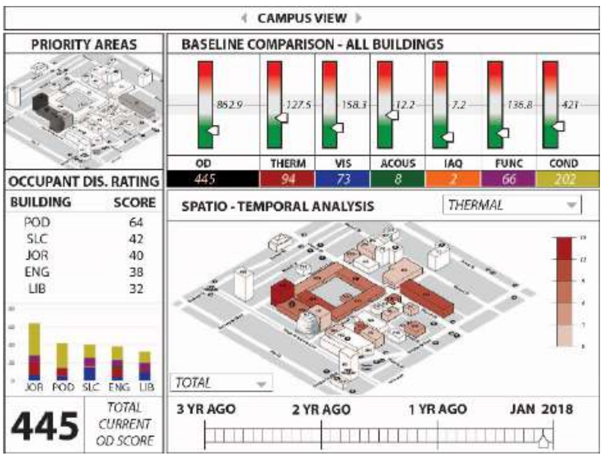

Figure 3. Sample campus-level navigation

This campus-level navigation could support several FM tasks. The top bar provides a real-time summary of campus issues compared to the baseline, allowing the FM team to quickly contextualize the individual results. From the leftmost pane, the FM team can readily identify buildings of concern for further investigation. For example, POEs are being planned for selected buildings across the campus. The campus map illustrated quickly provides a visual indication of the most critical buildings requiring further investigation due to high levels of occupant dissatisfaction. The integration of the time slider extends this visualization into four dimensions, providing insight into seasonal issues and facilitating identification of regular patterns of complaint. Key areas of improvement such as necessary HVAC plant upgrades serving multiple buildings would be informed by patterns of summer overheating and winter undercooling.

Navigating to the building level (Fig 4), the visualization format is retained, however the 2D representation of multiple levels in the building is not immediately user legible, and thus a column graph replaces this visualization. The user can select which metric to display, or whether to display the total OD using a stacked column graph made up of the individual dissatisfaction metrics.

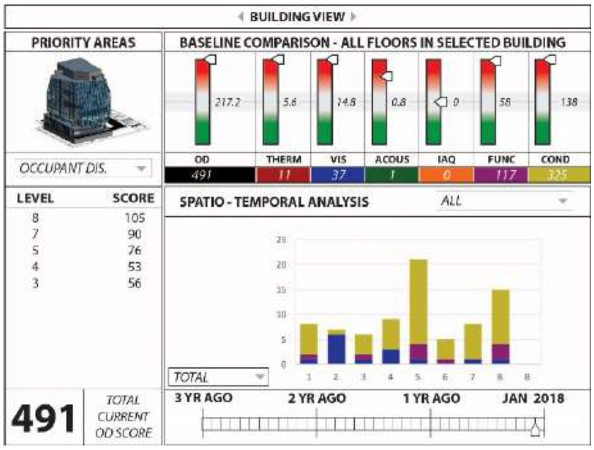

Figure 4. Sample building-level navigation

This view provides the FM team with insight on potential floor-level clustering of complaints. If one floor has a much higher level of dissatisfaction than others, it permits further POE prioritization within a building of concern identified from the campus visualization, and thus enable specific targeting of problem areas. This view also begins to provide insight on large-scale issues causing widespread discomfort or dissatisfaction. For example, high levels of visual discomfort could be caused either by problems with a lighting panel, as these typically serve an entire floor, or due to high levels of solar glare (or low levels of available daylight) in different locations within the building. Thermal and IAQ issues clustered on floors could indicate poor control of zoned equipment, while functionality issues could signal water pressure challenges. Finally, a high condition dissatisfaction score could inform either a custodial services audit to ensure that those floors are being adequately cleaned, or a targeted building condition assessment, depending on the underlying work orders. Given that each work order is flagged to any associated dissatisfaction score(s), queries using these terms would help narrow down underlying causes of clustered complaints.

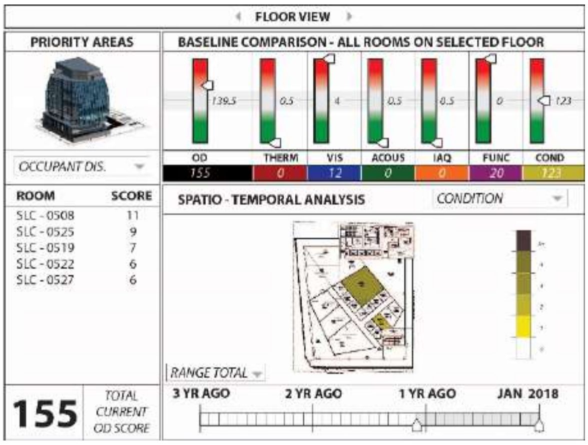

Figure 5. Sample floor-level navigation

The dashboard floor view (Fig. 5) returns to the map view, using the floor plan and colouring data by room, permitting Facility Managers to quickly identify problematic rooms or room clusters within the building. A room-level display has not been created; rather, the FM could refer to the FM-BIM for specific room and local equipment information at this scale. The latter is illustrated in Figure 6, which overlays truncated room and space views for the highlighted room in a real FM-BIM model.

The floorplan view supports similar functionality as the preceding views but with increased granularity. Specific rooms can be identified at this level, permitting a targeted response through reactive maintenance or interaction with the room occupant. The effectiveness of building retrofits or equipment replacement could be assessed by determining whether such action has resulted in a decrease in complaints, or vice versa. Similar conclusions can be drawn regarding the effectiveness of changes in control strategies or maintenance practices. Within the floor, clustering of problems within an area – for example the southwest corner of a building – could indicate faulty equipment, poor building condition in that area, zoning issues, or other underlying causes not evident without this graphical display. Seasonal patterns also become much more visible to FM team with this approach.

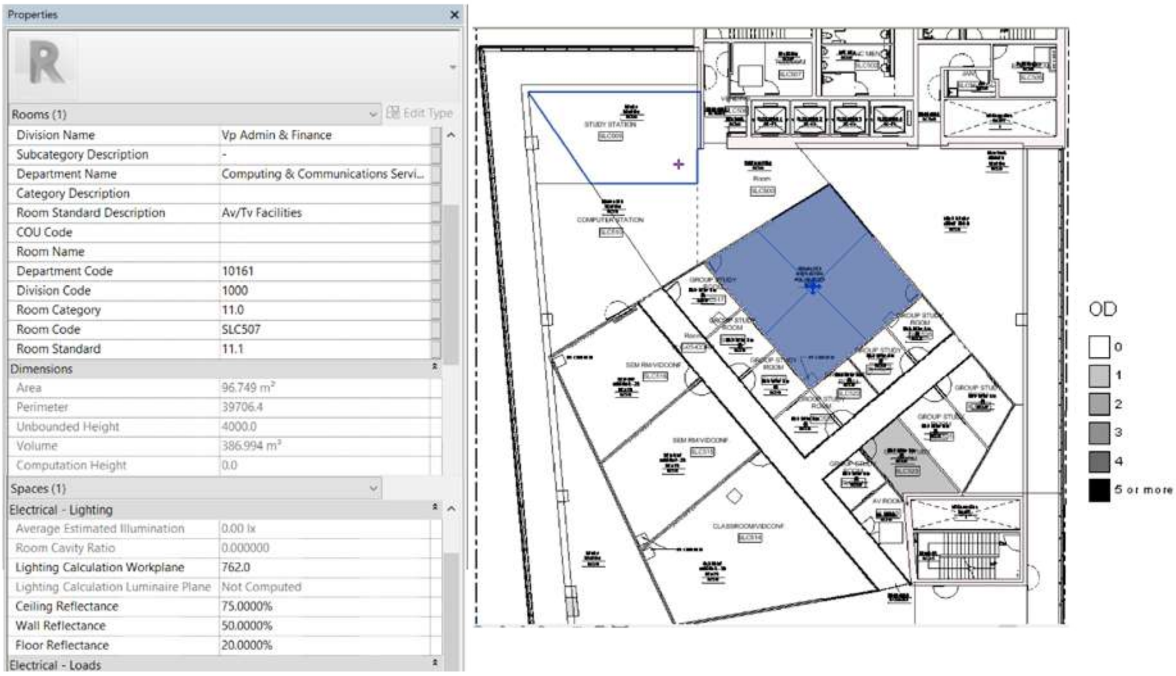

Figure 6. FM-BIM showing room-level information and integration of POE with building automation and other building data

7 Discussion and Conclusions

Given the known impact of the indoor environment on occupant health and productivity, post-occupancy evaluation is a topic of increasing significance.

The case study demonstrates that it is possible to extract relevant data from work orders of relevance to post-occupancy evaluations. Such data indicates the frequency of a high level of dissatisfaction – enough to compel a user to take action and report a complaint – which, in turn, identifies priority areas for intervention and for the deployment of a complete POE study. The data can also support POEs by providing longer-term insight on the frequency and type(s) of complaints reported by space users. By mapping this information into an FM-BIM, it can be readily overlaid with the broader building information, allowing the FM team to understand these complaints in the context of broader building operational parameters, for example current system performance (building automation system point data), equipment condition, and space management.

The conceptual visualizations presented leverage the inherent geometric, time, and semantic data management capability of BIM, and integrate best practices from HMI to provide increasingly detailed navigation through the sample campus and building through a series of dashboards (Fig 3-5).

While the pre-processing logic can be automatically applied to the work order data, this processing occurs in batches in a spreadsheet (Excel); future research will import this algorithm into Dynamo to integrate and fully automate this process. Further, the use of work order categories permits false positive classification and natural language processing algorithms to score dissatisfaction metrics of work orders automatically based on work description text is an avenue of future research to improve the specificity of this mapping and reduce misclassification. Further refinements of the visualizations informed by the test case would include more integration with the BIM and work order system to allow the text of specific work orders (lists at the building, floor, and room levels) to be readily accessed through this interface rather than simple totals. A second refinement would be to allow a side-by-side comparison of different times or ranges of time rather than the single views currently supported.

The single context demonstration is the major limitation of this study. Future research involving new case studies will permit rigorous testing and generalization, while POEs informed by resultant work order visualizations would provide further insight into visualization refinement. The resultant data would support development of a refined work order reporting strategy incorporating POE-supporting questions and mine the data generated to support root case analysis and enhance the decision-making value of this approach.

Abstract –

Exoskeletons can be seen as an archetype of a truly sustainable manufacturing technology since they empower human beings rather than aiming at their substitution. Exoskeletons have been characterized by rapid technological advances in the last decade, as well as an increase of activities attempting to develop feasible usage scenarios for many industries. However, usage concepts for this technology in the construction industry are still rare. This contrasts with the fact that exoskeletons are theoretically ideal for labor intensive industries such as construction. Therefore, in the study presented in this paper, we made a first attempt to conceptually bridge the gap between exoskeleton typologies and construction tasks so as to provide guidance for future target oriented scenarios and technology development. We utilized the Hong Kong housing construction industry as a case study. Consequently, we developed a construction specific classification of exoskeletons and analyzed the suitability and applicability of the resulting exoskeleton types for Hong Kong's housing construction tasks. Our study identified, amongst others, hotspot task areas with high appropriateness for exoskeleton use, task areas with similar needs and usage patterns regarding exoskeletons. Furthermore, our study sheds light on the regimes and rationales behind the identified appropriateness levels. Based on our findings, a set of basic guidelines was developed to support and govern future research and development activities targeting the exoskeleton usage in construction.

Exoskeletons; Classification; Task Analysis; Housing Construction; Hong Kong; Sustainability

1 Introduction

In the study "The Future of Employment", Frey and Osborne [1] argued that in the next decades labor intensive and repetitive jobs such as those in the construction industry will be gradually substituted by automation and robots. On the contrary, recent technological advances indicate that we are able to develop sustainable technological solutions that can literally "bring back humans to work" [2]. According to the authors of this paper, exoskeletons can be seen as an archetype of such solutions, since they empower human beings rather than aiming at their substitution. The term "exoskeletons" (i.e., robotic exoskeletons) refers to a specific branch of wearable devices employing person-external mechanical structures to assist or enhance the physical, motor, and cognitive power of a person [3]. The last decade has witnessed its rapid technological advancement, alongside an increase of projects and activities attempting to develop realistic usage scenarios for many industries (e.g., manufacturing, shipbuilding, agriculture, care, etc.). However, concepts for the usage of this technology in the construction industry are still rare. Exoskeleton technology could provide a couple of performance features such as force augmentation for human beings, high flexibility, the combination of human intelligence with machine capability and improved workplace ergonomics; features ideal for labor intensive and on-product customization focused industries such as construction.

The fundamental motivation to adopt exoskeletons in the construction industry - besides the demands for productivity increase - is to improve the health and safety of workers by enhancing their muscle strength, mobility, and endurance. Construction is a highly physically demanding industry, while musculoskeletal disorders, often caused by overexertion of repetitive works or from heavy lifting or squatting jobs, is one of the leading type of injuries in construction industry [4]. Exoskeleton technologies, therefore, have the potential to dramatically reduce the risk of injuries and illnesses by amplifying the power of construction workers and providing back support. Also, faced by the challenges of an ageing workforce and labour shortages in cities like Hong Kong, exoskeletons and other wearable devices can help to solve the problem by enabling elderly or female workers to perform physically demanding construction tasks in a highly productive manner. Besides, exoskeletons may also be capable of autonomous decision making to achieve certain goals such as being an agent of humans in construction activities [5]. Notwithstanding the tempting potentials, the unstructured and dynamic site environment, combined with the diverse tasks and complicated processes, highly raise the requirements of exoskeleton technologies for construction than traditional military or medical use. To avoid additional risks by wearing exogenous devices, it is of great importance to warrant a high level of portability, flexibility, and coordination with the wearer.

The study presented in this paper attempted to conceptually bridge the gap between existing exoskeleton technologies and construction tasks-based usage scenarios. The Hong Kong construction industry was utilized as a study setting due to its vibrant nature of demands for productivity as well as enhanced health and safety standards. At the same time, some unique characteristics such as Hong Kong's topography and building culture bring forth narrow and cramped sites and floor plans that largely restrict the usage of large machines or robots and demand for small-scale, human-centered approaches. This initial qualitative and exploratory study was conducted in order to pave the ground for larger, qualitative follow up studies involving extensive bottom-up input by relevant stakeholders. This initial study not only identified the relevant domains of knowledge but also combined a comprehensive literature review with a worldwide perspective to the secondary data on exoskeleton technologies by using the Hong Kong housing construction as a case study. The data was collected and developed through the analysis of relevant literature, reports, construction laws and guidelines, construction task descriptions, as well as product leaflets and documents.

The remainder of this paper is structured as follows; first, the background of exoskeletons is introduced, the important development tendencies are characterized, and the diversified technologies are analyzed and categorized. Then, while considering the housing construction practice in Hong Kong, work and labor structures are analyzed and task areas are identified and outlined. Next, usage scenarios that build on the task areas and specific types of exoskeletons to identify the usage scenarios are developed. Finally, a set of basic guidelines derived from the analysis is presented to support and govern future research and development activities targeting exoskeleton usage in construction.

2 Background

2.1 History of Exoskeletons

The development of the exoskeleton can be traced back to the 1960s when the first systems for power augmentation in the context of military applications [6] and physical therapy in medical services were developed [7]. Hardiman, the first full-body powered robotic exoskeleton prototype developed under the U.S. Office of Naval Research, was a heavy (680kg), hydraulically actuated wearable device, with the aim to amplify the muscular capabilities of the wearer [6]. Although its purpose to power up the human was never achieved, critical issues for future development such as power supply and human-machine interfaces were identified [7]. In 1991, the first energetically autonomous exoskeleton, Berkeley Lower Extremity Exoskeleton (BLEEX), powered by bidirectional linear hydraulic actuators, was developed to augment the human strength for material handling [8]. Continuous studies and development have been carried out on BLEEX, triggering out the spin-off company called Berkeley Bionics (now Ekso Bionics) [9]. BLEEX was initially funded by the U.S. Defense Advanced Research Projects Agency (DARPA), which has been regarded as a major impetus to the later development of performance augmenting exoskeletons for soldiers during load-carrying [10]. Medical use cases also played a major role in the evolution of exoskeletons [11] in terms of catalysing the recovery of neurological or orthopaedic patients in physical therapies [12], adding power to help people with muscular weaknesses while walking or stair climbing [13], assisting paralyzed people to regain mobility in daily life [14], etc.

In the recent years, the research and development of exoskeleton technology has prosperously spread in the USA, Japan, Korean, and in Europe. Currently, its applications are broad and vary from military and medical usage to emerging commercial and industrial applications [7, 11]. Although industrial grade exoskeleton usage is still rare in most-non-construction based industries, an enormous amount of research and development activities is currently taking place to crack the code for commercialisation.

2.2 Technological Development Tendencies

Technologically speaking, using exoskeletons as an integration of humans and machines into one system provides new possibilities to create assistive technologies for biomedical, manufacturing and aerospace industries. Even though human muscles have a limitation in power, they naturally use highly specialised control systems to perform complicated tasks. As opposed to humans, robotic manipulators can carry out higher forces on certain tasks, however, their artificial control algorithms compared to humans has less flexibility performance in a wide range of fuzzy conditions. Therefore, combining robotic manipulators directly with humans offers the opportunity to benefit from both sides and use advantages from each branch.

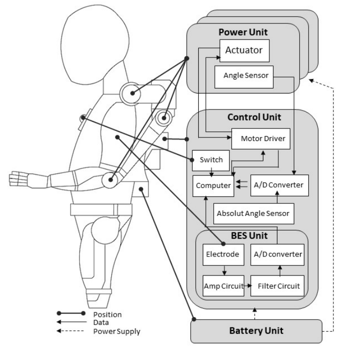

Figure 1. System configuration of the ULSS. All of the power units have the actuator and the angle sensor. The control unit contains the BES unit and the absolute angle sensor, and it controls the whole exoskelton [16].

First generation of exoskeletons used position command from human body to control the exoskeleton. Usually it consists of two layers; a master internal layer providing the position command for the slave and external higher power layer. However, technical problems such as overweight, errors between master and slave layers and poor performance for leg control to achieve the balance for the body movement initially made the achievement of unsupported walking a challenge.

Second generation exoskeletons applied the interface in a dynamic manner; using direct contact force between human and the wearable robot. The measured force is the main signal sent to the exoskeleton. With both the first generation kinematic-position command type and the second generation dynamic-contact force command type, a slight delay to trigger the exoskeleton response by applied action of the wearer [15] represents the challenge with regards to control.

Third generation exoskeletons set the interface at a higher level, i.e., the human neurological system. Likewise, in the human body, a delay is presented between the neurological functions and muscle and body part movements. During this inherent delay, the system gathers information regarding the muscle's neural activation level based on a processed neuromuscular (EMG) signal or even maybe the brain signal, the joint position, and angular velocity, which allow it to estimate the force before the mechanical movement. Thus, the earlier developed dynamic and kinematic feedback types from older generation exoskeleton systems have been integrated and re-combined in the 3rd generation systems. Figure 1 shows exemplarily the system configuration used in upper limb support system (ULSS) [16]. It benefits from using the bioelectrical signal (BES) and automatic changes in the control algorithm. Based on neural network and fuzzy logic, the control algorithms can be developed and designed for specific operators and even specific tasks to fit different physical conditions of the wearers [15, 17] and the requirements of specific work settings and processes. In the development of the fourth generation exoskeletons currently taking place, the key lies in the improvement of technical features such as lower weight, high performance actuators, human–exoskeleton interface, safety, energy efficiency, and lower cost [17].

2.3 Important Definitions

Even though a diversity of definitions exists, the terms "wearable robots" and "exoskeletons" are widely used in the context of wearable robotic technologies. Pons [18] defined a wearable robot as "*a mechatronic system that is designed around the shape and function of the human body, with segments and joints corresponding to those of the person it is externally coupled with*". De Looze, Bosch [3] regarded an exoskeleton as "*an active mechanical device that is essentially anthropomorphic in nature, is worn by an operator and fits closely to his or her body, and works in concert with the operator's movements*". In compliance with definitions used by the International Association of Automation and Robotics in Construction (IAARC) [19], robotic construction technology for on-site construction can be sub-classified into several sub-categories such as; 1) robotised construction machines, 2) single-task construction robots, 3) on-site logistics solutions, 4) Building Information Modelling (BIM), and 5) data acquisition, monitoring, and sensing approaches. Bock and Linner [20] extended this classification by adding amongst others, 6) on-site factory approach, 7) humanoid robot technology, 8) aerial systems, and 9) wearable robot technology. Wearable robot technology can further be sub-classified in approaches such as; a) smart helmets [21], b) smart glasses and virtual reality [22], c) body sensor systems [23], and exoskeletons (which this paper focusses on).

In the study presented in this paper, we principally followed the definitions of Pons and De Loze, by considering "wearable robots" as an umbrella term to describe digital and robotic systems, while defining "exoskeletons" as more specific skeleton applied devices that are worn on the human body to improve or sustain the wearer's ability to perform specific required tasks. In light of our focus on analysing particularly the usage potentials of exoskeletons in Hong Kong's housing construction industry, exoskeletons were further regarded as physico-mechanical support devices that a construction worker can wear to augment or assist his physical abilities, strength, endurance, speed, precision, or general performance on the site.

Table 1 A construction specific sub-classification of exoskeletons.

Main category	Subcategory	Basic kinematic composition	Graphical illustration	Power (type*)	Examples
Full body	Full body	Full body is actuated or powered		Active (*a*) Passive (*b*)	• HULC by Lockheed Martin and Ekso Bionics • Ekso by Ekso Bionics • MAX by SuitX
Upper limb	Shoulder type for back support (without arm)	Provide support to the back		Active (*c*) Passive (*d*)	*upcoming development activity expected* • FLx ErgoSkeleton by StrongArm Technologies
	Shoulder type for arm support	Provide support to the arm		Active (*e*) Passive (*f*)	• Titan Arm by University of Pennsylvania • AIRFRAME by Levitate Technologies
	Elbow	Provide assistive power to elbow joint		Active (*g*) Passive (*h*)	• HAL Single Joint Type by CYBERDYNE • PEX by UC Berkeley
	Hand	Provide assistive power to the wrist or fingers		Active (*i*) Passive (*j*)	• SEM Glove by Bioservo Technologies • Pneumatic Power Assist Glove by Daiya Industries
Lower limb	Hip	Provide support to hip joint or lumber		Active (*k*) Passive (*l*)	• HAL Lumbar Type by CYBERDYNE • AWN-03 by Panasonic ActiveLink • Hip Auxiliary Muscle Suit by Innophys
	Hip-knee-ankle type for leg support	Provide support to the leg and reduce fatigue during squatting, standing or walking		Active (*m*) Passive (*n*)	• Walking Assist Device with Bodyweight Support System by Honda • Chairless Chair Wearable Ergonomic Device by Noonee • Archelis by Wearable Chair
	Knee or ankle	Provide extra force to the knee or ankle to improve walking performance		Active (*o*) Passive (*p*)	• HAL Single Joint Type by CYBERDYNE • Exo-Boot by Carnegie Mellon and North Carolina State
Body extension	Tool holding	With an additional arm to support the holding of a heavy tool, while the weight of the tool is transmitted into the ground		Active (*q*) Passive (*r*)	• Lower Extremity Exoskeleton Robot for Concrete Placing (HEXAR-PL) by Hanyang University • Ekso Works by Ekso Bionics • Fortis by Lockheed Martin
	Extensional / Supernumerary	With two or more extensional arms to perform material handling or other works		Active (*s*) Passive (*t*)	• Exoskeleton for handling heavy steel elements by DSME • Supernumerary Robotics Limbs (SRL) by MIT *upcoming development activity expected*
	Extensional / Wheeled	Extension with wheels or mobile platform which could be further integrated into body parts		Active (*u*) Passive (*v*)	• EXOwheel by Sogang University • iReal by Toyota *upcoming development activity expected*

*letters in brackets are referred to classified types of exoskeletons.

Exoskeletons can themselves be classified based on a variety of viewpoints such as active/passive, the body parts covered, functionality, the types of actuators used, or the types of control and feedback systems used, etc. When considering the power source, there exists mainly the active, or powered exoskeletons using electric, hydraulic or other connections to run sensors and actuators, and passive, or un-powered ones that require no external power but use springs, elastic cords, or other resilient elements to transfer loads to the ground. According to the supporting parts to muscle strength, they can be further categorized into: upper limb, lower limb, and full body [17]. By functionality, they can be considered as power assistance, power augmentation, and cognition and sensing augmentation [20]. Regarding the types of actuators, electric motors and pneumatic systems are mainly used in exoskeleton design. In terms of feedback systems, for example, we can distinguish between a control of the robot based on bio-signals from the wearer or from acceleration forces.

2.4 A Construction Specific Sub-classification of Exoskeletons

In the study presented in this paper, exoskeletons were organized according to their applied body parts and active/passive features, considering that the analysis of the appropriateness of a certain type of exoskeleton for a certain type of construction task can best exploit these two factors. The body parts supported by an exoskeleton give a good hint about the task range and task type that an exoskeleton can cover, and the active/passive view indicates what payloads an exoskeleton can handle. Compared to many other manufacturing industries, building components cover a very wide range of loads and are key factors in deciding which construction processes and tools may be used.

Table 1 outlines the proposed construction tasks oriented classification of exoskeletons with key characteristics and example prototypes (or products) listed for each of the identified categories. The superordinate level of each category was formed by general body parts including full body, upper limb and lower limb, with body extension being considered as a fourth one to cover those with additional arms or support. Then, those four main types were further broken down into detailed body parts and kinematic features. Despite some overlaps, each second level category represents a distinguished body related feature, as manifested in the brief descriptions and graphical illustrations. In addition, the active/passive perspective was employed to determine the construction specific sub-classification of exoskeletons into 22 types, each backed with examples.

3 Housing Construction Tasks

To enable the assessment of the appropriateness of certain types of exoskeletons for specific housing construction tasks, we subdivided housing construction (Level 1) into basic task categories (Level 2) and then further into individual task areas (Level 3), as mapped in Figure 2 (mapping of housing construction tasks in Hong Kong). Relevant documents, like HK Cap. 123B Building (Construction) Regulations [24] and HK Cap. 583 Construction Workers Registration Ordinance [25], were analysed to define and develop the task areas map. On Level 2 the task categories identified are the following: 1) geotechnical and foundation work, 2) site operation, 3) main structure construction, 4) building services, 4) general interior finishing tasks, 5) general exterior finishing tasks, 6) landscaping, 7) ground investigation, site measuring, and monitoring, 8) civil works. Level 3 breaks down this task categories into specific task areas and is used as the basis for the analysis conducted in this paper. A further split down of this task areas as per the task specific execution or assembly process (i.e., sequence of sub-tasks and activities within an individual Level 3 task area; Level 4), would allow a very detailed assessment of the appropriateness of exoskeletons. However, this would require a very detailed decomposition which would go beyond the scope and resources of this initial study. In this study, we generally focussed on assessing the appropriateness of exoskeletons for Level 3 task areas. Our aim was to stimulate through this further research and development by Level 4 domain specific groups and consortia.

4 Analysis of Usage Scenarios

In this chapter, usage scenarios that were developed and built based on those identified in Level 3 task areas are presented. As outlined in Figure 3, we analyzed the previously developed classes of exoskeletons (Table 1) against the Level 3 task areas (outlined in Figure 2) and thus how specific categories and types of exoskeletons can be used within the context of specific task areas. We further identified technology appropriateness through pairwise analysis of task areas and types of exoskeletons (seen in Figure 3).

In general, our analysis revealed the following patterns in the usage of different exoskeletons in housing construction:

1. Active exoskeletons are appropriate in the context of tasks that involve the handling of rather large elements with high payloads (e.g., metal works, dry wall installation, etc.), whereas passive exoskeletons are suitable in the context of tasks that involve the handling of rather small and light components and fine motor skills (painting,

plastering, etc.).

2. Certain task areas show a similarity with regards to the type of exoskeletons used. So, for example, a relative task similarity can be identified within interior and exterior task categories. Also, tasks that involve similar tools and processes or have similar needs in terms of power augmentation, extra support or fatigue prevention (e.g., painting, plastering, etc.) result in similar requirements of exoskeleton use.

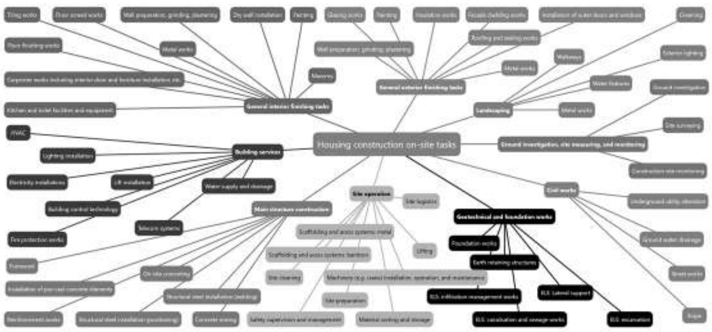

Figure 2. Mapping of housing construction tasks in Hong Kong. The map shows how housing construction (Level 1) can be subdivided into basic task categories (Level 2) and then further into individual task areas (Level 3) based on relevant building construction regulations in Hong Kong.

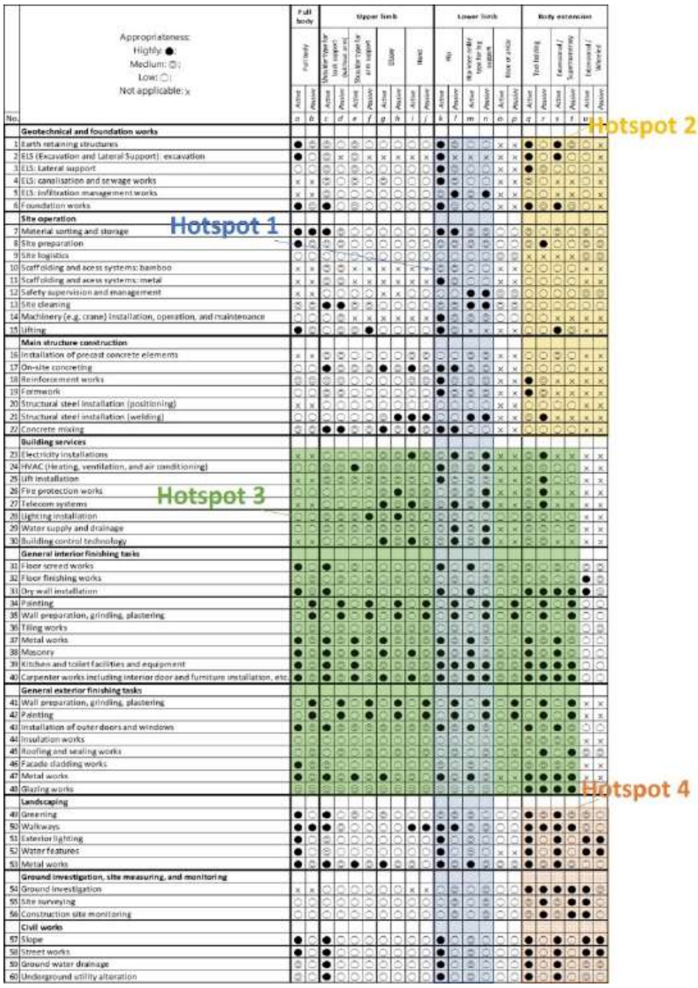

Figure 3. The pairwise analysis of task areas and types of exoskeletons. The previously developed classes of exoskeletons (Table 1) were analyzed against the Level 3 task areas (outlined in Figure 2).

3. Wheeled and full body exoskeletons face challenges in the rather unstructured environments related to geotechnical and foundation works and site operation works. Whilst after the superstructure construction, that the work environments are relatively controllable, the use of such types of exoskeletons is more suitable.
4. In Section 2.4, three exoskeleton types (types *c*, *t*, and *v*) were identified for which at present no developments or approaches are known. Our analysis revealed, in particular for type *c*, that a high appropriateness was identified for a number of tasks and that upcoming development activities for this type of exoskeleton would be justified.
5. Four hotspot areas were identified (see Figure 3):
   a) Hotspot 1: Preferred lower limb exoskeleton usage areas
   b) Hotspot 2: Preferred body extension exoskeleton usage areas
   c) Hotspot 3: Non-preferred body extension exoskeleton usage areas
   d) Hotspot 4: Preferred fully body-upper limb-lower limb usage areas

5 Discussion

The research and development towards exoskeletons usage are manifold, whilst the applications in the construction industry are still limited. Our analysis, with the assignment of appropriate levels for the construction of specific exoskeleton types to the task areas in Hong Kong housing construction, made a first step towards defining and detailing the problem and requirements for exoskeleton use. All in all, the analysis conducted provides guidance for the following follow up activities:

- **Definition of problem**: Once the task areas in which the exoskeleton can be used are defined, the development teams can then focus on creating incremental or breakthrough innovations rather than on basic science. In that context a particular focus could be laid at the sixteen main types of workers highlighted by the Hong Kong Construction Industry Employees General Union [26].
- **Multi-use scenarios:** Using our matrix and the outcomes presented in it (Figure 3), developers can identify task areas with similar or same use patterns for exoskeletons and then attempt to develop one exoskeleton (maybe with slightly adaptable features for each task area) hat can finally be used in a multitude of task areas.
- **Exoskeleton-oriented task and component adaptation:** Existing or efficiently achievable technological systems or breakthroughs shall be exploited in a broader way, developers may also consider changing task and materials/components to make certain types of exoskeletons applicable and suitable.
- **Transform site to be more like a factory:** The unstructured environment of the construction site greatly inhibits the use of certain types of exoskeletons (e.g., fully powered body exoskeletons, wheeled ones, etc.). This circumstance may be equalized through a better structuring of the construction site.
- **Exoskeleton surrounding site infrastructure:** To successfully use the exoskeleton on site, not only must the core tasks be executable but the surrounding tasks and activities have also to be integrated as well. In the context of exoskeleton usage, a key aspect will be how the wearer puts on the exoskeleton. Will there be frames or cabinets available to help the user "slip" into the exoskeleton? Or will there be as in the rehabilitation use, service personnel on the site to support with dressing/un-dressing operations? How will tools or parts be provided to the wearer of the exoskeleton? All these should be considered in the future research.
- **Systematic improvement of exoskeleton key technologies:** As part of a detailed task and applicability analysis, key technologies that require systematic technological improvement such as battery technology and the control interface can be identified (sensors, feedback system, user interfaces, etc.).
- **Identification of new exoskeleton categories:** The analysis shows that all of the existing exoskeletons are not explicitly appropriate for certain tasks, e.g., scaffolding. Consequently, this may lead to the definition of new categories for exoskeletons such as suspended gondola type exoskeletons.
- **Develop exoskeleton complementary technologies:** Complementary technologies (possibly based on BIM, worker guidance systems, new types of Graphical User Interfaces such as smart glasses, etc.) and their usages shall be well-defined and systematically developed towards higher technology readiness levels.
- **Exoskeleton and site usability engineering:** Since the human being is the most important element in the efficient and sustainable use of exoskeletons on the construction site, studies on the short and long-term impact of the use of exoskeletons on human physical conditions, muscles, psychological conditions, and overall health must be conducted and fed back into systems development. Similarly, system features and requirements that enhance motivation to use the equipment and ease of use on the construction site must be identified through user studies.
- **Sustainability:** Exoskeletons can indeed be seen as an archetype of a truly sustainable manufacturing technology since they empower the human being (his capabilities as well as his health at the workplace) rather than aiming at complete substitution of human labor by machine technology and automation.

6 Conclusions

The study presented in this paper examined and explored the usage scenarios of exoskeletons in the construction industry, drawing on the case of the Hong Kong construction industry as an initial use case setting. A construction specific sub-classification of exoskeletons was proposed to support the fundamental understanding of potential usages of exoskeletons for construction. A comprehensive mapping of tasks in Hong Kong housing construction was provided. A pairwise analysis developed usage scenarios for exoskeletons in construction to facilitate future application oriented research and development efforts directed at exoskeleton technologies.

Future work will further split down the identified task areas into sub-tasks (Level 4) to analyze what activities can be carried out by exoskeletons, human beings only, or solely by robots or machines. Also, we plan to analyze in more details the impact of exoskeletons, while being used in specific tasks, on factors such as mental and muscle stress, work organization, and social and legal aspects.

Abstract –

Scaffolding structures are important as a temporary structural element that are used to support workers, equipment, and materials during construction activities. Although 65% of construction workers work on scaffolding structures and often are exposed to safety hazards, the current method of monitoring scaffold structures still is premature. As an example of practices set by the U.S. Occupational Safety and Health Administration, a knowledgeable and experienced individual conducts a visual and labor-intensive inspection. However, one difficulty in conducting structural analysis of a scaffolding structure involves its boundary conditions and material design parameters, which vary depending upon loading conditions. This research explored a new method to accurately model the boundary conditions and design parameters of a scaffolding structure in real time by using wireless strain sensors. An Internet of Things (IoT) open-source Arduino module was used to develop wireless strain sensors to acquire strain data directly from a scaffolding structure. The strain data were transmitted to a finite element method (FEM) model, which was used to estimate the real-time structural behavior of a scaffold. A model-updating technique was used to improve the synchronizing accuracy between the FEM model (i.e., the cyber model) and the actual scaffold. The test results indicated that the proposed synchronizing method described the real-time structural behavior of the scaffold accurately, especially for modelling the boundary conditions and design parameters. The outcomes of this paper are expected to foster the use of wireless sensing technology for safety monitoring of temporary structures and to offer the potential of improving construction safety by preventing the collapse of temporary structures.

Keywords –

Temporary structures, monitoring, FEM, scaffold, wireless sensor

1 Introduction

In the construction industry, scaffolding structures have been the most widely used temporary structures; according the U.S. Occupation Safety and Health Administration (OSHA) as many as 2.3 million construction workers work on scaffolds [1]. Thus, proper inspection and the safety conditions of scaffolds are crucial to ensure the safety of construction workers. Currently, the entire structural condition of scaffolds is inspected visually by a knowledgeable and experienced individual [2]; this approach is labor intensive, subjective, and prone to error. However, due to the lack of systematic tools, it is difficult to continuously monitor and inspect multiple scaffolds in a dynamic construction site by using the traditional visual inspection technique.

The real-time monitoring of scaffolds is exacerbated even further by the external work environment, which often occurs under high-pressure conditions; difficulty in identifying defects in scaffolds when at full scale; and simple human errors [3]. As a result, the construction industry has suffered a high number of accidents – 50 deaths and 4,500 injuries (estimated every year) – and has incurred costs exceeding $90 million a year due to improperly managed scaffolds [4]. To improve the effectiveness of monitoring the scaffolds, thus ensuring safety of the scaffolds, there have been efforts to monitor temporary structures automatically with sensors, including load cells, switch sensors, an accelerometer, and a displacement sensor [5]. However, this approach focused only on measurements of the structural responses (e.g., strain, displacement, and load) at a local level without taking into consideration a global structural analysis. In this study, a structural FEM modeling technique was developed for scaffolding monitoring by proposing transforming the boundary conditions of and model updating for a scaffold.

2 Background

OSHA requirements and recommendations for designing, erecting, dismantling, and inspecting scaffolds [2] are the basis for conventional scaffolding inspection in the construction industry. OSHA regulations require inspection of each scaffold before each work shift and after any incident that might have affected its structural integrity as well as safety training programs to educate workers. Despite these efforts to identify and prevent potential safety hazards related to scaffolds, the actual application of this knowledge to a complex construction site still remains challenging.

Thus, researchers have sought more advanced methods to monitor temporary structures. Moon et al. [6] developed a sensing network to collect static structural responses – such as strain, displacements, and loading condtions – and compare them to allowable limits in order to determine structural safety conditions. By analyzing video streams to characterize deformations of targeted temporary structures, Jung [7] developed an image-processing method to automatically identify defects in scaffolding and shoring. Yuan et al. [5] introduced a cyber-physical system that synchronizes a virtual model and a real model of a scaffold with a sensor-based system to monitor its physical status.

However, such past research investigated only element-level behaviors of temporary structures and overlooked integral structural analysis; therefore, the potentially varying boundary conditions of a scaffold were not properly investigated. Since locally stable structures still can be globally unstable, resulting in structural problems, understanding global behaviors should be investigated to ensure the safety of scaffolds in a more comprehensive manner. Hence, there was a need to develop a more reliable scaffolding modelling technique that considers the global behaviors of scaffolding structures to ensure their structural stability as well as the safety of the construction workers and the general public.

3 Objective

The main objective of this study was to improve a structural modeling technique to precisely reflect the actual behaviors of scaffolding structures. In contrast to general structures, such as buildings and bridges, the boundary conditions of temporary structures can be unstable because they often stand on the site without having proper fixtures. To address instability issues in the boundary conditions of a scaffold, our research team developed a technique of a boundary transformation to describe structural behaviors more reliably. In addition, we developed a technique to update design parameter models using the finite element method (FEM). The proposed technique for parameter modelling uses wireless strain sensors to measure the strain data from each of the scaffolding components under given loading. By synchronizing real data with the corresponding data from the FEM model, we updated the model to reflect the actual conditions more accurately of a scaffold. Then, we applied various loading cases to the scaffold model in order to validate the proposed techniques with respect to the boundary conditions and design parameters of the scaffold.

4 Modeling Approach for Monitoring Temporary Structures

4.1 Overview

The overall approach of the proposed methodology was to synchronize the strain data that was collected from the columns of an actual scaffold with that of an FEM model, which represented the behavior of a scaffolding structure by transforming the boundary conditions. To improve accuracy of the FEM model even further, a model-updating procedure was conducted to optimize the material and geometry parameters of the scaffold.

Figure 1 shows an overview of the proposed methodology. The research team developed the wireless strain sensors with the combination of an Arduino Yun board, a strain-gage board, and commercial strain gages (350 Ω and gage factor 2.18). An interface shield provided electrical connections to integrate these three components.

The Arduino Yun board, which is an Internet of Things (IoT) open source hardware, converted an analog signal to a digital signal from the strain gages, and had Wi-Fi communication capability. The strain-gage board managed the measured voltage difference by amplification. The designed wireless strain sensor required 5 V for operation, and the wireless interrogation distance was 30 m of line-of-sight communication. Strain sensing ranged from –1,000 με to 1,000 με, with a resolution of 2 με.

To measure the strain responses, wireless strain sensors were installed on the column components of the scaffold. The wireless sensors measured the strain data for each column of the scaffolding and transferred the strain data to the FEM model. In the FEM model, the boundary conditions were transformed based on loading conditions and amplitudes, as described in Section 4.3. The FEM model sought to optimize the material and geometric parameters of the scaffold, as described in Section 4.4, by processing the model updating until the strain responses from the FEM analysis were close to the measured values.

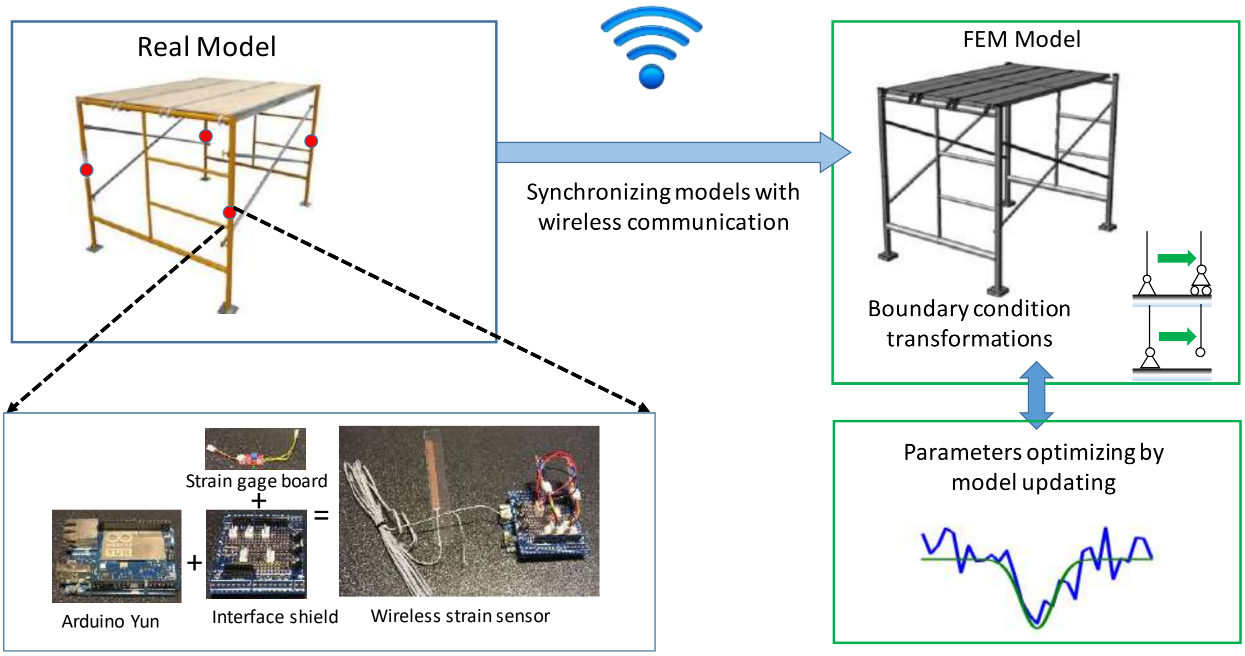

Figure 1 System overview

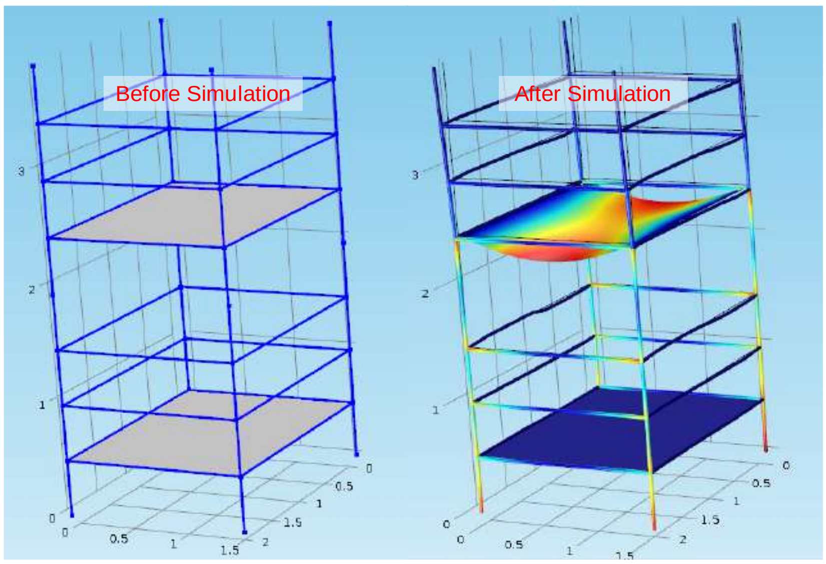
4.2 Scaffolding Models

For laboratory testing, as shown in Figure 2(a), the research team prepared a one-bay scaffold with two stories; this scaffold consisted of four columns and 24 side frames, with a circular pipe section that was 5-mm in diameter. The dimension of the scaffolding structure was 84 in × 62 in × 152 in (2,133 mm ×1,575 mm ×3,861 mm). Six steel scaffold planks having the dimensions of 84 in. × 10 in. ×0.12 in. (2,133 mm ×254 mm ×3 mm) were placed on each floor.

(a) Actual scaffolding model



(b) FEM model

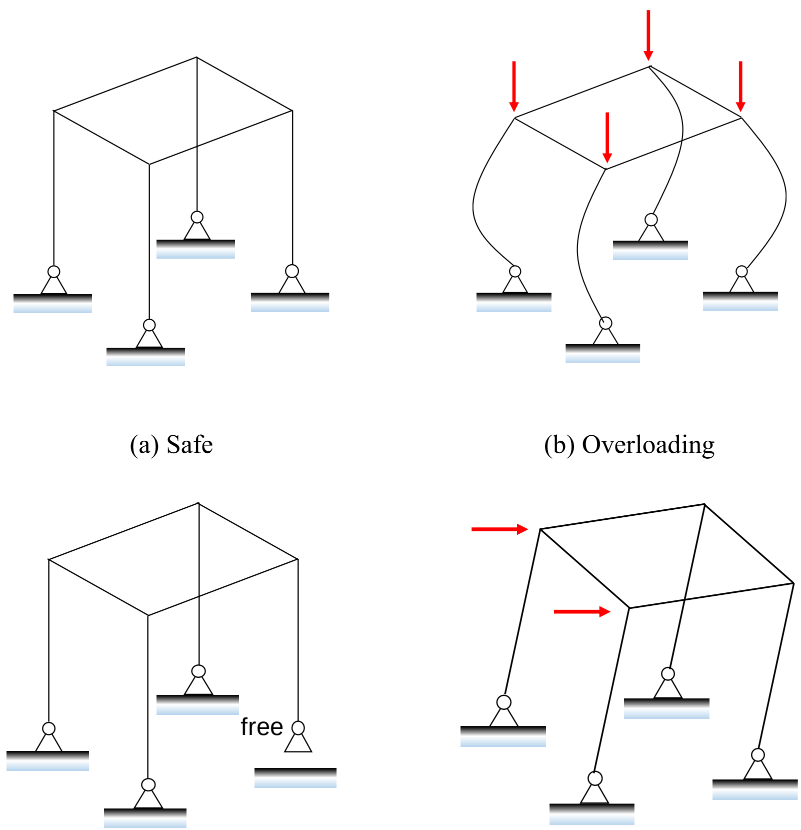
Figure 2 Scaffolding model

The columns of the scaffolding structure stood on wooden foundations; these were not the same type of boundary as conventional boundaries, such as hinges, and fixed boundaries. For convenience, it is a common practice not to attach the columns of a scaffold to the foundation; thus, the boundary conditions of a scaffold might be different from conventional ones. For modelling the scaffold, the research team employed a commercial FEM software package, COMSOL Multiphysics [8]. The frame of the scaffold was modeled by beam-column elements, and shell elements were used to model the scaffold planks.

Figure 2(b) shows the FEM model of the scaffolding structure before and after simulation. The deformed shape shown in Figure 2(b) is an example of a result of structural analysis. In the FEM simulation, each node was formulated with six degrees of freedom due to three-dimensional (3D) analysis.

4.3 Transformation of Boundary Conditions in an FEM Model

As described previously, the columns of the scaffold rested on wooden foundations. From a structural point of view, these boundaries were unstable, and were considered to be a free-boundary condition. While compensating for the boundary conditions of a scaffold, this study proposed a new method for modelling the boundary condition in order to analyze scaffold structures. The structural conditions of a scaffold were classified into four categories: safe, overloading, overturning, and unevenly settled conditions, as shown in Figure 3.



(a) Safe (b) Overloading

(c) Uneven settlement (d) Overturning

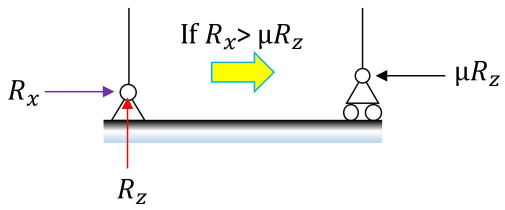
Figure 3 Structural conditions of a scaffold

The boundary conditions were transformed as follows:

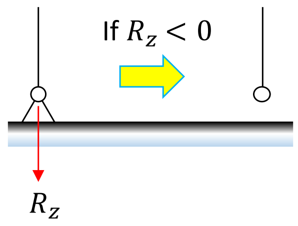
Case I: When lateral forces are greater than the maximum reaction forces of the wooden foundation, the column starts to slip. In other words, when lateral forces (R_x or R_y) are greater than the vertical reaction force (R_z) multiplied by a friction coefficient (μ), a hinge is transformed to a roller boundary with the lateral reaction force of μR_z, as shown in Figure 4(a).

Case II: A reaction force along the *Z* axis is less than zero, which means that the associated columns are unevenly settled or that a full structure is bounded to an overturning condition. Such columns disable to support any reactions. Therefore, the hinge boundary conditions of the columns are transformed to a free condition, as shown in Figure 4(b).

At this point, the FEM simulation performed another analysis on the structure with the transformed boundaries for both Case I and Case II, as shown in Figure 4.



(a) Case I



(b) Case II

Figure 4 Computational modeling for the boundary-conditions transformation

4.4 Model Updating

For structural analysis by means of FEM simulation, nominal parameter values, such as material properties and geometric dimensions were selected. However, these nominal values often are the main factors that lead to a discrepancy between numerical analysis and experimental measurements. To minimize this discrepancy, the research team employed a model-updating technique to extract the precise values of the parameters from experimental data. Upon updating the material parameters and geometric parameters in the model, the FEM model was able to reflect the physical reality of the scaffold more accurately as compared with the initial model, which relied on nominal parameter values. The optimization problem for model updating was formulated as:

$$\begin{aligned} &\underset{\mathbf{x}}{\text{minimize}} \left\| \text{Strain}_{\text{Exp}}(\boldsymbol{P}) - \text{Strain}_{\text{FEM}}(\boldsymbol{P},\mathbf{x}) \right\| \\ &\qquad \text{subject to } \mathbf{x}_{\text{L}} \le \mathbf{x} \le \mathbf{x}_{\text{U}} \end{aligned} \tag{1}$$

where:

$\|\cdot\|$ is the Euclidean norm;

$\boldsymbol{P}$ is a loading vector;

$\mathbf{x}$ is the updating vector parameter, which consists of Young's Modulus *E* and the thickness of a structural pipe *t* ($\mathbf{x} = [E, t]$);

$\text{Strain}_{\text{Exp}}(\boldsymbol{P})$ is a vector function to generate the experimental strain values against loading $\boldsymbol{P}$;

$\text{Strain}_{\text{FEM}}(\boldsymbol{P},\mathbf{x})$ is a vector function to generate simulated strain values with loading $\boldsymbol{P}$;

The updating parameters $\mathbf{x}$, $\mathbf{x}_{\text{L}}$, and $\mathbf{x}_{\text{U}}$ are (element-wise) the lower and upper bounds of the updating vector parameter $\mathbf{x}$.

5 Experimental Validation

To demonstrate the proposed method, three types of structural conditions – overloading, uneven settlement, and overturning conditions – were generated in an extensive experimental validation. Strain gages were installed and connected to the wireless unit for real-time strain measurement from the four columns of the scaffold (C1, C2, C3, and C4), as shown in Figure 5. Then, the strain data were synchronized with the FEM model. For the test of the overloading condition (Case I), the maximum loading capacity of the scaffolding – which as 84 in (213 cm) in width and 62 in (157 cm) in depth – was calculated based on OSHA standards. This specified that the maximum weight exerted on a heavy-duty scaffolding was not to exceed 75 lbs/ft^2, as follows [9]:

$$\begin{aligned} 7\text{ ft } (84\text{ in}) \times 5.16\text{ ft } (62\text{in}) \times 75\frac{\text{lb}}{\text{ft}^2} &= 2{,}709\text{ lb} \\ &= 1{,}229\text{ kg\_force (kgf)} \end{aligned}$$

However, for safety reasons, we limited a loading size up to 400 kgf. We recruited six subjects, and measured their weights prior to the experiment. The subjects stepped on the scaffold one by one until the weight reached near 400 kgf.

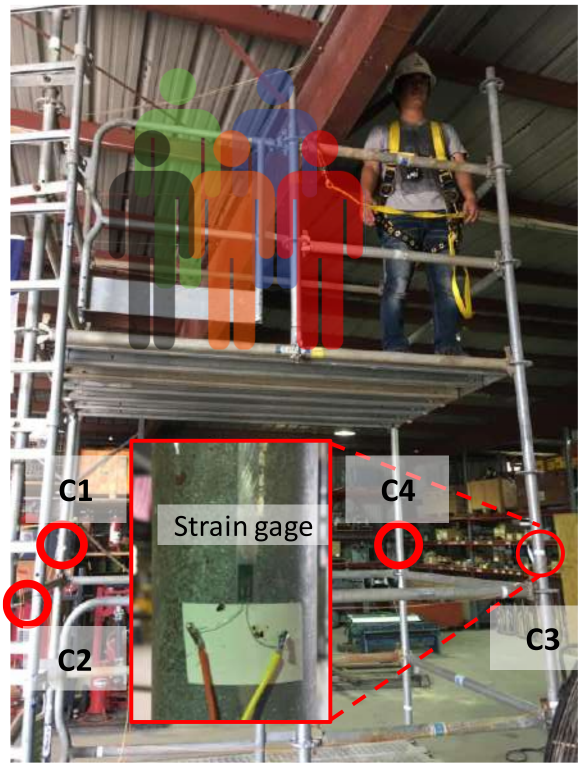


Figure 5 Experimental setup for overloading conditions

In the model updating procedure, initial parameters of vector $\mathbf{x}_0$ were chosen as:

$$\mathbf{x}_0 = [200\times10^9\,\text{Pa}, 3\text{ mm}] \tag{2}$$

The lower and upper bounds were set with a 10% difference from $\mathbf{x}_0$:

$$\mathbf{x}_\text{L} = [200\times10^9\,\text{Pa}, 3\text{ mm}] \times 0.9 \tag{3}$$

$$\mathbf{x}_\text{U} = [200\times10^9\,\text{Pa}, 3\text{ mm}] \times 1.1 \tag{4}$$

During the experiment, the loading step was 100 kgf, which was uniformly distribtied to the second-floor scaffold planks. The loading amplitude increased up to 400 kgf. For benchmark comparisons, the FEM model simulated the structural analysis with the identical loading conditions to obtain analytical strain values. A MATLAB™ optimization toolbox, `MultiStart`, was adopted and integrated with the FEM model to conduct the model-updating procedure. Since this objective function was not convex, we set 1,000 trial starting points for a global search (global optimization). The updating variables ($\mathbf{x} = [E, t]$) for each of the parameters were randomly generated. Starting from each of 1,000 points, the `lsqnonlin` (nonlinear least-squares solver) with the 'trust-region-reflective' algorithm found a local optimum around the point. Among local optimums, the most optimized value was as shown:

$$\mathbf{x}^* = [198.12\times10^9\,\text{Pa},\quad 2.612\text{ mm}] \tag{5}$$

Figure 6 presents the results of model updating. The Y-axis indicates the average strain values from the four columns. This figure reveals an intriguing finding in that the model updated by the proposed method showed more accurate behaviors for the tested scaffold compared to the initial model with nominal parameters. This indicated that the proposed updating technique was superior over the model with the initial parameters.

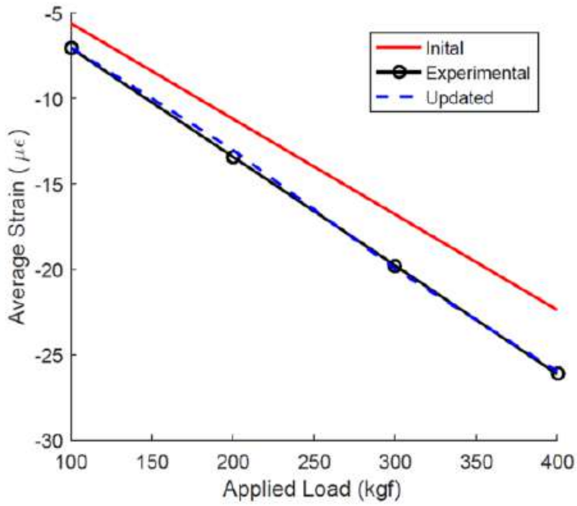

Figure 6 Comparison of strain data of various model updating

To generate unevenly settled (Load Case II) and overturning (Load Case III) conditions, we used a forklift to lift one or two columns, as shown in Figure 7. For safety reasons, the lifting height was limited to 2 in (approximately 5.1 cm). However, this small displacement was enough to emulate unevenly settled and overturning conditions.

Figure 7 Experimental setup for uneven settlement and overturning conditions

Table 1 Test Results shows the results of the experimental validation by comparing the strain data of the FEM simulation and those of the experiments conducted for all three cases to ascertain that the proposed method could perform reliably for various cases. For the overloading condition (Load Case I), the total loads approached near 400 kgf, and strain values were measured from the four columns of the scaffold. The average strain value from both the experiment and simulation indicated –75 με. For uneven settlement (Load Case II), C1 was lifted by the forklift, and its corresponding strain value was close to zero. Strain values from other three columns were from –7με to –8με. For the overturning condition (Load Case III), because C1 and C4 had zero strain, the other two columns needed to support the entire scaffold structure. Strain values from C2 and C3 were approximately –12 με. Thus, both experimental and simulation results were well matched in the three loading conditions.

Table 1 Test Results

Load Case		Strain (με)			
		C1	C2	C3	C4
I	Exp.*	-75.132	-75.142	-75.149	-75.123
	Sim.**	-75.069	-75.027	-75.954	-75.949
II	Exp.	0.013	-7.082	-8.041	-8.071
	Sim.	0.000	-7.004	-8.599	-7.004

	Sim.	0.000	-12.02	-12.02	0.000

* Experiment, ** Simulation

6 Conclusion

A scaffold plays an essential role as a temporary structure during construction. However, the current approach to monitoring scaffolding structures has focused mainly on local behaviors of a scaffold in spite of the importance of their global behaviors to understand their safety status. This study proposed a modeling technique that could compensate the unstable boundary conditions of a scaffold structure by transforming its boundary conditions based on loading cases. In addition, the model-updating technique improved simulation accuracy to more closely reflect on behaviours of a real scaffold.

For the validation, four structural conditions (safe, overloading, uneven settlement, and overturning conditions) were generated and tested with physical experiments and computational analysis. The results indicated that the proposed method, using boundary transformation and model updating techniques, was reliable for determining real-time structural condition of scaffolds. This result implies that the global behaviours of a scaffold could be modelled and analysed more accurately in an FEM model. In addition, real-time monitoring of a scaffold with rigorous analysis is possible when such an FEM model is synchronized with real-time strain data from an actual scaffold on site. Thus, application of such a technique in the construction industry is expected to significantly improve the safety of the workers at a construction site.

Despite the advancement made in this research, it is limited in the following aspects: it needs model information of a scaffold for initial FEM model development and the following updates. Also, the developed system was a prototype system that was applied to a small scaffolding structure with only four strain sensors applied to each of the four columns. For our findings to be converted to more practical results, the proposed approach should be validated with large systems with more variability.

Abstract –

Researchers have taken advantage of technological advancements to automate construction processes; as a result, significant progress has been made in designing and planning temporary structures. Despite this effort, relatively little attention has been placed on automating the monitoring of safety issues of scaffolding structures, which are one of the major elements used in the construction industry. A need has emerged for a reliable means to assess the safety conditions of scaffoldings. This paper proposes a method of integrating strain-gage sensing with a machine-learning algorithm (support vector machine) to assess the real-time safety conditions of scaffolds. Based on actual strain data of scaffolding members, which were collected using wireless sensors for various loading cases on the scaffolding structure, a support vector machine was applied to differentiate the scaffolding conditions into 'safe', 'overturning', 'uneven settlement', or 'overloading' conditions. Such an automated differentiation of the condition of a scaffold could help to determine whether or not the scaffolding is safe to use without deploying safety inspectors throughout the site. The proposed method was experimentally validated to be successful in estimating the safety condition of a scaffold with an average accuracy of 97.66% for the cases that were tested. The proposed methodology could serve as a real-time monitoring system to determine the status of scaffolding structures. Its application is expected to significantly improve reliability in assessing the safety conditions of scaffolding structures, compared to conventional safety inspections, and to resolve the related safety issues.

1 Introduction

Over last several years, interest about information and sensing technologies and their potential in applications has spread across the construction industry, and has resulted in research on automation during various aspects of construction, including design and planning as well as construction operation and management. Researchers [1,2] initiated the Building Information Modelling (BIM) Safety project to uncover potential opportunities using BIM to advance construction safety in planning. In addition, other studies [3,4] have incorporated BIM in scaffolding structures for scheduling and planning purposes [3,4].

While past research has identified new ways to use various resources to plan for safety, in reality, the construction industry still suffers from catastrophic events on a regular basis. To name a few large and deadly accidents, in 2002, the collapse of a scaffold at the Jon Hancock Center in Chicago killed three people and injured a number of people [5]. A recent scaffold collapsed in Houston in 2015, trapping six workers under piles of rubble until they were rescued; in this case, several citations were issued to the associated companies for not properly initiating and maintaining the safety of the scaffolds [6]. Many research articles [7-10] have discussed the problems in using manual inspections, which site managers are required to conduct, including ineffectiveness, unreliability, time consumption, and high cost. Given inadequate practices used currently and the past accidents, it is evident that safety issues of scaffolds during construction activities present challenges to the industry. It also is evident that there is an urgent need for an advanced method for safeguarding scaffolding.

The application of structural analysis in understanding the real time safety condition of a scaffold is an option for safeguarding scaffolding. However, structural analysis requires a full mathematical structural model and actual loading in each of the scaffold members for detailed analysis. However, in real time at construction sites, it is difficult to acquire all this information. Hence, this method may not be suitable for assessing the real-time safety of the scaffold as desired in construction sites. While, with a sufficient number of training data, the implementation of machine learning (ML) can address the limitations found in structural analysis as ML requires only a set of strain data from the strain sensors to predict the real-time stability condition of the scaffold. Thus, a ML approach has been implemented in the proposed methodology. As the structural conditions can be classified to specific categories, we selected SVM as a supervised ML approach.

The objective of this research was to develop an integrated method for assessing the structural safety conditions of a scaffold by using 1) strain sensors to collect real-time strain measurements from scaffolding structures and 2) applying a supervised machine-learning technique (support vector machine) to the strain data in order to analyze the safety conditions automatically of scaffolding structures.

2 Recent Research on Advanced Information and Sensing Technologies

Many researchers explored sensing technologies to assist in construction operation and management. Motion sensors [11,12]; radio-frequency identification (RFID) [13–15]; and ultra-wideband (UWB) [16–19], Bluetooth [20,21], vision [22–24], and laser [25–27] technologies have been studied extensively to discover advanced ways to collect and analyze data. Most of the safety applications from such research, however, are limited to directly using site data from deployed sensors. On-and-off-based violation detection is an example of the direct use of sensory data. Other studies have investigated methods of collecting data on safety issues, but those efforts were limited to handling safety issues directly.

To assist decision making regarding safety, a few researchers [28-30] have integrated sensing technology with machine-learning techniques. This advanced technique allows safety challenges associated with repeated actions to be captured automatically by the system. Researchers have also automated safety monitoring by integrating site information for various construction activities into the construction schedule [31-32]. As far as scaffolding safety is concerned, a minimal level of research has been conducted, with limitations. Moon et al. [33] installed a network of sensors to analyze the condition of a scaffold by using multiple types of sensors, such as an inclinometer as well as ultrasonic and strain gages. Yuan et al. [34] developed a new system, called the Cyber-Physical System (CPS) that links a virtual model of a scaffold with a sensor-based monitoring system. Despite the advancements that these researchers have made, the strain patterns based on structural responses have not been investigated properly, which can offer the potential for rigorous analysis. By applying machine-learning techniques, such patterns could be parameterized and used for analyzing the safety conditions of a structure (e.g., scaffolding).

3 Approach

Figure 1 shows the flowchart of the approach used in this research. It involves six stages, including the construction of a database for structural analysis, process of learning the training data, and the prediction of the conditions of a scaffold. Steps 1-4 pertain to the development of a database system for learning, and Steps 5-6 pertain to the prediction of safety assessments when using real scaffolding structures and strain sensors (CFLA-3-350).

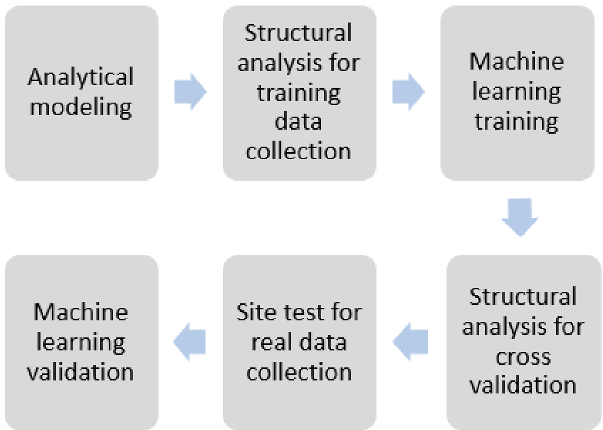

Figure 1 Flowchart of the proposed approach for safety monitoring of a scaffold based on machine learning

To conduct a structural analysis for safety assessment:

Step 1: First, we modelled a scaffolding structure.

Step 2: Then, the constructed structural model was analyzed by using various loading cases.

Step 3: The results of each of the cases were loaded into a database for the learning process.

Step 4: Then, the learning parameters of a machine-learning algorithm, support vector machine (SVM) in this research, were obtained such that the cross-validation produced reliable results, that is, over 95% accuracy.

Step 5: As the real-time strain data were collected, SVM was applied to implement automated analysis by predicting the safety state based on the trained data sets and associated learning parameters

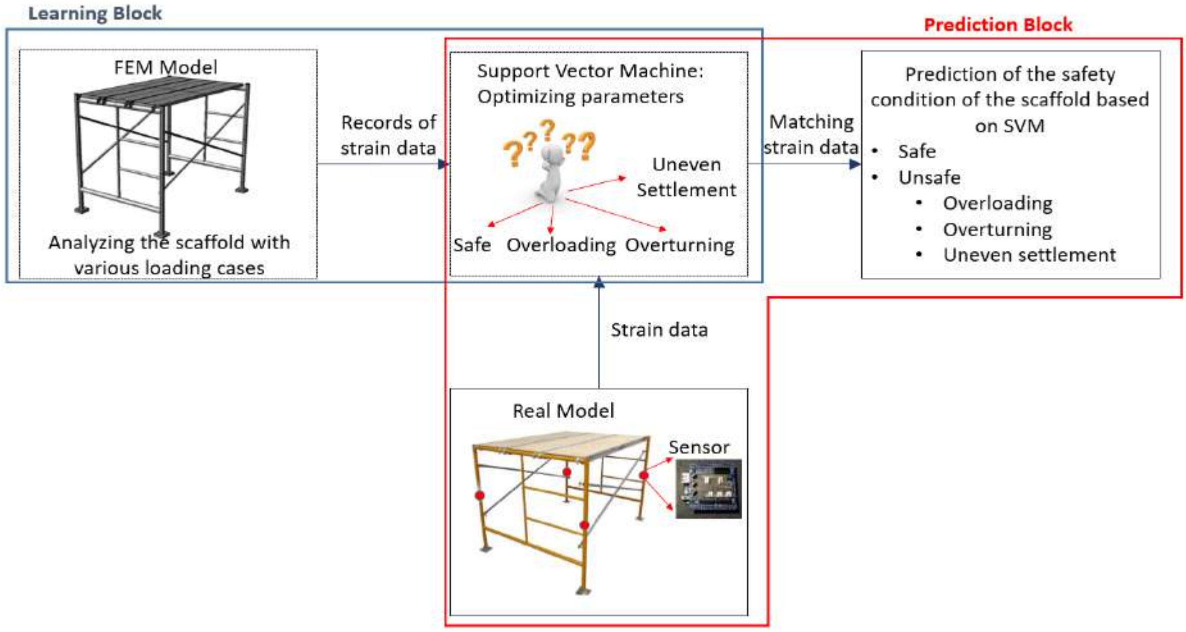

Figure 2 Framework of the approach, with four categories for safety assessment

Figure 2 elaborates the process of the proposed monitoring method and the relationship among the analytical model, analytical data, real model, real data, and encompassing machine-learning algorithm. Figure 2 shows the four categories of safety conditions that were possible as a result of loading conditions on a scaffold; safe, overloading, overturning, and uneven settlement. The SVM-based assessment analyzed the safety conditions of the scaffold with respect to these four categories.

3.1 Learning Part 1: Pre-Processing for the Generation of Training Data

One of the most important steps for machine-learning approaches is the generation of enough numbers for the training data, because the learning algorithms and their optimized parameters heavily rely on the availability of training data on which predictions are based that are used in decision making. Using a finite element model analysis, 300 data sets were generated for each of the four categories (1,200 strain-load data sets). Table 1 shows a sample of the training data sets, with four data sets for each category.

The loading was based on the four safety categories, and the strain data was collected from the four locations shown in Figure 2, based only on the elastic deformation of structure. Due to safety reasons, the tests were controlled to be safe with the following cases:

- Safe: we limited the weight to 400 kgf although the OSHA standard was 1229 kgf for the size of the tested scaffold; a heavy-duty scaffolding should not exceed 75 pounds per square foot applied uniformly over the span area [35].
- Overloading: we considered any weight beyond 400 kgf as overloading
- Overturning: to emulate the effect of overturning, we used a forklift to lift two columns by less than two inches
- Uneven Settle: to emulate the effect of ground settlement, we used a forklift to lift one column by less than two inches

Table 1 Sample of the training data sets

Category	Strain 1 (με)	Strain 2 (με)	Strain 3 (με)	Strain 4 (με)
Safe	-37.69	-48.07	-33.05	-50.81
Safe	-49.26	-54.51	-45.35	-52.28
Safe	-60.46	-54.37	-57.06	-52.07
Safe	-55.40	-42.07	-16.39	-33.73
Overturning	12.29	-5.33	-17.36	0.24
Overturning	1.97	-5.31	-3.01	10.67
Overturning	16.69	6.12	-0.20	14.22
Overturning	1.47	-7.01	2.67	11.78
Overloading	-71.81	-47.46	-47.22	-53.17
Overloading	-59.43	-52.97	-68.76	-54.25
Overloading	-75.59	-62.33	-37.29	-61.37
Overloading	-51.43	-46.94	-62.33	-74.08
Uneven Settle	-17.72	5.91	2.99	-15.95
Uneven Settle	-8.83	0.65	5.57	-9.95
Uneven Settle	-14.98	6.11	0.05	-22.08
Uneven Settle	-24.75	-8.96	8.77	-3.33

The four categories represented different aspects of the structural behavior of a scaffold, and each behavior was indicated by the analyzed strain values corresponding to one of the categories.

3.2 Learning Part 2: Pre-Processing for Training with a Support Vector Machine

This research used one of well-known machine-learning techniques, a support vector machine, to train the data sets that represented the pre-processed load-and-strain values. The load-related strain data (inputs) were processed by SVM to train SVM classifiers (outputs) with the four categories (i.e., safe, overloading, overloading, and uneven settlement). SVM is a binary classification technique that formulates a plane to separate the data into two groups:

$$f^{(i)}(x) = \boldsymbol{\omega}^{\mathrm{T}}\boldsymbol{x}^{(i)} + b = 0, \qquad (1)$$

where $x^{(i)}$ is the feature vector at the i^{th} order, and $\boldsymbol{\omega}$ and b are updating parameters. Then, the classification was made by plugging the function, f(x), into a sigmoid function as shown:

$$h\left(x^{(i)}\right) = g(\boldsymbol{\omega}^{\mathrm{T}}\boldsymbol{x}^{(i)} + b) = \frac{1}{1+e^{-\left(\omega^{\mathrm{T}}x^{(i)}+b\right)}}, \qquad (2)$$

where g is a sigmoid function. Because the outputs of a sigmoid function range from 0 to 1, a classifier function can be applied with two labels (i.e. $\mathrm{y}^{(i)} \in \{1, -1\}$), as shown:

$$\mathrm{y}^{(\mathrm{i})} = \begin{cases} 1 \ \ if\ h\left(x^{(i)}\right) \geq 0.5 \\ -1\ if\ h\left(x^{(i)}\right) < 0.5 \end{cases}, \qquad (3)$$

As the data sets are classified by a plane, each classified set is separated by a margin, and the functional margin is defined as:

$$\mathrm{r}^{(i)} = \mathrm{y}^{(i)}\left(\boldsymbol{\omega}^{\mathrm{T}}\boldsymbol{x}^{(i)} + b\right). \qquad (4)$$

The maximum margin classifier that is the key step for parameter optimization is expressed as:

$$\max_{r,\omega,\mathrm{b}} \frac{r}{\|\omega\|_2} \quad \text{such that } \mathrm{y}^{(i)}\left(\boldsymbol{\omega}^{\mathrm{T}}\boldsymbol{x}^{(i)} + b\right) \geq r,\ for\ all\ data\ sets\ i. \qquad (5)$$

As the value of r can be set to a constant, and because it only scales the values of the updating parameters, Eq. 5 can be simplified further to:

$$\min_{\boldsymbol{\omega},\mathrm{b}} \|\boldsymbol{\omega}\|_2 \quad \text{such that } \mathrm{y}^{(i)}\left(\boldsymbol{\omega}^{\mathrm{T}}\boldsymbol{x}^{(i)} + b\right) \geq 1,\ for\ all\ data\ sets\ i. \qquad (6)$$

For a more sophisticated classification, we used the Gaussian kernel method:

$$K(\boldsymbol{x}^{(i)}, \boldsymbol{x}^{(j)}) = \exp\left(-\frac{\left\|x^{(i)}-x^{(j)}\right\|_2^2}{2\sigma}\right) \qquad (7)$$

The corresponding change in the classification function is:

$$\boldsymbol{\omega}^{\mathrm{T}}\boldsymbol{x}^{(j)} + b = \sum_{all\ i} w_i K\left(x^{(j)}x^{(i)}\right) + \mathrm{b} \qquad (8)$$

Using these equations for a binary classifier, one category can be classified. To further classify more categories (e.g., four categories), the one-versus-all (OVA) method [36] was applied to all the training data sets; accordingly, we extracted the optimized parameters for each of the four categories. Figure 3 illustrates a conceptual example with four classifiers defined by the optimized parameters and four cases classified by the classifiers.

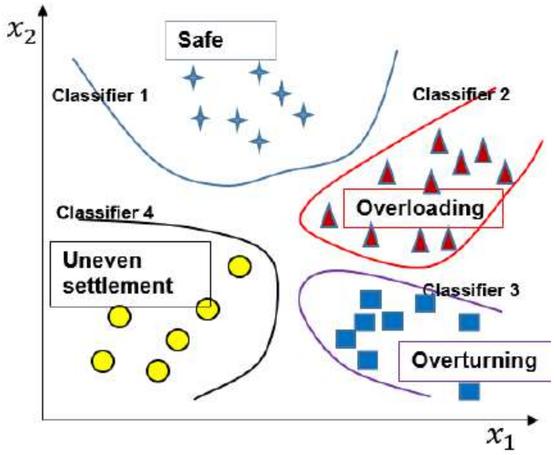

Figure 3 Classification with four classifiers

3.3 Prediction: Real-Time Data Collection and Estimation of the Safety Conditions

As the parameters for the four classifiers became available after the learning step, real-time strain data from an actual scaffold were processed by SVM to predict the safety conditions of a scaffold. To collect such strain data, this research developed customized strain sensors on an Arduino platform and installed them on the four columns of the scaffold being tested. This step was straightforward because the parameters for the classifiers were available from analytical Finite Element Method (FEM) solutions to the load-strain relationship and also because the actual strain data could be collected by strain

Figure 4 Experimental setup with a one-bay scaffold

sensors attached to the scaffold. Actual strain data were validated with respect to the four classifiers for prediction purposes. For statistical assessment of the accuracy of the SVM used in this research, the prediction rate was computed for each of the categories:

$$\text{Accuracy} = \frac{\text{TP} + \text{TN}}{\text{TP} + \text{TN} + \text{FP} + \text{FN}} \times 100 \qquad (9)$$

where:
- TP = true positive
- TN =true negative
- FP = false positive
- FN = false negative

3.4 Experimental Validation

To test the proposed method of real-time assessment of the safety of a scaffolding structure, a one-bay scaffolding structure was set at an indoor site, as shown in Figure 4. The dimension of the scaffold was 213 cm (L) x 158 cm (W) x 386 cm (H); in addition, four strain sensors were attached to the four columns of the scaffold. As soon as strain data were measured and transmitted to a computer equipped with the SVM algorithm, they were analyzed to predict the safety conditions of the scaffold for given loading conditions. We purposely tested 150 cases of each of the unsafe conditions (50 trials x 3 categories), and evaluated the analyzed results compared to the actual safety conditions of the scaffold.

Table 2 shows the results of the three unsafe cases, and Table 3 shows the binary classifications (i.e., TP, TN, FP, and FN) of the predictions and the prediction rates. For the overloading test, the SVM predictions were 100% accurate. However, for the cases regarding the uneven settlement and overturning tests, few cases were encountered where the classifiers were incorrect; yet, the accuracy was 96.5% for both cases. Results for the uneven settlement cases showed that there was one case where the prediction was partially incorrect; this case showed positive results for uneven settlement and overturning, while it should have been positive for uneven settlement only. Due to this redundant classification, the total number of classified cases was 51 (47 + 4), although the number of the corresponding test case was 50. However, the overturning results suffered a different problem in that the classifier was not able to make correct predictions for five trials.

Table 2 Prediction of the Safety Conditions of the Scaffolding Using Real-Time Strain Data and SVM

Actual Conditions	Categories (SVM Outcome)			
	Safe	Overloading	Uneven Settlement	Overturning
Overloading	0	50	0	0
Uneven Settlement	0	0	47	4
Overturning	0	0	2	45

Table 3 Summary of the Binary Classifications and Prediction Rates

Actual condition	Categories (SVM outcome)				Accuracy
	Safe	Overloading	Uneven Settlement	Overturning	
Overloading	TN(50) FN(0)	TP(50) FP(0)	TN(50) FN(0)	TN(50) FN(0)	100.0%
Uneven settlement	TN(50) FN(0)	TN(50) FN(0)	TP(47) FP(3)	TN(46) FN(4)	96.5%
Overturning	TN(50) FN(0)	TN(50) FN(0)	TN(48) FN(2)	TP(45) FP(5)	96.5%

Despite these drawbacks, resulting from the SVM, the accuracy was high at 100%, 96.5%, and 96.5% for the three unsafe test categories in order of overloading, uneven settlement, and overturning. On average, the SVM classifier had 97.66% accuracy.

4 Conclusion

Researchers have used information and sensing technology to advance various aspects of operations related to temporary structures. Such endeavors have resulted in significant progress in safety design and the planning of temporary structures. However, as far as safety monitoring is concerned, the construction industry still relies on human efforts. The limited ability of people doing the safety monitory entails various challenges with respect to sporadic inspections over space and time, inconsistencies, and associated costs.

This research proposed a method to assess the safety conditions of a scaffold in real time by using real-time strain sensors and a machine-learning algorithm. For the machine-learning analysis, the research used a FEM technique to generate training data with respect to four cases (i.e., safe, overloading, overturning, and uneven settlement) and then applied real-time strain measurements from an actual scaffolding structure to the optimized (or learned) machine-learning method in order to predict the safety conditions of the scaffold. Such an automated process to evaluate the safety conditions of a scaffold could help to determine whether or not the scaffolding is safe to use without deploying safety inspectors throughout the site.

The proposed method was validated experimentally to be successful in estimating the safety condition of the scaffold, with an average accuracy of 97.66% for the cases tested. Thus, the proposed methodology demonstrated its ability to serve as a real-time monitoring system for determining the status of scaffolding structures. Its application is expected to significantly improve reliability in the assessment of safety conditions of scaffolding structures, compared to conventional safety inspections, and to resolve the related safety issues.

Although successful, this research identified challenges with using SVM. For example, SVM produced redundant classifications or else did not produce predictions (i.e., when all the classifiers did not generate any positive prediction). For the tested cases, the performance of SVM was acceptable; however, it should be further validated for a larger system, with more various loading cases and a greater number of strain sensors. We suspect that this change may negatively affect the performance of the SVM, as it will introduce more complexity in the optimization of the parameters and thus make prediction more difficult. Additionally, future study should consider more advanced machine-learning algorithms, such as neural network, which are known to manage more complex systems.

Abstract

Building Information Modeling (BIM) as a new method presents a number of opportunities and challenges for the architectural, engineering and construction (AEC) industry. Obviously, there are many issues in the way of implementing BIM. Some of these issues have been largely eliminated over time and by the advancement of related technologies; however, various issues are emerging when dealing with the details of BIM implementation. Contract and legal barriers, cultural problems, management system, and economic and security issues are the most important challenges against implementing this technology. In order to bridge the gap between researchers and practitioners, this paper aims to summarize available information related to the implementation of BIM in the construction industry (about 47 papers) and its related barriers. This research focuses on the most repetitive challenges and barriers that have been more fundamental than the rest and other related issues have been ignored. Distribution of these barriers and challenges is different from region to region. Finally, challenges, which need to be addressed before we can fully benefit from BIM, are highlighted

Keywords –

Building Information Modeling (BIM); Challenges; Implementation barriers

1 Introduction

Building Information Modeling (BIM) as a new method presents a number of opportunities and challenges for the architectural, engineering and construction (AEC) industry. BIM is an evolution of the computer-aided design (CAD) system, which provides more intelligence and interoperable information and is named as project modeling, virtual building, virtual design, construction and finally nD modeling [1]. BIM is also unequivocally a tool of collaboration. Collaboration in the design and construction decreases design mistakes and increases the productivity of the construction industry [2].

Contract and legal barriers, cultural problems, management system, and economic and security issues are the most important challenges toward implementing BIM. Understanding the challenges ahead in implementing BIM is the first step in finding a solution for them [3]. Therefore, this article attempts to present a statistical report of worldwide problems and obstacles that have been linked to the implementation of BIM by studying the articles published in the past decade, and then presents the most important challenges..

Obviously, there are many issues in the way of implementing BIM. Some of these issues have been largely eliminated over time and by the advancement of related technologies whereas various other issues are emerging when dealing with the details of implementing BIM. The focus of this research is on the most repetitive challenges and barriers that have been more fundamental than the rest, and other related issues have been ignored.

2 BIM History

The early concept of BIM dates back to the 1970s and 1980s when the computer-aided design (CAD) was introduced [4]. The creation of the ArchiCAD software in Hungary in 1982 is the real beginning of BIM, and Revit software in 2000 is considered a major turning point in the implementation of BIM [5]. Given that about two decades have passed since the advent of BIM, its implementation in the construction industry has been relatively slow in comparison to other industries, such as manufacturing and engineering industries [6]. However, in the last few years, there has been a lot of advancement in the technology and implementation of BIM, and the construction industry has realized that it can take advantage of using this technology. A brief history of BIM is given in Fig. 1.

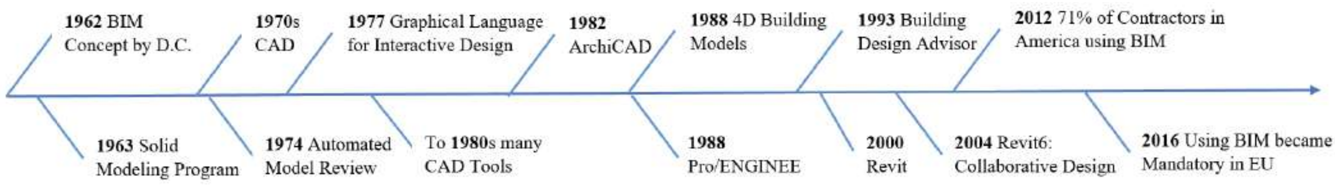

Figure 1.The History line of BIM

Many studies have been conducted to examine BIM implementation issues, which often emphasize the positive impacts of its implementation on the construction industry. Research has shown that major changes have taken place since the launch of BIM, and in recent years, the use of BIM has increased dramatically. In North America, the use of BIM by contractors has increased from about 28% in 2007 to more than 70% in 2012 [7]

Recent surveys also show that BIM implementation is accelerating in leading countries such as the United States and the United Kingdom, as well as in new adapter countries such as Brazil and Australia; more government and private owners want to recognize its benefits [1].

The EU made an important decision in 2014. Accordingly, 28 EU Member States may encourage, specify or mandate the use of BIM in public projects from 2016 onwards [8]. Until now, the United Kingdom, Denmark, Netherlands, Norway and Finland considered it necessary to use BIM in publicly funded projects. The first step in achieving the BIM utopia is to recognize the barriers and challenges of implementing it [1].

3 BIM Implementation Challenges

Despite the great benefits of BIM, there is still no clear strategy for its widespread use in the future. [9]. There exist vast variety of classifications in different studies with regard to barriers against implementing BIM .

After reviewing over 100 studies and selecting 47 final papers that were more related to this subject, five major problems in BIM implementation are divided by location listed in Fig. 2.

The USA with 19 papers and the UK with nine papers are the top countries working on issues related to BIM implementation. The map point of origins of the articles is shown in Fig. 3. Accordingly, 62% of the articles are from journals and 38% are collected from conference proceedings. Fig. 4 shows the distribution of the reviewed articles by year of publication.

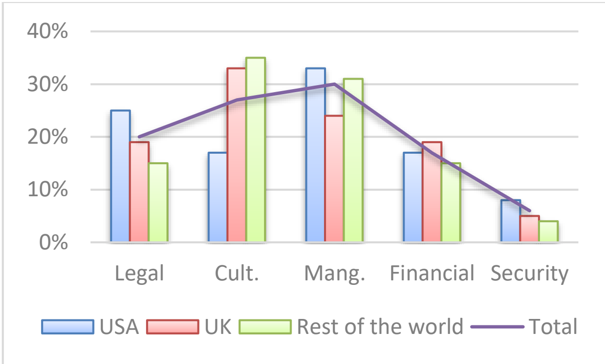

Figure 2. Distribution of BIM implementation Challenges

Figure 3. Map point: origins of reviewed articles

Figure 4. Distribution of reviewed articles by year of publication

Major issues according to the author's opinions and frequency of appearances on articles are management (30%), cultural (27%), legal (20%), financial (17%) and security issues (6%).

However, in the USA, arrange of barriers is slightly different from the world. Accordingly, issues related to management are first, but legal issues are more important than cultural and financial aspects of BIM implementation..

The UK is known as the leader of implementing BIM in the world. The most common problem in the UK is cultural-related issues, followed by the management, legal and financial problems.

If we ignore the papers from the USA and the UK, in the rest of the world, main barriers are related to cultural, management, financial, legal and security issues. Problems related to security appear only in a few articles; however, authors believe that this challenge is one of the major challenges in the future. The second point from this chart is that the order of problems is similar to that in the UK.

A short review of five more important issues is collected. Order of subjects is according to authors' opinions on the importance of subjects and different from the frequency of appearances on the articles.

Table 1. Literature on BIM implementation barriers

Challenges	Articles
Legal	[1],[10],[11],[12],[13],[14],[7],[15],[16],[17],[18],[19],[20],[21]
Cultural	[22],[23],[2],[24],[10],[11],[12],[13],[25],[8],[16],[26],[17],[27],[28],[29],[30]
Management	[31],[1],[32],[12],[33],[15],[34],[35],[36],[17],[37],[38],[39],[40],[41]
Financial	[22],[11],[12],[13],[42],[25],[38],[19], [43],[44],[41],[45],[20],[46]
Security	[22],[9],[7],[44],[18]

3.1 Legal and Contractual Issues

Despite the fact that BIM technical issues have been highly considered in recent years and considerable energy has been spent on these areas, “maturity of the legal body of BIM as well as its contractual configuration is more unsophisticated than its technical aspects. [18]” This weakness has a special effect on contractual terms and there is a challenge that limits the responsibilities of legal issues related to BIM implementation. Therefore, an appropriate substrate for implementing BIM in contract clauses of projects should be created or added.

3.1.1 Legal issues

In addition to technical barriers, resistance to changes in employment patterns and the need for education and training on the path toward implementing BIM in the industry, legal issues are the most neglected challenges against BIM implementation. These legal problems are generally due to:

1. Liability issues: Legal liabilities are due to the multiple number of stakeholders contributing to the model and/or dependent on the precision and quality of the data in the model [1]. Moreover, fraction of sufficient legal structure for managing owners’ comment in design, construction and installation is one of them [11].
2. The need for regulations: Executive regulations in this regard and their coordination at international level to create a common language, reduce conflicts and create a clear path to resolving the dispute are essential.
3. Intellectual property rights: Because BIM models can be easily extracted and copied, intellectual property rights are determinative in BIM implementation [18]. For example, a BIM protocol may need a higher price intellectual property licensing than that procured under traditional contracts [9] For intellectual property rights in contracts, these provisions are important: model ownership, copyrights, authorized and unauthorized uses of models and e-documents, and the level of exposure of the special trade information.

3.1.2 Contractual Issues

Poor contractual agreements in addition to failing to implement BIM may pose a significant risk to the success of the entire project. BIM contractual language must deal with two important risk categories, including:

1. BIM behavioural risks: Which may include collaboration issues, efficiency level of coordination, and collaborative information development..
2. Issues in BIM technological aspects: Arise in forms of information reliability, model accuracy, model management and maintenance, and model ownership.

BIM contractual provisions refer to levels of BIM maturity, which, in higher maturity level contract, should address more issues and more details on BIM implementation. This is because responsibilities, relationships, interactions, and technologies are different at each maturity level [18].

Thus, to avoid arguments concerning BIM responsibilities, limitations and liabilities, a new form of contract/amendment should be implemented. This would cover all the parties directly involved or any other party that may be affected by BIM working method. On the other hand, BIM protocols should be developed by taking into account legal issues, which could be used as an emendation to the main contract to make it adequate for BIM [9].

A recent survey in the AEC industry revealed that approximately 40% of the professional BIM users are unaware of BIM standard forms of contract. This shows that many projects have incorporated custom manuscripts in their contracts [18].

In addition to the amendments, which are intended as a text to improve and correct the main agreement, an addendum is an informational or explanatory note of the requirements of the parties concerned, which has not been specified in the main contract document. Thus, BIM has entered into some of the contracts that have been produced in recent years in format of specific BIM addenda to contracts. Those addenda have the purpose of defining the scope of BIM for facilities designed and constructed for each owner. Owners such as the United States Army Corps of Engineers (USACE), Pennsylvania State University, and the United States Air Force Centre for Engineering and the Environment have developed their own BIM addenda, some of which are used with a whole package of other documents aiming to optimize and ensure the successful implementation of BIM. Those efforts subscribe to the goal of overcoming the challenges that have accompanied BIM use.

In addition to the owners mentioned above, two industry leaders, AIA and AGC, have developed BIM contracting standard forms to address BIM contracting requirements. These include Consensus DOCS 301: BIM Addendum: Building Information Modeling Protocol Exhibit [18].

3.2 Cultural Issues

In general, about 30% of the total number of articles studied in this project referred to cultural problems. Cultural problems are the background of other problems and by solving them, a great step can be taken to solve the problems of implementing BIM.

Cultural problems include many aspects and the most important ones are resistance to change, lack of cooperation between project stakeholders, and the absence of the real BIM-based sample.

3.2.1 Resistance to Change

Actually, only small fractions of companies are aware of BIM and are using this technology to benefit their own projects. While other companies do not have experience in this field and carry out their own projects traditionally as they are unwilling to use BIM technology. These companies believe that BIM is an underdeveloped technology with limited capabilities; they also feel that using BIM is very complicated and thus it is best to do their own projects using non-BIM tools.

The lack of knowledge and education is another factor; engineers and companies are doubtful about learning BIMs concept and they believe that it is costly to train their employees in this regard.

In addition, the lack of knowledge and trained staff as well as inability to persuade other stakeholders to handle BIM implementation costs is among other issues that makes it difficult for individuals to carry out their projects using non-traditional methods.

3.2.2 Lack of Cooperation between Project Elements

In the success of BIM-based projects, there are many people involved; the collaboration and reflection of the project team can help ensure the success of the project, rather than discussing the goals that contribute to the success of the project. Lack of cooperation from any of the stakeholders can cause serious damage to the entire project. In general, BIM implementation in construction projects requires more collaborative and integrated delivery of the project.

3.2.3 Absence of a Real-World BIM-Based Sample

Another approach to persuading stakeholders to use BIM technology is the availability of run-time examples of projects implemented using BIM technology. If project stakeholders and companies visit a real sample of BIM-based project, they are more willing to do their projects using BIM technology.

By organizing several meeting sessions with activists in the AEC and introducing BIM technology and its benefits along with showing a real BIM-based sample, they can be familiar with BIM concept and its advantages. To this end, catalogues that briefly introduce BIM and its benefits are published and presented in the building industry exhibitions; moreover, experts are invited to these exhibitions to provide explanations and answers to questions. It is also possible to add a course to the university curriculum and invite BIM experts to train students in BIM area and related software. Companies and organizations can also arrange classes for their employees to become familiar with BIM technology. Moreover, BIM experts could be asked to prepare educational videos for teaching BIM software. Because BIM-based projects require teamwork, before the start of the project, it is necessary for one of the specialties to be selected as the head of the group and clearly describes the responsibilities and duties of all the team members. It is also necessary to control the work of all the members to guarantee a collaborative work.

3.3 Management

There is much debate on the benefits of implementing BIM. This improvement surely will make the project managers more likely to be happy since BIM helps managers reduce their concerns in the following areas:

1. “Complexity of infrastructure development projects needs strong project management for (a) a multidisciplinary management system (s) to support decision making and (b) to motivate many practitioners involved in the design process” [47].
2. The role of information in the management of the design phase workflow [47].
3. Knowledge management for better risk management: One of the principles of risk management in the project is that all the team members must contribute to the risk database in different phases of the project. It is complicated to manage these databases with traditional methods [41].
4. Based on the main failures identified, and compared to international standards, cost management is one of the main categories, arising as the most recurrent issue [41].

In addition to the above, there are plenty of other things that cannot be considered here. With BIM, project management is better to be performed in these areas, and its quality becomes better through using less energy. However, to reach this point, the project manager should face the following challenge:

1. Need to upgrade the communication platform: Vital communication is more than ever before; it puts new risks on the project.
2. The complexity of team building in this new environment: The performance of virtual teams requires their own techniques, which usually require managers to master their skills. It should be recalled that in the last 40 years, the productivity of human resource in the construction industry has been less than productivity in the non-farm industry. Therefore, the use of experiences and other techniques of the basins (e.g., IT) is remarkable in this regard. The third party as BIM implementation manager can help in this category, since specific professions will have synergy with the project team members [26].
3. Challenges are caused by longer project engineering time, especially in EPC projects, where its nature is the integration of the stages of engineering and construction. Justifying the expectation of completing the model and engineering will be to some extent difficult.
4. Considering the production of the visual model: Stakeholders seem to be more willing to comment. Since prioritization is different from each stakeholder’s point of view, their summing up in stakeholder management processes sometimes will be more challenging.

However, due to the benefits and facilities BIM provides for project managers, it is justifiable to spend energy on overcoming the above problems. However, overcoming the above problems and other challenges mentioned in this article, especially EEFs, In practice, the implementation of BIM in projects has encountered obstacles. What is certain is that after the transition period has passed and BIM has been stabilized in future projects, one of the most beneficial stakeholders in this implementation will be project managers.

3.4 Financial Issues

Financial and investment issues are the determining factors in any project. These issues become more important during emerging BIM technology. As mentioned in the "cultural" section, the lack of a real and complete implementation of the model creates many doubts for investors and stakeholders. There are two main questions in this area, which will be answered in this section: 1- Is it reasonable to have a high initial investment to equip the company with BIM technology? 2- What is the rate of return on investment?

Implementing any new technology requires an initial investment. Most of the investment required to implement BIM is spent on purchasing software, hardware, personnel training, and recruiting specialized staff. The main challenge is to justify and explain these costs to project stakeholders. In 2012, equipping each workstation with BIM technology costed about 10,000 pounds. One point to note is whether this cost is estimated at project cost or considered as part of a larger process. These costs are only seen as purchases of software and personnel training, or as part of a business change process. The answer to these questions can greatly justify the initial investment [25].

The return on investment (ROI) is one of the main concerns of investors. Analysis of the ROI is one of the ways to evaluate the investment; ROI = earning/cost. According to the survey, 48% revealed average or higher ROI. In one study, BIM ROI was measured in 10 different projects, varying from 140% up to 39900%. An average of 1630% for all projects and 640% for projects without a value analysis phase were obtained. Although ROI values are very different and the way to calculate the savings is different for each project, it is shown that implementing BIM has a large impact on reducing costs . The actual BIM ROI can also be much larger than reported [19].

3.5 Security

Reputable organizations in the world predict that in 2019, cybercrime and information theft will cost $ 2 trillion to the world economy. This figure has been rising for years to come and will be up to $ 6 trillion by 2021. The goals of a cyber-war are not limited to military complexes and installations and public and private financial and economic activities are also important goals.

The lack of proper civil law for cybercrime results in the ineffectiveness of international law in this area. Among the examples of these weaknesses, one can disrupt the electricity grid of Ukraine, hack the National Committee of the Democratic Party and the NSA, hack Taiwan and Philippines Government Networks, and attack on Russian banks, which is worth mentioning.

Cyber threats are not just about governments; individuals and companies are also threatened by these attacks. Since BIM is a shared knowledge centre for information about a facility creating an important basis for decisions during its product life cycle" [7]. Therefore, the feature of its being shared in the network context has led to security risks have been taken into account since the beginning of research on BIM implementation [44].

Now it can be even said that one of the main challenges facing the BIM adoption and implementation is the security challenge. Because parties' agreement on model access, software, security, information, archiving, transmitting, etc., is different, the safety of the model has always been and will be sensitive [9]. These security challenges arise from the following:

Intellectual property [9]- Since models can be easily transmitted, extracted, and reused (in whole or in parts) [18].

Cyber security of BIM tool outcomes As information sharing makes project data accessible to team members, cyber security is a concern due to the possibility of online unauthorized access and copyright infringement [9]. Data security is essential to avoid snooping, theft, virus and worms, and hacking [18]. One of the major challenges in BIM implementation at the AEC industry in the UK is security issues [22].

Clearly, solving this issue is beyond BIM control. As stated above, cyber security is a global challenge; however, it should be considered as one of the main challenges facing the implementation of BIM. Since there are fewer projects, all stakeholders do not have the same sensitivity to the information leakage. Therefore, solving the cyber security problem is crucial for the development of BIM implementation.

4 Discussion

In the previous section, we were acquainted with BIM implementation problems. This familiarization helps to better understand the subject and find the right path and think of the necessary arrangements for implementing BIM. The five categories of problems identified in the section 3 are fundamental issues, today. However, familiarity with problems that have been solved over time or problems that will arise in the future will be needed to implement BIM.

4.1 Challenges Resolved over Time

It seems that problems related to the software issues were largely resolved. In the early papers (early 2010), widespread mention was made of technical problems, especially software problems; Problems such as the lack of single software, lack of coordination between the software used in different sectors, and lack of a single standard for software output. However, today, with the advances in software, the standard definition of the unit and the acceptable coordination between different softwares have been largely resolved.

4.2 Future Challenges

Problems that will emerge in the future on BIM implementation path will be mainly contractual and security issues. Both the issues have been discussed in detail in Section 3. However, in short, the successful implementation of BIM requires new contractual types. IPD contracts may be a way out of this turbulent path.

Making secure information in BIM also requires defining a new protocol security. Defining and limiting access to various levels of software and clouds is an interdisciplinary field that requires more research.

5 Conclusion

This article introduces BIM implementation issues. Five fundamental issues including managerial, cultural, financial, legal, and security issues were fully introduced in this paper. By knowing more about the issues of the day, better solutions could be found. In general, from the discussed issues, it can be concluded that many problems would be resolved over time by providing more real world examples. In addition, project stakeholders will invest on BIM with low risk. In addition, the support and guidance of governments as well as the mandatory use of BIM in specific projects will increase the speed of BIM implementation. Although software problems have been largely resolved, there is still a need for more secure software. The reason is that the construction industry compared to other industries is less advanced in the automation sector. However, the need to use modern tools like BIM is increasingly understood. The path to outdo other competitors in this competitive market is BIM implementation.

Abstract –

Temporary construction structures (TCSs), such as formwork and scaffolding, attract a lot of attention due to their impact on the schedule and cost of construction projects. In many cases, the determination of the consumption (i.e., labor, materials, and equipment) of TCSs is a complex process subject to errors. This paper presents a general framework to automatically generate the consumption of TCSs based on the geometry and quantification of building elements in the BIM model, coupled with applicable building codes and industry standards. The framework has been implemented to automatically generate the consumption required for the formwork in a BIM test model. The findings show that the framework provides an efficient way to determine the consumption requirements for formwork. Compared to the current consumption estimating tools for TCSs typically used, this BIM-based tool improves efficiency, allowing the project participants to account for TCSs during the preparation of the project schedules and cost estimates during the early phases of a project. With small modifications, the proposed framework could be applied to other TCSs.

Keywords –

BIM; Temporary construction structures; Formwork; Consumption; Quantity take-off

1 Introduction

As an indispensable part of construction resources, temporary construction structures (TCSs), such as formwork and scaffolding, play a significant role in the proper planning and smooth progress of construction projects. They are large in quantity and numerous in category, and due to their complex construction process, can take a long time to be built as well as take considerable amounts of labor and equipment [1]. According to Ko et al. [2], formwork alone, generally accounts for approximately 15% of the total construction cost. Therefore, the consumption of TCSs (i.e., the quantity and cost of the TCSs, as well as their accessories, and associated labor and equipment required) is a critical factor in project profitability [2][3]. In the construction industry, there are applicable building codes and industry standards (i.e., consumption standards), such as *RSMeans Building Construction Cost Data* [4] and *Standard for the Consumption of Construction Engineering in Hunan Province of China* [5], that are used to estimate the consumption of TCSs. For example, the consumption standard [5] specifies the consumption of formwork based on the area and type of formwork used, as well as the type and height of the corresponding building elements. Similarly, the consumption of scaffolding depends on the structure type (e.g., frame structure and shear wall structure), as well as on the building height and area. The information required includes the characteristics and dimensions of the building, the characteristics and quantity of the TCSs, and the type and height of each building element. The collection of this information is a tedious and error-prone process, which becomes difficult in large and complex projects.

Traditional 2D estimating tools were developed to assist estimators in the preparation of quantity take-offs by having a visual representation of the materials to be quantify [6]. This quantification could then be used to determine their consumption. Nevertheless, the main challenge remains when quantifying TCSs as they are not shown in the drawings (or models) from the designers. In recent years, with the advancements in 3D technology, the tools have shifted toward 3D-based estimate as they result in reduced errors and time when compared to 2D-based estimate [7]. But they still have a few disadvantages [8][10]. For example, some tools cannot be used with the building information modeling (BIM) model so its industry foundation classes (IFC) file has to be exported to the new platform to recreate the 3D model for further use. This causes unnecessary duplication of work and the loss of model information because many of the features of the original model are lost due to software compatibility issues (i.e., interoperability problems), and creates problems when changes are made at different project phases. In addition, some tools require to manually selecting the items of the consumption standards to connect quantity take-offs, which can easily lead to errors due to the estimators' interpretation of the consumption standards. Currently, BIM technology based on parametric modeling and three-dimensional digital representation has been widely applied to extract information needed to support project management [8]. Users can expediently obtain the information generated through the creation of building elements automatically. For instance, Kim et al. [11] used information such as location, geometry and quantity of building elements stored in the BIM model to automate the generation of construction schedules. Wang et al. [12] proposed the use of building elements to integrate schedule and cost to establish a cost-based progress curve used to control construction project schedules by extracting the quantities of cost items associated with each activity. In order to make BIM models effective, more and more projects strengthen the collaboration amongst participants, and the BIM models provided by the designers are used by the general contractors to support project management [8][9]. However, except for a few proprietary BIM tools, general BIM authoring tools do not have the ability to work with TCSs, including formwork and scaffolding, in the model [1] [6] [13][14][14]. Although it is possible to create TCSs utilizing the functions used when creating building elements, this process is time consuming and inefficient. The study by Monteiro and Martins [14] has shown that the modeling time would double when considering the creation of formwork.

Some researchers have made beneficial efforts to improve the automation level in generating information for TCSs based on BIM. For example, Kim and Teizer [1] developed a rule-based system that automatically plans scaffolding systems in BIM, which can recognize geometric and non-geometric conditions in building models and estimate the required materials for scaffolding. Monteiro and Martins [14] explored the possibility to develop a tool for ArchiCAD that would automatically provide a formwork model based on the building elements. Users could determine the building elements through a selection of Types, IDs and Layers, and then define the formwork parameters, such as thickness and material type. The formwork quantity would be obtained from the formwork model created automatically. Le [15] presented an algorithm to quickly calculate the quantity of formwork using the application programming interface (API) provided by Autodesk Revit. The algorithm accounted for the areas of intersecting faces. Wei et al. [16] proposed a BIM-based method for the calculation and management of temporary materials. They calculated the formwork quantity taking into account the thickness of formwork when different building elements intersect. Kim et al. [17] developed a semi-automated system to select the correct scaffolding. It included a feature lexicon to formalize the representation of factors essential to scaffolding planning. Singh et al. [18] used BIM data as input to compute the quantity of formwork and generate the visualizations and the schedule of quantities for formwork. Formwork elements were developed as parametrically constrained objects, and by using dimensional parameters, their size, number of sub-elements, and alignment can be adjusted. In previous studies, there are two main types of methods to automatically generate TCSs information. One is to create TCSs elements through a developed BIM-based tool, and the other one is to generate TCSs information directly based on building elements in the BIM model. For the estimate of the consumption of TCSs, the characteristics and quantity of TCSs needs to be determined [5]. Therefore, the latter method is better suited to obtain the information from the TCSs required by the consumption standards while minimizing unnecessary manual operations to generate it.

To address the shortcomings of current estimating tools, this paper presents a general framework that integrates BIM and consumption standards to automatically generate the consumption of TCSs. The framework uses the generation of the consumption required for formwork based on the geometry and quantification of building elements in the BIM model as an example. Compared to previous related studies, this study accounts for the location relationship of different categories of building elements, making the generation results of the formwork more accurate, and the generation process more efficient. A Revit-based tool to generate the consumption required for the formwork is developed and tested by a BIM structural model. By using Revit API [19] and MySQL [20], the whole generation process reaches a high level of automation.

2 General Framework

This section presents a general framework for integrating BIM and consumption standards to automatically generate the consumption of TCSs, which consists of four parts (Figure 1), and uses formwork as an example for its implementation.

The first part is to obtain a BIM design model. The

Table 1. Formwork consumption according to [5]

			Item		
			A 13-20	A 13-21	A 13-22
			Rectangular Column	Special-Shaped Column	Column Height Exceeds 3.6 m
			Bamboo Plywood Formwork		Excess Part is Within 3 m
			Steel Shoring		
Category		Unit	Usage Amount (Per 100 m² Formwork Area)		
Labor	General Labor	Man-day	34.8	51.64	9.42
Material	Sporadic Fixture	kg	-	27.94	-
	Steel Pipe and Coupler	kg	45.94	59.53	10.11
	…	…	…	…	…
Equipment	Truck Crane (5 Tons of Loading Capacity)	Machine-team	0.18	0.18	0.012
	Truck (6 Tons of Loading Capacity)	Machine-team	0.28	0.28	0.03
	…	…	…	…	…

model should include basic building elements such as columns, walls, beams, slabs and stairs, without creating temporary construction structures directly. In addition, the naming of the same type of building elements should be distinguished from other types, so that the consumption of different types of building elements can be calculated according to the corresponding rules of the consumption standards. For example, the consumption standard [5] classifies structural columns into rectangular columns and special-shaped columns in the section of formwork consumption, so different naming is needed to distinguish between these two types.

The second part is to extract and integrate building information required by the consumption standards. As previously indicated, the information required by the consumption calculation of different TCSs is not the same, and specific information needs to be extracted according to the corresponding requirements. For instance, the consumption of formwork is determined by the area and type of formwork used, as well as the type and height of the corresponding building elements [5]. Therefore, this information should be extracted and integrated. It is worth noting that information that is not automatically generated in the BIM model requires additional provisions. In this instance, the area and type of formwork is not readily available, so they need to be determined in this part so that they can be stored in the database for further use, as explained in the next section.

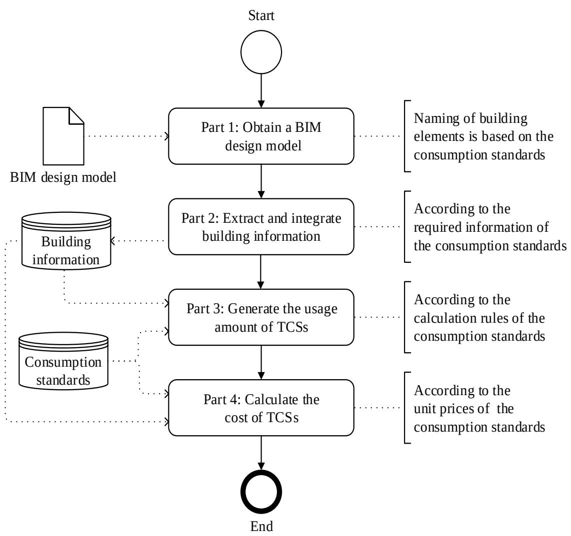

Figure 1. General framework

The third part is to generate the usage amount of TCSs according to the calculation rules provided by the consumption standards, including their quantity, as well as their accessories, how much labor is needed, and which and how much equipment is required. The associated consumptions are coded for a given work and they are accounted in the consumption standards into different items. The applicable items are used based on the information provided in part 2. For example, according to [5], for a rectangular column using bamboo plywood formwork with steel shoring, the usage amount of formwork is defined in item “A13-20” (Table 1). Similarly, for a special-shaped column using bamboo plywood formwork with steel shoring, the usage amount of formwork is defined in item “A13-21” (Table 1).

The fourth part is to calculate the cost of TCSs based on their unit price. With the generated usage amount of TCSs from part 3 and the unit price provided by the consumption standards, the cost of TCSs, including labor, materials, and equipment, can be calculated.

3 Adaptation of the General Framework: Using Formwork as an Example

This section shows the process to automatically generate the consumption of formwork using the general framework presented in Section 2. The process is shown in Figure 2.

In part 1, building elements of every type for which its material is cast-in-place concrete is classified (i.e., giving a specific name) during the modeling to identify the applicable items in part 3. The classification of the types of building elements such as columns, walls, beams, slabs and stairs should be done in accordance with the requirements of the consumption standards.

Part 2 determines the formwork area of the building elements, the projected area of the stair elements, and the formwork type required by the consumption standard [5]. First, the formwork area of the building elements with a material classified as cast-in-place concrete is calculated without considering intersection among building elements. The calculation rules are different based on the real construction situation. For example, the formwork area of columns and walls only calculates the side areas of the building elements, while that of beams, floors and stairs includes the bottom and side areas. The direction of the element surface can be judged by obtaining the vector of the max point of the bounding box of each surface in the elemental solid. If the vector is (0, 0, 1) and (0, 0, -1), it is shown that the surface is the top and bottom of the element. Then obtain the bounding boxes of the solids from the building elements and the midpoint of their surfaces, and convert bounding boxes into new outlines. Two building elements intersect when the midpoint of the surface of a building element is contained within the outline of another building element (to within a predefined tolerance). The tolerance depends on the thickness of the formwork used. The area of the intersecting surface is deducted from the formwork area of the building element.

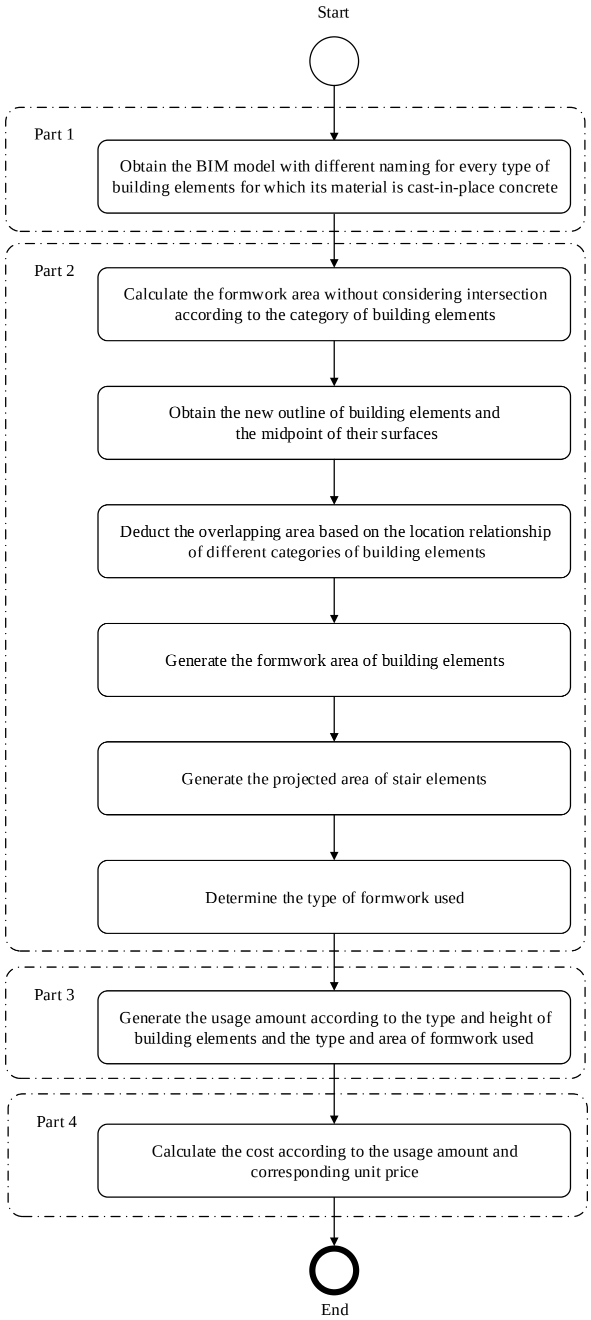

Figure 2. Process to automatically generate the consumption required for formwork

According to the location relationship of different categories of building elements, it is not necessary to judge whether a building element intersects all the other building elements of the BIM model, and it can be summed up as three types of rules. Firstly, intersection is only carried out in building elements including columns, walls, beams and slabs of the same floor. Stairs are the exception because they connect adjacent floors. Secondly, a certain category of building element would selectively judge the intersection with other types of building elements. For example, when a column intersects a beam, the intersection rule is required. On the other hand, when a column intersects a slab, no intersection rule is required because the top and bottom of the column have been previously deducted. Thirdly, a certain category of building elements has a specific intersection judgement process when it intersects with different categories of building elements. For instance, when judging whether a column intersects with a wall, the midpoint of the column surface and the outline of the wall would be retrieved; however, when judging whether a column intersects with a beam, the outline of the column and the midpoint of the beam surface would be retrieved. Through the selective intersection rule based on the consideration of the location relationship of different categories of building elements, the calculation results of formwork area would be more accurate and the calculation would be more efficient. Once the building elements are calculated in accordance with the above rules, the formwork area of those building elements is generated. The consumption of stairs depends on their projected area, and the projected area is generated based on the area of surfaces with vectors that are (0, 0, 1) from stair element. After that, the type of formwork, including material and its shoring (according to the actual situation), is determined.

The last two parts are to generate the consumption of formwork, which represents the usage amount and cost of labor, materials, and equipment that need to be consumed to complete the work content of the formwork including production, installation, maintenance, demolition, stacking and transportation. The consumption value depends on the type and height of the building elements, and the area and type, including material and shoring, of the formwork [5]. For example, a rectangular column using 100 m^2 of bamboo plywood formwork with steel shoring requires 34.8 man-days, 45.94 kg of steel pipes and couplers, and 0.28 machine-team of a truck with a loading capacity of 6 tons (Table 1). When the height of the column exceeds 3.6 m and the excess part is within 3 m, then the excess part requires 9.42 man-days, 10.11 kg of steel pipes and couplers, and 0.03 machine-team of a truck with a loading capacity of 6 tons (Table 1). The type and height of the building element can be obtained from the BIM model, and the area and type of the formwork has been determined in part 2.

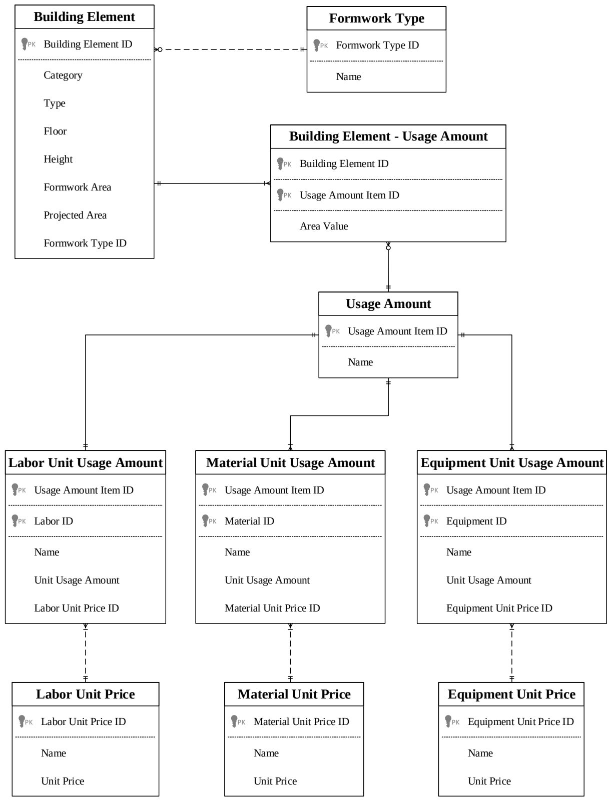

Figure 3. Entity relationship diagram of database structure

To store and manage data efficiently, a database structure containing 10 tables was designed to be used by the BIM-based tool (Figure 3). Using the reference IDs, the tool could parse attribute information from tables by following the paths from the reference IDs to the attributes. Thus, the consumption of formwork can be generated.

4 Case Study

Based on the presented framework, a Revit-based tool was developed to automatically generate the consumption required for the formwork, and was tested using the BIM model of a four-story cast-in-place concrete frame structure. The structure is 17.1 m high and has a building area of 5,028 m^2, which includes concrete columns, concrete walls, concrete beams, concrete slabs and concrete stairs (Figure 4).

All building elements have been named separately according to the classification of the consumption standard [5]. For example, rectangular columns are named “RC”, when the developed tool searches for the building elements with this name, only the consumption of rectangular columns is used.

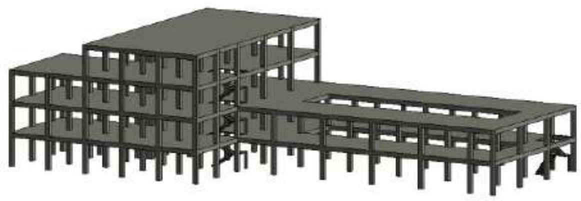

Figure 4. A BIM structural model

The formwork area of each building elements has been calculated using the adapted framework shown in Section 3, the output is shown in Figure 5. The total area calculated for the formwork is 8,436.46 m^2. The type of formwork is selected as the bamboo plywood formwork with steel shoring in the user interface (Figure 5).

After generating the formwork area of the building elements and the projected area of the stair elements, and determining the formwork type, the tool generates the usage amount and cost of labor, materials, and equipment. An example of the output is shown in Figure 6, Figure 7, and Figure 8. Figure 6 and Figure 7 show for each floor the labor usage amount, and cost and their percentage respectively. From the first floor to the fourth floor, it takes 1,509, 1,481, 800 and 623 man-days respectively. The cost per floor is 105,600, 103,659, 55,998 and 43,631 Chinese Yuan (1 CNY = 0.15 USD), also shown as a percentage of the selected cost for each floor; in this case 34.19%, 33.56%, 18.13%, and 14.13%. It can be clearly seen that the first and second floors have the highest labor consumption, while the fourth floor has the lowest. Different categories of total cost and their percentage are shown in Figure 8. The labor cost amounts to 308,888 CNY, which accounts for 64.41%, almost two-thirds of the total cost; while the cost of materials and equipment amounts to 142,470 and 28,222 CNY, or 29.71% and 5.88% of the total cost respectively.

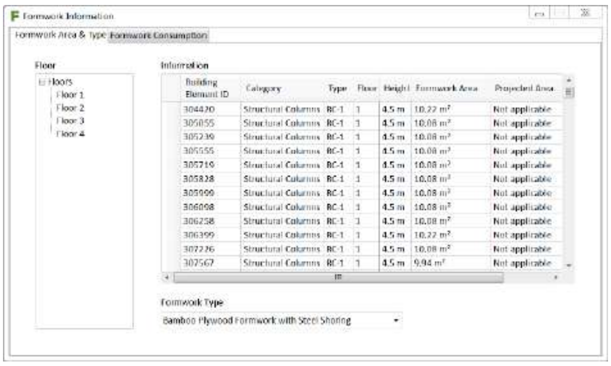

Figure 5. Generation of formwork area and determination of formwork type

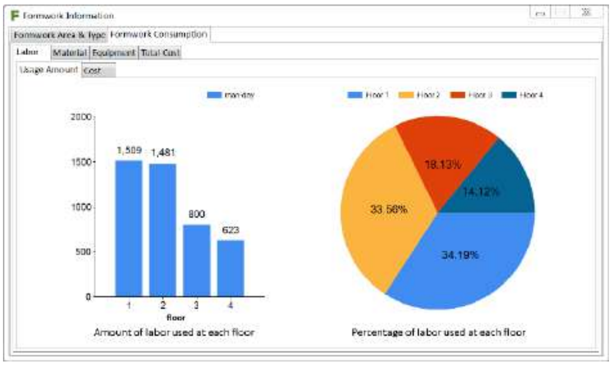

Figure 6. Amount (man-days) and percentage of labor used at each floor

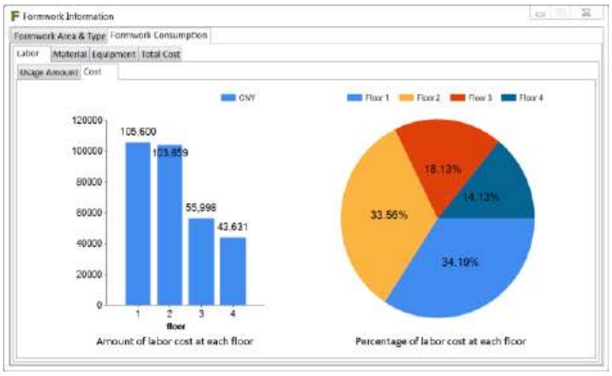

Figure 7. Labor cost (CNY) and percentage at each floor

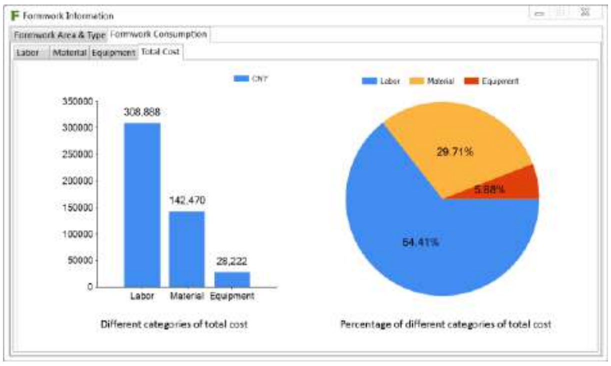

Figure 8. Different categories of total cost (CNY) and their percentage

5 Discussion

The current 3D estimating tools for TCSs typically used in construction projects have a few disadvantages (e.g., some tools cannot be used with the BIM model and/or require to manually selecting the items of the consumption standards to connect quantity take-offs). The framework proposed in this paper only needs the

Table 2. Scaffolding consumption according to [5]

			Frame and shear wall structures	
			24 m < BH* ≤ 30 m	30 m < BH ≤ 50 m
			A 12-12	A 12-13
Category		Unit	Usage Amount (Per 100 m^2 Building Area)

BIM model provided by the designer to automatically generate the consumption of TCSs, which improves efficiency. Although this study adopted proprietary API for Revit, this limitation can be removed by using the IFC compliant BIM model. When comparing the total area of formwork calculated by the presented algorithm to the one calculated by hand, it was found that the difference was negligible (about 0.02% difference). The algorithm considers the general sense of the location relationship of different categories of building elements, though it is not absolute accuracy to every project, it provides a sufficiently accurate way to estimate the formwork area at the early stage of the project. The calculation time using the proposed framework is less than one minute, far less than the time of the hand calculation. In addition, when changes are made to the building elements (i.e., new building elements are added, existing building elements are reduced or the dimensions of the building elements are modified), the TCSs could be recalculated effortlessly using the proposed algorithm.

The presented general framework has lots of potential with respect to other types of temporary construction structures such as scaffolding, which has some differences from the formwork. Fox example, in part 1, the BIM design model should include the area elements in addition to the basic building elements (e.g., columns, walls, beams, slabs and stairs). The consumption of general scaffolding is determined by the structure type (e.g., frame structure and shear wall structure), height and building area [5], therefore, part 2 should extract and integrate the values of the level elements and the area elements, and determine the structure type of the building.

In addition, there is also different in the classification criteria for items. For a building with a frame structure and a total height of 30 m, the usage amount of general scaffolding is defined in item "A12-12" (Table 2). Similarly, for a building with a shear wall structure and a total height of 50 m, the usage amount of general scaffolding is defined in item "A12-13" (Table 2).

6 Conclusions

TCSs is not only critical for the successful completion of construction projects, but is also one of the most significant cost factors in the construction projects. This paper presents a general framework to automatically generate the consumption of TCSs integrating BIM and consumption standards and shows an application to determine the consumption of formwork in a sample project. Information about the amount of resources needed, as well as the cost breakdown, was generated in an efficient manner. The output of the presented framework includes the usage amount and cost of labor, materials, and equipment that need to be consumed to complete the work content of the TCSs. The information provided allows project participants to focus on planning and logistics of the procurement of TCSs as well as having reliable information about their consumption to be accounted during the preparation of the construction schedule and cost estimates during the early phases of a project, rather than spending valuable time in their quantification. Future research will combine schedule information with the consumption, making it a more beneficial tool to the project management team, and more sophisticated algorithms should be developed to provide more accurate results in a more efficient way.

Abstract – Railway infrastructure projects provide required physical and organizational facilities for transportation networks. Production flows in railway construction are complex especially when a hybrid of on-site and off-site processes is in progress. With railway projects still experiencing budget and time overruns, there is need to re-examine production flows. Towards this aim, a framework to investigate production flows in railway infrastructure projects is presented and discussed. A three-dimensional view of construction production including portfolio, process and operation aspects is found capable of improving performance measures in both design and construction. Such improvements include minimized rework and re-entrant flows, flexible prefabrication, enhanced multidisciplinary collaborations, and efficient planning of temporary works. This research contributes to the construction body of knowledge by examining production flows in a complex infrastructure setting. Construction managers would benefit from the presented model of production flows and its customization in the context of their projects to improve productivity and performance.

1 Introduction

Dynamics of workflow have been explored in the construction management literature [1-4]. However, there is need to investigate production flows in complex environments of infrastructure projects [5, 6]. Management of production flow in construction of railway, utility and energy projects is more challenging than residential and commercial construction [7, 8]. Among others, challenges are caused by involvement of many collaborating teams [9], lack of established frameworks for managing project production flows [10], and large numbers of stakeholders [11]. Recently, mainstream research in construction has been focused on Building Information Modeling (BIM) as a facilitator to support production flows in construction [12, 13]. Although useful, there are sparse studies aimed at improving the construction understanding of project production flows [14].

Off-site production, which is a hybrid of construction and manufacturing, has the potential to improve production flows in infrastructure projects [15], and increase flexibility in processes and operations [16]. The challenge, however, is the complexity of production flows within infrastructure project settings [17]. Not much research has been conducted to investigate project production flow dynamics in complex infrastructure construction where prefabrication is a major player [18].

The current study aims to bridge this gap by analyzing railway infrastructure projects within the framework of the production flow model developed by Sacks [19]. Towards this aim and in a similar approach to Liu, et al. [20], a case study approach was adopted as it is capable of responding to "how" and "why" types of research questions and allows retaining a holistic approach towards the research problem at hand [21]. Selected railway projects in Australia were deemed suitable to analyze production flows within infrastructure project settings. A purposeful selection of case studies targeted maximum level of complexity in project production flows. Main factors contributing to project complexity included the hybrid production mode (on-site and off-site), the concurrency of construction and train operations, numerous engineering scenarios and production alternatives, collaboration of many multidisciplinary teams, and complicated design and construction processes across several project modules.

To streamline complex production flows, railway infrastructure projects are often broken down to smaller manageable zones (modules). Geographic proximity and similarity of construction methods mainly drive the exercise of project modularization. The purpose-built production flow model in projects should realizes three dimensions of project portfolio (module), process and operations. The production flow model in infrastructure projects aims to maximize flow continuity for design and construction of on-site assembly and off-site prefabrication. This paper analyzes and discusses four major improvements resulting from the three-dimensional flow model in the following order. After describing the base model, most important improvements in terms of minimization of rework and reentrant flows are discussed. This is followed by series of performance enhancements including flexible prefabrication, improved multidisciplinary collaborations, and efficient planning of temporary works. Finally, conclusions are presented followed by discussion of limitations and opportunities for future research.

2 Design and construction complexity-implications for production flows

In the context of infrastructure construction, project teams need to frequently evaluate and compare different engineering solutions to optimize performance measures [22-24]. In the case projects, an elevated rail solution was selected over a rail-under alternative. Elevated railways minimize construction impacts on local utilities and major gas, water and electricity transmissions across the rail corridor [25, 26]. Furthermore, risks of flooding and manipulation of water tables are minimized by using this engineering solution [27, 28]. Finally, elevated rail projects require lower amount of land acquisition as opposed to traditional open cut trench solutions [29, 30].

Design in infrastructure projects is more complex than other project types in which respective processes are often entirely completed before commencement of construction [31, 32]. In order to address complexity in railway infrastructure projects, design processes are split into different packages. The interdisciplinary design teams comprise architects, engineers, scientists and consultants. Detailed design drawings that are produced by design teams are reviewed by major stakeholders including local councils, road authority, electricity and gas distributors, public transport network, and government agencies. Considering the projects is a challenging task.

Production flows in large infrastructure projects are complex to manage with high levels of variability in both design and construction. For an effective management of production flows in railway infrastructure projects, a three-dimensional view of production, proposed by Sacks [19], is adopted. In this flow model, processes and operations of multiple project zones are managed in a three-dimensional (3D) space. The model has been customized to reflect the dynamism involved in design and construction of prefabricated elements in railway infrastructure projects. As can be seen in Figure 1, inclusion of the project portfolio (module) axis reflects the simultaneous occurrence of design and construction across several project modules. The model's objective is to achieve maximum production flow continuity at the project level.

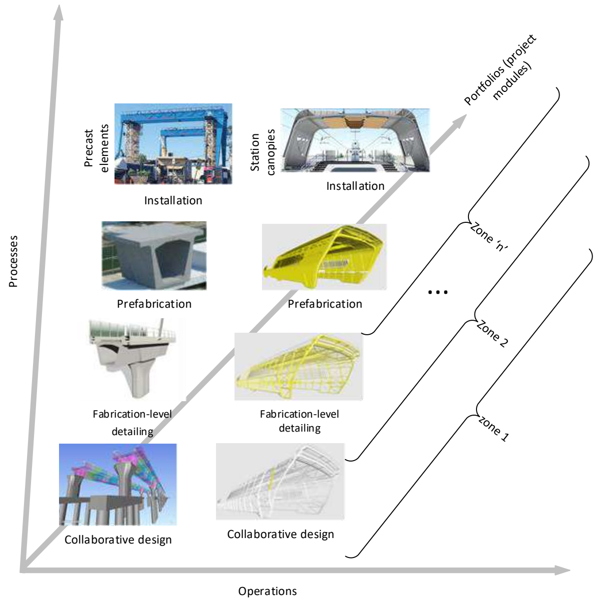

Figure 1. Three dimensional view of production flows in infrastructure projects

3 Robustness of the 3D view of project production flows

The balancing of production flows across different project modules results in several improvements that are discussed in the following sections. Improvements in the context of infrastructure projects include but are not limited to minimization of rework and re-entrant flows, maximization of flexibility in prefabrication, improvements in multidisciplinary collaborations, and efficient planning of temporary works.

3.1 Minimization of rework and re-entrant flows

In complex environments of infrastructure projects, resources often have to return to work locations more than once to complete processes. This creates reentrant flows resulting in delays and discontinuity of work [33, 34]. One contributor to reentrant flow is planning and management of process and operations without considering the production flow continuity at the project level [35]. For example, installation processes of station canopies in the investigated railway projects require teams to return to same work locations several times to complete assembly of canopy elements that have complex geometries and connections. Adoption of the customized 3D flow model resulted in real-time prioritization of installation processes across different project modules and minimization of reentrant flows.

The second contributor to project reentrant flow is defective work and resultant rework [36, 37]. After identification of defects by successor trades or inspectors, responsible resources are called back to undertake rework in respective work locations [38]. Defects in construction are caused by inaccurate design and/or errors in completing the work [39]. Both issues in the analyzed railway projects were managed by using the 3D project production model. This along with the use of building information models facilitated collaborations in detecting design faults and clashes ahead of fabrication-level detailing. Furthermore, the model created continuous production flows for off-site manufacturers and on-site installation teams. As an example, collaborative review of initial design across project modules revealed several inconsistencies in the design of station canopies. Furthermore, frequent comparisons of planned and actual construction, resulted in early detection of errors in column locations for elevator shafts in railway stations.

Reduction of rework and reentrant flows by using the portfolio- process- operations model of production flows improves performance measures at the project level. This is due to the fact that reentrant flows often pass through bottleneck resources and cause further delays in completing activities on the project critical path [40, 41].

3.2 Flexible decision making for prefabrication

Implementation of the 3D model of project production facilitated the postponement of differentiation points in manufacturing of prefabricated elements such as viaduct segments, super T beams, precast piers, and elevated station canopies. The portfolio dimension facilitates continuity of process and operation flows at the project level and in accordance to unique requirements in each and every project module [42, 43]. Furthermore, the production flow structure provides required interfaces between preliminary design, prefabrication and on-site assembly. This allows completion of more design iterations before fabrication-level detailing and prototyping prior to mass manufacturing of non-standard elements.

The extraction of component data for fabrication can be deferred to optimize production of elements for different project modules. As an example, complex hyperboloid geometries and novel fabrication procedures to construct station canopies were developed by postponing decision making and achieving the maximum possible level of design maturity.

Furthermore, the production flow model allows temporal flexibility for consecutive design stages. As can be seen in Figure 2, preliminary design of the steel structure for station canopies significantly improved during detailed design stages and fabrication-level detailing. The final structure is lighter by removing excessive horizontal members and more stable because of increased number of braces.

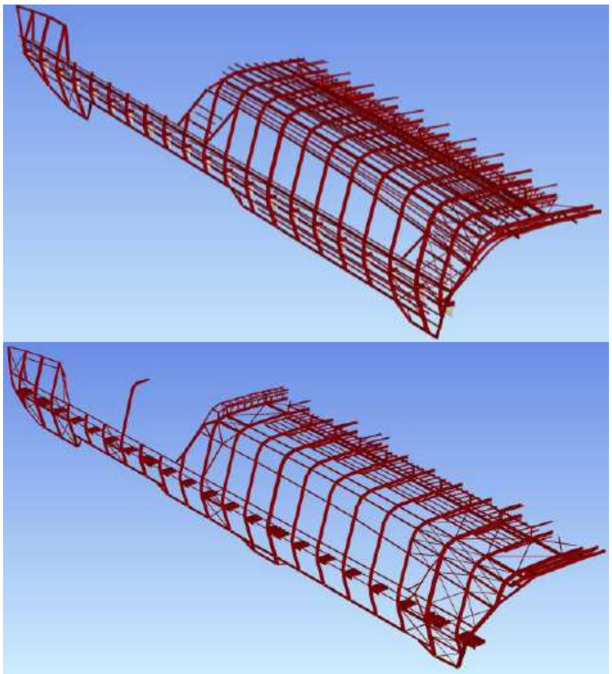

Figure 2. Flexible decision making- Initial design of canopy structure (top) and final design (down)

The continuity of production flow at the project level is maintained by considering the three dimensions of project portfolio, process and operations [44]. The modularity of project production in the railway case facilitated collaboration and information transfer amongst project teams. This is in line with findings of Williams, et al. [45] and confirms that a robust production flow structure should cover all project dimensions from design to fabrication to assembly. This holistic view maximizes temporal flexibility in decision making on downstream project processes that are often dependent to upstream work.

3.3 Improvements in multidisciplinary collaborations

Continuity of production flows across different project modules can only be achieved by efficient collaboration of multidisciplinary teams [46, 47]. This collaboration is essential for each and every project process including development of shop drawings. These drawings provide fabrication-level details of different structural and non-structural project elements. In the traditional approach to review and finalization of shop drawings, 2D documents sequentially pass through different discipline teams and necessary corrections are made [48]. This time consuming and error-prone process causes prolonged delays in downstream processes related to prefabrication and on-site installation [49, 50].

Departing from a file-based mode of reviewing and finalizing shop drawings, a cloud-based approach was used in the investigated infrastructure projects. Multidisciplinary collaborations were enhanced by the parallel use of commercial packages such as BIM360 Glue and Navisworks to facilitate reviewing fabrication-level details by collaborating multidisciplinary teams. As an example, in prefabrication of steel structures, comments from architecture, engineering and manufacturing teams were collaboratively addressed to finalize shop drawings.

The portfolio- process- operations view of production flows (Figure 1), provides a collaborative platform for exchanging fabrication-level information across different disciplines such as architecture, civil, rail and services. Modularity of the production flow structure and existence of the portfolio dimension (project modules) resulted in prefabrication of bespoke elements across different project modules.

3.4 Efficient planning of temporary works and structures

Temporary structures and works such as hoardings and scaffolding support construction of projects [51, 52]. Decision making on temporary structures and works requires consideration of both temporal and spatial limitations [53, 54]. Traditionally the decision making has been based on experience of design and construction teams, often causing delays and time-space conflicts [55, 56]. The portfolio- process- operations flow model facilitates decision making on temporary structures and works by considering multidisciplinary requirements across different project modules.

Temporary works are of great importance to the investigated project cases because of simultaneous operation of trains and construction. Hoardings next to rail tracks were designed considering safety of train users and construction crews, spatial limitations on worksites, duration of use, and possible workspace conflicts. After multidisciplinary analysis of optimum distance from hoardings to center of nearest tracks, project teams agreed on 2.1 meters to satisfy constraints. Understandably, this base distance is re-examined in different production scenarios to evaluate suitability to each project module.

Scenario analysis and evaluation of alternatives to temporary works often result in minimizing cost and maximizing performance measures at the project level [57]. For example, alternative use of scaffolding and scissor lifts as the work platform in the assembly process of elevated stations was deemed suitable in different project zones.

The portfolio-process-operation model of production flow facilitates consideration of multidisciplinary constraints in planning and design of temporary works with the aim of maintaining flow continuity at the project level.

4 Conclusions

Previous research has realized the complexity of managing production flows in large construction projects [58, 59]. However, studies that take holistic approaches to manage process and operations across different modules of infrastructure projects are sparse [60]. To bridge this gap, the current research analyzes railway infrastructure projects to evaluate the three-dimensional production flow model developed by Sacks [19].

The findings present significant improvements in terms of production flow continuity at the project level. Adopting the portfolio- process- operation view of project production resulted in minimization of rework and reentrant flows, flexible prefabrication, enhanced multidisciplinary collaborations, and efficient planning of temporary works. Results of the current analysis are in line with those of Mullens [61] and Sacks, et al. [62], confirming that all dimensions of production flow need to be holistically considered in order to maintain flow continuity at the project level.

This work contributes to the literature by analyzing dynamics of production flow in complex infrastructure projects where a hybrid of on-site and off-site processes across several project modules are in progress. Furthermore, the paper’s approach to customize production flow model is of practical use to those planning and managing infrastructure construction. Early adoption of production flow model facilitates creation of a holistic approach to manage process and operations across different project modules.

5 Research limitations and further opportunities

Investigation of production flows in the current study is limited to infrastructure cases in the railway context. Future research would benefit from investigating other types of infrastructure projects to test the generalizability of findings. Furthermore, the results of this study are limited to four aspects of re-entrant flow, decision flexibility, collaboration and temporary works. With a more in-depth analysis of production data, there will be opportunities to investigate other production aspects.

Abstract

Unmanned Aerial Vehicles (UAVs) have opened a wide range of opportunities and applications in different sectors including construction. Such applications include: 3D mapping from 2D images and video footage, automated site inspection, and performance monitoring. All of the above-mentioned applications perform well outdoors where GPS is quite reliable for localization and navigation of UAV's. Indoor localization and consequently indoor navigation have remained relatively untapped, because GPS is not sufficiently reliable and accurate in indoor environments. This paper presents a method for localization of aerial vehicles in GPS-denied indoor construction environments. The proposed method employs AprilTags that are linked to previously known coordinates in the 3D building information model (BIM). Using cameras on-board the UAV and extracting the transformation from the tag to the camera's frame, the UAV can be localized on the site. It can then use the previously computed information for navigation between critical locations on construction sites. We use an experimental setup to verify and validate the proposed method by comparing with an indoor localization system as the ground truth. Results show that the proposed method is sufficiently accurate to perform indoor navigation. Moreover, the method does not intensify the complexity of the construction execution as the tags are simply printed and placed on available surfaces at the construction site.

Indoor localization; construction performance monitoring; Building Information Model (BIM); AprilTags; Automated monitoring; Facility Management;

1 Introduction

Unmanned aerial vehicles (UAVs), also known as drones, have recently attracted attention from various industries including construction. Employing UAVs equipped with visual sensors for construction site monitoring is beneficial due to the vehicles' maneuverability and rotary features. UAVs can access points that are inaccessible or unsafe to be reached by humans. UAVs may also be equipped with other devices such as a laser scanner, thermal sensors, or hyperspectral/multispectral sensors that can be used for acquiring further insights and then generating very informative analytics about the status of the construction component being monitored. Specific applications in the construction industry include 3D mapping for dimensional measurement of construction components [1], visual progress monitoring, and visual inspection [2].

The key capability of UAVs that makes them useful in so many industries is their ability to be programmed to perform tasks autonomously. One critical module of such autonomous robots for automated task performance is the localization system. For outdoor environments, autonomous flight planning is less challenging, because the localization module is based on global positioning systems (GPS), which is accurate and reliable. Localization results are then fed to the control systems as the state sensing component (feedback loop). Navigation and path planning can then be performed based on the accurate and reliable localization results obtained in outdoor environments. However, indoor localization using GPS is not sufficiently reliable because of the weak signal and other interferences present in indoor environments such as walls and other interior components under-construction.

Using reliable indoor localization systems that already exist commercially, such as wireless networks, UWB, or vision-based positioning cameras (e.g. Vicon system) intensifies the complexity of construction sites and, indeed, requires additional costs for deployment. This paper investigates the use and employment of fiducial markers (AprilTags, in particular) for potential deployment in GPS-denied indoor construction environments. The 3D coordinates of fiducial markers are hardcoded into 3D CAD drawings integrated with the building information models (BIM). Camera-equipped UAVs can identify their relative pose to the tags and then calculate their location in the global coordinate frame give the tag's location.

2 Background

The related background information is investigated from three different perspectives: (1) indoor localization state-of-the-art, (2) fiducial markers for indoor localization, and (3) localization of construction equipment and materials. These areas are extensively discussed in the following sections.

2.1 Indoor localization state-of-the-art

Indoor localization and the related research area is used when objects are to be detected in a location where a global localization signal such as GPS is not reliable [3,4]. According to Ibrahim and Moselhi (2016) [5], indoor localization techniques can be divided into three major categories:

- Wave characteristics and propagation: various ultrasonic and sound waves and receivers such as radio frequency (RF), ultra-wideband (UWB), and wireless local area network (WLAN) are used for indoor localization [3,6,7]. Indoor localization using ultrasound waves may result in 9 cm accuracy, however, it requires direct and interference-free access to the objects. Other techniques such as UWB and RFID have reported accuracy of 5-9 m, which is insufficient for high accuracy applications and analyses. Localization systems with such low accuracies are used for sensing and roughly locating materials in warehouses and other indoor environments.
- Image-based/vision-based localization: image-based localization uses computer vison to identify the location of objects in the global coordinate system. Image-based localization has been categorized in two major groups: (1) global feature detection, identification and localization such as edge and corner detection, and (2) local feature detection such as fiducial tag and marker detection and localization. Image-based localization requires line-of-sight to extract features; therefore, it is significantly impacted in dynamically changing environments and also by markers' deterioration throughout the project lifecycle. Recently, simultaneous localization and mapping (SLAM) has been found to be capable and reliable for indoor localization and mapping [8]. The method proposed in this paper belongs to this category and aims to investigate and overcome some of the existing challenges using fiducial markers.

- Inertial navigation systems: indoor localization can be performed, given an initial location and navigating using on-board accelerometers, inertia measurement units (IMU's), and other motion sensors. Inertial navigation and IMU-based indoor localization drifts from actual measurements as movement progresses, if motion components are not appropriately updated. Ibrahim and Moselhi [5] developed an IMU-based localization technique combined with a Kalman filter, which was found to be more accurate compared to the wave-based method. However, relying on IMU for UAV navigation is very risky and may lead to serious hazards such as loss of control and subsequent collision with objects in the environment. SLAM [8] may also be used with inertia measurement units (IMU's) or some other motion sensors for facilitating the localization. In such cases, processing is less computationally demanding and therefore closer to real-time.

2.2 Fiducial markers for indoor localization

Visual tags are designed to be easily detectable by camera systems. If a camera system is well calibrated, the relative pose of the camera with respect to a tag can be calculated, and therefore the camera system can be localized with respect to the tag's coordinate frame. Challenges for employing and implementing fiducial markers include: (1) the processing cost for decoding the tags, and (2) the difficulty of generating template tags that are orthogonal with each other [9].

Among fiducial markers, AR Tags were found to be very easily detectable and quickly decodable. AprilTag Tags were then introduced to overcome the inadequacies of AR Tags, which included the accumulated error when distancing from the target [10]. AprilTag Tags were proved to be more robust for indoor localization, and, since then, they have been used for many applications such as robot localization and navigation. AprilTag Tags are used in this study to investigate the localization of UAVs using their on-board camera systems [11].

2.3 Localization of construction equipment and materials

The previously explained techniques and technologies have been used for locating construction equipment and materials on site. Razavi and Haas [12] presented a method for localizing construction equipment and materials using RFID tags. In another study, indoor localization was tested using passive RFID tags for sensing. Song et al [13] used RFID tags for automating the task of tracking the delivery of materials on construction sites. As reviewed in the literature, localization frameworks are either performed outdoors or only for the purpose of sensing if performed indoors. This study aims to test and assess the performance of AprilTags for indoor localization of UAVs.

3 Methodology

For the purpose of localizing UAVs used for indoor task performance, on-board cameras are employed to detect AprilTag Tags with known locations in the world coordinate frame, and therefore linked to the building information model. On-board cameras are first calibrated to identify the physical and intrinsic parameters required for pose identification. An overview of the proposed framework is illustrated in Figure 1.

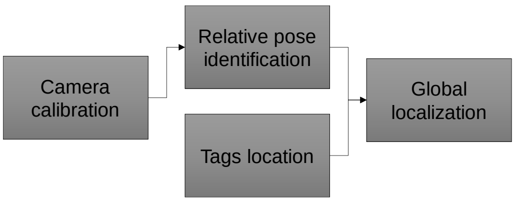

Figure 1: Overview of the proposed framework for indoor localization

3.1 Camera Calibration

Camera calibration is required to estimate the parameters of a lens and image sensor of an imaging system. Camera calibration parameters are thus required for accurately measuring distances to perceived objects. The Robotics operating System (ROS) package for camera calibration is used to estimate the camera parameters using a large checkerboard (8×6) with known dimensions (108 *mm*) for camera calibration.

3.2 Tags location

UAVs are going to be employed for indoor monitoring of construction elements. To identify the critical elements to be monitored, different filters can be applied on the building information model to extract the world coordinates and assign them to the tags used for localization. For example, a filter can be applied on object types, in case a specific type of object, such as drywalls or electrical outlets, is to be monitored. The construction of some objects may become behind schedule; they are the purpose of task monitoring using UAVs. In that case, a filter on object status can be applied to the BIM objects to extract the critical locations in the world coordinate system. Moreover, project managers might be interested in tracking and monitoring the tasks performed by specific subcontractors or vendors.

In summary, filters can be applied based on the search criteria in order to extract critical locations to be monitored by the UAVs employed in indoor environments. Extracted coordinates are assigned to tags, which are then employed for the localization of UAVs. Tags link the UAV's location to the world coordinate system as explained in the following section.

3.3 Relative pose identification

Once the on-board camera on the UAV is calibrated and tags locations are identified, UAVs can be localized with respect to the tags placed on construction sites. The relative pose is reported as a relative translational vector (x, y, z) and a rotational vector $(roll, pitch, yaw)$. These two vectors are reported as a relative transformation denoted as T_t^l, which relates the position of the UAV measured locally and in the tag's local coordinate system. Given the transformation that relates the position of the tags in the global coordinate system T_g^t, the UAV can then be localized globally. The required transformation for localizing the UAV in the global coordinate system T_g^l is calculated as: $T_g^l = T_t^l \times T_g^t$.

4 Design of experiments and results

An experimental setup is designed to collect the required data for verifying the accuracy of UAVs under various circumstances. A Parrot Bebop 2 equipped with a camera and on-board accelerometers is used as the UAVin this study. Detailed specification of the vehicle is provided in Table 1. AprilTags of type *36h11* printed at two different sizes are used to identify the impact of the tag's size on the accuracy of detection and pose identification. For integrating the on-board sensors of the UAV used in this set of experiments, a ROS driver for the Bebop device is used [14].

Table 1: Parrot Bebop 2 technical specifications

Feature	Specifications
Video resolution	14 MP
Image resolution	1920×1080 pixels, 30 frames/sec
Flight time	~ 25 min
Networking	Wi-Fi Dual Band 2.4 & 5GHz
Weight	500 g
Operation range	Up to 2km (Wi-Fi controller)

4.1 Effective variants

Four parameters are investigated to identify the accuracy of the proposed indoor localization framework:

1. Tags' placement orientation: construction sites and environments are dynamically changing during the projects' lifecycle. If the tags are planned to be placed on vertical walls, there might be a delay on the deployment of tags when a new floor is being inspected. On the other hand, tags placed on floors may be covered by building materials and elements. Both situations are tested to better understand the limitations.
2. Tags' size: the accuracy of the detection and pose identification with respect to the size of the tags is investigated. Larger sizes are more visible and therefore their detection accuracy is expected to be higher; however, smaller sizes are more practical to implement and deploy on construction sites.
3. Distance from tags: the UAV must see at least one tag at all times during the flight. This is crucial because if no tag is, the navigation control switches to on-board odometry which is neither reliable nor safe. The reason is that the UAV may lose its pose and location in the world coordinate system. In order to identify the threshold distance at which the UAV has a sufficiently accurate level of pose identification with respect to the tags, the impact of distance on localization should be investigated. The results can then be considered as a constraint in optimizing the tag placement plan on a building map.
4. Angle of view: similar to the previous variant, the angle of view is also of crucial importance in pose identification. The threshold angle value for which UAVs are localized with sufficient accuracy should be identified and considered in the tag placement optimization plan.

4.2 Experimental setup

An experimental setup is designed to measure the accuracy of the tag-based localization system. Tags are placed at previously known locations linked to the world coordinate system in the BIM. Figure 2 illustrates how world coordinates are calculated using the tag locations and how they are measured with the ground truth indoor localization system (Vicon cameras).

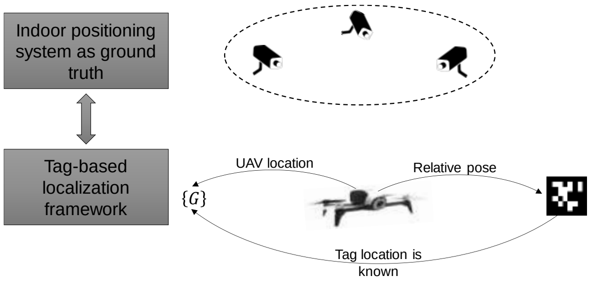

Figure 2: Tag-based indoor localization. For verification and validation of the calculated location, the results are compared with ground truth indoor positioning system. Tag-based localization results are compared with the Vicon system used as the ground truth (Section 4.3).

4.3 Ground truth indoor positioning system

An overhead camera system is used to assess the accuracy of the proposed tag-based localization framework. The overhead camera system detects markers that uniquely identify various objects. Once markers are detected, the position of the object is estimated as the ground truth. In the laboratory setup, the Vicon system is integrated with the ROS and the localization results are reported in a *rostopic* recorded for further result analyses.

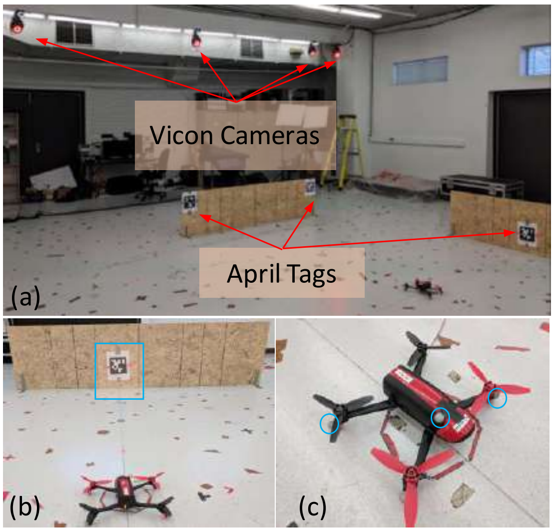

Figure 3: Experimental setup for testing the accuracy of the proposed indoor localization framework. (a) Ground truth system (Vicon cameras) are shown within the laboratory. AprilTags are also placed at various locations. (b) Take-off position where the UAV is faced to Tag-id=0 to be initially localized. (c) Markers are put in a specific pattern on the UAV, so as to be recognizable by the ground truth indoor localization system.

5 Results

In order to investigate the impact of the effective variants, the localization results are compared with the ground truth system under various scenarios. Each scenario is designed to capture the effective variant being investigated.

First, the effect of the orientation of the tags is investigated. For this purpose, localization results for vertical tags placed on walls and horizontal tags placed on the floor are compared with the ground truth system (see Figure 4). Figure 5 illustrates the accuracy of the localization system as the angle from the tag chages for horizontal tags.

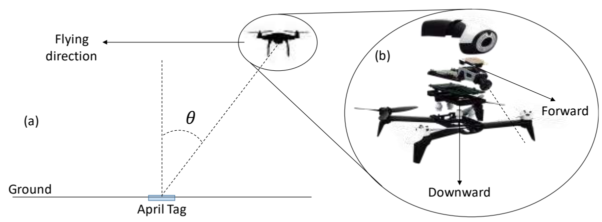

Figure 4: Side view of the experimental setup. (a) Auto-flight plan for calculating the localization accuracy when tags are placed horizontally on the ground. (b) Configuration of the on-board camera of the UAV used in this study. Figure is from Bebop forum [15].

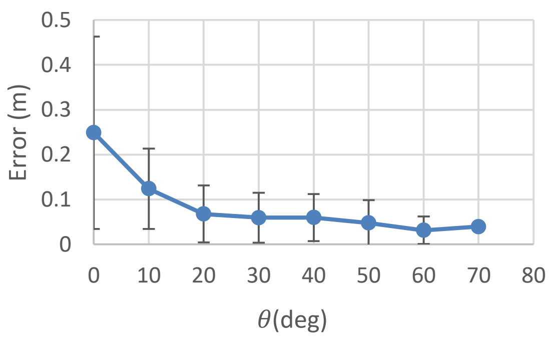

Figure 5: Localization error for horizontal tags placed on the ground. The UAV flight height is fixed at 2 m. Camera angle (θ) with respect to the tag is variable.

As seen in Figure 5, the accuracy of the localization increases as the angle increases. Moreover, the standard deviations (error bars) decrease as the angle increases, which implies more stability in the localization system as the angle increases. This is due to the orientation of the on-board camera used in the experiments. As shown, the camera is angled between forward and downward directions, as shown schematically in Figure 4-(b).

To understand the effect of distance from tags, the UAV is programmed to fly at different distances perpendicular to the tag's plane. Figure 6 schematically shows the automated flight plan programmed to investigate the effect of distance on the localization results. Figure 7 shows how accuracy changes while the UAV is flying at various distances with respect to an AprilTag.

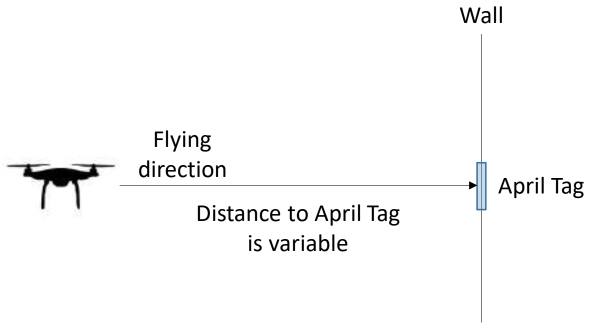

Figure 6: Automated flight plan for investigating the effect of distance to an AprilTag on the localization results

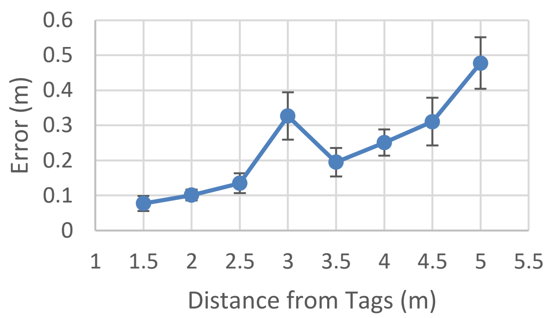

Figure 7: Localization error at different distances from tags. The on-board UAV's camera is facing perpendicular to tag's plane.

As seen in Figure 7, localization accuracy decreases as the UAV gets further from the AprilTag. The discrepancy at 3 m distance is due to the take-off position. Although, a tag is visible even before taking off, the localization is not sufficiently accurate and robust while the UAV is moving. It is expected that the graph monotonically increases if the data associated with take-off is filtered out from the results. Another observation is that the standard deviation increases as the UAV gets further from the AprilTag. This implies that the localization is more robust at closer distances.

Finally, the yaw angle of the UAV at a fixed distance (2 m) from an AprilTag is investigated to quantify the localization accuracy at various view angles. An automated flight plan (depicted in Figure 8) is implemented and the localization error is reported (in Figure 9) at various yaw angles (ψ).

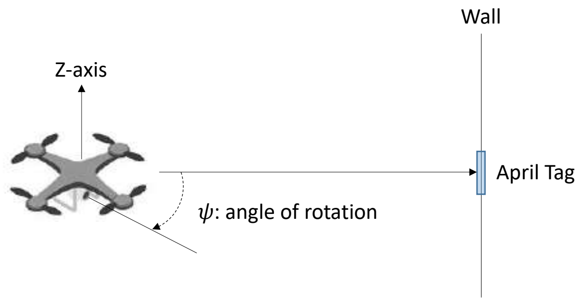

Figure 8: Automated flight plan to quantify the effect of yaw angle (ψ) on the localization accuracy

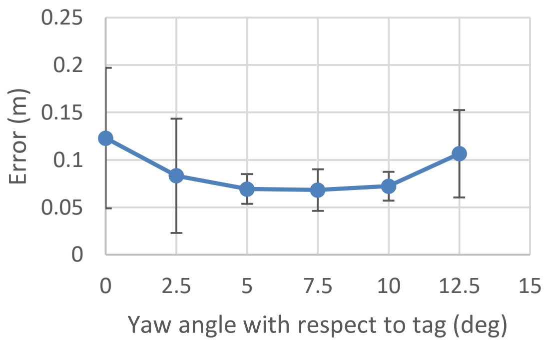

Figure 9: Localization error at different yaw angles. The UAV is flying *2 m* away from the tag and the yaw is variable.

As seen in Figure 9, the localization is robust and the accuracy is very stable for the yaw angles investigated. The large discrepancy at $\psi = 0$ is due to the take-off position, and if the data associated with the take-off is eliminated, the graph becomes even more stable and robust. Comparatively, the standard deviation is expected to be as low as the same values reported for $\psi = (5, 7.5, 10)$; however, the take-off localization inaccuracy is affecting the standard deviations as well. It should be noted, that the further the UAV is from an AprilTag, the lower the expected maximum yaw angle because of the line of sight and angle of view.

6 Conclusions

An indoor localization system using fiducial markers was developed in this study. AprilTags were used to globally localize flying UAVs in indoor construction environments. UAVs will then be used to capture some critical information about building components under-construction. Such information is then linked with a global system like BIM in order to measure the actual construction performance metrics with designed values to update plans accordingly. Progress of construction components can, for example, be measured at different locations in order to update the schedule accordingly. A robust indoor localization framework will provide an opportunity to fly autonomously and perform the whole process automatically. In order to verify and validate the performance of the proposed framework, an experimental study was designed. Some key findings are summarized as follows:

- Localization error decreases as the angle of view to horizontally placed tags on the grounds aligns with the on-board camera orientation. As the angle of view becomes steeper with respect to the camera orientation, the error increases.
- As expected, localization error increases as flying vehicles get further from AprilTags. The localization error will be higher than 30 cm if the UAV is flying further than 3.5 m from an AprilTag.
- Localization accuracy is very robust and stable for the yaw angles at which an AprilTag is visible by the UAV's camera.

For all cases, localization during take-off and landing is not sufficiently accurate to be reliable. Hence, the data associated with those situations must be filtered out for more accurate analyses. Future work includes incorporating the findings with automated flight plans on real construction sites. Threshold values are going to be extracted as constraints for distance and view angles to optimally place the tags on a construction site to be monitored.

Abstract -

The Indoor Environmental Quality (IEQ) in a building affects occupants' well-being and productivity. Traditionally, models are developed to predict IEQ satisfaction from physical measurements. These approaches work fine in a laboratory environment but tend to fail in real-world applications. Recent work focuses on collecting direct human feedback on IEQ. However, existing approaches either lack the ability to capture the multiple dimensions of IEQ or the integration with other domain knowledge, e.g. from building information modeling or building automation systems. To tackle this problem, we have developed a novel approach based on Semantic Web Technologies (SWT) which enable interoperability and reasoning. In this paper, the HBC (Human Comfort in Building) ontology is presented, which formally specifies the domain of IEQ in multiple dimensions and relates it to adjacent domains. An online survey is designed in order to specify ontology requirements and collect human feedbacks for evaluating the ontology. We evaluate the use of the HBC ontology in two use cases in an office building: recommendation of spaces based on IEQ factors and recommendation of settings for technical equipment from collected feedbacks.

Human Experiences; Indoor Environmental Quality; Semantic Web Technologies; Ontology; Office Buildings

1 Introduction

In modern life, people spend between 80% and 90% of their time indoors [1]. Recent studies have shown that Indoor Environmental Quality (IEQ) not only can affect occupants' well-being, but also their productivity [2]. Dimensions, or factors, of IEQ are amongst others indoor air quality (IAQ), thermal comfort, visual comfort and acoustic comfort. In the past, researchers have identified a number of physical measurements which correlate with IEQ. In experiments, human satisfaction is determined from questionnaires while measuring physical quantities identified to correlate with IEQ (e.g. [3]). From the results, models have been developed to predict IEQ satisfaction from measurements.

However, since standards have often been found to be at odds with the requirements of occupants [4], recent work focuses on using direct human observations on IEQ with the aim to improve IEQ satisfaction of users [5, 6].

In the current state of art, several studies and tools exist to capture occupant experiences in buildings: Comfy [7], TherMOOstat [8], CrowdComfort [9], CBE Occupant Feedback Toolkit [10] and MYBUILDINGMESSAGE [11].

Comfy, TherMOOstat and CrowdComfort share a common downside: the inability to capture other IEQ factors besides thermal comfort. For CBE Occupant Feedback Toolkit and MYBUILDINGMESSAGE, although they can capture various IEQ dimensions, they lack the ability to integrate the occupants' experiences automatically with information from adjacent domains, e.g. Building Information Modeling (BIM).

There are also projects which try to capture occupants' experiences while integrating with adjacent domains. For instance, Twitter surveys have been used to integrate occupants' thermal comfort experiences [12]. YouSense is a web-based application which can capture human observations of spaces. It is built on the expressiveness of the EXPERIENCE vocabulary—a lightweight vocabulary for describing human experiences [6]. The authors argue that it is usable for linked data applications via collecting human experiences. However, it is notable that EXPERIENCE has a more general scope beyond IEQ factors.

To address these limitations of existing approaches, we developed an ontology that formally specifies human experiences on the several dimensions of IEQ in spaces. The ontology is aimed to derive a better understanding of perceived comfort, spaces, and relations between them. Further on, this ontology-based approach allows to infer new information given rules and linkages to information modeled according to BIM and BAS. We also designed a survey for collecting experimental data. The process of ontology development follows a well-known approach called METHONTOLOGY [13]. Semantic Web Technologies are used for ontology implementation, such as

OWL DL and SWRL rules. The ontology is populated based experimental data using OWL API. We evaluated the ontology by means of SPARQL queries with regard to the targeted scenarios.

The rest of this paper is organized as follows. Section 2 describes the designed online human experience survey. Section 3 presents the HBC ontology and the development process of HBC. Section 4 shows the application of evaluation of HBC ontology in two use-cases. Section 5 discusses the limitation and future work. Section 6 provides the concluding remarks.

2 Online Human Experience Survey

We designed a human experience survey using an online questionnaire tool in order to gather data as an input for ontology development and validation.

There are thirteen questions that are about location (question 1), IEQ (question 2-5) and settings of building objects (question 6-13). Questions related to IEQ are the core parts. Apart from reviewing literature, we interviewed domain experts on common terms used. We designed questions and possible answers for assessing the IEQ aspects of human experiences.

Occupants can assess the quality of a certain IEQ as positive, neutral and negative. For instance, according to a person's experience, the thermal comfort can be assessed as positive. However, it is unknown whether the positiveness of thermal comfort is caused by feeling warm or cold. People can feel warm positively, or on the other hand cold positively due to differences in their age, culture or psychological factors. Therefore, we not only capture thermal comfort by quality, but also thermal sensation. In this way, thermal comfort can be assessed by the combination of them. Similar design choices were made for questions about acoustic comfort and visual comfort.

However, there is no duality for IAQ. Since, normally, people have a positive feeling when the air is fresh; when the air is stuffy, the quality assessment is negative.

The last part of the survey is about the settings of building objects. After finishing the questions about IEQ assessments, occupants have to report settings of building objects at that moment.

3 Human Comfort in Buildings (HBC) Ontology

3.1 Ontology Engineering Methodology

METHONTOLOGY [13] is an ontology engineering method we adopted for building the HBC ontology. It is widely used as it provides sufficient descriptions and allows ontology reuse [14]. It is an iterative process along with knowledge acquisition and evaluation as supporting activities. In this section we provide an overview of the steps of METHONTOLOGY.

3.2 Specification

The *Specification* stage consists of domain analysis and knowledge acquisition in the course of expert interviews and literature reviews. While designing the survey questions, the requirements of the ontology are identified which include the scenarios in which the ontology is used. Also a set of terms along with their characteristics are identified.

The HBC ontology models the scenario that an occupant describes about his/her experience at certain times in a space. Conceptually, the HBC ontology is divided into three modules: Hex ontology, bim4Hex ontology and Time ontology (see Figure 1). The module of Time describes necessary time concepts for the Hex ontology. Modularizing the HBC ontology is good for (1) reusing ontologies, (2) maintaining and extending ontologies.

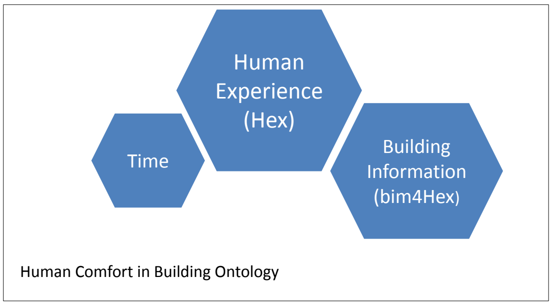

Figure 1. Modules of HBC ontology

Competency questions are the set of the questions that the ontology should be able to answer (See Table 1). These competency question are evaluated via specific use-cases.

3.3 Conceptualization

As proposed in METHONTOLOGY [13], the domain knowledge is conceptualized into a model that satisfies the ontology requirements in the *Conceptualization* activity. It is worth mentioning that there is no single correct way to model the domain of interest. There are always alternative design choices.

Figure 2 shows the overall conceptualization of the HBC ontology. This graphical representation has been created using the *Graffoo* method [15].

3.3.1 Hex Module

The concept classification of IEQ factor is shown in Figure 2. Thermal comfort, visual comfort, acoustic comfort and IAQ are the factors considered for IEQ factors, which makes them subclasses of *IEQFactor*. Also, they

Table 1. Basic (1-9) and complex (10-11) competency questions.

Competency Questions
1. What are the spaces where people experienced positive thermal/visual/acoustic comfort and air quality?
2. What are the spaces where people experienced negative thermal/visual/acoustic comfort and air quality?
3. What are the spaces where people experienced neutral thermal/visual/acoustic comfort and air quality?
4. What are the spaces where good/bad/neutral experiences?
5. What are the spaces where people experienced as a quiet space?
6. What are the spaces where people experienced dim light?
7. When do people usually have good experience of space?
8. When do people usually experience positive visual comfort?
9. When do people experience quietness?
10. What are the equipment settings when people feel cold and report negative thermal comfort?
11. What could be the adjustment of shading device settings when people report negative visual comfort in a certain space?

are primitive classes. Furthermore, *IEQFactor* can be decomposed into *PostitiveIEQFacotr*, *NegativeIEQFactor* and *NeutralIEQFactor* based on the value of *Quality* that it connects to via object property *hasQuality*. Hence, these three subclasses are defined classes.

Figure 3 shows the concept classification tree of sensation. The modeling corresponds to the design of questions in the human experience survey.

The core concept in the Hex module is *Experience* (see Figure 2). It connects to *IEQFactor* by object property *isAbout*. *Experience* is also a bridge linking the Time module (via *hasTime*), and the bim4Hex module (via *withObjectSetting* and *hasLocation*) with the Hex module.

3.3.2 bim4Hex Module

The bim4Hex ontology contains all concepts, properties and axioms related to building information in HBC. According to ontology requirements, window, air terminal, shading device and space heater are the types of building objects considered in the domain, but can be extended when required.

Figure 4 shows the concept classification tree of `BuildingSpace`. Spaces are defined based on whether they contain certain types of building objects or not, and they are all subclasses of `BuildingSpace`. For example, the concept definitions of `SpaceWithHeater` and `SpaceWithoutHeater` are presented in listing 1 and they are written in Manchester OWL syntax [16]. The rest of the subclasses are defined in the same fashion.

Listing 1. The concept definitions of `SpaceWithHeater` and `SpaceWithoutHeater`.

```
Class: SpaceWithHeater
    EquivalentTo:
        BuildingSpace some SpaceHeater
    DisjointWith:
      SpaceWithoutHeater

Class: SpaceWithoutHeater
    EquivalentTo:
        BuildingSpace and (contains only
                        (not SpaceHeater))
    DisjointWith:
      SpaceWithHeater
```

Rules are used to infer rooms that are similar to each other in terms of building objects (see Listing 2). There are nine rules in total. Six rules are omitted here for simplicity, since they are defined in the same fashion as the first two rules. For each type of building objects, there are two rules defined in order to formally specify similar spaces in terms of that specific type. For instance, if two instances are members of class `:SpaceHeater`, then they are in the relation of `:isSimilarSpaceHeaterTo`. Similarly, if two instances are members of class `:SpaceWithoutHeater`, then they are also in the relation of `:isSimilarSpaceHeaterTo`.

The last rule is defined for inferring spaces that are similar to each other taking all types of building objects into account.

Listing 2. Rules defined for inferring similar rooms in terms of building objects

```
SpaceHeater(x),SpaceHeater(y)
              ->isSimilarSpaceHeaterTo(x,y)
SpaceWithoutHeater(x),SpaceWithoutHeater(y)
              ->isSimilarSpaceHeaterTo(x,y)
...
isSimilarWindowTo(x,y),isSimilarSpaceHeate-
rTo(x,y),isSimilarShadingDeviceTo(x,y),isS-
imilarAirTerminalTo(x,y)
                    ->isSimilarObjectTo(x,y)
```

3.4 Integration

3.4.1 Reusing Existing Ontologies in the Field

One of the principles for designing an ontology is to reuse ontologies whenever it is possible—this idea has served as our guide here as well.

According to the requirements of the ontology and the human experience survey, we identified three areas where

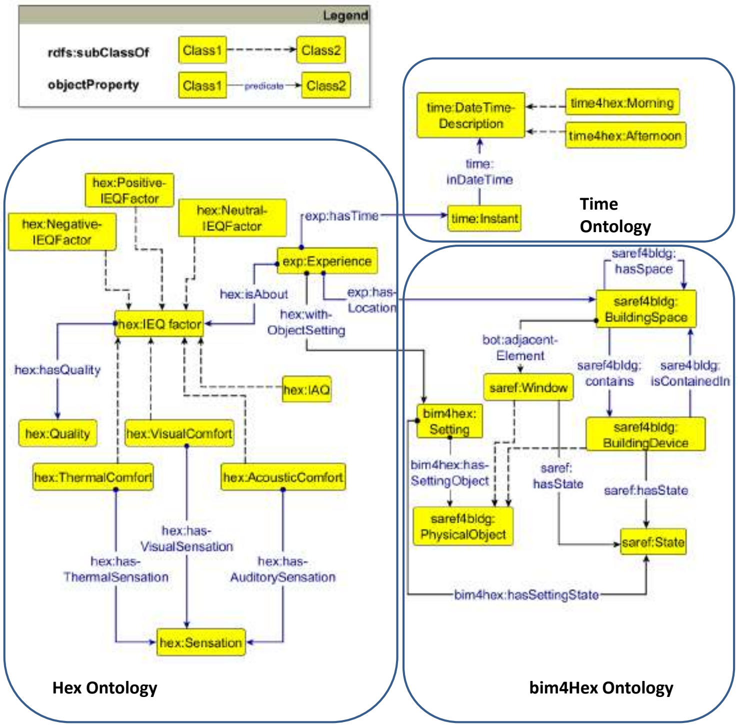

Figure 2. The overview of HBC ontology and its submodules.

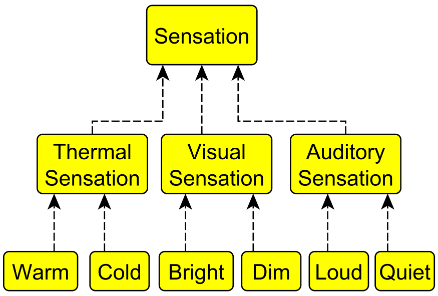

Figure 3. Concept classification tree of Sensation.

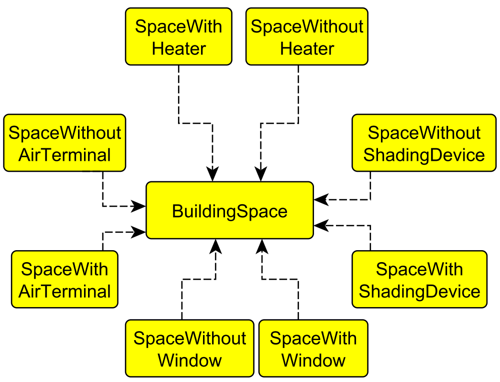

Figure 4. Concept classification tree of BuildingSpace.

existing ontologies may be reused. These areas are experiences, building information and time. The Linked Open Vocabularies repository (`lov.okfn.org`) is used to search desired vocabularies. A brief summery of selected ontologies of the current research domain is presented below:

- Experience Vocabulary [6] is used to describe experiences;
- The *SAREF* (Smart Appliances REFerence) [17] ontology is used for specifying the devices in a space where experiences are provided;
- The *S4BLDG* ontology [18] is an extension of the SAREF ontology. It is created based on the Industry Foundation Classes (IFC) standard for building information. In our approach, it is used for specifying the building information about a space that experiences are about;
- The *BOT* (Building Topology Ontology) is an ontology "covering only the core concepts of a building" [19]. It provides extra vocabularies for describing the building elements which are not included in the *S4BLDG* ontology, for example the vocabulary describing the relation between windows and building spaces;

- *OWL-Time* [20] specifies temporal properties and it is a W3C candidate recommendation. Currently, although this is a draft version and may be updated in future, the main concepts and properties are likely to remain unchanged;

For this article we surveyed also other ontologies about building information, such as ThinkHome [21], DogOnt ontology [22], ifcOWL ontology [23] and Brick schema [24]. However, in terms of the coverage of concepts based on ontology requirements, *S4BLDG* ontology contains major elements that we needed to for the work reported in this paper.

3.4.2 Reused Ontology Fragments

We reuse fragments from the mentioned ontologies as follows. From the *Experience* vocabulary, we use the concept `:Experience` and the object properties `:hasTime` and `:hasLocation`. From the *S4BLDG* ontology, we use the concepts `:BuildingSpace`, `:PhysicalObject`, `:BuildingDevice`, `:SpaceHeater`, `:ShadingDevice` and the object properties `:contains` and `:hasSpace`. Furthermore, after the evaluation of the reusable ontologies, some of the terms used in the human experience survey are replaced by corresponding terms in existing ontologies. `:AirTerminal` is defined in the *ifcOWL* ontology [23].

We reuse from the *SAREF* ontology the concepts `:Window`, `:State`, `:OnOffState`, `:OpenCloseState`, `:ShadingDevice` and the object properties `:hasState` and `:hasSpace`. We make also use of `:adjacentElement` from the *BOT* ontology and `:DateTimeDescription`, `:Instant` and the object properties `:inDateTime` from the *OWL-Time* ontology. Moreover, the data properties `:year`,`:month`,`:day`,`:hour` and `:minute` are also reused.

3.5 Implementation

The ontology was developed using the Protégé editor 5.2. Protégé is extensible and provides a plug-and-play environment. Its editor supports editing SWRL rules and importing ontologies. HermiT [25] supports reasoning with SWRL rules and it is available as a Protégé plug-in. The implementation of the HBC ontology followed a practical guide presented in [26]. Furthermore, we have taken into account the common errors for modeling with OWL DL pointed out by [27].

The collected data of the human experience survey and building information data is converted into OWL from CSV using OWL API. The ontology is published online[1].

[1]https://github.com/TechnicalBuildingSystems/Ontologies/tree/master/hbc

3.6 Evaluation

Our leading principle has been that the evaluation is not only done at the very end of the process of the development. Rather, it is performed in each phase and between activities of the life cycle. If any mismatch is found, the activities of conceptualization, integration, implementation and evaluation will be performed once more.

In this section we evaluate the correctness of `:isSimilarObjectTo` object property defined using SWRL rules with sample data presented in Table 2.

Table 2. Sample data to evaluate similar rooms (R) in terms of their equipment.

Room Name	Air Terminal	Space Heater	Shading Device	Window
R16.2.28	X			
R16.3.29	X			
R16.2.05	X	X		
R16.3.05	X	X		
R16.2.11		X	X	X
R16.3.11		X	X	X
R16.2.10	X	X	X	X
R16.3.32	X	X	X	X

Figure 5 shows the obtained results after executing the SWRL rules. Among all inference results the reasoner correctly inferred that `:Room16.2.05` is similar to itself and `:Room16.3.05` in terms of building objects.

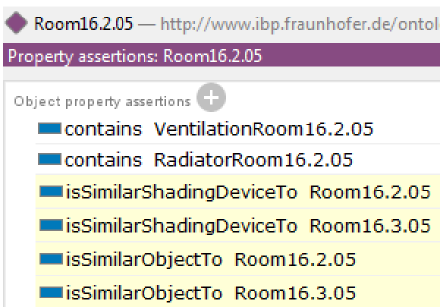

Figure 5. The results after executing the SWRL rules in Protégé.

4 Use-Case

We evaluate the ontology by means of answering all of the competency questions (see Table 1). Essentially, those questions can be categorized into two use cases: *Space recommendation* (1-6) and *Setting recommendation* (10-11). Question 7-9 are about the time feature of experience which further specifies both of the use cases. Hence, all the competency questions are covered by these two use cases. In this section, we describe the use case scenarios, the related queries and results.

4.1 Space Recommendation

4.1.1 Scenario

Often in our daily life we would like to find a certain kind of a space to meet the situation at hand. For example, for studying a textbook,say, in the morning, one might prefer a quiet space. In order to address this need the straightforward question one might ask is, ”which spaces are quiet in the morning?"

4.1.2 Query and Result

In order to retrieve answers to the question of finding a quiet space, we envision a SPARQL query depicted in Listing 3. `?QuietPercent` is the percentage of experiences about acoustic comfort assessed as quiet.

Listing 3. SPARQL query for recommending quiet spaces in the morning.

```
select ?location (count(*) as ?NrOfAC)
       ?NrOfQuietAC
       (?NrOfQuietAC*100/?NrOfAC
       as ?QuietPercent)
where{
     ?exp1 hex:isAbout ?AC;
          exp:hasLocation ?location.
     ?AC rdf:type hex:AcousticComfort.
     {select ?location (count(*) as
             ?NrOfQuietAC)
      where{
          ?exp hex:isAbout ?quietAC;
              exp:hasLocation ?location;
              exp:hasTime ?datetime.
          ?quietAC rdf:type
              hex:QuietAcousticComfort.
          ?datetime time:inDateTime ?time.
          ?time rdf:type time4hex:Morning.
        }
       group by ?location
     }
}
group by ?location ?NrOfQuietAC
order by  desc (?QuietPercent)
```

Figure 6 shows the result of the above query with the experimental data obtained through a survey conducted in an office building. According to the chart, `Room16.2.20` is the space that receives the highest percentage of experience feedbacks about quiet acoustic comfort in the morning. Consequently, this room seems to be recommendable in a first attempt.

The competency questions 1-6 can be verified by similar SPARQL queries. It is only necessary to replace the type of `?quietAC`, `?AC` and `?time` by changing the part after `rdf:type`.

4.2 Setting Recommendation

4.2.1 Scenario

Equipment settings can be recommended to occupants depending on their comfort requests, if the system that exploits the Hex ontology is integrated with a building control system. For example, if an occupant experiences that the light is too bright in a certain space and requests for a dim light, then the system can recommend settings for the controllable devices in order to provide better visual comfort. The query corresponding to this example is ”what kind of shading device settings can be applied for providing positively dim light in a space?”.

4.2.2 Query and Result

The query shown in Listing 4 is about obtaining the objects and their related states when the occupants report their positive visual comfort with dim visual sensation. The rooms which are similar to each other in terms of objects can be retrieved by property `:isSimilarObjectTo`—inferred using the mentioned SWRL rules. Figure 7 shows the result of this query.

Listing 4. SPARQL query for recommending settings of dim visual comfort in the morning.

```
select  ?location ?object ?state
        (count(*) as ?NrOfSetting)
where{
     bim4hexAbox:Room16.3.12
     bim4hex:isSimilarObjectTo ?location.
         ?exp hex:isAbout ?com;
          exp:hasTime ?time;
          exp:hasLocation ?location;
          hex:withObjectSetting ?setting.
     ?time time:inDateTime ?datetime.
     ?datetime rdf:type time4hex:Morning.
     ?com rdf:type hex:PositiveIEQFactor,
                   hex:DimVisualComfort.
     ?setting rdf:type
              bim4hex:ShadingDeviceSetting;
              bim4hex:hasSettingObject
                              ?object;
              bim4hex:hasSettingState
                              ?state.
    FILTER (?location !=
             bim4hexAbox:Room16.3.12)
}
group by ?location ?object ?state
order by  desc (?NrOfSetting)
```

The presented query corresponds to the competency question 11. Similarly, the query can be designed for question 10 by changing the types of `?com` and `?setting`. The query and result for competency question 10 are omitted here.

5 Discussion

We evaluated the ontology in two use cases by means of SPARQL queries. As we reported the results are promising.

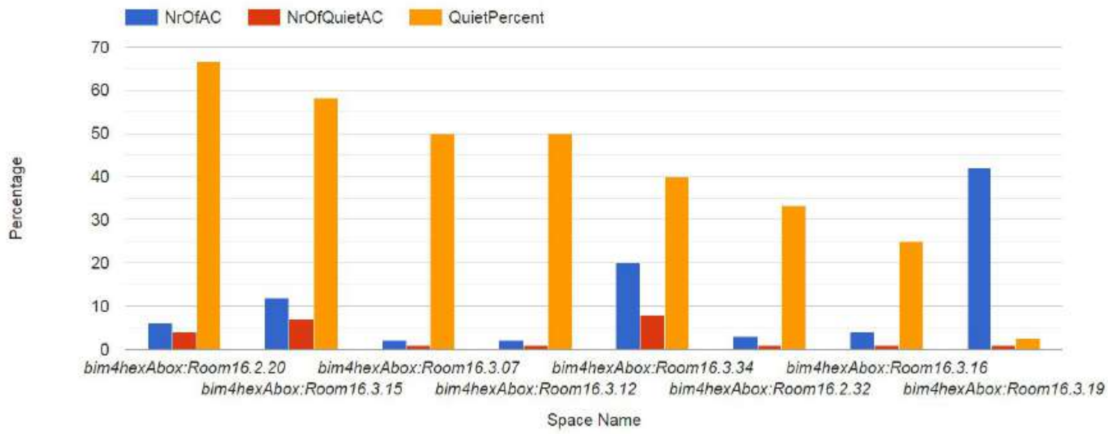

Figure 6. Quiet spaces in the morning.

Location	Object	State	NrOfSetting
R16.3.15	WindShutR16.3.15	PartlyDeployedStateInst	3
R16.3.19	WindShutR16.3.19	FullyDeployedStateInst	2
R16.3.19	WindShutR16.3.19	PartlyDeployedStateInst	2
R16.3.15	WindShutR16.3.15	FullyDeployedStateInst	1
R16.3.16	WindShutR16.3.16	FullyDeployedStateInst	1
R16.3.22	WindShutR16.3.22	NotDeployedStateInst	1

Figure 7. Ordered recommended settings for positively dim light.

However, we have identified some limitations. First of all, ontology serves merely as an aid for the initial step for analyzing data. Further on, data analysis techniques are required when one desires more profound and rigid results. This is in particular the case when evaluating quantitative or time-encoded data. For instance, an experience about a room from one day ago should in an extended analysis treaded differently than an experience from last year (see the first use-case).

Furthermore, although human experiences can reveal some facts of the reality, it is not sufficient to utilize human experiences alone in an objective way. The great strength comes from combining human experiences within the context of more objective information, such as sensor observations, weather information and so on.

6 Conclusion

Understanding human experiences of Indoor Environmental Quality (IEQ) has potential benefits including reducing energy demand and enhancing occupants' comfort. We provide an ontology for capturing human experiences about the several dimensions of IEQ in spaces by means of which we confirm the following hypotheses:

- Human experiences about IEQ factors can provide insights about their spaces;
- Human experiences about IEQ factors can inform building settings.

The ontology consists of three modules: Hex, bim4Hex and Time. It formally defines the domains of IEQ, experiences and their relationship to Building Information Modelling (BIM) and time.

In order to evaluate the HBC ontology, we collected data through designed human experience survey and converted them into the Resource Description Format (RDF) compliant with HBC ontology. With the help of reasoning, all desired implicit data were obtained. SPARQL queries were designed for answering questions based on two identified use cases corresponding the hypotheses. The queries performed over the gathered data are able to provide expected results. This supports a conclusion that HBC has the ability to leverage the Semantic Technologies to provide insights of spaces and inform building settings.

With large sources of human experiences, such as hotel reviews written in text, the system can provide the advanced searching options based on IEQ, e.g. quiet rooms or rooms with good visual comfort. In addition, the ability to predict human IEQ could assist towards more informative control decisions in specific Building Management Systems.

Abstract -

Everything starts from a piece. Bits and pieces are collected to form an entire structure. PIECE 3D is a framework for developing 3D education for the construction engineering field. Construction processes are dynamic and complicated. There are many components, and some processes are hard to understand from 2D pictures or even clips/videos. Thus, to improve the education system, this paper presents a portable interactive 3D education framework. As a case study, we developed rebar work process and measured students' performance and satisfaction. Compared to existing BIM education model, PIECE3D outperformed in portability, conveying educational objectives in 3D, enhancing understanding the processes of rebar, and triggering the interest of students.

Keywords -

3D education; Virtual Reality; BIM; Portable

1 Introduction

Building Information Modeling (BIM) has various features such as integrating and managing the information, illustrating the progress of work and visualizing finished models. Recently, BIM has been used as an educational tool because of its 3D visualization feature. However, education and training are not BIM's main objectives; thus it cannot serve well as an educational tool due to its functional constraints.

Education needs adequate scenarios with objectives and methodologies. For some fields like art and music, creativity should be emphasized without fixed direction. However, when it comes to engineering knowledge transfer, there are terms and processes which are worth remembering. This holds true with construction engineering education. Terms and processes of work need to be taught with objectives and a specific scenario so that students can grasp the concepts quickly, and those concepts become embedded in long-term memory. The delivery method needs to be intuitive and convenient.

For delivery, we decided to use a smartphone-based platform as most people possess smartphones these days and carry them wherever they go. Thus, we concluded that users can review the learning materials whenever and wherever they want with smartphones. Smartphones also have the advantage of possessing touchscreens rather than mouses or keyboards. Touchscreens can aid intuitive understanding of 3D models due to their gestural interfaces.

Considering both software and hardware, this study designed a framework for 'Portable Interactive Education for Construction Engineering in 3D (PIECE 3D).' In order to do so, we first analyzed needs and determined the work types to develop a model. Then, a 3D model was designed, an interactive scenario was constructed, and an interactive scenario-based 3D model was programmed. Once the model was developed, an experiment was conducted to measure students' learning performance and satisfaction with and without PIECE 3D in a controlled experiment. Control material was built on BIM-based learning, and experimental material was built on PIECE 3D. Finally, the difference between the experimental and control groups was evaluated with the t-test.

2 Literature Review

Three dimensional technologies have been used creatively to create different course materials. Ku and Mahabaleshwarkar proposed a new concept of Building interactive Modeling which augments the concept of Building Information Modeling to facilitate interaction [1]. They focused on safety training and equipment operation training. Irizarry et al. introduced layers that bring up exterior walls or even a house in order to execute structural analysis between formwork and loads [2]. They compared 2D and 3D views of rebar and recorded answers from students. Kim focused on teaching construction details and material quantity take-offs and assessed the effectiveness of BIM [3]. However, these BIM-based studies are not portable nor scenario-based as compared to the approach suggested in our paper.

Virtual Reality (VR) has been applied to general education with positive effects. Construction engineering educators have adopted VR to increase understanding and immersiveness through visualization and interaction. Messner et al. programmed cave-shaped IPD (Immersive Projection Display) to allow students to interactively develop a sequence of arrangements for a room [4]. The room consisted of 'air handling units', 'off-module platform', 'fire protection valve station' and so on. Sampaio and Henriques programmed a 3D exterior wall and bridge [5]. For instance, in rebar work, the components are grouped into 'footing', 'column', 'wall', and 'beam'. Sampaio et al. separated construction engineering education based on life-cycle and provided a 3D VR education model in each section [6]. Sampaio and Martins compared two different construction engineering methods for bridge construction [7]. Park et al. suggested IBAM (Interactive Building Anatomy Modeling) for experiential education [8]. They focused on assembly & disassembly of the building elements in terms of anatomical breakdown. However, as they created the materials based on a finished model, the compositions of building components were limited to components that remain in the finished model. For instance, components that are used temporarily such as forms and scaffolding were not considered.

The history of traditional education based on paper and pencil is far longer than that for any other tools. Paper and pencil allow writing, drawing and modification to be easy and quick. However, paper has some limitations. It is demanding to retrieve paper documents as they take physical space. It is also difficult to manage and classify the large amount of papers when accumulated. The advent of computers overcame the limitations of paper. However, though computers have many advantages, there are limitations to using them in a lecture. First, computers are difficult to configure for each student in each class. Also, they are relatively heavy to carry. Thus, portable devices such as laptop and pocket PC were devised and applied in construction engineering education.

More recently, smart devices such as smartphones and tablets influenced not only the social atmosphere but construction engineering education. Smart devices are handy as they are portable and touch-based. While there are many construction engineering education studies based on computers, there are few based on smart devices. Pedro et al. tried smartphone-based education [9]. However, the content was in 2D rather than in 3D and was limited to finding safety issues between two similar pictures. Nevertheless, because of the numerous advantages that smartphones have, such as communication, search and entertainment, we developed a smartphone-based platform.

3 The Framework of Portable Interactive Education for Construction Engineering in 3D (PIECE 3D)

3.1 Need Analysis & Work Type Selection

In order to discover the needs of PIECE 3D, a survey of 31 practitioners was conducted. Participants' work experiences and positions varied. Participants consisted of 20 practitioners with less than 5 year experience, 4 practitioners with more than 5 years and less than 10 years, and 7 practitioners with more than 10 years. The participants' main duties varied as well: 11 construction workers, 7 office workers, 4 managers, 4 researchers, and others. Five questions were asked in this survey.

Experienced tools during construction engineering education

Perception towards current education system

Applicability for 3D (VR) learning

Selection of topics to develop in 3D

Possible limitations

The results indicated that educational institutions mainly use textbooks (33.8%), handouts (29.9%), site visits (18.2%) and videos (13.0%). Concerning the current education system, 12 respondents were positive, 13 were neutral, and 6 were negative. This number indicates that the current education system is helpful to many, yet has gaps to be improved. Based on the survey, we concluded that PIECE 3D should neither exclude nor neglect current education paradigms. Rather, the new model should be an additive one that could improve the existing ones.

Although some (22.5%) of the respondents had a negative opinion of VR due to the ambiguity of VR's role and the time and cost it will take to build the model, most (77.4%) of the respondents agreed that virtual reality-based content will be effective when applied to construction engineering education.

3.2 Scenario Setup

A generalized method for learning module development that we also followed for our own module development is described in this section. Based on the survey, needs were identified. A scenario for the contents could be developed either from scratch by receiving advice from practitioners, or it could be excerpted from existing content sources such as textbooks. For this study, we used both methodologies. We used textbooks for terms and visited experts to learn how the processes work in the site. We created a representative scenario for a typical case for a given topic.

3.3 Model Development

To design the components in 3D, it was reasonable to acquire an existing BIM model. We acquired an existing model from 'Tekla', and imported it to 'Revit' to modify or remove some components. Then, to build a scenario with interactions, 'Unity' was used.

3.4 Model Validation

To validate the suggested model as an integrated learning tool for effective teaching in construction engineering education, a series of assessments were conducted in undergraduate-level courses before actually implementing in traditional lectures.

4 Case Study: Reinforcement Bar Work

4.1 Need Analysis & Work Type Selection

Based on 'Korean Standard Specification for Building Construction (2013),' 20 out of 28 major work types and 51 out of 203 detailed work types were selected. These topics were chosen considering complexity, importance and 3D visualization potential. The survey ranked construction work types that could be visualized in interactive 3D.

According to the survey, steel work should have been selected for the case study (Figure 1). However, after consideration, rebar work was selected, because respondents with less than 5 years experience strongly insisted on the importance of rebar work. As less experienced practitioners tend to rely more on knowledge and experience from the universities or other institutes, their needs were considered to be more critical than the overall needs of the respondents.

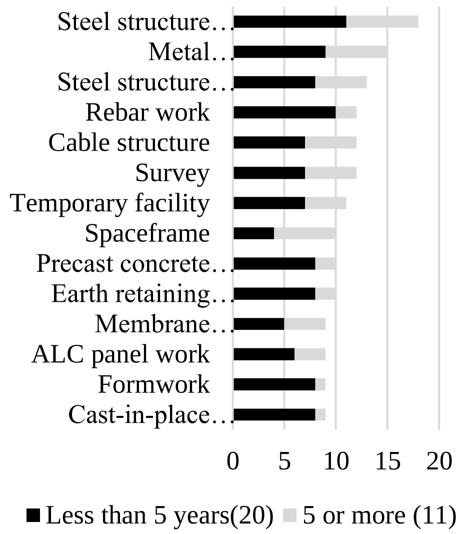

Figure 1. Survey results for work type preferred to be developed in 3D

4.2 Scenario Setup

We set up an example scenario. Actual processes can be flexible. The process sequences from foundation, column, wall, beam to slab were designed. The sequences are illustrated in Figure 2. Before any footing or foundation is built, the elevator pit is constructed in order to dewater the excavation volume. To construct the elevator pit, bottom bars, rebar supports, top bars, vertical bars and horizontal bars are built in that order. Rebar supports exist to support top bars. Vertical bars should be placed before horizontal bars as horizontal bars cannot stand alone in the air. Mostly, internal bars are constructed before external for the convenience.

Once the elevator pit is constructed, types of footings or foundations are selected. Single footings support one column while strip footings support multiple columns in a row. Mat foundations also support multiple columns but in multiple rows. They contain rebar supports between bottom and top bars.

In order to connect footings/foundations and columns, dowel bars are planted. Then, main bars are connected to the dowel bars in the vertical direction followed by tie bars in the horizontal direction. Walls are constructed with the same principle.

Beams have a special process. For beam, top bars are separated into two parts: (1) the edge and (2) the rest. Two top bars on the edge are placed on the wedge to carry the stirrups. The workflow of the beam is top bars (edge), stirrups, bottom bars, top bars (rest) and the cover bars.

Lastly, for the slab, the end parts of the bars go before bent bars. The middle part goes after bent bars. It is due to the shape of the bent bars, which adds tensile force of the rebar. Main and sub bars refer to the position of the rebar.

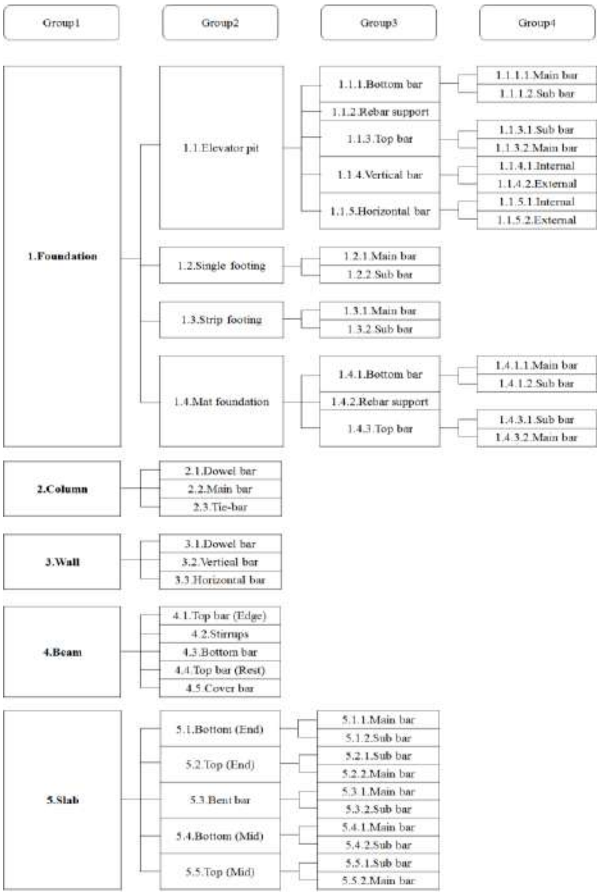

Figure 2. Summary of rebar work processes

4.3 Model Development

PIECE 3D was developed in three steps. The first step was to design the components in 3D. As we acquired an existing building model from 'Tekla', and imported to 'Revit,' (Figure 3) it was not difficult to dissect some components. Once the main components, such as foundation, column, wall and slab were ready (Figure 4), we saved the files respectively. These were used in a "hint" level to demonstrate finished shape as a reference and line silhouette in level 1. Then, components were dissected once again as subcomponents, subsubcomponents and so on. Subcomponents and subsubcomponents were used in level 0, level 1 and level 2.

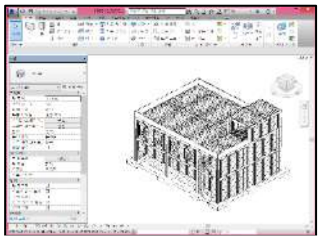

Figure 3. Entire BIM model

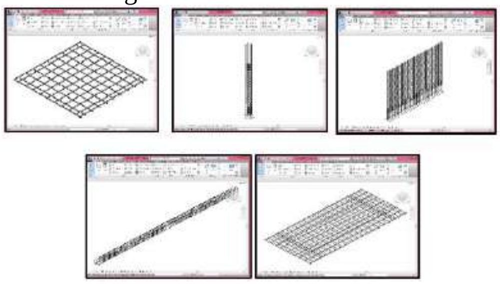

Figure 4. BIM model components (Foundation, Column, Wall, Beam, Slab)

The second step was to create a scenario (Figure 5). From level 0, students can learn the terms of rebar components not only top or bottom rebar but specific terms such as support rebar, stirrup and dowel bar. Students can zoom, move and rotate the components in any direction. In this level, students can also learn the process of rebar work as it is arranged in sequences. From hint level, students can view the finished design before moving on to next level. Level 1 shows line silhouette in green. Students can zoom, move and rotate the given components in order. From level 1, students can review the process and learn the right positions of rebar components. Finally in level 2, students are required to perform their learning experience from previous levels. A black space is given, and students can assemble the components in the right sequence at the right position. The labeling is not in order but is in random to check student's understanding of the processes. Screenshots of each level are illustrated in Figure 6.

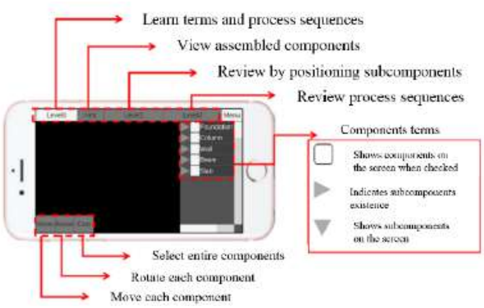

Figure 5. Roles of different levels and buttons

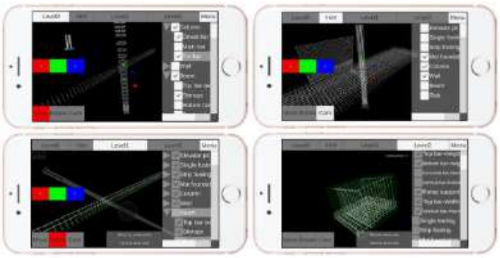

Figure 6. Screenshots of each level

The third step was to create interactions. There are unique features in PIECE 3D. Because the model is based on smartphone, it is touchscreen-based. In this case, it is complicated to move or rotate in 3D as the smartphone can only recognize two fingerprints at once. To overcome such barrier, we decided to integrate a feature called 'Gizmo,' which allows user to view in 3D directions.

4.4 Model Validation

To evaluate the usefulness of PIECE 3D as an integrated learning tool for an effective teaching approach in construction engineering education, we conducted a series of assessments in an undergraduate-level course, 'Building Systems' in the Department of Civil, Environmental and Architectural Engineering at Korea University. The experiments compared the effectiveness of PIECE 3D for learning with that of a tabletop computer. The course is a three-credit course for second year or higher grade students. Every year, 50-80 students take this course as a prerequisite for 'Building Construction' so that consistency in prior knowledge is maintained. 'Building System' introduces various kinds of wooden, reinforced concrete and/or steel buildings. 'Building Construction' investigates deeper the processes and methods of building construction.

The experiment was designed to meet two objectives: 1) learn the terms of rebar and 2) learn rebar fabrication processes. We believed students taking 'Building System' were suitable for this experiment, as they have learned the basic concepts and characteristics of rebar. This experiment would facilitate overall and detailed understanding of rebar work before taking 'Building Construction' and would also engage the students' interest in learning by doing.

Out of 29 students who participated this experiment, 26 students were taking Building Systems in Spring 2016. All 29 students were in department of Civil, Environmental and Architecture Engineering. Participants consisted of 11 second year students, 16 third year students and 2 fourth year students. Students were asked to come to the office (Engineering Building 351) individually or in pairs. A laptop and a smartphone were prepared in the office.

The operating system of the laptop was Microsoft© Windows© 8.1K (64 bit version) and it contained 8GB RAM. The BIM program used for the experiment was Autodesk Revit 2015.

The operating system of the PIECE 3D was Microsoft© Windows© 10Pro. The virtual reality engine used for this smartphone-based program was Unity 5.3.1f, and the IDE (Integrated Development Environment) was Visual Studio 2015. The language was C# and the test phone was a Samsung Galaxy Alpha.

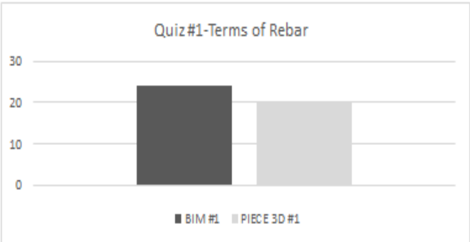
It took 40 min to an hour for students to complete the experiment. Students were first asked to keep the objectives in mind. Then, the instructor explained how to view 3D models from a BIM program embedded in the laptop. By using keyboard (shift) and mouse (scroll wheel), students were able to zoom, move and rotate each and overall components. With the 'view cube' that assists visualization in Revit, students were able to view from the direction they wanted. Students could see eight components: elevator pit, single footing, strip footing, mat foundation, column, wall, beam and slab. Students were asked to pay attention to terms and processes. Students were allowed to ask questions to the instructor freely so that interactive atmosphere could be created. The instructor kindly explained basic principles of processes so that students can infer the sequences. For instance, the instructor gave hints such as 'top bar' is built after 'bottom bar,' 'internal bar' is built before 'External bar,' and as horizontal bar cannot stand alone in the air, 'vertical bar' is placed before 'horizontal bar'. After viewing all eight components, students were asked to answer three questions in a quiz including terms and processes of rebar work. Question 1 was to recognize 'column' components terms, and questions 2 and 3 were asked to measure the understanding of the sequences of 'mat foundation' and 'beam.'

Then, students were told to control smartphone-based model. The instructor showed how to check/uncheck the checkbox, how to zoom and move and rotate the components. Students went through all four levels (level 0, hint level, level 1, level 2) and were asked in another quiz to answer three different questions. Question 1 was recognizing 'elevator pit' components terms, question 2 and 3 were asked to measure the understanding of the sequences of 'wall' and 'slab.'

Finally, based on students' experiences, they were asked to evaluate BIM model and PIECE 3D. The survey included 15 criteria and they are assorted into four groups: 1) device suitability, 2) scenario quality, 3) device convenience and 4) user interest.

Based on the quiz and satisfaction evaluation results from 29 students, we conducted the t-test to find the significance of the satisfaction difference between the BIM-based model and the PIECE 3D model. SPSS 12.0 K was used to analyze the data.

Since the sample size is small (N=29), the normality of data need to be examined before proceeding to the t-test. As the results of the quizzes do not follow a normal distribution, because they are scored either right or wrong, we decided to evaluate them separately. Figure 7 represents the results of the quiz. While BIM-based excelled in questions about terminology slightly, for processes, PIECE 3D outperformed considerably.



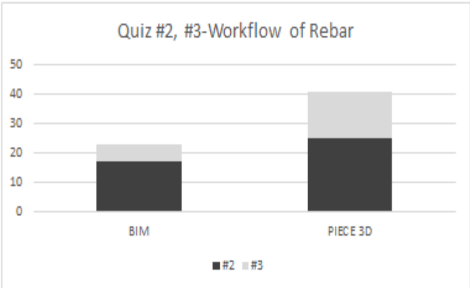


Figure 7. Result of quiz (Total: 29)

Once the students finished the quiz, they were asked to fill out the survey questionnaire to measure PIECE 3D satisfaction. Results are presented in Figure 8 and criteria are explained in Table 1.

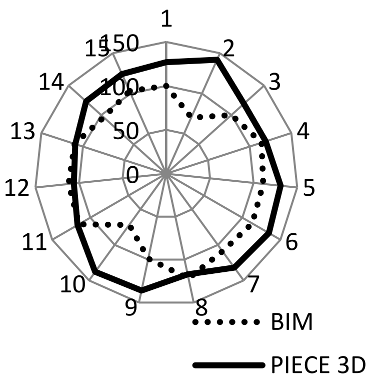

Figure 8. Results of satisfaction survey

Table 1. Criteria of satisfaction survey

Criteria (1: Strongly disagree, 5: Strongly agree)
1) Easy to access
2) Easy to carry
3) Adequate during the lecture
4) Complements traditional materials (e.g. textbook)
5) Successfully achieves objective
6) Increases understanding in 3D
7) Logical contents included
8) Detailed contents included
9) Easy to learn the terms
10) Easy to learn the processes
11) Adequate device speed
12) Easy to use
13) Convenient to use
14) Immersive
15) Interesting

Before conducting paired t-test, normality test of difference between paired data was carried out. As criteria 3, 12, 13, 14 have p-value higher than 0.05, it can be said that they follow normal distributions. Thus, a paired t-test can be conducted. For the other criteria that had p-value lower than 0.05, a Wilcoxon test was conducted.

Though there are differences in amount, for all eight pairs, PIECE 3D scored higher when it came to comparing means. Considering p-value, the author concluded that criteria 14 had significant differences between BIM and PIECE 3D. In other words, when it comes immersiveness, PIECE 3D surpassed the previous tabletop based BIM model. We also executed Wilcoxon test for the rest of the criteria.

The results reveal that for criteria 1, 2, 5, 6, 7, 9, 10 and 15 the alternatives are statistically different, and PIECE 3D outperforms the existing BIM model. Not only was PIECE 3D portable, but as it conveyed the educational objectives successfully in 3D, it was effective for students to understand the materials especially the terms and processes of rebar. It also triggered the interest of students.

5 Conclusion

This study proposed an effective education system using BIM and VR technologies. From needs analysis to model validation, four steps were taken to build ‘Portable Interactive Education for Construction Engineering (PIECE 3D).’ First, we discovered the needs from industry to find which topic would be preferred to be taught in 3D. Then, we set up a standard or a common process for the topic we want to develop. Next, we developed smartphone-based content. Finally, we compared PIECE 3D with an existing BIM-based tabletop model in two perspectives: hardware and software.

From the quiz results and satisfaction survey, it became evident that PIECE 3D outperforms the tabletop model overall. PIECE 3D not only successfully helped deliver course objectives, but it facilitated understanding in 3D. Reviewing processes from ‘Level 0’ to ‘Level 2’ enabled students to learn the terms and processes of rebar work easily.

The case study of rebar work is only a part of the whole of construction works. For the future studies, more models can be developed from earthwork to demolition. Also, this model could be extended to different types of construction such as infrastructure or plants. Although we had some technical limitations due to the small screen and touchscreen system because of our smartphone-based platform, it was intuitive and immersive.

Lastly, we would like to emphasize the importance of current education systems. The suggested framework should not replace the current systems but complement them, so that students can interact better and effectively learn in class.

Acknowledgement

We would like to record our appreciation to Jujin Kim, for developing the application, Myungdo Lee for providing BIM data and Jihong Koo for guiding us to learn the terms and processes of the rebar work. Special thanks to Professor Hunhee Cho and Kyung-In Kang for supervising Master’s thesis.

Evaluating artificial intelligence tools for automated practice conformance checking

S. Kang[a] and C.T. Haas[a]

[a]Department of Civil and Environmental Engineering, University of Waterloo, Canada

E-mail: s43kang@uwaterloo.ca, chaas@uwaterloo.ca

Abstract –

Checking conformance of construction management practices to practice specifications is typically performed manually by experts in the Engineering and Construction (E&C) sector. Though conformance checking is known to increase performance of a project, this process takes considerable time as several professionals have to go through thousands of pages of documents, complex workflows, and personal interviews. This paper aims to evaluate AI tools including Text mining, process mining, and image data mining for their utility in assisting conformance checking in construction management. Automated conformance checking may not only reduce manual and repetitive work by experts but also reduce human errors. Examples are demonstrated for initial validation.

Keywords –

Conformance; Artificial Intelligence; Software Evaluation

1 Introduction

The Engineering and Construction (E&C) sector is slower to adopt new technologies than other industry sectors. Its conservative approach to new technology is partly due to its large scale which leads to greater risk and its complexity that involves many stakeholders. However, considering that a 1% rise in productivity could save $100B a year worldwide [1], the industry should move forward to exploit new technologies. Especially in the construction management field, the use of the state-of-the-art technology is promising.

Good construction management balances professional judgment with conformance to references such as best practices, policies, standards, and procedures. 'Conformance,' 'conformity,' and 'compliance' are used as synonyms. There has been intense debate on use of the words. ISO 9000:2000 suggested to use 'conformity' and drop both 'conformance' and 'compliance' for quality management system. The word 'conformance' seemed to have lost its status. However, according to ISO 9001:2015, 'conformance' is redefined as choosing to do something in a recognized way and 'compliance' is doing what one is told to do. Both words still exist and are widely used throughout the literature. While ISO still prefers to use the term 'conformity,' the term 'conformance' was selected for two reasons. First, 'conformance checking' is a term that already exists and is commonly used in the process mining field. This could maintain consistency and avoid confusion. 'Conformance' rather than 'compliance' was adopted because of the intention to define something less strict than abiding by the law or meeting regulations. Compliance fits better with laws or regulations, whereas conformance better suits with pursuing best practices, policies, standards and procedures.

'Checking,' 'measuring' and 'evaluating' imply different meanings, although commonality exists. Checking usually implies yes or no, true or false, or pass or fail. Measuring implies numeric results, and requires metrics, observations, and formulas to derive the values. Evaluating implies not only quantitative but qualitative assessments. This paper introduces tools that can 'check' conformance, and 'evaluate' commercial software. Thus, the objective of this paper is to evaluate how artificial intelligence (AI) technologies can be adopted to aid automated conformance checking in construction management.

In order to check conformance, relevant AI technologies were evaluated. AI is a generalized term for computers replicating human intelligence in learning, decision-making, vision, speech, etc. Text mining, process mining, and image data mining tools that have artificial intelligence background were investigated in this paper.

2 Literature Review

The concept of artificial intelligence (AI) existed since the 1950s, but the modern definition was built from research done in the 1970s. AI can be defined as a system that rationally thinks and acts like humans [2].

AI has been divided into parts, as the technology is still limited to integrate all capabilities in a single entity.

In E&C sector, AI has been constantly used to solve problems in structural engineering [3], transportation [4, 5, 6], and geotechnical engineering [7]. A conceptual model such as Industry Foundation Processes (IFP) for conformance checking has been developed [8] as well as Genetic Algorithms [9]. Though some researchers insist that much of them are often theoretical and are difficult to apply in the real world [10], the recent explosion of commercial applications of AI challenges that assessment.

For project management in E&C sector, AI was used to solve problems such as site-layout modeling [11] and generating construction project plans [12]. Levitt et al. [12] suggested that AI technology can provide ways to generate and update plans in actual project progress from stored knowledge. Tommelein et al. [11] enabled computers to mimic designer's layout and add flexibility and functionality to existing model.

Conformance checking and measurement has been investigated since early 1990s. Rajamani, and Rehof [13] developed a mathematical model for contract conformance. Abdul-Rahman [14] derived costs from non-conformance and suggested a quality cost matrix for construction projects. Yurchyshyna et al. [15] proposed an expressive model and a knowledge-based system for checking a construction project against technical norms by matching the project with the norms. Lipman et al. [16] reviewed and assessed conformance testing methods for product data models used in the construction industry. Nawari [17] optimized and simplified automated code and standard conformance checking by leveraging building information modeling. Zhang and El-Gohary [18] suggested Semantic Natural Language Processing (NLP) based information extraction for automated regulatory compliance checking.

3 Methodology

To measure conformance, four components were identified and they are illustrated in Figure 1. This paper covers documents and workflows components. However, people and actions are also included in these two components as people build and implement these components. For each component, what to check and how to check the conformance are also listed in Figure 1.

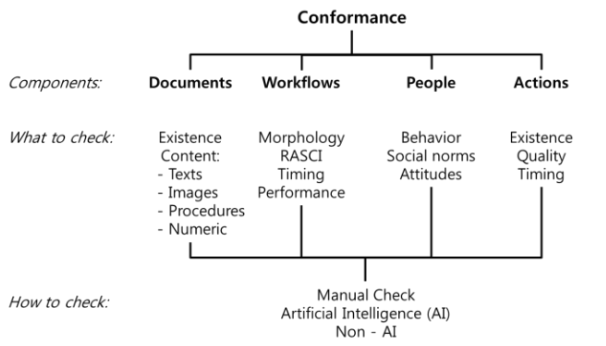

Figure 1. Conformance components

Despite the history of artificial intelligence (AI), application challenges remain in the E&C sector. The difficulty of identifying the appropriate tool to suit a new situation; the need for large amounts of input data for tools to be usable; the opaqueness of most tools; and the difficulty of realistically interpreting the solutions to highly tailored problems are some of the reasons behind [10]. On the other hand, this paper focuses on how to apply AI to improve conformance problems.

Throughout this paper, technologies that could be applied to check conformance are introduced and evaluated. Data mining is the computing process of extracting patterns in large data sets. Its goal is to transform the extracted information into an understandable structure for further use. Data mining is divided into three categories in this paper: text mining, process mining, and image data mining, and some AI tools are introduced (Figure 2).

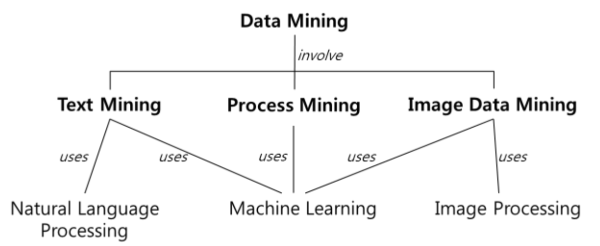

Figure 2. Tools for conformance checking

Text mining is the process of deriving high-quality information from text. Natural Language Processing (NLP) and machine learning algorithms can be used for text mining. NLP is an ability of computer software to understand human language such as speech and text. NLP is widely used to analyze large pools of legislation or documents. NLP can summarize blocks of text by extracting the central ideas and ignoring irrelevant information, automatically generate keyword tags and identify the sentiment of a text and reduce words to their roots using stemmer & lemmatization. Plagiarism detection tools, wordcloud generator tools and resume screening tools utilize NLP technology in this paper.

Process mining is also part of data mining that requires specific data such as an event log (i.e. case ID's, activities, timestamps, etc.), and machine learning algorithms. With event logs, practical workflows can be derived (process discovery), and conformance to the driven workflow can be checked (conformance checking).

Image data mining is a technology that aims at finding useful information and knowledge from large scale image data. It enables computers to gain high understanding from digital images or videos. This technology is intended to convert an image into digital form to extract information.

Machine learning is the computer ability to learn without being explicitly programmed. Machine learning enables construction of algorithms that can learn from data and make predictions or decisions. Machine learning is used for all categories in data mining.

4 Case Studies

To facilitate understanding, some commercially available software for Natural Language Processing (NLP), process mining, and image processing are introduced. Explanation of the purpose of these software, and ways to adopt them from management perspective are presented.

4.1 Natural Language Processing (NLP)

Among all the Artificial Intelligence (AI) technologies, NLP plays a critical role, as documents are mostly in the form of text. NLP can be used for preprocessing such as detecting copy and paste with plagiarism detection tools, analyzing frequency of words with wordcloud generator tools, and matching selected keywords with resume screening tools.

4.1.1 Plagiarism Detection Tools

There are two types of plagiarism detection tools: one that searches from the web or a relevant database (e.g. journal papers (iThenticate), class homework (Turnitin)) to match the result, and the other that finds similarity between two documents. To find potentially useful software tools, assessment of 15 commercial software were investigated. Texts excerpted from Construction Owners Association of Alberta (COAA)'s best practices and distortions of them, accuracy of software performance was tested (Table 1).

Table 1. Example used for plagiarism detection tools

Text A (Original Text from an institution): "It is recognized that the use of illicit drugs and the inappropriate use of alcohol and prescription and non-prescription drugs can have serious adverse effects on a person's health, safety and job performance. A solid industry-wide model, including both a policy and guidelines, will help to enhance the level of health and safety at the workplace."
Text B (Distorted text version from Text A): "The use of illegal drugs and the unsuitable use of alcohol and prescription and non-prescription drugs can have severe hostile effects on a person's well-being, safety and job performance. A solid model, including both rules and guidelines, will help to improve the level of health and safety at the workplace."

Among the 15 software tools, eight different ones were evaluated, as they were either free or offered free trials. Among them, five offered plagiarism detectors browsing the web or databases, two offered text comparison, and one offered both.

The best plagiarism detector was PlagScan. It found the original source from the web computing 98.8% as plagiarized. Even when the distorted version of the excerpt was entered, it was still able to identify the original version computing 71.8% as plagiarized. According to PlagScan, the plagiarism percentage should be less than 5%. SmallSEOTools also found the exact source of the original text estimating 100% as plagiarized; however, estimated 0% as plagiarized for the distorted version and could not the find original source. Duplichecker, QueText and Plagium were not able to identify the right source; thus, estimated 0% as plagiarized.

Next, comparison between *Text A* and *Text B* was drawn. Copyscape was the best software in terms of comparing two texts resulting 75%, 83% matching. The reason for two values is because the total numbers of words in *Text A* and *Text B* are different. Table 2 provides the results. However, Copyscape is limited to word matching. It does not understand semantics within the context. Plagium estimated 40.8% as plagiarized. Interesting part of Plagium is that it provided sentence plagiarism as well as paragraph and page plagiarism. Copyleaks estimated 16% as plagiarized only considering continuous words that are identical.

Table 2. Results for word matching (Source: Copyscape)

59 words, 75% matched	**Matching word count**	**53 words, 83% matched**
It is recognized that

Plagiarism detection tools can check conformance in construction management. Not only the original sources of documents can be found but copy and paste phrases may be detected. If two documents' matching level is higher than a threshold that has been set, conformance is no longer valid. Software that compare two sets of texts may be applied as well using same words or same sentence structures detecting techniques. By setting a threshold, conformance can be checked.

4.1.2 Wordcloud Generator

Wordcloud generator can count words included in a document. It can automatically remove stopwords. Stopwords are the words that do not have important meanings such as articles and prepositions. Frequency of words can be automatically detected and more frequently to less frequently used words can be recognized. However, this software cannot recognize synonyms nor read sentences by context. For example, 'environment' and 'environmental' are considered as two different words, and 'construction' that has two different meanings are counted as one word.

This software can be adopted to identify keywords. High frequency of words does not necessarily mean that those words are more important than others. However, it is useful to track all words at once after processing such as removing the stopwords. Once keywords or key phrases are identified, the existence of them can be an indicator among others to check the conformance. Figure 4 and Figure 5 are result screenshots for examples from Construction Extension to the PMBOK Guide section 3.1.11 Project Health, Safety, Security, and Environmental Management (HSSE) (Table 3).

Table 3. Example used for wordcloud generator

Text C: "Site security and controlled access are discussed for construction job sites. Employee health and wellness are introduced for construction personnel as these directly affect construction project risk and safety. Trends include virtual technology and environmental certifications. While HSSE is applicable to all industries, the unique hazards in construction projects intensify the need for additional measures. The Planning Process Group includes a proactive view of health, safety, and environmental policy compliance. In addition to employee health and site security, a comprehensive health, safety, and environmental management plan is developed to address specialized stakeholders, reporting requirements, documentation and record storage requirements, training, and additional government requirements."

For this paper, "wordclouds.com" was used.

Figure 4. Screenshot of wordcloud generator results (Wordcould.com)

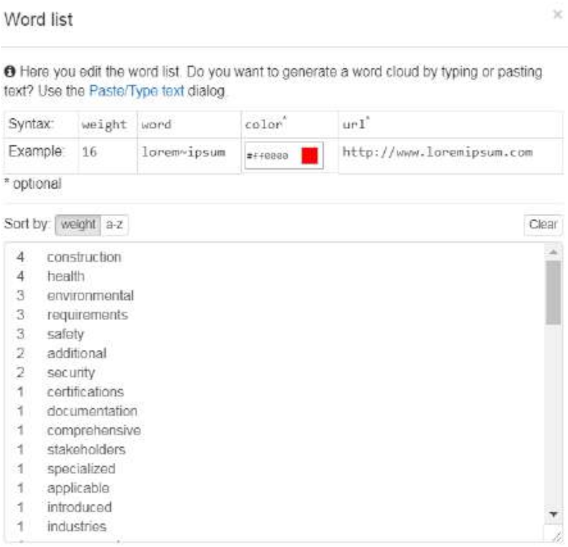

Figure 5. Wordlist from high frequency to low frequency (Wordcould.com)

4.1.3 Resume Screening Tools

Human Resources (HR) departments receive dozens of resumes a day. In order to reduce repetitive work, they use automated screening tools to match keywords they are looking for with candidates' resumes.

'Ideal.com' offers an artificial intelligence (AI) based recruiting system. Ideal's software can match keywords and can filter unqualified candidates. Powered by machine learning, next generation candidate screening software uses feedback from previous decisions. By using automated resume screening, HR can avoid skipping candidates who are competent. Candidates are screened and shortlisted instantly, so that HR knows whom to contact first.

By applying resume screening tools, comparing practice specifications with construction execution plans is feasible. If construction execution plans does not includes practice specifications, conformance cannot be achieved. With machine learning algorithms, conformance can be checked and data could be accumulated for the future usage.

4.2 Process Mining Tools

Process mining tools are for reconstructing workflows and representing them in formal process notation or iconography. They also can detect vulnerabilities automatically, analyze processing times, and detect bottlenecks. There are commercial process mining tools available such as Celonis, Disco, EDS, Fujitsu, Icaro, LANA, Minit, mylnvenio, Perceptive, and ProM. Once the process or workflow is discovered based on streamlined event logs, unrefined original event logs can be replayed or overlapped over the refined workflow, and conformance can be checked and deviations can be identified. By simply using filters, 'Disco' has allowed users to create process models. Pseudo case for Change Management was designed as illustrated in Figure 6. Case IDs, activities, and timestamps were entered and result is shown in Figure 7.

	Case Id	Activity	Timestamp

Figure 6. Eventlog input (Disco)

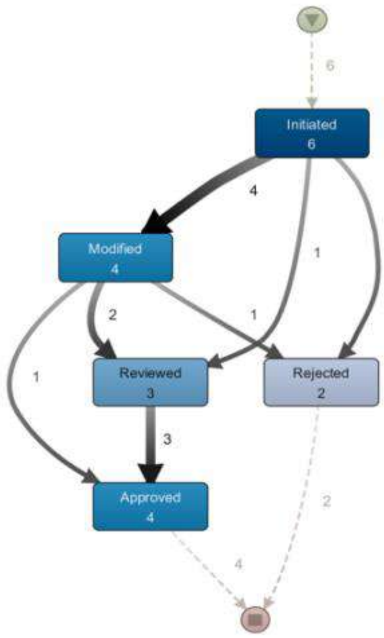

Figure 7. Result screenshot of process discovery (Disco)

LANAlab provides another software for process mining. It provides an academic version for free. LANA can discover a process model as well as develop a reference model. Figure 8 is the result screenshot of process discovery. For the input data, the same data that were used for Disco were entered (Figure 6).

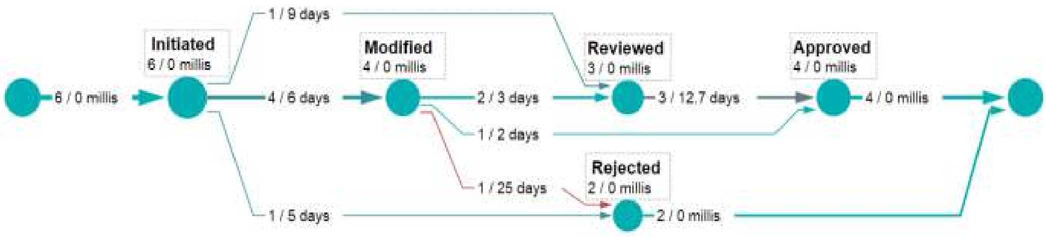

Figure 8. Process Discovery (LANA)

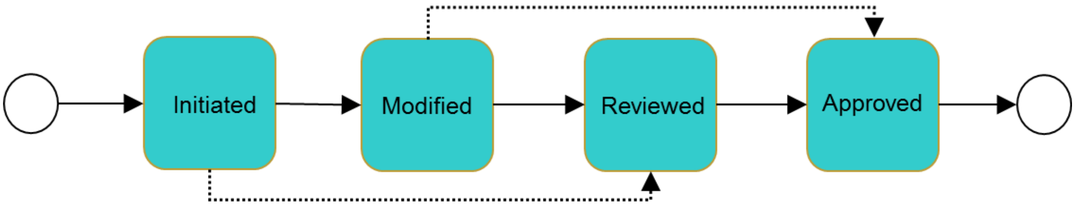

Figure 9. Reference Model in the Form of BPMN (LANA)

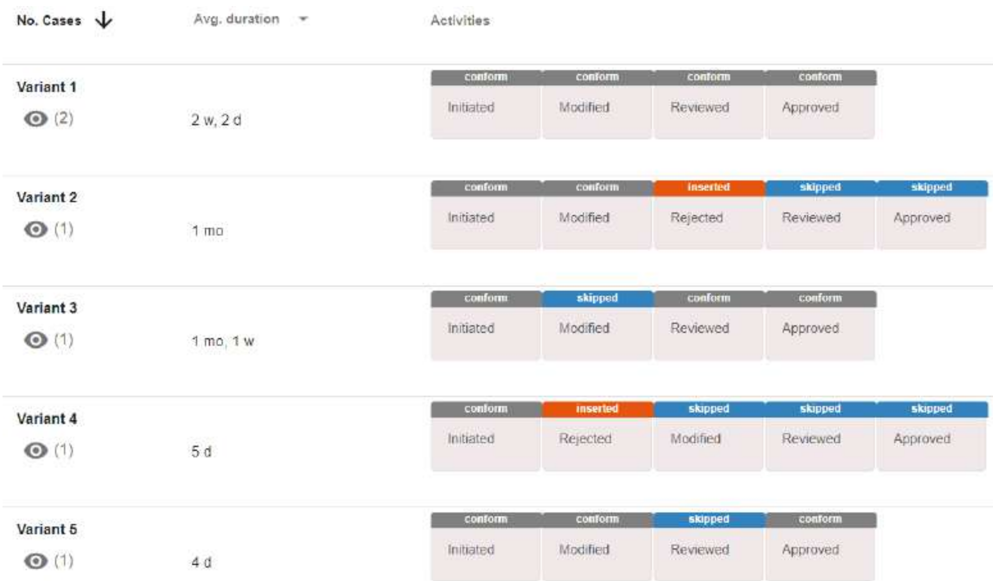

Figure 10. Variants Detected (LANA)

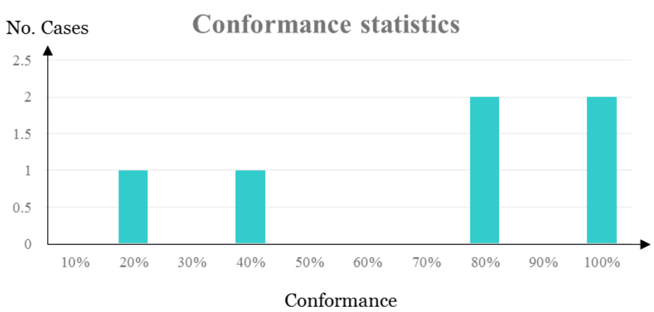

Figure 11. Conformance Statistics

The numbers in Figure 8 represent the number of cases and the average duration it takes. The reason why values are not assigned for activities is because only one representative timestamp has been entered for simplicity, and not start and finish. LANA is more advanced than Disco in terms of providing information. LANA also allows to develop reference model with process model. With the process model discovered from Figure 8, reference model was developed (Figure 9). Once the reference model was developed, variants were identified, and automated conformance checking became possible (Figure 10 and Figure 11). There are five different cases including one which is equivalent to the reference model. Conformance statistics computed how much each case conforms to the reference model. The x-axis of Figure 12 refers to conformance and the y-axis refers to number of cases.

Automated conformance checking tools from LANA can be useful for finding deviations from planned workflow. Planned workflow can be a reference model. Actual activities can be recorded in the form of event logs. These two can be automatically compared and checked.

4.3 Image Processing Tools

When communicating and implementing a good practice, images and/or photos may be included to facilitate understanding. With image processing tools, similarities or differences between two similar images or photos can be detected.

In this section, image search and image matching tools are introduced. Image search tools can browse the web to identify the original source of the image. Image matching can take place against a reference image. When it comes to conformance checking, image search tools can detect whether the query image is novel or not. Image matching tools can only be used conceptually yet because computers cannot understand the images to verify whether the images implies the same concept or not. Currently, only physical similarities or differences such as colors and shapes are detected. However, the importance is in the meaning and representation of images.

4.3.1 Image Search Tools

Image search tools are typically used for media intelligence, brand and/or copyright protection, and social media monitoring by browsing the web. It is composed of two key steps: indexation and retrieval.

The first step is to create a descriptor of the image content which can be referred as indexation. 'LTU Engine' suggests a visual signature for each image and describes its visual content with features such as color, shape, and texture. These descriptors are also called image DNAs. These image DNAs are then stored in a database. Retrieval is a special comparison technology by which an image signature can be compared at high speed with other image signatures from a database or the web for up to millions of images.

4.3.2 Image Matching Tools

LTU Engines' image matching tools use distinct pixel features to analyze visual content and identify matching images between a query image and references. Its image matching algorithm includes an optional matching zone parameter. The matching zone highlights where a query image matched with references. The matching zone details can be represented visually, as coordinates and as a percentage. The matching zone can be used to explain where and why two images matched.

4.4 Machine Learning

Machine learning can be adopted to all three types of AI software by receiving feedback from users or by learning autonomously, and learn to make better decisions. By retrieving results after checking the conformance, the computer can learn where conformance is maintained and where not. This information can be used for future conformance checking. Machine learning is often understood as data mining from a statistical point of view. It is partly because statistical cases have been solved more effectively with practical machine learning research.

5 Discussion and Conclusion

In this paper, artificial intelligence (AI) tools that can automate conformance checking have been evaluated. Although they cannot be the complete solution, there is potential for AI technology to be used as a basic toolset for aspect of conformance checking. By assisting construction management, this will not only save time and reduce human errors but also provide different perspectives and ways of checking the conformance. For future studies, more software, test cases, and data will be investigated as well as evaluated. Conformance will be measured and evaluated beyond just checking. Similarity of practice definition is necessary but not sufficient to ensure conformance. Implementation is most critical.
Plagiarism algorithms can be used in various ways. However, they are challenged to identify lexical changes, structural changes and multi-sources. Wordcloud generator should apply more of features related to semantics. There are Process Mining software tools commercially available. However, as

most of them are not open source, only two software were tested. Acquiring proper event logs was also difficult. Image processing technology still has performance gaps to be used in conformance checking. Computers should be able to understand the images so that it can categorize them.

Abstract –

Masonry structures in historical sites are deteriorating due to ageing and man-made activities. Regular inspection and maintenance work is required to ensure the structural integrity of historic structures. The inspection work is typically carried out by visual inspection, which is costly and laborious, and yields to subjective results. In this study, an automatic image-based crack detection system for masonry structures is proposed to aid the inspection procedure. Previous crack detection systems generally involve the extraction of hand crafted features, which are classified by classification algorithms. Such approach relies heavily on feature vectors and may fail as some hidden features may not be extracted. In this study, we propose a crack detection system which combines deep Convolutional Neural Networks (CNN) and Support Vector Machines (SVM). CNN is used in extracting features from RGB images and SVM is used as an alternative classifier to a softmax layer to enhance the classification ability. A dataset containing images of cracks from masonry structures was created using a digital camera and an unmanned aerial vehicle from historical sites. The images were used for training and validating the proposed system. It is shown that the combined CNN and SVM model performs better than the model using CNN alone with the detection accuracy of approximately 86% in the validation images. It is also shown that the system can be used to detect cracks automatically for the images of masonry structures, which is useful for inspection of heritage structures.

Keywords –

Convolutional Neural Network; Support Vector Machine; Masonry structures; Crack detection, Computer vision

1 Introduction

Maintenance and condition assessment of historic structures are vital for Thailand as they are the country's cultural heritage. Cracks are considered to be the primary concern for the durability and safety of masonry structures. Therefore, crack detection is very important for the maintenance of structures and must be detected at the earliest stage to avoid unwanted situations, such as damage to buildings, or the collapse of structure due to severe cracks.

Visual inspection is a common procedure that is used in the examination and assessment of the current state of historical buildings. However, this procedure is laborious and time-consuming as it requires the experience and specialised knowledge of inspectors to assess structural conditions based on the visual appearance of structures. Furthermore, the procedure cannot be conducted frequently due to high labor cost and prone to human-error, and often the sites cannot be easily inspected due to inaccessibility. Figure 1 shows an example picture of a temple in Ayutthaya province in Thailand, where the top of the stupa is extremely high and is not accessible for human inspection. Figure 2 shows a picture of the Chapel viaduct, which is a masonry structure, and cracks and other damages in the structures need to be detected and monitored. In this paper, we propose an image-based crack detection system to inspect these masonry structures. Figure 3 shows example images of cracks that are found from various locations around the temple and the viaduct.

Cracks in images can be detected by either using techniques related to handcrafted feature extraction or by using automatic feature learning, i.e. a deep learning, which is a technique proposed in this paper. Crack detection systems based on handcrafted feature extraction techniques generally consist of two main steps. The first step is to extract relevant features, such as edges [1], features based on a percolation model [3-4] and multi-features [6] from input images. Then, in the second step, classifiers such as Support Vector Machines (SVM) [5] and Neural Networks [8] are trained to determine if extracted features are crack or non-crack. Since cracks can have various types and forms, this makes the features extraction task difficult. Therefore, deep learning algorithms are better in learning features automatically from raw images and complex high-level features can be built from low level features [12]. Deep learning has been applied in many problem as it proves to be a better technique in the classification task [10].

In this paper, we propose an image-based crack detection algorithm, using convolutional neural network (CNN) as a feature extractor and SVM as a classifier. The image data has been collected using an Unmanned Aerial Vehicle (UAV) and a handheld DSLR camera from heritage masonry structures in Thailand and from a masonry bridge in United Kingdom as shown in Figure 1 and 2. The rest of the paper is organized as follows, Section 2 presents related works about automatic crack detection. Section 3 and 4 describe the methodology of the proposed system and experiments. Discussion and conclusion are drawn in Section 5 and 6.

Figure 1: A masory structure from Ayutthaya, Thailand, which is inaccesible for manual inspection. Hence, images are acquired using a drone.

Figure 2: The Chapel viaduct, Essex, United Kingdom, a masonry structure many visible damages.

Figure 3 :Sample images of cracks in masonry structures

2 Related Works

Many automatic crack detection systems are based on extracting handcrafted features. Abdel-Qader et. al. [1] applied four different edge detection techniques, i.e. Fast Haar Transform (FHT), Fast Fourier Transform, Sobel and Canny detectors for concrete bridges. The FHT was the best one among other detectors in the study. The limitation of edge detection algorithms is generally due to noise. Liu et. al. [9] applied image intensity features and Support Vector Machine (SVM) for tunnel crack detection. This method is prone to error due to noise.

Prasanna et. al. [7] proposed a crack detection system based on histograms for a bridge deck. Principle

Component Analysis (PCA) techniques are used for automatic inspection for concrete bridge decks in [2]. Yamaguchi et. al. [3-4] applied a percolation model for crack detection in concrete surfaces. Fujita et. al. [12] proposed a concrete crack detection system for noisy data using different filters for preprocessing to remove noise, followed by probabilistic relaxation and adaptive thresholding for the detection of cracks. Similarly, Prasanna et. al. [6] used STRUM (Spatially Tuned Robust Multi-feature) classifier for automatic crack detection on concrete bridges. In Prasanna's work, the proposed system applied intensity-based and gradient-based features with the combinations of scale-space features as the crack features, which were then classified. They demonstrated that the efficiency of the STRUM classifier was better than other image-based approach for crack detection.

For different types of cracks and images containing noise, the techniques based on handcrafted features fail to perform. Hence, automatic feature extraction based on learning techniques such as deep learning can perform well when compared to the techniques based on handcrafted features. Zhang et. al. [11] applied deep convolutional neural network for road crack detection from images collected using a low cost smart phone. Cha et. al. [13] used deep convolutional neural network (DCNN) for automatic concrete crack detection and presented 98% accuracy. Ellenberg et. al. [14] discussed several algorithms, including percolation approach, fractal method and tensor voting for crack detection. The paper also conducted a study on masonry crack detection although the paper did not provide details on their results.

3 Methodology

The outline of the proposed system is shown in Figure 4. The proposed system consists of three modules. Firstly, images are acquired using a UAV and a DSLR camera, Then, images are classified by a crack detection system based on CNN as a feature extractor and SVM as a classifier. The results from the crack detection module can then be used to localize cracks in the final module. Each module in the proposed system is explained below.

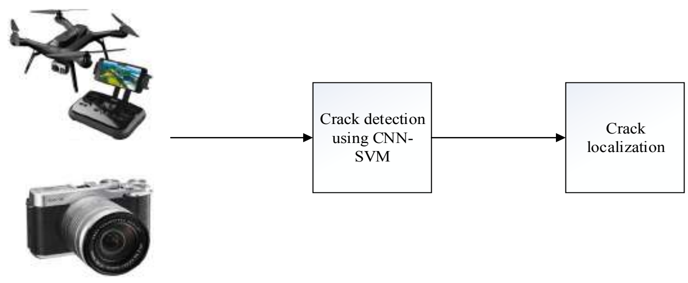

Figure 4: The outliine of the proposed methodology

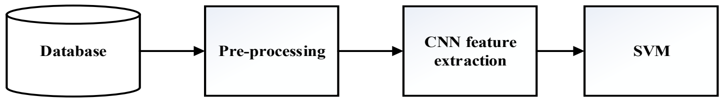

Figure 5: The outline of the proposed crack detection system.

3.1 Image acquisition

In recent years, UAVs have been utilized in surveying as an alternative to conventional surveying methods since they are faster, simpler and cheaper. UAVs can also be utilized to collect images for inspection as shown in this paper. We collected images from a stupa from Wat Chai Watthanaram, which is located in Ayutthaya in Thailand. The images were collected using a DJI Phantom 4 drone. The drone was programmed to fly around the stupa to collect images at two different heights. At the ground level, a DSLR camera were used to collect images of the stupa near the ground. Sample images taken from the drone are shown in Figure 6. As shown in this figure, the top of the stupa cannot be easily reach by human inspectors, and utilizing the drone to collect images around this area clearly provides great benefits for data collection.

In addition, with the collaboration from the Cambridge University team, more sample of masonry structures were also collected from the Chapel viaduct. This is a railway viaduct that crosses the River Colne in the Colne Valley in Essex, UK. The images were collected using a Sony DSLR camera from various locations around the viaduct. The sample images are shown in Figure 7.

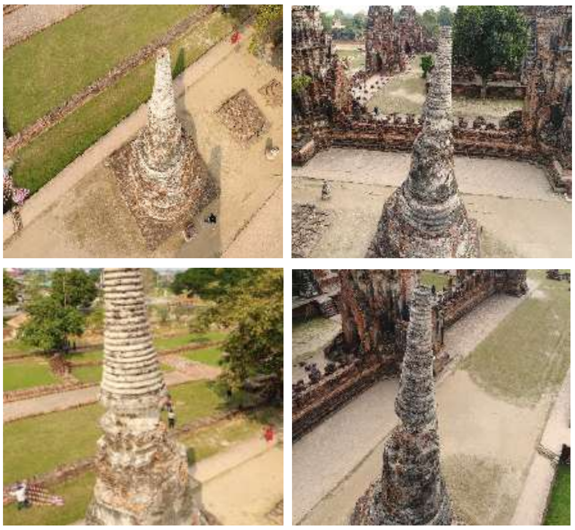

Figure 6: Sample images acquired using a UAV

Figure 7 :Samples images of the Chapel viaduct

The images collected using the drone were converted into patches of size 96x96 using a Matlab algorithm for training and classifying by CNN. Only patches belonging to masonry areas were selected and used for training, the patches containing surrounding objects (e.g. trees) were ignored. The total number of image patches used in this work were 6002, which were manually separated into cracks and non-cracks images. Out of all patches, 3162 patches were used for training and validation, and the remaining 2840 patches were used for testing the proposed system. The crack and non-crack patches were manually labelled as either 0 or 1. The example of crack and non-crack patches are shown in Figure 8 and 9.

Figure 8: An example of crack patches

Figure 9: An example of non-crack patches

3.2 Crack Detection

In the proposed crack detection system, we applied Convolutional Neural Network (CNN) as it has ability in solving many real-world problems efficiently. The architecture of CNN used in this paper is shown in Figure 10.

The multilevel deep feature extractor and a classifier are the two main tools of the CNN architecture. The role of multilevel deep feature extractor is to retrieve discriminant features from image pixel intensity values presented in the RGB colour channels and SVM is used as a classifier for the purpose of classification. In our proposed CNN architecture, Keras sequential model was used, which was composed of convolutional, activation and max pooling layers. The first convolutional layers consist of 32 filters of size 3x3 pixels as shown in Figure 10. After filtering, the max pooling operation was activated with a ratio of 2.

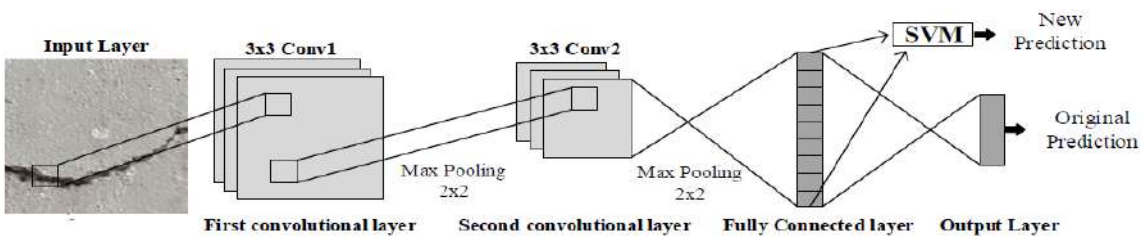

Figure 10: The architecture of CNN used in the proposed system

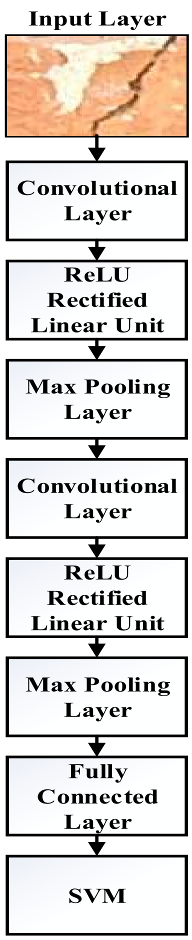

Figure 11: The architecture of CNN-SVM technique.

Figure 11 shows a more detail architecture of CNN used in this study. As shown in the figure, the key role of the convolutional layers is to detect the local connections of features from the previous layer. The output result of the feature maps is then passed to the activation layer ReLU. The max-pooling operation was used in the vision systems for two reasons, (1) to eliminate non-maximal values, which helps to reduce computation time for layers, and (2) to down-sample operations for 2x2 sub-regions to reduce the dimension of intermediate feature vectors .The filters are stacked together and fully connected layers can then be used in computing the class scores. In the proposed system, the output from the fully connected layer become the input feature vectors of size 2352 for the SVM classifier as depicted in Figure 10 and 11.

An SVM classifier was applied in the final stage of the proposed crack detection system. The SVM classifier was used to replace the softmax layer in CNN. The main objective in SVM is to find a hyperplane that separates the largest fraction of a labelled dataset for binary classification. The training data is a set of training samples pairs $\{(x_1, y_1), \ldots, (x_i, y_i)\}$, where x_i is the observation or input feature for the i^{th} sample and $y_i \in \{1, 0\}$ is the associated class label .The SVM classifier is the discriminant function that maps an input feature space x_i into a class label y_i. An interested reader is referred to read [16] for the detail of Support Vector Machines.

4 Experiments and Results

The evaluation of the proposed crack detection system was conducted on validation and testing datasets. The system was evaluated against our own ground truth data, which was manually labelled, to estimate inaccuracy that can occur from the proposed system. As mentioned in Section 3.1, a total of 6002 image patches were labelled either crack or non-crack patches in our experiment, 3162 patches were used in training and validation. The 2840 patches were used for testing. The Receiver Operating Characteristic curve (ROC) analysis, confusion matrix and classification report were used to evaluate the performance of the proposed system.

For SVM, the Radial Basis Function (RBF) was used as a kernel, hence a cross-validation technique was employed to obtained the optimal values for the kernel. Table 1 shows a parametric study for SVM, where a different combination of C and gamma values were tried in the validation dataset to obtain the maximum accuracy. As shown in the table, the best accuracy occurred when C = 4 and gamma = 1.

Table 1: Parametric study for SVM

C	gamma	Accuracy
1	0.5	0.770
1	1	0.72
2	1	0.72
3	1	0.73
4	1	0.73
5	1	0.71

The classification report and ROC curves were obtained based on the confusion matrix, which can be explained as shown in Table 2.

Table 2: Confusion matrix for class classification

Ground Truth Label	Predicted Label	
	Positive (Crack)	Negative (Non-crack)
Positive (Crack)	True Positive (TP)	False Negative (FN)
Negative (Non-crack)	False Positive (FP)	True Negative (TN)

The following equations are used for the classification analysis in the classification report.

$$Accuracy = \frac{TP + TN}{TP + TN + FP + FN} \quad (1)$$

$$Precision = \frac{TP}{TP + FP} \quad (2)$$

$$Recall = \frac{TP}{TP + FN} \quad (3)$$

$$F1score = \frac{2xPrecxRecall}{Prec + Recall} \quad (4)$$

We conducted experiment by comparing the results between the method with the CNN alone and the proposed system, where we combined CNN and SVM. Table 3 shows the results of the proposed crack detection system on the validation dataset. It can be seen that the combined method CNN-SVM offers the better accuracy of 85.94 than the CNN method with the accuracy of 82.94. Other metrics, including Precision, Recall and F1Score are also better for the CNN-SVM method.

Table 2 shows results on the testing dataset. From Table 2, it can be seen that, again, the CNN-SVM method is more accurate than the CNN method. The combined method improved the accuracy by 7.4%.

Table 3: Results of the proposed system on validation dataset

Method	Validation Accuracy	Precision	Recall	F1 score
CNN	82.94	0.83	0.71	0.74
CNN-SVM	85.94	0.84	0.79	0.79

Table 4 :Results of the proposed system on testing dataset

Method	Accuracy	Precision	Recall	F1 score
CNN	67.5	0.80	0.68	0.73
CNN-SVM	74.9	0.82	0.78	0.78

The ROC curve is shown in Figure 12. The ROC is a plot between True Positive Rate (TPR) and False Positive Rate (FPR) for the probabilities values of the output as computed by comparing predicted labels to ground truth values. TPR and FPR are calculated by the following equations,

$$TPR = \frac{TP}{TP + FN} \quad (5)$$

$$FPR = \frac{FP}{FP + TN} \quad (6)$$

It can be seen that, from Figure 12, the CNN-SVM method is better than the CNN method as the ROC curve of the CNN-SVM method appears to approach more towards the top left corner of the graph.

To localize cracks, some sample images were used to show the result. We divided an image into grid and each grid was classified by the proposed crack detection system. If the grid is classified as crack, we highlight the grid as red. Figure 13 shows an example of crack localization. It can be seen that, on the top pair of images, most crack regions are correctly identified, although some misclassification can still be observed. However, the bottom pair of images contains many false negative areas, which may be due to the proposed system was confused with the grout lines as cracks. The bottom pair of images also has many false negative, especially around the grout lines. This suggests that the inaccuracy of the system may be due to these regions as the appearance of the grout lines is similar to cracks. Nevertheless, with more training dataset, the result should improve.

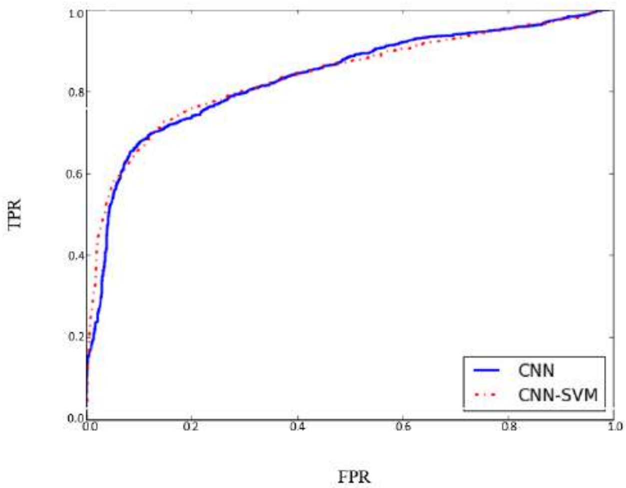

Figure 12: The ROC curves between the CNN technique, and the combined CNN-SVM model

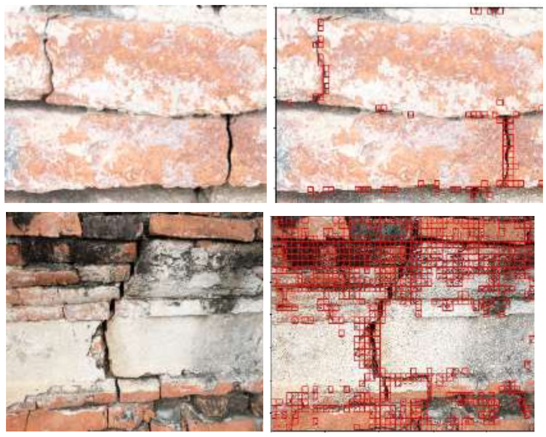

Figure 13: Crack localization of selected sample images

5 Discussion

The combined model, i.e. CNN-SVM, shows an increase in accuracy as shown in Table 3 and 4. It can be seen from the results that CNN-SVM is extremely good at extracting features and classification, although it relies heavily on good datasets. Good dataset can be difficult to create as they rely on human as a gold standard and the database may need to be verified by multiple sources. In our database, we have many non-crack patches but fewer crack patches. To overcome the problem with a small dataset, transfer learning and data augmentation may be applied.

Crack detection on masonry structures are difficult as cracks cannot be easily identified in images. Cracks in masonry structures have similar appearance to grout lines, which can be mistaken as cracks, unlike the problems of crack detection on simple concrete surface shown in previous studies. Therefore, it can be difficult to create good datasets since this type of scene, i.e. the masonry surface, is complex and confusing, even for human inspectors themselves. Nevertheless, good datasets are still required for any CNN systems.

6 Conclusion

From the experiments, we can conclude that the emerging class of technologies known as deep CNN offers the possibility of automatic crack detection for masonry structures. The combined techniques known as CNN-SVM has been implemented in this work to automatically classify image patches and to localize crack regions on masonry images for inspection. The proposed method is successfully applied to classify image in our validation and testing datasets, although with better and larger datasets, our system performance can be improved further.

We also concluded that the efficiency of the model can be further improved by fine tuning the CNN architecture and its parameters, such as adding more layers to CNN. From the results shown in this work, it can be concluded that the combined model, namely CNN and SVM performs better than the method using CNN alone. As shown in this work, CNN is best to be used as a feature extractor, and these features can be classified by any classifiers. In the future work, different classifiers can be explored to see if the accuracy of the system can be improved.

7 Acknowledgment

The authors would like to thank the grant from the Research Division, Department of Engineering, Thammasat University and Thailand Research Fund to allow the work and collaboration of this research project to be successfully completed.

Abstract –

Although several research studies on the application of machine learning to the construction field are actively underway, no study has yet been done on the areas where the application is primarily needed. Using the importance–performance analysis method, this paper identified the top five areas of construction sites where machine learning technology needs to be applied. Furthermore, it suggests application plans developed by using the Delphi method. The identified top five areas were unmanned tower crane, inspection of joint connections, prediction of construction safety accidents, operation of construction lift, layout of tower crane. This study is expected to facilitate the effective application of machine learning technology at construction sites in the future. Ultimately, the purpose of this study is to reduce waste of labor and the safety risks at construction sites through machine learning technologies.

Keywords –

Machine Learning; IPA method; Delphi method; Construction site

1 Introduction

In response to the reduced supply of functional labor, the increased demand for reduced construction times, and an increase in safety-related construction accidents, construction automation technologies are actively being developed. Artificial intelligence technology is a representative technology that can be used to realize construction automation. It was confirmed that the number of papers related to artificial intelligence in the field of construction in major journals increased from nine in 2000 to 50 in 2016 [1]. In particular, machine learning among artificial intelligence technologies is an effective way to respond to this trend. Much research related to machine learning is actively being carried out, such as construction accident prediction [2], analysis of construction equipment operation [3], and assumptions about the compressive strength of concrete [4]. However, it has not yet been properly identified which one of the various machine learning technologies is primarily needed to be applied for construction sites. Therefore, the purpose of this paper is to identify which elemental technologies are required on the construction site and to find those that need to be applied and developed first. Furthermore, the paper suggests approximate plans for the application of machine learning at construction sites. To achieve objective validity, experts in machine learning technology were consulted and a survey amongst field staff was conducted. First, a questionnaire was used to identify the areas of interest at construction sites that require urgent improvement. Alternative ways to improve those areas of interest using the proper machine learning technologies were suggested. The questionnaire surveyed the importance and satisfaction levels of specific elements of machine learning technologies that are considered to be applicable. In analyzing the results, the importance–performance analysis method (IPA) was used to identify the most urgent problems at construction sites.

To solve those problems, the particular problems that require improvement are presented with the appropriate machine learning skills using the Delphi method. Machine learning technologies such as artificial neural networks, support vector machines (SVMs), random forest, and genetic algorithms were selected as applicable methods to solve these problems.

The scope of the research included construction sites in and outside Korea, and includes the elements of construction work, such as construction safety, foundation work, and finishing work.

2 Literature review

2.1 Current study for application of machine learning in construction

As used in applications such as self-driving cars, drones and robots, artificial intelligence technology is an essential technology by which intelligent systems can overcome the performance limitations of traditional computing systems [5]. In particular, machine learning, one of the artificial intelligence technologies, enables the machine to directly evaluate a certain situation and take appropriate actions by collecting big data and learning from it on its own.

The application of machine learning technology in the construction field is already actively underway. As a result of analyzing articles published in major journals up to 2016, it has been established that the machine learning technologies used mostly in the construction field include artificial neural networks (50.8%), genetic algorithms (21.8%), composite models (16.3%), fuzzy theory (8.2%), and support vector machines (SVMs) (2.9%) [1].

Lee J et al. [6] suggested using machine learning technology in the analysis of reinforcement-bar images. In their study, a program for the analysis of reinforcement-bar images was separately realized using OTSU binarization through random forest and superpixel clustering. Park U et al. [7] constructed a selection model of retaining wall methods using a support vector machine, one of the machine learning technologies. As a result of its application in a real case, and with an accuracy rate of 93%, it has been proven that this particular machine learning technology can be used effectively in the construction field. Tixier AJ-P et al. [2] and Kim Y et al. [8] used machine learning technology not only to improve construction methods, but also to predict safety-related construction accidents. Kang I et al. [1] recently identified trends in the study of machine learning in the construction field by year, by category, by topic, and by technology. However, they failed to identify how certain elemental technologies were applied and the practical use of them.

Likewise, machine learning technologies are actively being studied in various areas of the construction field, but those technologies that are primarily needed have not yet been scientifically prioritized. In this paper, the elemental machine learning technologies primarily required in the construction field are identified and application plans are proposed.

2.2 Artificial neural network

An artificial neural network is a structure that has been modeled to imitate interactions among the components of the brain of a living creature. The biological brain consists of neurons that are connected to each other through synapses, and it solves problems by changing the degree of connections. Similarly, an artificial neural network also learns about solutions for certain problems by adjusting the weight between artificial neurons. Thus, it is easy to solve complex problems, since solutions can be learned not only from linear functions but also from nonlinear functions based on input variables [9].

2.3 Support vector machine

The support vector machine (SVM) is considered as one of the most robust and accurate methods among data mining algorithms [10]. Based on structural risk minimization, SVM creates a separating hyperplane that can divide multiple data types into two classes. SVM is originally an algorithm for the classification of binary data. Therefore, to distinguish between multiple data types in more than two classes, either the one-against-all (OAA) or pairwise method must be used. Because of the advantages of the SVM algorithm in solving nonlinear problems, it can be used at a construction site that has many variables.

2.4 Random forest

Random forest is an ensemble technique that overcame the shortcomings of decision trees by using bagging and random space methods. Decision trees vary greatly depending on the learning data and therefore it is difficult to use them in generalization [11]. However, random forest generates and learns multiple decision trees from the data. This characteristic allows users to avoid overfitting in the classification and enables more proper generalization than decision trees.

2.5 Clustering

Clustering is a one of the unsupervised learning methods that classifies data by creating criteria and sorting data itself by classifying data without any base information. Clustering is usually used for processing image data and can be more useful when used with deep-learning technology than when used independently. The most famous and simplest example of clustering is K-means clustering. The technology is widely used in various fields, including classification of movies or TV scenes, and clustering related to users of social networking services [12].

2.6 Genetic algorithm

Genetic algorithm is one of the techniques for stochastic search or learning and optimization. The algorithm is based on Charles Darwin's theory of survival of the fittest and Mendel's laws of genetics. The former is the theory that creatures that are well-adapted to nature survive but those that are not are eliminated. The latter is the law that the genetic characteristics of offspring are inherited from their parents [13]. Based on these characteristics, the genetic algorithm can be especially useful for optimization of various fields.

3 Method

3.1 Questionnaire development

Prior to conducting the questionnaire survey, six major journals of construction were used to define relevant categories for the questionnaire. The validity of each category was verified by two experts from the construction field. In this questionnaire survey, each category addresses a part of the construction field where it is considered necessary that machine learning technology must be applied. The number of categories for the questionnaire determined through this process was set at 12. The detailed contents of the categories are listed below in Table 1.

Table 1. Detailed categories of questionnaire survey

Categories	Division
Operation of construction lift	A
Layout of tower crane in high-rise building construction	B
Assumption about compressive strength of concrete	C
Counting the numbers of reinforcemet bar	D
Inspection of joint connections	E
Unmanned tower crane	F
Determination the lifting order between the tower cranes	G
Selection of retaining wall methods	H
Prediction of safety-related construction accidents	I
Forecast of deep excavation wall movement	J
Inspection for correct installation of the forms	K
Determination the time of procurement	L

In this study, the survey was conducted to establish the level of importance and performance of each category on a five-point scale. The number of participants in the survey was 30. Most of the participants were working for construction companies then and had experience in working at construction sites. Their average experience at construction sites was 12 years. The positions of the participants were broadly from employees to managers. The experience at construction sites and their assigned roles in their companies of the participants are presented in Table 2.

Table 2. Information about the questionnaire survey participants

Experience in construction site		Main tasks in companies	
Years	Number of participants	Tasks	Number of participants
~1	1	Construction	17
1~5	6	Office work	4
5~10	7	Quality control	4
10~20	11	Design	3
20~	5	Others	2

3.2 IPA method for prioritizing elements that need improvement

The IPA method is an easily-applied technique to measure the importance and performance for users of each surveyed category. Before using the IPA method, a survey is usually conducted that can check the importance and performance on a five-point or a seven-point scale. The survey results are then analyzed with an appropriate method and displayed on a four-quadrant grid. On the four-quadrant grid, the vertical axis indicates importance, and the horizontal axis indicates performance [14]. Note that the second quadrant includes the categories with high importance and low performance, which indicates where the primary improvements need to be made. The IPA method is highly applicable not only to marketing and the business field, but also to machinery, education, and even the construction field.

In this paper, each category of the IPA method consisted of an area that needs improvement through the introduction of machine learning technology. These categories were selected through consultation with experts from the construction field and experts in the field of artificial intelligence technology. The reason for using the IPA method was that it was impossible to deal with everything that needed improvement and the categories had to be prioritized by using an appropriate method.

4 Results and Discussion

4.1 Analysis of IPA results

The results of the questionnaire survey of each category are outlined in Table 3. To easily identify the priority of categories that need improvement, the contents of Table 3 are displayed on the four-quadrant grid as shown in Figure 1.

Table 3. Average value of importance-performance by category

Category	Importance	Performance	Category	Importance	Performance
A	3.800	2.400	G	3.833	2.567
B	4.267	2.767	H	4.200	2.900
C	4.033	2.733	I	4.167	2.600
D	3.767	2.533	J	4.067	2.900
E	4.167	2.600	K	4.033	2.667
F	3.800	2.000	L	3.700	2.400

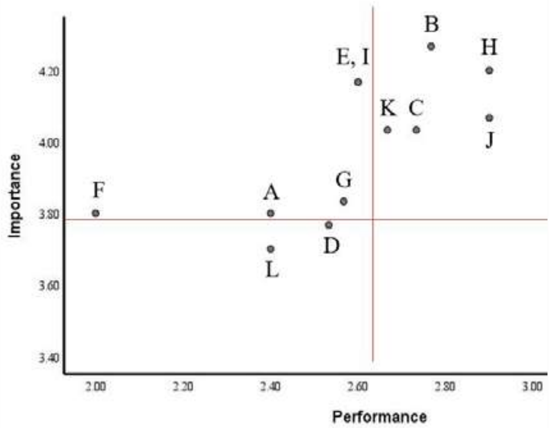

Fig 1. The values of importance-performance displayed on the four-quadrant grid

As shown in Figure 1, categories A, E, F, G, and I are located on the second quadrant. It means that these are the primary categories that need to be improved. However, the importance/performance values of the categories do not correspond exactly to Figure 1. To identify the top five categories easily, their importance/performance values were displayed as shown in Table 4. This study suggests application plans of machine learning technologies for construction sites only for these top five categories.

Table 4. Top five of categories that have the highest importance/performance values

Categories	Importance/performance value
Unmanned tower crane	1.9000
Inspection of joint connections	1.6026
Prediction of construction safety accidents	1.6026
Operation of construction lift	1.5833
Layout of tower crane in high-rise building construction	1.5422

4.2 Application plans using the Delphi method

To develop application plans for machine learning technology for the top five categories, two consultations with a group of four experts in machine learning technology were conducted. The following are proposed application plans using the Delphi method.

4.2.1 Unmanned tower crane

The tower crane is a very important piece of lifting equipment that can make or break construction work, especially in high-rise building construction [15]. It means expenses and the duration of the construction work can vary depending on the ability of the tower crane operator. Moreover, operating the tower crane is very dangerous work for the tower crane operator. Therefore, the commercialization of unmanned cranes is essential for construction sites. There are several elemental technologies for the development of unmanned cranes.

First, voice recognition technology is needed. When a person gives orders through a radio, the unmanned crane should recognize the orders and act on them. To recognize voice, the sound waves should be learned. Because of the difference in the waveforms of sounds among people for any one command, several similar waveforms should be learned as shown in Figure 2.

The waveforms are saved as coordinates. Later, when a person gives an order through the radio, the unmanned crane can find similar coordinates and act on the order by itself. In this procedure, classification technology such as clustering can be applied. This technology can increase the accuracy of voice recognition on noisy construction sites.

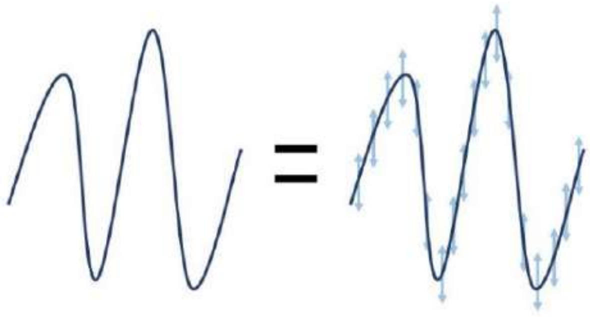

Fig 2. Original waveform and similar waveforms of voice

Second, location recognition technology is needed. When there are several cranes, the movements and distances between the cranes should be perceived by each unmanned tower crane, as the tower cranes may collide with each other while moving. This problem can be solved using global positioning system technology.

Third, material identification technology is needed to enable the tower crane to stop exactly where hoisting of the material is needed. In this case, using sensors to identify material is a more appropriate method to use than machine learning.

Proper combination of these three technologies could facilitate the development of the unmanned crane.

4.2.2 Inspection of joint connections

Construction work on joint connections requires special care and inspections on these areas are not easy. In particular, if a building consists of reinforced concrete, it is also necessary to ensure that the steel is distributed properly, as intended. Since the inspections are carried out by inspectors, there is a risk of incorrect inspections and a waste of labor. Therefore, if a technology can be developed to take a photograph of the joint connections and automatically compare it to a drawing, these problems can be solved.

For such comparisons, image classification technology is needed. Among the machine learning technologies, random forests and superpixel clustering are appropriate methods for image classification. Before image classification can be done, a technology to capture internal images of reinforced concrete, such as x-ray or MRI, is needed. Then, many images of reinforced concrete need to be learned to determine which pixel corresponds to which area. These data values make up many decision trees of the random forest. Superpixel clustering is used for separating pixels in different areas. Combined with the random forest, it can be used to correct a pixel that is incorrectly classified. The overall procedure of image classification is shown in Figure 3.

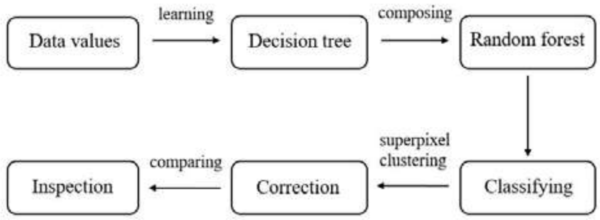

Fig 3. Overall procedure of image classification for inspection

Through this application plan, autonomous inspection of the joint connections can be done. This application plan was based on the work of Lee J et al [6].

4.2.3 Prediction of safety-related construction accidents

Safety-related construction accidents should be prevented by taking into consideration the varying and dynamic natures of construction sites [8]. Therefore, notifying workers in a timely manner of potential accidents that are most likely to happen would be very helpful to prevent such safety-related construction accidents. There are many variables at construction sites, such as types of work in progress, weather, and location. Proper prediction of safety-related construction accidents can be achieved by compiling several variables.

To predict safety-related construction accidents, the artificial neural network is useful, as is shown in Figure 4.

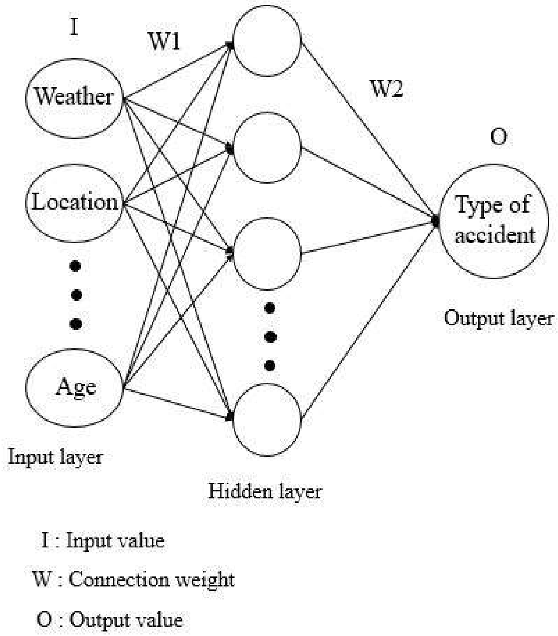

Fig 4. A structure of the artificial neural network

The variables that can affect construction safety are input values. Output values are the types of accidents, such as falling, crashing, and being hit by machines or objects. First of all, to build a model of an artificial neural network, large volumes of data from real cases of safety-related construction accidents should be learned. Then, using proper learning methods, such as error back-propagation, the connection weight for each node is determined. If input values are entered later, the connection weights are multiplied to determine the appropriate output value that is the most probable safety-related construction accident. In this way, the workers can be notified daily of the most probable safety-related construction accidents to happen. Detailed work on this topic was done by Kim Y et al [8].

4.2.4 Operation of construction lift

As more high-rise buildings are being built, the types and volume of materials that need to be lifted are increasing. Thus, the lifting plan of construction lifts is becoming increasingly important to increase efficiency of the construction work [16]. However, the decision-maker for the lifting plans faces an uncertain situation that can result in inaccurate prediction and definition of the various variables in dynamic construction sites [17]. Therefore, development of smart construction lifts that can operate themselves efficiently by referring to a schedule of construction and current situation, is needed.

The smart construction lift needs a combination of several functions. When calling the lift from a specific floor, the current loaded weight and the weight to be loaded should be considered. If the weight to be loaded will result in the total loaded weight exceeding the capacity of the lift, the lift should not answer the call. Furthermore, the lift should recognize the construction schedule by itself. If a task on a critical path is scheduled, the lift must always be waiting to execute the task. These functions of the construction lift can be realized using logical algorithms.

In addition, the ability of the lift to self-zone in context by itself is needed. The construction lift is similar to an elevator, but the number of floors it runs varies as the construction work progresses. To realize the function of self-zoning, it is more efficient to reflect on the latest data than on data of the remote past. Therefore, a recurrent neural network (RNN) that can handle time series data, is useful. RNN can further reflect the latest situation, by placing a higher connection weight on the latest time series data and forgetting the data of the remote past. In this case, the input values are information about the operation of the lift such as the number, time of driving, starting floor, and arrival floor. By learning large volumes of data about this information, the construction lifts can decide about running zones by themselves. The result of zoning the construction lift is shown as the output value. A combination of this machine learning technology and logical algorithms can realize the development of the smart construction lift.

4.2.5 Layout of tower crane in high-rise building construction

The importance of the tower crane was mentioned in Section 4.2.1. Not only the ability of the tower crane operator, but also the model, location, and number of tower cranes can have a significant influence on construction expenses and time. In particular, for high-rise building construction, the layout of tower cranes should be done by systematic calculation, not by human intuition.

In this category, the genetic algorithm is the proper method for optimization. To use the genetic algorithm, the function and the output variable of it must be determined. Using an advanced type of tower crane and a large number of tower cranes can shorten construction duration, but it can increase the daily rental fee of the tower cranes. Based on this principle, the output variable of the function was set to the total rental fee. It can be calculated from multiplying the daily rental fee and the rental duration for each tower crane. The input variables are the number, location, and model of the tower crane. A diagram of the optimization is shown in Figure 5. Next, the construction site should be displayed on a three-dimensional coordinate system. Each part of the tower crane should be displayed as well, as shown in Figure 6.

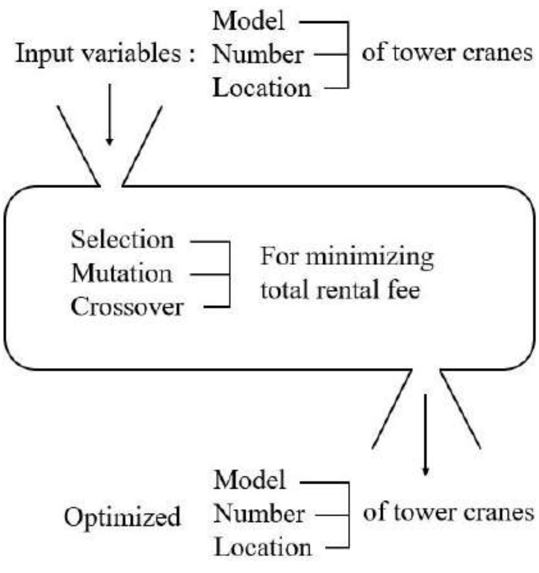

Fig 5. A diagram of the optimization

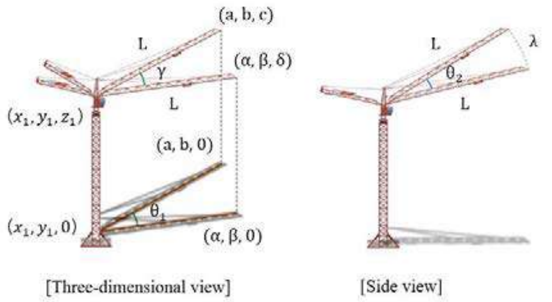

Fig 6. Images of tower crane displayed on three-dimensional coordinate systems

In Figure 6, $(\alpha, \beta, 0)$ is the location of the stock yard, (a, b, 0) is the location of the place where the material must be put down, and L is the length of a jib boom that varies depending on the model of the tower crane. Using appropriate functions, the distance that the tower crane should move can be calculated. Then, dividing the total distance by the operating speed of the tower crane, the rental duration can be calculated. The daily rental fee of a tower crane depends on the model of the tower crane.

The genetic algorithm automatically calculates the minimized total rental cost by changing the number, location, and model of the tower crane. In this way, the number, locations, and models of the tower cranes that will minimize the total cost can be obtained.

5 Conclusion

In this paper, the parts of the construction field that primarily need improvement were identified from the results of a questionnaire survey and the IPA method. Furthermore, using the Delphi method, improvement plans with machine learning technologies were suggested.

The results of the IPA method showed that the areas in the construction field that need urgent improvement are varied, and include unmanned tower cranes, inspection of construction, safety-related construction accidents, operation of construction lifts, and layout of tower cranes. It means that even though various research studies are actively underway to address problems in the construction field, many areas still exist that need further improvement.

This study will be used for the effective application of machine learning at construction sites by prioritization categories. Ultimately, it is expected to contribute to the construction field by facilitating more economical and safer construction sites through minimizing unnecessary waste of labor at construction sites. However, there are still additional areas to be examined in future studies. Above all, the proposed application plans of machine learning technologies for construction sites in this paper were too sketchy. Detailed plans for application and materialization of models for each category have not yet been proposed. Therefore, in a future study, the specific model for each of the top five categories that need urgent improvements should be developed using machine learning technologies. Furthermore, the effectiveness of the specific models should be properly verified.

Abstract –

In this study, a sound analysis-based detection and reporting system for accidents that occur during concrete pouring is proposed. First, the process of the existing monitoring system was examined and problems were noted, and studies and technical approaches to sound analysis were analyzed. Pouring sound samples were then collected from construction sites, the frequencies and patterns were identified, and accident sound patterns were created by superimposing leakage and other noise onto pouring sound samples. Finally, logic and an algorithm to identify accidents were proposed based on the results of patterns retrieved from the above datasets. In the future, it is expected that accident notification systems using the sound analysis proposed in this study will be useful not only for the prevention of accidents but also for safety management throughout construction sites in general.

Sound analysis; Accident notification; Concrete pouring

1 Introduction

1.1 Background and purpose

Accidents due to the collapse of forms and struts occur frequently while concrete is being poured. It is necessary to monitor the status of both the inside and outside of the concrete and formwork during pouring because concrete leaks due to formwork collapse pose a great threat to the quality of a structure as well as human and material loss during the project.

Direct, manual inspection by a project manager is the best case scenario, but condition management of formwork is typically performed using surveillance cameras and measuring sensors due to the unpredictable nature of pouring sites and safety issues. However, surveillance cameras cover a limited range of vision and require numerous installations in order to monitor the project area. Moreover, the measuring sensors require attachment at each formwork and are not economical. For that reason, constructing a monitoring system that covers a wide construction area economically is necessary.

1.2 Method of research

In this study, sound analysis-based detection and a reporting system for accidents during concrete pouring are proposed. First, the process of the existing monitoring system was examined and problems were noted, and studies and technical approaches to sound analysis-based monitoring systems in the construction industry were analyzed. Pouring sound samples were then collected from construction sites, the frequencies and patterns were identified, and accident sound patterns were created by superimposing leakage and formwork rupturing sound patterns onto pouring sound samples. Finally, logic and an algorithm to identify accidents were proposed based on the analyzed sound patterns retrieved from the above datasets.

2 Literature review

Sound is a wave transmitted by the vibration of an object, and an accident may be detected using the sound pattern of a unique frequency. Women scream at a frequency of 1,000–2,000 Hz, while men scream at a frequency of 500–1,500 Hz. Studies using the frequency and pattern differences of sound have been performed in many different areas.

Existing studies using speech analysis are mainly conducted in humanities by analyzing the characteristics of rhyme change, intonation, and the rate of accentuation. The biomedical field aims to develop a medical system for laryngeal cancer detection and voice therapy. In the field of information and communication, techniques for matching the facial expression and voice of a character in an animated game are being developed. This is also seen in artificial intelligences such as Siri in the form of speech recognition. It may be used to detect a situation around a car, identify diseases and anomalies through the cries of livestock, and determine whether a person is the guilty party during the investigation of a crime. Speech analysis technology has also been applied to disaster response by judging human emotions or reactions.

Figure 1. Sound analysis of vehicle road[10]

Figure 1 shows an analysis of sound in an intersection. Though it is typically in the frequency range of 30–40 dB and 5,000 Hz or less, the sound of a skid occurs in the range of 1 kHz–3 kHz[10]. An accident notification system for tunnels is being developed using the frequency differences taken from the road, as above. An automatic accident detection system in the transportation sector installs CCTV in the designated area and analyzes the data in real time to automatically detect an accident in the tunnel while also providing information for the prevention of secondary accidents [3][4]. However, since this study is applied to a tunnel, which is a linear space, its application to a construction site in a three-dimensional space is limited.

Studies for detecting accidents have been steadily carried out in the field of construction. In recent years, many studies have monitored risk situations in real time using miniaturized equipment. In an existing study on accident monitoring using advanced equipment, real-time monitoring based on USN was performed with various measurement sensors (ultrasonic, load, slope) in formwork construction [6][9]. However, there are limitations with installing measurement sensors at a construction site, and there are economic problems regarding their application to a large-scale construction site.

A landslide monitoring system in the civil engineering field detects the change in water temperature with a temperature meter and analyzes the sound when the ground is pushed out to predict risk in advance. However, since it is necessary to perforate the ground and detect the accident sound in a state where external noise is blocked after perforation, it is difficult to apply due to the characteristics of the construction site since such a wide variety of sounds are generated. Studies monitoring the work status and productivity of heavy equipment through sound analysis seem to have improved the problems of monitoring through the attachment of existing sensors [1][2]. However, since heavy equipment monitoring only analyzes single machine activity at a distance from external noise, sound analysis is not performed for the construction site.

An accident detection system that analyzes the frequency and pattern of the sound can detect a wide range if it is installed at a single point rather than attached to individual members. Therefore, it can be combined with noise management in the construction site in an economical and efficient fashion.

3 An accident notification system

3.1 The process of accident notification based on sound analysis

It was found that most of the causes of collapse occurred while concrete was being poured. Therefore, it is necessary to understand the accidents that may occur during concrete pouring and to propose a process to detect and respond to these accidents.

While concrete is being poured, the form or the shore may break down due to the side pressure of the concrete, resulting in loss of life or material damage. Even if there is no collapse at the construction site, if a gap is created due to the weight, a concrete leakage accident will affect the structural quality of the building.

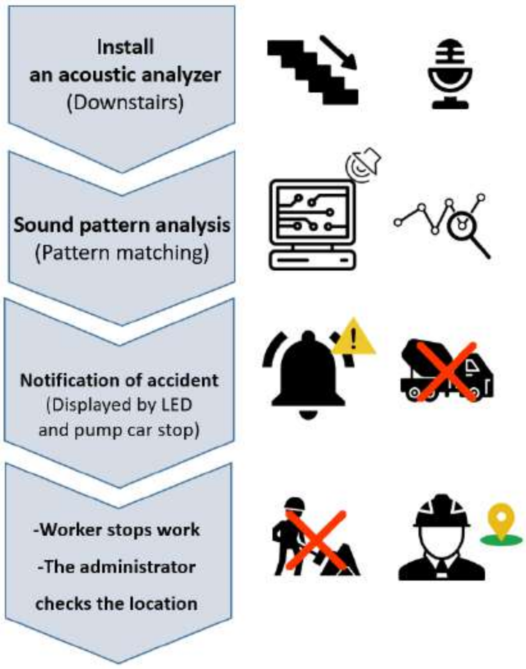

Figure 2. Accident notification process

Accidents that occur while concrete is being poured require quick action, but this is generally not possible. The problem with accidents is that when concrete is being poured, an accident in the lower layer goes completely unnoticed by those pouring concrete in the upper layer. In order to solve these problems, we propose a process to detect an unexpected situation while monitoring the downstairs situation through sound analysis during concrete pouring

First, a portable sound analyzer is installed under the concrete pouring layer. In the next step, the sound collected by the sound analyzer is sent to the server in real time. When a pattern that is similar to previously collected accident sounds is detected by the server, the installer's LED indicator warns of danger. When this sign is displayed, the pump car automatically stops and the worker is forced to stop as well. The administrator knows that the sound is coming from the server, finds the exact location, and takes action.

3.2 Sound analysis in concrete pouring

A A basic experiment was conducted to propose an accident detection process using sound analysis. Before the prototype of the portable sound analyzer was developed, a basic experiment was conducted to determine if it would be possible to distinguish between noise and accident sounds at a construction site.

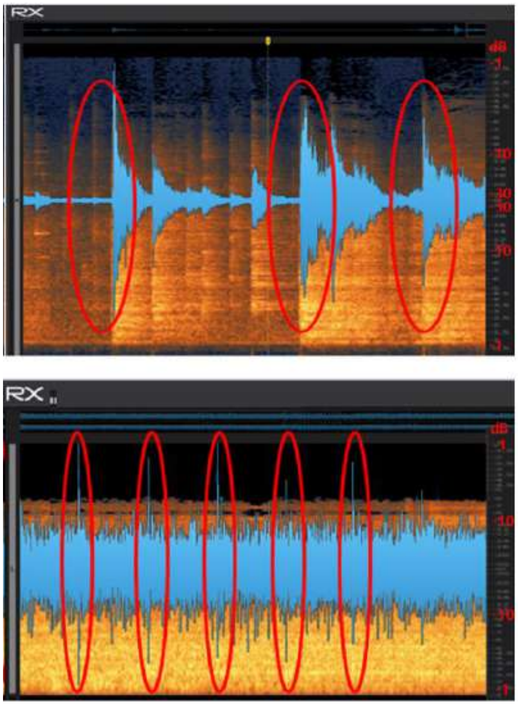

Figure 3. Sound analysis of concrete pouring

The upper picture in Figure 3 shows the analysis of the pattern created by generating impact noise among the noise of a general construction site. In the lower part of Figure 3, the pattern of the impact and plosive sounds during concrete pouring were analyzed. It can be seen that the upper picture clearly distinguishes the impact sound. High impact sounds and plosives are clearly visible in decibels because of the low ambient noise.

In the lower picture, a very loud noise was generated during concrete pouring. At the time of direct recording, the putting noise was too large to check other sounds with the ear. However, frequency analysis showed that the impact sound and the plosive sound were distinguishable by their unique pattern and size even in a loud noise situation. It was confirmed that the impact noise and the plosive sound have different threshold values from general noise, as found in previous studies that classify work noise at the construction site. It was judged to be possible to use sound analysis monitoring in the concrete pouring section.

3.3 An algorithm to determine an accident

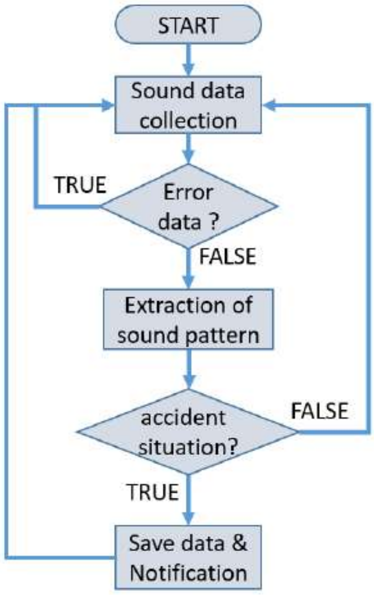

Figure 4. An accident detection process

An accident detection process based on data analysis using an sound collector was designed. Analog signals of accidental sounds and various noises in the field were digitized and converted into data. The more data is collected by applying the Big Data Analysis Theory, the higher the accuracy of the judgment algorithm. The algorithm works by probing and filtering the data collected, generating an accident sound data pattern interval, and examining the similarity between the real time sound data and the accident sound pattern. Data collection and filtering implement logic to filter error data because there is the possibility of collecting noise and error data. The similarity between the generated accident section pattern information and the currently collected sound pattern is examined, and when the value of the currently collected sound deviates from the threshold value, it is judged to be an out-of-sight condition.

4 Conclusion and Future research

This study investigates the current status of sound analysis research through literature review, and a process for an accident notification system based on sound analysis was proposed. Through a basic experiment in which the system was applied, the noise pattern was analyzed at a concrete pouring site and the validity of the system's application was confirmed.

A sound analysis-based accident detection system is a field of interest and research in transportation. So far, accident detection has been dependent on CCTV, but the present limitations of image reading have been reached. However, it is possible to identify and prevent many accidents using the immediate and wide range advantages of sound.

The following is the future directions for this study's sound analysis. First, a significant amount of sound data is required to apply an accident notification system using sound analysis in the field. There is also a need for data not only regarding the mechanical sounds and noise of a construction site but also of actual accident sounds. To design a program using a Neural Network or Deep Learning, accuracy is improved when many data points are collected. Collecting ample noise and accident sound data through case studies at various sites will contribute to the detection rate of the system in the future.

In addition, it is necessary to know the positioning of the sound's source. According to the patent registered by Samsung Electronics, each of the input sound source signals inputted through two or more microphones are combined to generate output signals, and the generated microphone output signals are calculated. The distance to the sound source may then be calculated using the distance between the calculation result and the frequency of the input sound source signal. Using this technique, the system can create a map of the source and determine the direction and distance of the source. When applied to accident monitoring, an accurate location for accident sound in the field can be obtained.

An accident notification system based on sound analysis will increase the accident detection rate by fusing various sensors, deep-running technology, and wireless network technology. In addition, accurate positioning and the immediate response of the system will contribute greatly to the field of safety management.

Abstract –

Facility maintenance tasks require extensive historical data and information to be stored, retrieved and managed. Although several mobile-based devices have been proposed to access the maintenance information from three-dimension (3D) building information model (BIM) environment, these devices are deficient in simultaneously updating the maintenance information both in the field and the BIM. This study proposes a BIM- and mobile-based system that integrates BIM model, MySQL database, Microsoft Access database, and Android App modules for supporting facility maintenance management. The Android App module consists of the functions of 3D visualization, information inquiry, and view/edit maintenance work orders. While MySQL stores all the BIM information and work order databases, the manager can then update the BIM model. Allowing to update maintenance information in the BIM model in a cloud environment improved the existing relevant systems. Thus, by updating all the information in a cloud environment, it can then update the maintenance information simultaneously both in the field and the BIM with simple mobile-based devices.

In this study, it applied BIM-and Mobile-Based System for Supporting Facility Maintenance Management on a case project. In this project, it demonstrated how this system worked in a project. The results of the case project show that the maintainers in the project can immediately update the latest information and so reduce not only the time that takes but also the potential mistakes that may happen. To sum up, the efficiency of Maintenance Management boosted significantly.

1 Introduction

Considering the importance of building maintenance and a rise in BIM technology all over the world, many are paying more attention towards the study of maintenance management systems. A NIST study suggested that by improving interoperability and efficiency during facility operation and maintenance, a total of $15.8 billion annual cost could be significantly reduced [1]. In order to have a successful facility management (FM), managing information about facilities will be a major contribute [2].

Recently, building information model (BIM) have been a trending topic regarding the implementation and potential applications of BIM into the whole building lifecycle [3]. More importantly, BIM is increasingly considered as an Information Technology (IT)-enabled approach that allows design integrity, virtual prototyping, simulations, distributed access, retrieval and maintenance of the building data [4]. With the vast amount of information in BIM model, intra-disciplinary collaboration and multi-disciplinary collaborations will be needed to be able to efficiently utilize these information [5].

Currently, to develop a BIM-based maintenance management system, several mechanisms must be present. Frist, a BIM-based 3D model is developed using commercial BIM software (such as Bentley MicroStation or Autodesk Revit). Second, information in the BIM model will need to be exported and stored externally, since information could not be retrieved straight from the BIM model file format. Third, a maintenance management system developed on a selected platform (such as website based, API based, or mobile based) for users to retrieve information.

However, the current maintenance management systems are limited in that they do not fully integrate BIM into the maintenance management system. That is, other systems utilize the information exported from BIM model as if it is an independent entity from the BIM model. Though this allows a much better flexibility with the usage of information, such as 3 inserting or deleting information, but it doesn't fully tackle the problem of information exchange in BIM, since it lacks the information exchange from the maintenance management back to the BIM model.

To improve the BIM's integration with maintenance management systems, this work develops a maintenance management system that enables information to be synchronized from the management system and BIM model. The proposed system processes the information in different way. By separating the model and information to two, the proposed system can then apply on mobile computing, and for the information, it will be processed and stored in the cloud database. Applying mobile computing and cloud database technology into the system allows instant information sharing and retrieving.

2 Review of Current Studies

This section reviews current studies of maintenance management systems that address issues regarding building maintenance management. Previous researches have tried several ways of integrating BIM with maintenance management systems and had come up with some very interesting results. Unfortunately, information exchange between software still remains a crucial issue when it comes to BIM based maintenance management systems. Many provided methods to link information, once it had been exported out, but rarely talked about how to import information back into BIM model. It should be noted that this research believes BIM model collects and holds vital information throughout the building lifecycle, and that it should continue to do so when used in operation and maintenance phase.

2.1 Building Maintenance Management

To define the term building maintenance, according to Seeley (1976) [6] building maintenance is work undertaken in order to keep, restore or improve every part of a building, its services and surrounds, to a currently accepted standard, and to sustain the utility and value of the building.

While others proposed a list of objectives to define building maintenance, as listed below [7].

- To ensure that the buildings and their associated services are in a safe condition;
- To ensure that the buildings are fit for use;
- To ensure that the condition of the building meets all statutory requirements;
- To carry out the maintenance work necessary to maintain the value of the physical assets of the building stock
- To carry out the work necessary to maintain the quality of the building.

In maintaining a building, there are usually several strategic options available to management, and many alternative decisions to be considered. There is, for example, the possibility of reducing the demand for maintenance by addressing the actual cause of failure and identifying its consequences. Therefore, we could also define building maintenance by dividing it into three strategies [8]: Reactive/Corrective Maintenance.

Corrective maintenance is the simplest type of maintenance, where a component of a building is used until it breaks down, meaning that the component no longer performs its required function. When this happens we perform corrective maintenance to repair or replace this broken component to restore the component to its original functioning state. This type of strategy is also referred to as reactive maintenance because it happens when a component had already broken down, in which the maintenance crew then reacts to this failure in building component. Even though corrective maintenance can be expensive, it is still an important management strategy because it is how we collect vital predictive information. Corrective maintenance can be extremely expensive because of two reasons:

1. The failure of the component can cause large amount of consequential damage to other components in the building.
2. The failure of a component is unpredictable and may occur at a time when it's inconvenient to both the user and the maintaining authority.

2.2 BIM-based Maintenance Management System

Recently all over the world, scholars are starting to pay more attention towards the study of BIM-based management systems. Scholars are researching on how to integrate the cloud into BIM-based management systems, so in this section we would be reviewing what other scholars have achieved throughout the years First we'll review the study regarding using BIM to construct a building facility management system [9]. Second, Chuang (2011) [10] constructed a webpage providing 3D visualization while also showing construction progress. Third, Lin and Su (2013) [2] developed a maintenance management system through Navisworks API. Jian (2011) [9] constructed a BIM-based management system on a webpage, providing users the ability to search, insert, delete, and edit component information exported from Autodesk Revit. This system also utilizes the Autodesk browser plugin to provide users with 3D visualization of the BIM model through the constructed webpage. His research used ODBC export function to export information into Microsoft

SQL database, then by using ASP.NET to create webpages.

Lin and Su (2013) [2] believes that the performance of facility maintenance management can be enhanced by using web technology for information sharing and communication. They proposed quite an innovative system regarding BIM-based facility maintenance management. Unlike what other scholars had proposed, this research constructed a facility maintenance management system through Autodesk Navisworks API which enables the user to operate the 3D BIM model in Autodesk Navisworks while integrating cloud computing to retrieve maintenance related information

The main reason that the system they proposed is unique is because it stores all the information in an independent database, instead of storing the information in BIM model. In the management layer, the maintaining authority edits the BIM model and then export it into NWD file for Navisworks to read and open. When the user opens this read-only BIM model (NWD file), the system will start data mapping all the components in BIM model to all available information in FMM database. This means that all the crucial information regarding maintenance will be stored in the FMM database instead of the BIM model. The reason behind this setup is because the author believed that the amount of maintenance information stored will increase over time if all FMM pieces of information are recorded in the BIM model. Since BIM models cover a wealth of building information, central BIM models storage space should be reserved for crucial information, such as spatial information, facility ID and name of facility, facility location, and other critical information. In order to keep the system performance at an acceptable level, the information derived by other applications should be stored in an external location [2].

Though this is the most thorough system compared to others, the fact that it was constructed on Navisworks API still causes problems. This means that the user will need to use a tablet or light weighted notebook in order to actually use this system because it needs to be able to operate Autodesk Navisworks. In order to truly enhance and promote the benefits of cloud computing, a system that works on something more convenient, something that everyone would carry wherever they go need to be constructed.

2.3 Interoperability of BIM and Maintenance Management Systems

The main exchange format for BIM files is Industry Foundation Classes (IFCs). However, the initial problem with IFCs is that they are not intended to store and carry all relevant data for all multi-featured construction processes. Furthermore, not all relevant data can be structured in a single super schema [11]. Many BIM software provides IFC conversion when exporting files, but there are still some issues when implementing IFC which was stated in Redmond's research. For example, IFC information models use schemas represented in EXPRESS (data modelling language).

3 Proposed System

The key to developing the proposed system is to store and provide information indirectly from BIM model to the maintenance management system.

In this system, it consists of four parts: BIM model, MySQL database, Microsoft Access database, and Android App. The following sections provide detailed explanations of each part.

Figure 1 presents the framework of the proposed system; it shows the main relationship between four parts of the system and how the system cooperates with each other.

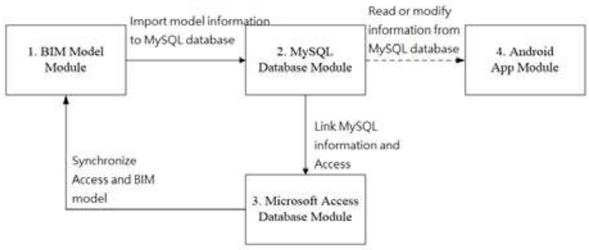

Figure 1. Framework of the System

As shown in figure 1, the proposed system divides the model and information into two, and links to two different parts, Microsoft Access Database (see section 3.3) and Android App (see section 3.4). Compare with other system, usually the information and model are unseparated, the proposed system can both read and modify the information on Android App devices.

3.1 BIM Model

Autodesk Revit is used to develop the BIM model owing to its popularity in Taiwan, and in case to implement the proposed system, a BIM model with level of detail (LOD) 300 is required.

A LOD 300 BIM model contains different objects such as columns, beams, walls, slabs, windows, and doors, along with these objects' information like sizes, shape, locations, orientation and geometric data (such as length, area, and volume). Also, non-geometric information/data (including the maintenance related data) are included in the 3D BIM objects.

To ensure this system work properly, some required fields in Autodesk Revit needs to be set up. The most crucial part of constructing a workable BIM model is to make sure the information required in the maintenance system exist in Revit as component's custom parameters, and that it is exactly identical as to the name we presented, since the android application will be retrieving information from that specific column. These parameters created in the BIM model are determined by interviews conducted with the maintenance unit and through the system proposed by Wang et al. (2013) [12].

These maintenances related shared parameters were created manually in Autodesk Revit 2014 and can be separated into four main information categories: maintenance company information, inspection information, component's property information, and historical maintenance information. These four categories consist of all the information that will be retrieving through our android application all of them would be crucial regarding the backend usage for queries in MySQL database, below are the detailed explanations of what information are included in each category.

3.2 MySQL Database

In the system, MySQL database management system is used to store all of our information that will be used by the simple mobile devises application. There are several advantages for using MySQL database, for it is supported by different computer operating systems and it is also very user-friendly. But the main reason is due to MySQL is an open source system, in which it is convenient in searching for other users' shared experience and any other related information that helps with solving problems. In this section it will highlight on the setup of MySQL database management system for model data to be exported to and stored in. It includes two procedures; First procedure includes a total of five steps for installing WAMP and configuring the system settings. Second procedure includes Creating and editing MySQL databases.

3.3 Microsoft Access Database

The proposed system used Microsoft Access to enable synchronization of model data in MySQL back to BIM model in Revit, in order to tackle the problem regarding the inability of interoperability between MySQL and Revit BIM Model, see figure 2.

As shown in figure 2, the information between BIM model and Access Database is a double-side path. Compare with traditional application of BIM, since traditional works as a one-way path, the proposed system can both read and rewrite the BIM information, which makes it possible for operators read and modify the information by their simple mobile devices immediately. Eventually, reduce the work time for transferring the information, and the potential mistakes that may happen.

Figure 2. Information flow from Access

3.4 Android App

In order to create a convenient yet user-friendly platform for interacting with the data stored in MySQL database, android operating system is applied to build an android application. Two reasons explain why android system is applied. First, android is the most common operating system nowadays. Second, it is easy to obtain for most of the people.

By developing an android application, the proposal aims to provide users with a more user-friendly platform in accessing data through the cloud. Any person with an android operating system mobile device would be able to open up this application and view or update the BIM information in MySQL database.

The main profit that Android app offer is convenience, and since AR (Augmented Reality) tech is imported in this app, users can view the model through AR by the markers. Compare with traditional 2 dimensional blueprint, viewing the model in AR makes it more intuitive for the users. About AR function, it will be fully introducing in section 4.1.

4 Application Selections of Android App

In the application, it consists of three different modules. First, 3D Model Visualization Module, providing users with the function to view the desired 3D model. Second, Information Inquiry Module, providing users with function to search for component information in four different ways while also providing instant updating capabilities regarding the information acquired. Last, Maintenance Work Orders Module, providing users with the function to generate maintenance work orders upon the selected components and to review previous generated maintenance work orders. Figure 3 shows the framework of application functions, and the following sections will introduce the three modules step by step in detail.

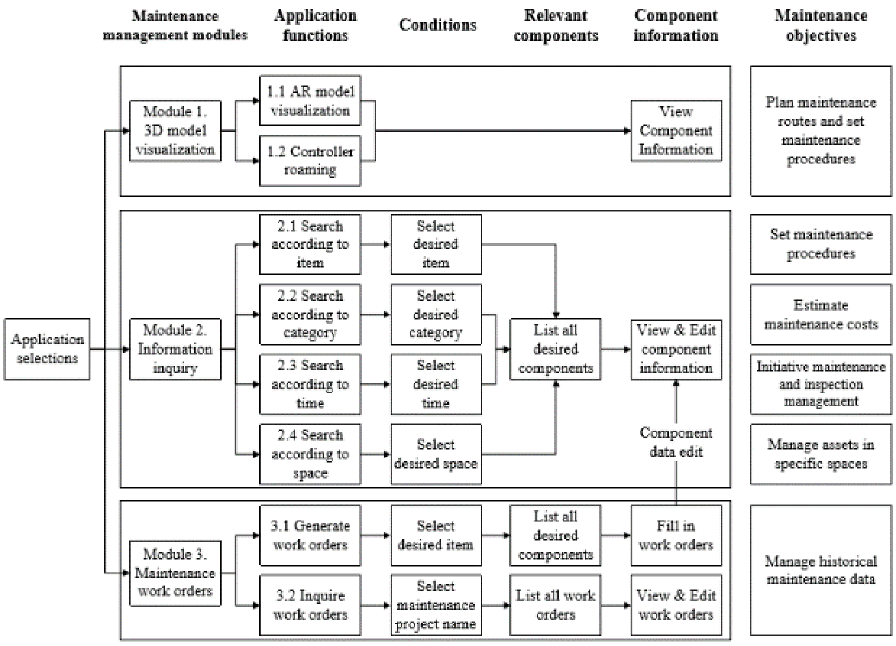

Figure 3. Framework of application function

4.1 3D Model Visualization Module

In 3D model visualization module, it can divide into three parts; 3D model, mobile screen, and QR code markers. 3D model's information is stored in MySQL database, and will be presented on mobile screen by scanning the QR code markers.

In this module it provides two types of unique functions; AR model visualization and controller roaming. Users are allowed to view 3D models created by Revit and stored in MySQL database through this module with AR technology or with controller roaming function. Both functions will be able to acquire information from MySQL database by pressing the component on the mobile screen, which is accomplished by querying the information through component element ID generated by Revit.

In the proposed system, both functions put emphasis on offering users a much more convenient operating environment. As figure 4 shown, users can view the information and model by scanning the AR markers. And for figure 5, it shows that the users can also use controller roaming function to travel around in the model by SMD. Before the proposed system, users had to carry lots of devices or papers for operation, however, the proposed system overcomes these inconveniences.

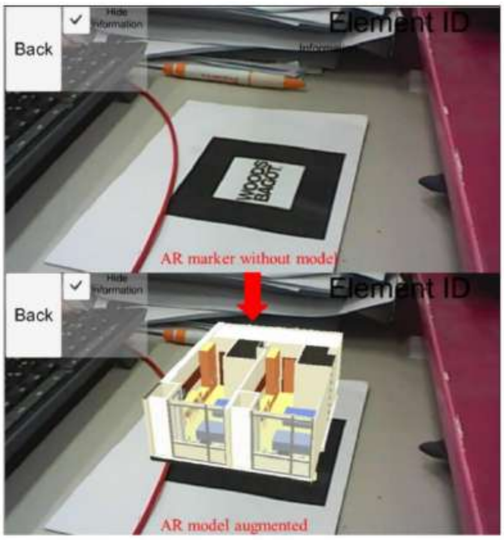

Figure 4. Markers and AR model augmented

Figure 5. Controller roaming function

4.2 Information Inquiry Module

There are two types of information that would be displayed in application. The first type of information is the basic information. It includes type name, component dimensions (width x height), serial number, location (space number), level, construction cost (direct cost), net width and height, room area, and material names.

This type of information is linked with the model directly, so the users are unable to modify the information by app (mobile devices), but are able to view the information.

The second type of information is the maintenance information in which the data are changeable by users. Including maintenance company name, person in charge, installation date, previous and next inspection date, previous maintenance cost, condition, general and detail category, all the information can be change on the app which the users are using.

Since the proposed system consists of two databases, it guarantees that the information changed from app can imported back to BIM model, compare with other systems, the BIM model and database are setted up together, people can only view the information yet are not able to modify it. For the second type of the information, which just mentioned, can then be able to change on the app in the proposed system.

To search for the desired component and its information, the information inquiry module provides two types of inquiry functions, namely, search according to item and category. Shown in Figure 6 and described as follows

Figure 6. Information Inquiry

- Search according to item: This function lists the six types of components in the spinner for users to choose. For example, if a user knows which door to search for, then the user would only need to choose the component type to be "door" and then search through all the doors to acquire information regarding the desired door, see Figure 7.
- Search according to category: This function provides two spinners for users to choose the general and detail category of maintenance work. General category is the architectural construction, and detail category includes maintenance work for masonry finishes, paint finishes, water leakage, doors and windows, room partitioning, metal materials, plumbing fixtures, and ceilings. These detail category describes several maintenance projects that components would undergo.

Figure 7. Demo of search according to item

4.3 Maintenance Work Orders Module

In Maintenance work orders module, it consists of two parts. The first part is Generate work orders. By selecting desired item, it will then list all the desired components which the users can fill in the work orders. After filling the work orders, the users can both View & Edit component information. The second part is Inquire work orders. By selecting maintenance project name, users are able to view and edit the work orders.

The main purpose of this module is to allow the users generate and search for work orders at any time and any place. The other purpose of this module is to help users manage historical maintenance work orders, with all the maintenance work orders stored in MySQL, maintenance work orders database, the users will be able to effortlessly manage this historical data. Additionally, each maintenance work order was created based on a component, meaning that this one to one relationship between work order and a component will decrease any uncertainties when users are reviewing work orders.

Since all the work orders are stored in MySQL database, the information of the work orders will also be able to store back in the model.

- Generate Maintenance Work Orders: Generate maintenance work orders based on a selected component.
- Inquire Maintenance Work Orders: Inquire maintenance work orders based on the selected maintenance project name

5 Case Study

The proposed system is applied to a building project of a national research center located in northern Taiwan. This building built with reinforced concrete (RC), including four upper-structure floors and two underground-structure floors, which is a multi-purpose building that provides guests with accommodations, parking spaces, several event venues or spaces to host conferences and meetings, and a dining hall.

All of the 75 housing rooms in this building include various types of furniture components, which can be further divided into several categories including, beds, closets, cabinets, electronic devices (TV and refrigerators), tables, and chairs. These added up to more than a hundred of components to be managed.

5.1 Maintenance Practice of Case Project

The case study of this research focus on a new-built academic center (four upper-structure floors with RC), during construction stage, BIM model is built. The manager of the building is a team of construction from the owner. Usually the team focus on 3 different works. First, planning and constructing for the new building. Second, maintaining and repairing the existing build and facilities. Last, Space setting and numbering for the building. After starting the operation management stage, the owner proposes an operation management system in order for the convenience of the building in the future. This research helps the manager establish the operation management system.

5.2 Applications

Based on the information exported from the BIM model to the MySQL database, one can start using the application (maintenance management system) by first logging into the system by entering the correct email and password. The system will then go to the module selection page of the system.

Next, users can choose to visualize 3D models through AR or controller roaming functions. For example, a maintenance staff could be able to visualize the whole floor and identify each component located and seen on that model. This helps maintenance personnel with planning maintenance route, since they will be able to easily observe the whole layout of the floor in 3D. The users could also be able to have a better idea of where the component is located at and the difficulty of maintenance. Figure 8 shows a user using a mobile device to visualize the AR model of a room from the case study.

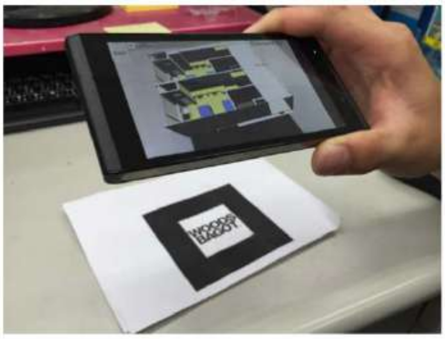

Figure 8. AR model application

Users can also quickly acquire information through Information Inquiry Module by using condition-based functions to find the component and view its information, as shown in figure 9 as an example. Users first select the conditions then choose the desired component from a list in order to view and modify information.

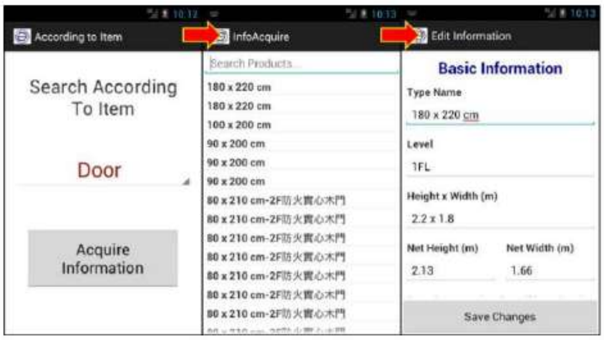

Figure 9. Steps for information inquiry

Lastly, the users will be able to generate and view maintenance work orders. The first function, generate maintenance work orders, let users create maintenance work orders targeted to one component, meaning each maintenance work order corresponds to a single component. The second function, inquire maintenance work orders, let users search for all the maintenance work orders by their maintenance project, which would list out all the components that belongs to a maintenance project.

6 Conclusions

This work demonstrated that integrating BIM based maintenance management system and mobile computing is feasible via the development of a mobile application. The integration provided by this system is significant in three aspects. First, BIM can support information exchange through the internet by providing BIM model information to MySQL database. Second, the 3D model visualization module allows BIM model to be viewed through mobile devices with augmented reality technology. Third, a truly complete integration between BIM and maintenance management system in enabling data exchange from maintenance management system back to BIM model. Overall, the proposed system demonstrated its effectiveness in enhancing the current BIM-based maintenance management system applications.

Future research in this area may also include the following directions in expanding the proposed system. First, while the current system considers 6 popular component types, other types of components, such as MEP system components can be included. Second, implementation of this system towards various BIM software could be tested. Third, evaluation of maintenance companies or other analytical functions can be included into the application, to focus on how information can be used to help make better decisions. Last, the AR tech in this project imported markers, however, it is possible to make it mark-less, which enable that in future, operators no need to carry papers or find the markers that is hided in the structures.

Acknowledgments

This research is financially supported by the Ministry of Science and Technology of Taiwan (Contract No. MOST 104-2622-E-009-021-CC3 and MOST 104-2221-E-009-175-MY3). We also like to sincerely express our appreciation to Ming-Wei Hung in Concord Tech Taiwan Company for his technical assistance. In addition, the valuable assistance and collaboration of several practitioners involved in the case study are greatly appreciated.

Do Handstorm Principles Support Creative BIM Collaboration?

Frans van Gassel

Handstorm Competency Centre | Eindhoven University of Technology (TU/e), The Netherlands

E-mail: info@handstorm.nl

Abstract –

Building Information Modelling (BIM) and Internet-based tools are communication aids. During the product and process design phase partners must coordinate, cooperate and collaborate with stakeholders. Creative and collaborative work is necessary in order to create value for the end consumer and society and to develop smart buildings. For this type of work design managers must have collective skills, expertise, understanding and knowledge. Furthermore, there must be an atmosphere of openness, honesty, trust and mutual respect. Merely using the current BIM tools may not be enough for future creative and collaborative work.

To enhance creative and collaborative work, the Handstorm principles have been developed based on a literature review and empirical research on collaborative design. The Handstorm principles are interventions that encourage professionals to be creative, to work collaboratively, and to support each other during design meetings. To help professionals learn and practice these skills, a *creativity facilitation* course has been developed, tested and validated.

The research question in this paper has been formulated as follows: *Do the Handstorm principles support creative BIM collaboration?* During the first phases of BIM, the collaboration can be effectively realized by using models and internet-based tools. However, subsequent phases must involve more of the knowledge and experiences of the stakeholders. To encourage this involvement, design managers must have specific skills to plan, organize and lead creative processes. These skills can be learned in a creativity facilitation course based on the Handstorm principles.

Keywords –

Social BIM, collaboration, creative thinking, design meetings, design principles

1 Introduction

In this paper the results of the PhD study *Handstorm Principles for Creative and Collaborative Working* [1] have been used to determine whether these principles support creative BIM collaboration. In this paragraph we will first discuss the field problem of the PhD study and the solution approach. Subsequently, the limitations of BIM and the research question will be addressed and then the structure of the paper will be described.

1.1 Field problem and solution approach

A field problem is a problem that occurs frequently in practice and for which there is still insufficient generic knowledge to solve it [2]. At the moment, professionals, stakeholders, clients and users in the Architectural Engineering Construction (AEC) sector make too little use of each other's knowledge, skills and experience during design meetings. This poor collaboration is evident in the way in which building joints are sometimes engineered in practice. It is important for designers to ask questions that can help determine whether the following issues have been sufficiently addressed: preventing thermal bridging, labour-friendly delivery, positioning and fixing of building components on the building site, and environmentally friendly ways of dismantling building components [3]. The conclusion reached during a seminar that was organized by the Universitair Centrum voor Bouwproductie (UCB) was that intensive collaboration between various professionals is needed when designing joints in a changeable and sustainable building [4]. In his PhD research, Olie [5] characterized this problem of collaboratively designing building joints as follows: "Good joints in buildings depend on good connections between parties."

For the PhD study, the field problem has been described as follows: *Creative and collaborative working during face-to-face design meetings in the AEC sector is not planned, organized or conducted with adequate knowledge and skills.* The word "meetings" in this problem description can be defined as a "process undertaken by two or more interested individuals, sharing their collective skills, expertise, understanding and knowledge (information) in an atmosphere of openness, honesty, trust, and mutual respect, to jointly deliver the best solution that meets their common goal" [6]. The aim of a design meeting can be any of the following: (i) assessing the situation, (ii) exploring the vision, (iii) formulating the challenge, (iv) exploring ideas, (v) formulating solutions, (vi) exploring acceptance and (vii) formulating a plan [7]. Meetings in the AEC sector are primarily conducted in a face-to-face setting. Rhoades and O'Connor stated that "in face-to-face groups the affect, or emotion, experienced by group members has an impact on the group's cohesiveness" [8]; this factor has implications for group performance, which is not the case with computer-mediated groups.

One approach to solving the field problem is to augment the knowledge and skills of the professionals by having them take part in a creativity facilitation course. The main aim of the creativity facilitation course is *to teach professionals to better plan, organize, and conduct face-to-face design meetings in the AEC sector*. The following aspects of successful creativity facilitation are listed below.

(i) Oriented to the AEC sector

The participants of (design) meetings in the AEC sector generally originate from very diverse professional groups. These professionals often have their own language, tools, codes, unwritten rules, and scientific paradigms. Facilitating a creative meeting that effectively makes use of this diversity requires a specific approach to make the participants responsible for the wishes of the client, and to help them let go of their personal solutions. By definition, participants of a meeting do not form a team; if a participant is unable to attend, he/she may send a replacement without announcing this in advance.

(ii) Involved facilitation

In most meetings, the project leader guides the meetings by focusing on his/her own issues, and insufficiently considers the contributions of the participants. In order to avoid this lack of participation, a leader should have an enterprising spirit and a proactive attitude which can contribute to an atmosphere of involved facilitation.

(iii) Stimulating cooperative learning

The professionals participating in design meetings are very experienced in their own disciplines. Collaborative working means that aspects of each discipline contribute to a final concept or idea. To realize this synergy, the facilitator must stimulate the participants' empathy and eagerness to learn

(iv) Using varied skills and intelligences

Professionals come from diverse disciplines, and have their own specific skills and intelligences. To help them work together, the facilitator should make use of all of their skills and intelligences by incorporating effective working methods that can be characterized by the values of playfulness, imagination and inventiveness.

(v) Creating an open culture

Participants of a meeting often have their own agenda to optimize their interests. There is a lack of transparency regarding these agendas, minimal respect for other participants' professionalism, and poor exchange of knowledge and experiences.

(vi) Consulting a set of design principles

Planning, organizing and conducting design meetings is not part of the (design) process manager's or project manager's daily work. He/she is engaged in construction engineering and management processes and not in running group creativity processes. Therefore, these managers must learn how to use scientific prescriptive statements, which in this study is a set of design principles. A safe environment, such as a course can be very helpful in this regard.

The knowledge and skills required to plan, organize, and conduct face-to-face design meetings can be taught with a course that has been developed using a suitable set of prescriptive statements or design principles.

1.2 Limitations of BIM

Building Information Modelling (BIM) and Internet-based tools are aids for automated workflows. These 'hardware' aids have an impact on the interactions during product and production design of building objects. Some impacts have been described in the literature and are identified hereunder.

In the study *BIM-based collaboration design and socio-technical analyses of green building*, El-Diraby, Krijnen and Papagelis [9] "noticed a few limitations/opportunities in the way current BIM tools address the needs for integrated design, collaboration and analysis", namely communication and interactions did not use BIM tools and end users were not engaged.

The bibliometric-qualitative literature review *Collaboration in BIM-based construction networks* (BbCNs) [10] aims to analyse the scholarship on collaboration on BbCNs. Two factors that need to be investigated are team members' knowledge, skills and abilities and the match between different members in BbCNs.

By developing and prototype validating a dedicated collaboration platform for Integrated Project Delivery (IPD) [11] to improve efficiency and reduce waste AEC projects, the researchers came to the conclusion that "offline meetings are still needed when complex and important problems are discussed".

1.3 Research question

Design managers need specific knowledge and skills to enhance creative BIM collaboration. These skills can be learned by following a course on planning, organizing, and conducting face-to-face design meetings. Therefore, the research question in this paper is formulated as follows: *Do the Handstorm principles support creative BIM collaboration?*

In the following paragraph a summary will be given of the PhD study *Handstorm principles for creative collaborative working* [1] and in paragraph three the developments of BIM collaboration will be explored. Paragraph four will provide an answer to the research question.

2 Handstorm principles

In this paragraph the above-mentioned PhD study will be described, focussing on the following aspects: (i) research design, (ii) the necessary conditions for successful automated collaboration in construction, (iii) developing a design principles-based creativity facilitation course, (iv) validating the set of design principles, and (v) conclusions, reflection and discussion.

2.1 Research design

The research set-up is design based and scientific. Research activities were formulated using the *research-design-development cycle*, which is a framework that describes knowledge flows and experience flows between praxis and science [12].

The central research topic, *developing a creativity facilitation course based on validated design principles,* has been broken down into three main research topics:

- Finding parameters to describe collaborative working in design meetings
- Developing the creativity facilitation course based on design principles
- Validating the set of design principles

When carrying out the research on these topics, the following research strategies were used: desk research, case study, experiment, and survey research.

This *design scientific research* aimed to achieve maximum practical relevance and maximum methodological thoroughness. The latter was achieved by developing the design principles on the basis of existing scientific knowledge and by validating them through practical implementation and evaluation. The requirement of maximum methodological thoroughness was also met by assessing the validity of the evaluation and qualification results by applying the rival explanations method. The requirement of practical relevance was met by implementing the course, which is based on a set of design principles, in practice. A beta test was carried out by publishing some of the design principles and evaluation questions at an early stage and inviting fellow academics to experiment with and report on them. The methodological thoroughness requirement was also met by the triangulation of this data – the use of different samples, spaces and persons.

2.2 The conditions for collaboration

For the first main research topic, *finding parameters to describe collaborative working in design meetings,* desk research and a case study were carried out. The desk research yielded a research perspective from which to consider collaborative working. The case study consisted of the analysis of 37 meetings held during the design and production phases of a prototype for an industrial, flexible and demountable construction system. The parameters found – ‘aim of meeting’, ‘control of meeting’, ‘participants’, ‘tools’ and ‘outcomes’ – were linked to the basic elements of the Structured Analysis and Design Technique (SADT). This resulted in a system model that can be used to describe and design meetings. An article on the implementation of this main research topic was published by Van Gassel, et al. [13].

2.3 Developing creativity facilitation course

The second main research topic, developing the creativity facilitation course based on design principles, has been broken down into four sub-topics:

1. Finding mechanisms that enhance collaborative working in a literature review of PhD studies.
2. Finding successful interventions based on the practical experience of the researcher.
3. Developing the design principles by synthesizing the mechanisms and the successful interventions.
4. Developing the creativity facilitation course based on design principles.

The research consisted of desk research and experiments. Sub-topics 1, 2 and 3 yielded 15 design principles; the syntax for each was classified on the basis of Context Intervention Mechanism Output (CIMO) logic. These design principles are described briefly below.

The set consists of 15 design principles, which can be summarized as follows: (i) plan a detailed meeting scenario, (ii) invite a variety of participants, (iii) explain work methods simply, (iv) have participants listen to each other, (v) put reluctant participants to work, (vi) create rhythm in the group’s activities, (vii) reformulate the definition of the problem, (viii) don’t be afraid to deviate from the meeting plan, (ix) continually change the circumstances, (x) take participants out of their comfort zones, (xi) let the participants do the work, (xii) let the hands do the thinking, (xiii) alternate between strict and lenient, (xiv) close the meeting with perspective, and (xv) choose the work method most appropriate for the meeting. To plan and conduct these meetings, design managers need knowledge of creative and collaborative work and creative (leadership) behaviour.

The final sub-topic yielded a course program and an enrolment leaflet. This leaflet sums up the aims of the course: oriented to the AEC sector, about involved facilitation, about stimulating cooperative learning, about using varied skills and intelligences, about creating an open culture, and about consulting a set of design principles.

The design principles and development process have been reflected upon. The design principles cover the meeting parameters ‘control of meeting’, ‘participants’ and ‘tools’ equally for each design principle. Background information was provided for each design principle and it was demonstrated that design principles strengthen the sub-aims of the course. The development process has yielded a method that synthesizes scientific knowledge and practical results into new design principles.

2.4 Validating the set of design principles

The third main research topic, validating the set of design principles, was broken down into three sub-topics:

- Evaluating the creativity facilitation course in practice;
- Qualifying the implementation of the set of design principles;
- Assessing the validity of the evaluation and qualification results.

The course was evaluated after it had been delivered six times. A questionnaire was used to measure learning results and participant satisfaction. This measurement showed that the course scored well regarding ‘knowledge of joint creative thinking’ and it was scored very highly regarding ‘improvement of creative behaviour’ and ‘improvement of creative leadership behaviour’. Course participants were very satisfied and after the course exercised the skills they had learned in practice.

The qualifying of the implementation of the set of design principles involves considering the measurement results of the learning outcomes and demonstrating the coherence between the three learning outcomes ‘knowledge of creative and collaborative thinking’, ‘creative behaviour’ and ‘creative leadership behaviour’, and the set of design principles. The coherence between the descriptions of the learning outcomes and survey questions can be qualified as fair based on the 5-point Likert scale (i.e. poor, fair, average, good and excellent).

The beta test was carried out at the Federal University of Juiz de Fora in Brazil, as part of a bachelor course based on the use of design principles. The answers given to the evaluation questions show that students were satisfied with the course (on a scale of one to five with a mean score of 3.75 (standard deviation 1.28 and $N = 8$)). Although there was initially some resistance among the students, it disappeared during the test. The coaches found that the results obtained when applying the design principles were better in comparison with situations in which the design principles were not used. It would seem reasonable to conclude that the use of the design principles is useful. The beta test was described by Pinheiro and Queiroz [14].

2.5 Conclusions, reflection and discussion

The central research topic, *developing a creativity facilitation course based on validated design principles,* results in an attractive and broadly applicable solution to the mentioned field problem, and fulfils some needs of ‘structuring face-to-face meetings’ and ‘guidelines for trained facilitators to enhance group creativity’ from the academic domains of *building design management* and *small group creativity*.

The creativity facilitation course is *applicable* for the professionals working for companies that are involved in performance-oriented tenders in the AEC sector and the course now forms part of the education program at the BAM Business School. The research has also yielded a set of Context Intervention Mechanism Output (CIMO) structured design principles that can be used as a guide when planning, organizing and conducting all kinds of design meetings. The principles can also be used to develop creativity techniques, such as two simulation games (‘Partner selection’ and ‘Creative supply and demand’) and two creativity techniques (‘Constructing a platform’ and ‘Constructing metaphoric objects’). The practical use of the design principles is publicized under the brand name Handstorm® on the www.handstorm.nl website.

The research further yields the following tools and findings for the domain of *design science research*: (i) a system model that can be used to devise and describe meetings, (ii) a procedure that has been devised to develop design principles by synthesizing successful interventions and mechanisms, (iii) a questionnaire in which participants evaluate the course, (iv) the *research-design-development cycle* has proven to be very suitable for designing the research, and (v) a procedure for the assessment of the validity of the evaluation results attained on the basis of the plausible rival explanations method.

To enhance the *reliability* of the results, the researcher has implemented the course six times in practice, used existing knowledge, initiated a beta test, and evaluated the course on the ‘indicative’ level.

The *validity* of the set of design principles has been assessed by qualifying the evaluation results and the results of the beta test. To estimate the validity of the set of design principles, the plausible rival explanations method has been used. The beta test that was carried out at a university in Brazil shows that design principles are useful when devising, organizing and planning education-related meetings.

Regarding the *generalizability* of the design principles, these principles are described as a robust basis for attractive and broad applications for creative and collaborative working.

The research has a number of *limitations* and thus suggestions are proposed for *future research*. Only the *indicative* evaluation level was chosen for the course because the course had been implemented only once in practice. In future research the higher evaluation level *causal* should be chosen, as now more are data available regarding the impact of the interventions on the outcomes.

The experiences of course participants were measured with a survey. The learning outcomes were only measured at the end of the six courses. In this study, the participants were asked to rate how much they had learned during the course. This form of self-assessment is less objective than taking measurements before and after training. In future research, it might be better to measure the knowledge and behaviour of participants at the beginning and at the end of each course.

The usefulness of the set of design principles was determined by measuring the coherence between the text of the questionnaire and the keywords of the 15 design principles. This coherence can be considered *fair* but there are clearly differences between the learning outcomes ‘creative behaviour’ and ‘creative leadership’ in relation to the design principles. Further research can more explicitly test the course participants’ knowledge about the set of design principles as a part of the evaluation and can thereby enhance the coherence.

The Structured Analysis Design Technique (SADT) system model for meetings is based on just one case study, but it has on numerous occasions been used to analyse and describe various construction processes during the Master’s degree program in Construction Management and Engineering at the Eindhoven University of Technology. It is recommended that further research be carried out on the validity of the SADT system model for meetings (e.g., in the form of additional case studies).

Other worthwhile research would involve testing the effectiveness of the Handstorm principles during every phase of creative and interdisciplinary collaboration processes, for example in the ICT, government and health care sectors. In addition, it would be advisable to establish whether the principles are applicable outside a Dutch or Brazilian context.

3 Developments BIM collaboration

Answering the research question in this paper, *Do the Handstorm principles – as learned in a creativity facilitation course – support creative BIM collaboration?* requires insight into the developments in BIM collaboration and the competences desired by design managers to enhance this collaboration. The findings of several authors regarding theses aspects are summarized hereunder

Grilo and Jardim-Goncalves [15] distinguish five interaction types along the x-axis: communication, coordination, cooperation, collaboration and channel. Each type of interaction has three value levels along the y-axis: efficiency, differentiation, and value innovation. Collaboration is related to value innovation and described as 3D BIM & Collaborative working environment. During the design of the product and production processes for the built environment, partners must coordinate, cooperate and collaborate. Creative and collaborative work is necessary in order to create value for the end consumer and society and to develop smart buildings.

Uhm, Lee and Jeon [16] have analysed BIM jobs and their required competences. The BIM jobs were classified into eight BIM job types: BIM project manager, director, BIM manager, BIM coordinator, BIM designer, senior architect, BIM mechanical, electrical and plumbing coordinator, and BIM technician. According to their study, the BIM project manager did not require a number of *common* competences in relation to creative collaboration. Some relevant competences include the following: “work styles of cooperation”, “design knowledge”, “work activity of thinking creatively”, “work activity of commutating with supervisors and peers”, and “work activity of providing consultation and advice”. This study may contribute as a guide to developing a training program for BIM design managers.

In the study *Enhancing collaboration in BIM-based Construction Networks (BbCNs)*, the authors Mignone, Hosseini, Chileshe and Arashpour found four main approaches for enhancing BIM collaboration in the literature. The second approach “suggested the incorporation of the principles of effective team working in tertiary education programmes” and the third “contended that members of BbCNs should be regarded as constant learners to foster collaboration” [17].

Future generations of BIM systems need real-time co-creation capabilities during the development phase. It is the people who collaborate and not the systems. Therefore, the future systems, which are known as Social BIM, focus “on the *procedural aspects of BIM* by encapsulating the metacognitive, behavioural, interpersonal and confidence skills that shape effectiveness of collaboration”. This statement comes from the study *Social BIM: Co-creation with shared situational awareness* [18].

Based on the findings of these authors, it is clear that enhancing creative BIM collaboration requires collective skills, expertise, understanding and knowledge by design managers in an atmosphere of openness, honesty, trust and mutual respect.

4 Do the Handstorm principles support creative BIM collaboration?

The research question in this paper has been formulated as follows: *Do the Handstorm principles support creative BIM collaboration?* During the first phases of BIM, the collaboration can be effectively realized by using models and Internet-based tools. However, subsequent phases must involve more of the knowledge and experiences of the stakeholders. To encourage this involvement, design managers must have specific skills to plan, organize and lead creative processes. These skills can be learned in a creativity facilitation course based on the Handstorm principles.

The automation of the process of updating the curing time activity in 4D schedule

T. Funtík[a], P. Mayer[b] and J. Gašparík[c]

[a,b,c] Slovak University of Technology in Bratislava, Faculty of Civil Engineering
E-mail: tomas.funtik@stuba.sk, jozef.gasparik@stuba.sk, pavol.mayer@stuba.sk

Abstract –

In todays practice, we encounter different approaches to solving the problem of planning a curing time for wet processes. The article focuses on concrete processes where the length of the curing time needed for formwork removal is dependent on numerous factors. By using sensors that monitor the internal temperature in the concrete, we can determine the time of stripping of the formwork more precisely. The aim of this article is to describe the process of possible automation of the update in the duration of the technological break (curing time) and the integration of this data into the BIM model. The proposed process will be used to solve the active link to the update of the formwork removal activity in 4D simulation of the construction.

BIM, 4D simulation, Formwork removal

1 Introduction

The effectiveness of cooperation between construction participants can be clearly increased by sharing information from the BIM model. However, it is essential to ensure the sharing of digital files, not only between design applications but across all stages of the building's life cycle. In the past, it was almost impossible to open and edit files in a different environment than where they were created. Such an approach has limited cooperation and also freedom in choosing software. Today the situation is different.

Updating the 4D models, if done manually, is time-consuming and labour intensive, which discourages their use among industry practitioners (Lopez et al. 2015). There is a need for solutions that automatically incorporate the detected progress data into 4D BIMs and update the schedule and tasks associated with 3D model objects (Chen et al. 2015; Kim et al. 2010).

According to our study, there is potential in optimization of the process of updating the construction schedule with partial automation. Such an example is formwork removal activity that could be updated without the need of manual input. This can lead to savings related to cost and time and providing direct source of information in order to make a right decision.

2 Building Information Modelling

2.1 Process

The goal of BIM is not to create a model itself, but to gain complete, reliable, accessible and easily exchangeable information to anyone who might need it throughout the whole life cycle of the building.

The data rich information model, today interpreted as BIM model basically consists of three parts. We can characterize it as a combination of graphic and non-graphic data and any documents related to a construction project according the definition of English standard PAS1192-2. In some definitions, metadata is included as part of the information model except for the three above mentioned components. For BIM to be complete, we need all this information for each element, object, product, material or system that is included in the project. The detail of this information can be referred to as the Level of Definition, which includes the level of detail and level of information, and therefore describes the specification of the information model on a graphical and non-graphic base.

Graphic information can be 2D or 3D and are expressed in shape and layout in space. This information is basically a 3D model, its graphic, a geometric representation (in native or exchange format) that provides visual orientation, location and context, defines relationships between rooms, spaces, and other elements in the model. Although it is estimated that the graphical representation, respectively. A 3D model that contains geometry only represents only 5% of the project information, this part of the model is necessary for computer coordination (for example, for collision detection) and serves to link and determine relationships with the systems. Simplified, the 3D object serves as a container for some non-graphical information or parameter information and potentially provides a link to other information in other formats and placements.

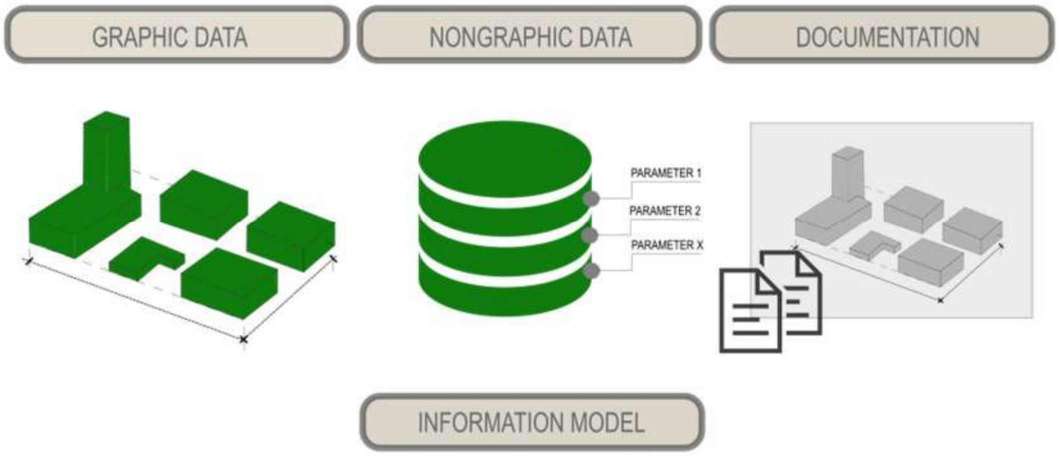

Figure 1 Building Information Model

The Level of Detail (LOD), i.e. the detail of its geometric representation, can define the relevant standard or is defined in the BIM (BIM Execution Plan) and expresses the required detail in each phase of the project.

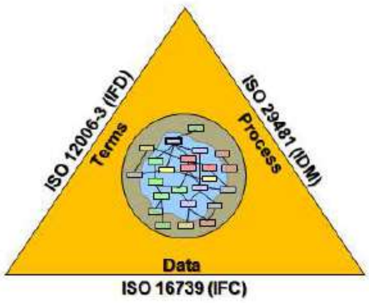

Figure 2 Basic schema of standards

2.2 Interoperability

Another fundamental prerequisite of BIM process is interoperability. Individual software applications store information primarily in their native formats, which is a major challenge in the digital world of the construction industry. In order to make information available to all participants throughout the life cycle, software applications must enable and secure reliable data exchange.

Interoperability refers to the property of a product or system communicating and working with other products or systems without any limitations. It could also be said that interoperability is the ability of a system or product to work with other systems or products without the need for particular effort on the part of the user. It is true that interoperable systems are capable of communicating and exchanging information to avoid uncontrollable modification and loss.

IFC (Industry Foundation Classes) file type – a neutral data format used to describe, exchange and share information between stakeholders and various software.

There are various methods, software systems and information, respectively. communication technologies that deal with effective data exchange between software applications. Basically, it can be plug-ins and programs, individual file-sharing formats created by software vendors, DXF (Data eXchange Format), or standards and open data models such as XML (Extensible Markup Language) and IFC (Industry Foundation Classes - a standardized and fully documented file format created and defined by buildingSMART).

The BIM itself is based on open cooperation and also through the IFC ensures the exchange of information from the data model between the different professions within the life cycle, thus also between different program environments. In this area, it is good to rely on the available ISO 16739 standards, which define the data themselves - IFC, ISO 29481 which defines the Information Delivery Manual (IDM) and ISO 12006-3, which define the framework for object-oriented information.

The development of IFCs is constantly advancing, and standards are tailored to the needs of the industry. In fact, the IFC1.0, IFC1.5, IFC1.5.1 and IFC2.0 have been on the market before 2000, are no longer used today. In October 2000, a stable IFC2x platform was launched, a year later updated with IFC2x-Add1. In 2003, the IFC2x2 platform was also released, which was also updated by IFC2x2-Add1. Currently, IFC2x3-TC1 - "IFC2x Edition 3 Technical Corrigendum 1" is the most used platform - it supplements version IFC2x3 from July 2007.

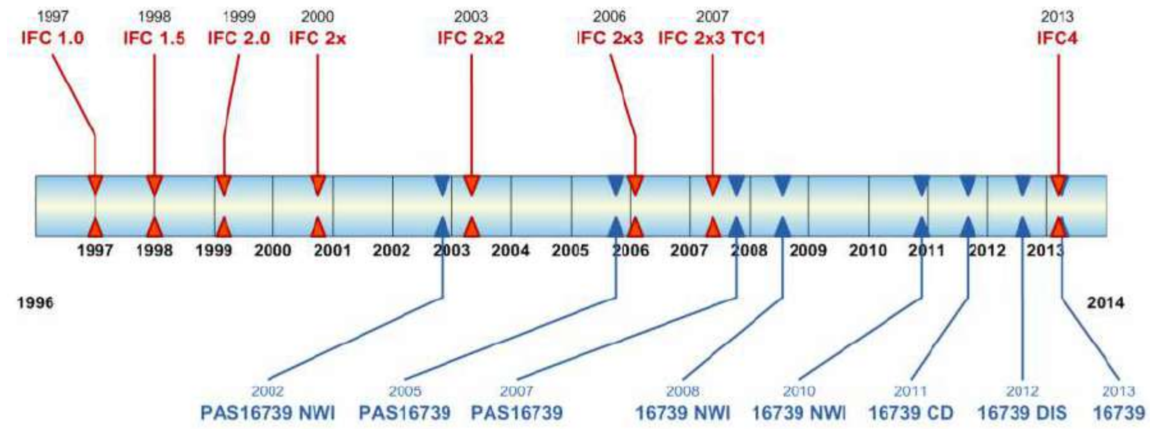

Figure 3 IFC schema, BuildingSmart

The new version, released in 2013, is the IFC4 platform (formerly IFC 2x4). IFC4 includes additional extensions related to the building, component, geometry improvements, resources, significant quality enhancement, and fully integrated ifcXML. In July 2015, IFC4 - Add 1 (Addendum 1) was released, incorporating the necessary improvements that were discovered during pilot implementations and development activities for MVD (model view definition). The next version of IFC5 is currently under preparation. The date of its issue has not yet been confirmed.

The basic schema of the most frequently used version of IFC2x3-TC1 is shown in Fig. 1. The IFC schema consists of a set of defined ways to divide information into individual classes along with the information structure that defines the objects. This structure formally specifies the attributes within the classes and defines the form in which the data will be exchanged within ISO 10303, Industrial Data Systems and Integration (Part 21, 22). The diagram is divided into three basic layers respectively. level, namely Core, Interoperability, and Domain. Platform components are shown in green.

Although definitions and structures are comprehensive, many types of information that individual users want to replace are not directly part of the IFC Model. However, it is possible to define them within the IfcPropertyResource scheme.

3 Formwork removal

Concrete is a composite material composed of fine and coarse aggregate bonded together with a fluid cement that hardens over time. Many types of concrete are available, distinguished by the proportions of the main ingredients. The rate of hardening of concrete or the concrete strength depends on several aspects.

The curing period may depend on the properties required of the concrete, the purpose for which it is to be used, and the ambient conditions, i.e. the temperature and relative humidity of the surrounding atmosphere. These aspects affect the formwork removal time. The process of removal of formwork in the process of casting concrete is also known as striking time. Once the concrete has achieved the initial recommended strength, to support the self-weight and any imposed loads, the shuttering is removed for further curing.

Curing is the process of controlling the rate and extent of moisture loss from concrete during cement hydration. (Curing of Concrete, 2006).

Leaving formwork in place is often an efficient and cost-effective method of curing concrete, particularly during its early stages.

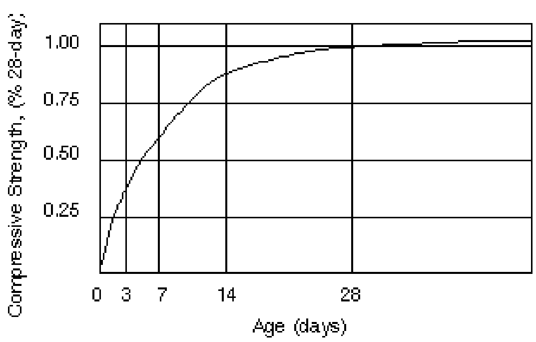

Figure 4 Typical strength-gain curve, University of Memphis

3.1 Actual approach

Stripping should be carried out only after the time when concrete has gained sufficient strength. This time represents the time lag between concrete casting and formwork removal activity.

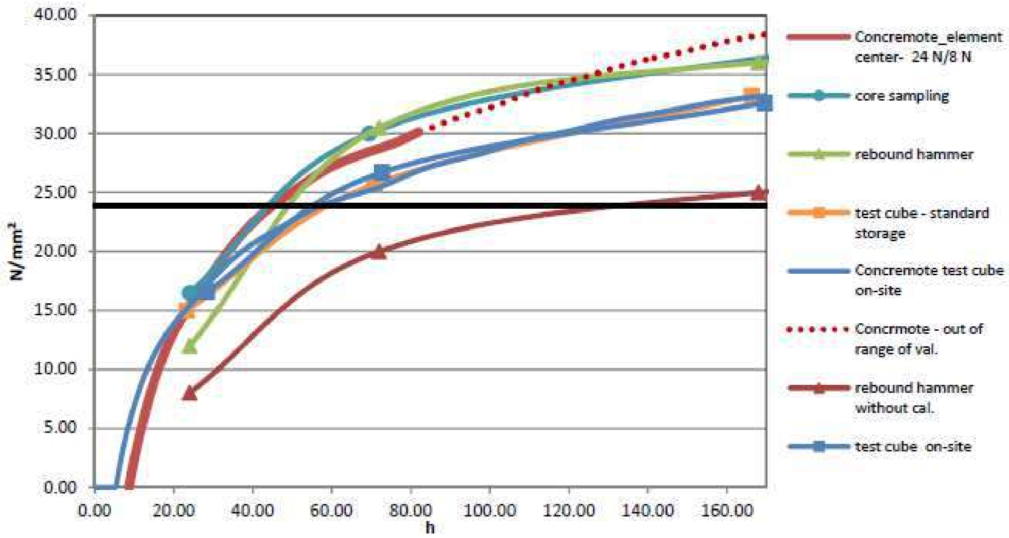

Figure 5 Compressive-strength-developments derived from different methods

"The delay after the first activity completes and before the second activity starts (wait period), is called lag and this delay is known as the Lag Time." (Project Management, book)

Throughout local construction industry, the most common understanding of the process of hardening is that it takes 28 days to cure and reach 100% of proposed strength. This is strongly connected to lag time and according to our research, this affect their estimate of duration of this task. In some cases, constructors estimate for necessary time lag until striking is possible is 28 days (form and complete set of support removal). Of course, the decision to specify date of formwork removal activity need to be confirmed via various methods.

Nowadays, companies tend to estimate striking time unsystematically, mostly relying on their previous experience or company´s internal standard. They use non-destructive tests (mostly Schmidt hammers) or obtain this information from reference samples or query the information from structural engineer.

The most common approach is using rebound-hammer to confirm the date of formwork removal. However, construction companies frequently use uncalibrated rebound-hammer and it is proven that uncalibrated rebound-hammer deliver the most inaccurate results.

In many cases, the removal of formwork process could have occurred sooner, which has a major impact on the construction process and the optimization of concrete workforce.

3.2 Sensor-based strength measurement

Non-destructive methods based on maturity calculations can be applied. There are several commercial systems on the market (Concremote, Con-Cure NEX, SmartConcrete, ...) providing non-destructive measurement of fresh concrete strength based on real-time hydration heat.

„*Most of the destructive test methods have the disadvantage of the late availability of the data. The evidence for strength is usually too late in time to make decisions regarding the building process (e.g. striking times). For optimising construction processes the real-time concrete strength methods on the basis of the calculations by de Vree are generally a promising technology.* " (Reinisch et al, 2015)

Using such a system for sensor-based strength measurement have advantages in various cases e.g.:

- decision on striking time of wall and ceiling formwork,
- information about load capacity for special type formwork for vertical concrete structures e.g. climbing formwork,
- temperature monitoring and recording due to prevent possible cracking,
- casting concrete roads to estimate cutting times for concrete joints,
- estimate aesthetic concrete maturity in order to achieve the same shade

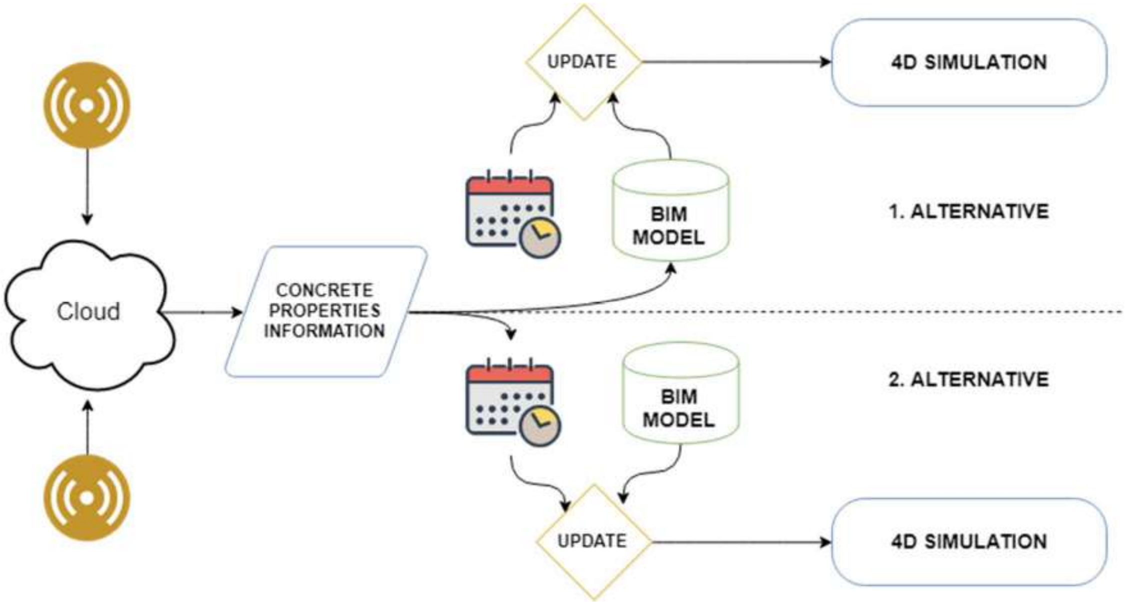

Figure 6 Flowchart diagram of proposed methodology

Primary benefit of this approach is that the measured data are collected, stored and reachable from cloud-based service. Some systems store (backup) data through local storage device e.g. SD card. Prior to use, all sensors must be calibrated to provide reliable information.

Sensors can be wired or communicate remotely and most of the built-in sensors available on the market can be used multiple times. After activation, sensor record measured temperature on predefined time span (for example each 5, 10, 30 min). Individual values are incorporated into diagram representing strength of concrete. Once the strength predefined by the customer is reached, the system automatically notifies the person responsible for the construction management via SMS or e-mail. This capability of the system to communicate autonomously in a predefined form is a base for further development of the platform for the automation of the process of updating the curing time activity in the schedule as activities related to striking task management which are its successors could be linked dynamically.

4 Proposed methodology

For the purpose of the possible automation of the process of updating the curing time activity in 4D schedule we will consider two approaches.

One approach is based on enriching 3D BIM model either by modifying IFC file or model in native format and the second is based on modifying time schedule.

4.1 Modification of 3D parametric model

Approach based on modifying BIM model either by through IFC file or native format is the platform where time information about the exact date of striking is delivered directly into model as a parameter using excel predefined template custom macro or Dynamo script. Further update of schedule by modification of the input value of model objects with assigned tasks is done in 4D scheduling software.

4.1.1 IFC based modification

Modifying IFC file allows the wider spectrum of utilized software. There are several software allowing you to edit IFC data without having access to the original model. Various authors already worked with the topic of IFC-based automation of schedule progress updating (Hamledari, et. al, 2017)

It is known that the IFC 2x3 schema specification provides a reasonable basis for the use case of model-based scheduling. The benefits of model-based scheduling are widely recognized (Porkka, Kähkönen 2007).

The aim of the rule-based linking approach is to reduce the effort for the overall set-up process by using semi-automated linking mechanisms and improve the management of data dependencies to react more efficiently on design changes. (Weise et. al, 2016)

Each IfcTask is distinguished from others by its GUID. The schedule control information, on the other hand, is modeled through subtypes of IfcControl, such as IfcScheduleTimeControl, which holds all the necessary attributes for scheduling a task such as early and late start and finish dates, duration, and float information.

For each task, the ScheduleDuration and ScheduleFinish attributes of the IfcScheduleTimeControl are updated (Hamledari et.al. 2017).

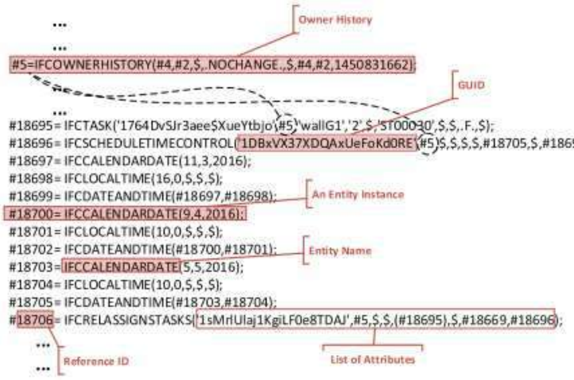

Figure 7 Parts of an IFC data model, Hamledari et.al.

Using special software, you can edit properties of IFC model. In general, you can modify property values, combine and split values and move values from one property to another. It is also possible to Enrich the model by adding new data to IFC models from external data sources (import and export of IFC2x3 and IFC4 models using the .ifc and .ifczip file formats) allowing to export the property data of BIM model into Excel.

4.1.2 Modification of model in native format

Option that we are considering is also modification of time information directly in the native format. This allows the user to work in an environment they already know and without investment into additional software. For this purpose, we are using the Navisworks to simulate construction processes. We can either manually enter information about project tasks or import schedules from many project planning software applications (MS Project, Primavera,..) and to follow with linking the elements in the model with tasks in the schedule. The procedure in Navisworks would be to link Revit model and the project plan document; followed by mapping Revit Elements to corresponding construction activities. After this Navisworks can simulate the virtual construction on Revit model using the dates provided in project plan.

In order to tag the Revit Elements with four construction dates (Planned Start Date, Planned End Date, Actual Start Date and Actual End Date).

For achieving this you can create mentioned dates as a Project Parameters (Text Type & Instance). Further you can select the individual elements as required and update fields.

4.2 Modification of time schedule

Approach based on modification of the time schedule apply when time information about the exact date of striking is delivered directly into schedule using excel predefined template and custom macro. Further update of schedule by modification of the input value of the formwork removal task is done in master scheduling software (either directly in 4D environment or in MS Project).

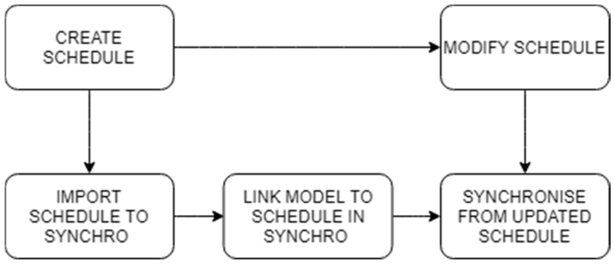

Figure 8 Synchro update process

Synchro PRO, that could be used as a tool uses XML format to Synchronise when working with MS Project. In a process of updating the schedule in 4D environment (e.g. Synchro PRO) you should skip task synchronization when synchronizing with an IFC file that contains a 3D model only, since IFC files may contain task data too.

When using Synchro PRO, it is important to be aware of various techniques of schedule modification. You can use Skip, Synchronise, Consolidate of Integrate option. For the purpose of prolongation of shorten of the lag time for striking, Consolidate of Integrate option must be used where the new schedule will be merged with previous version of schedule and depending on selection objects that were deleted in update version will be deleted (Integrate) or not (Consolidate).

5 Conclusion

Interoperability and BIM itself provides wide options for construction optimization either for reaching higher quality or mostly by using advanced techniques for partial or full automation of some processes and therefore reducing the need of manual inputs and reducing time consuming activities.

We assume that solving even partial tasks of automation of construction schedule results in better construction management.

In the local industry, the topic of formwork removal appears to be solved unsystematically. We believe that by using sensors to accurately determine the achievement of the required strength of concrete and linking the information about actual time lag to the model, we can simplify the process of schedule update. Moreover, we can provide reliable information that the striking can be done and when it can be done to the person in charge in an efficient way.

Further research needs to be performed in order to develop exchange templates, to verify reliability of proposed method and compare versatility of suggested approaches and evaluate most effective way of data exchange.

Abstract

Despite its documented success, the use of Building Information Modelling (BIM) continues to raise questions related to its implementation at an institutional level. Therefore, several institutions have produced guidelines specific to BIM to communicate their expectations in regard to BIM in their projects. However, such guidelines do not exist among Canadian post-secondary or public institutions despite the wide implementation of BIM technology. To better address the requirements of BIM usage by public post-secondary institutions, a review of existing BIM guidelines is needed. The research includes three phases: (1) assessment of existing processes; (2) a comprehensive review of twelve guidelines from institutions with various backgrounds; followed by (3) recommendations for further BIM implementation. We reach the conclusion that no one institution's BIM guidelines are capable of fully accommodating the context and requirements of all Canadian public post-secondary institutions. Hence, a BIM guideline based on the key findings of the analyzed documents for each stage of the building lifecycle, as well as knowledge about current operations and local context, is recommended as future research. To achieve a comprehensive set of guidelines, the local construction industry should be consulted to account for existing BIM expertise; the guidelines should also incorporate important documents found in the guidelines of other institutions. Moreover, it is recommended that the future guidelines focus on the management of the BIM model for the operation and maintenance phase since this phase incurs the highest costs in a building's lifecycle, and is the responsibility of the owner (i.e., the institution).

BIM; BIM Guidelines; Post-secondary institutions; BIM Implementation;

1 Introduction

Building Information Modelling (BIM) has made a significant impact on the construction industry, affecting all areas of a facility's lifecycle. However, there is a lack of standardization with regard to the implementation of BIM across different areas, thus constituting a major barrier to the adoption of BIM with its associated benefits for the construction industry [1].

To streamline BIM requirements and expectations, organizations develop documents that regulate the technical and contractual aspects of the BIM models provided to the owner/client by the consultants and contractors. These documents, i.e., BIM Guidelines or BIM Standards, help the local design and construction market to standardize design and construction services and the use of BIM models to contribute to the maturation of the local industry [2].

A guideline consists of a "general rule, principle, or piece of advice", while a standard is a "required or agreed level of quality or attainment" [3]. According to [4] the implementation of BIM at an institutional level is highly dependent upon guidelines and standards since they provide a common orientation to the local community. However, these documents are dependent on the level of understanding, readiness, and implementation of BIM within the given jurisdiction, such that applying the guidelines or standards from one jurisdiction to another one is an ineffective practice.

Considering this, the University of Alberta—one of the leading post-secondary institutions in Canada—performed a review of existing BIM guidelines and standards in North America, since the adoption of BIM in Canada is still in its early stages and no other post-secondary or government institution in Canada has this kind of documentation in place.

1.1 Methods

The research presented in this paper consists of a review of existing guidelines with the objective of investigating procurement strategies and the potential use of BIM by the University of Alberta. Figure 1 provides an overview of the methodology employed in this research, which is performed in three phases: (1) an assessment of the existing processes within the University of Alberta to gain understanding of its existing process and expectations pertaining to the use of BIM; (2) selection and review of existing guidelines in North America relevant to the context of this research; and (3) a set of recommendations for the procurement and use of BIM models for the University of Alberta.

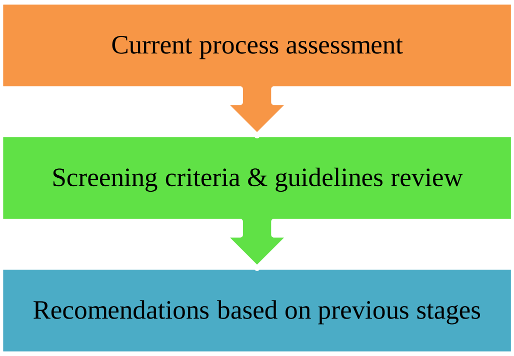

Figure.1 Overview of research methodology

This assessment endeavors to define the needs of a given organization with regard to the implementation, use, and management of BIM, and thereby tailor the development of future guidelines accordingly. Based on the requirements of an organization, a set of criteria is developed to assist in the selection of existing relevant documentation that is to form the basis of the new guidelines. Existing guidelines that satisfy the selection criteria are then reviewed to match the BIM requirements of the organization with the components of the existing BIM guidelines.

Although it is a qualitative assessment, the research presented in this paper makes use of semi-structured interviews and structured questionnaires in order to provide metrics and quantitative data to be used during the screening and review processes and direct the process toward addressing existing issues pertaining to the use of BIM at the University of Alberta. These methods are explained in detail in the following sections.

2 Current Process Assessment

The current process assessment aims to identify the existing requirements and expectations of the University of Alberta's Facilities and Operations (F&O) with regard to the use of BIM, to evaluate the existing procedures of each organizational unit, and identify possible improvements that could be realized by adopting BIM for its capital projects. Table 1 summarizes the organizational units assessed and their primary responsibilities under the F&O portfolio.

As described in Table 1, these organizational units which F&) comprises are responsible for the planning, design, construction, operation, and maintenance of all facilities at the University of Alberta, thus controlling every aspect of the performance of each building in the institution's portfolio throughout its lifecycle. The Office of the University Architect (OUA) carries out the planning for new facilities and retrofit of existing buildings. After the Request for Proposals (RFP) stage is complete, the Project Management Office (PMO) procures the project to a general contractor and oversees the construction until the facility is commissioned and handed over to the University; Operations & Maintenance (OM) then assumes the role of maintaining and operating the facility.

Table **Error! No text of specified style in document.**1 Units investigated and their respective roles

Unit	Main role
Office of the University Architect (OUA)	Planning of new construction or retrofit while overseeing design compliance during construction
Project Management Office (PMO)	Procurement and control of new construction or retrofit
Design and Technical Services (DTS)	Document management for operation and maintenance of existing buildings
Operations & Maintenance (OM)	Maintenance of existing buildings and management of daily operations
Energy Management & Sustainable Operations (EMSO)	Optimization of operations of existing buildings with a focus on energy management

During commissioning, Design and Technical Services (DTS) receives all drawings and documents related to the project and manages these documents throughout the facility's lifecycle, including updates and generating new documentation as necessary. Energy Management & Sustainable Operations (EMSO) assesses performance of existing buildings in order to optimize their operations and provides key information to OUA that can inform future renovations and new construction across campus. A semi-structured interview is developed to gain understanding about the requirements and expectations of each organizational unit while generating data for use in future assessments. Using the data collected during this process, a review of the guidelines is conducted for addressing the needs identified and concerns raised by the various organizational units.

Table 2 presents the results of the semi-structured interviews. It is clear that the different organizational units vary considerably in size, but all face challenges in with regard to communication, lack of resources, and tight schedules as per the first and second questions. The response to the third question indicates that each unit has their own experience with BIM in isolated cases with little to no communication between units. In fact, the use of BIM—since it is not mandated by the University—is driven by consultants and contractors that already use BIM in their own operations and is perceived by the University as an add-on rather than a fundamental component of its design, construction, and facility management operations.

Despite the fragmented use of BIM in F&O's existing operations, organizational units such as OUA, PMO, and DTS acknowledge the potential use of BIM to improve communication among units and other stakeholders (e.g., consultants, general contractors, etc.) while OM and EMSO see value in the application of BIM to improve other decision-making processes such as predictive modelling and lifecycle assessments.

Still, as can be seen in Table 2, responses to the final two questions indicate three main challenges and concerns regarding BIM implementation at an institutional level: (1) further maturation of the existing BIM implementation framework, and training both of University personnel and other stakeholders in its capital projects (e.g., consultants, trades, etc.) in order to increase the University's capacity to implement BIM in its projects and facility management; (2) the interoperability of BIM models between various platforms and other existing management systems (document and asset management); and (3) concerns about the ownership of the model.

Table 2 Results of semi-structured interview according to each unit

Question	OUA	PMO	DTS	OM	EMSO
Number of employees in each unit	6 to 10	15 to 20	13	200 + 200 from subcontractors	4
Current challenges in unit	Short deadlines	Bureaucracy and change management	Communication among various stakeholders	Communication across different stakeholders and short-term planning	Lack of trained personnel
Current use of BIM	3D imaging during conceptual phase	Mainly used to communicate consultant’s proposal	Uses parametric tools non-related to BIM for document management	None	Uses model (when available) for energy modelling
Potential use of BIM	More information during conceptual phase and design oversight	Enhance communication and constructability analysis	Enhance communication and integrate operation documents with drawings	Predictive maintenance and personnel training	Lifecycle assessment and decision making
Current challenges for BIM implantation	Personnel training	Scope required from the model and actual benefit from BIM	Interoperability between existing infrastructure and BIM systems	Personnel training, incomplete models, and clarity regarding the ownership of the model	Sharing information across different platforms
Questions about BIM and its applicability	Possible interaction between BIM and existing systems	Maturity of local community (consultants and general contractors)	None	Ownership, cost of the model, and impact on daily routine	Ability to develop custom solutions for each project

3 Screening Criteria & Guideline Review

Based on the current process assessment, this section will discuss the screening criteria used to select which documents shall be included in the analysis and the review of these documents based on the findings of the previous sections.

3.1 Screening Criteria

Based on the data gathered in the assessment of existing processes, a series of questions is developed by the research team which are then incorporated into a structured questionnaire to streamline the review process and create data that can be compared on a quantitative basis when applicable. The following is a list of statements incorporated into the structured questionnaire:

1. Information exchange through the model during its lifecycle.
2. Workflow change due to the use of BIM.
3. Which software to use (use of open or closed architecture application approach).
4. Ownership of the model.
5. Costs incurred from BIM.

The criteria used to select which documentation to review are described below:

1. Only documents from North America are considered due to the geographic location of the case institution, with the exception of standards from the United Kingdom and Singapore due to their relevant work on BIM implementation at an institutional level.
2. Guidelines from post-secondary institutions: to evaluate the requirements of other similar institutions imposed on their contractors.
3. Guidelines from public institutions to address how these institutions overcome barriers such as interoperability and how they standardize their requirements across a larger sample of contractors.
4. Standards from national standardization organizations to address general requirements from each jurisdiction of origin.

Table 3 presents the documents selected for review based on the presented criteria, listed according to the areas of interest addressed during the current process assessment stage. As per Table 4, the documents are separated into three groups: (1) third-party organizations, which regulate the use of BIM through standards and have a national range; (2) guidelines from government organizations, which regulate the use of BIM in their respective jurisdictions (e.g., state/province, city, etc.); and (3) university guidelines, which regulate the use of BIM for a given post-secondary institution.

All the documents selected encompass the use of BIM during the design stage and address the interoperability of the various systems involved, and thereby speak to the questions raised in the current process assessment of the case institution. Moreover, the government and university guidelines reviewed predominantly encompass the use of BIM during the construction stage, while relatively few cover the use of BIM for facility operation or energy modelling assessments.

It is also important to note that most of the documents reviewed specify procedures to be performed during the delivery process of BIM models and the respective legal aspects of that delivery.

3.2 Guidelines Review

This section presents a summary of all the guidelines reviewed, important findings regarding the questions raised during the current process assessment, and relevant information for each stage of the facility lifecycle. The structure of this section corresponds to the list of questions raised during the assessment of existing processes.

3.2.1 Information exchange through the model during its lifecycle

Government and university guidelines provide further clarity in addressing this question since these institutions need to inform consultants and general contractors of their requirements throughout the entire project. The guidelines identified as having the greatest potential to clarify information exchange through the BIM model are from the University of Southern California, the City of New York, and the State of Ohio, and these guidelines are thus recommended for use as a benchmark by the case institution when preparing their BIM guidelines.

3.2.2 Workflow change due to the use of BIM

After the analysis of the guidelines is complete, it is observed that the introduction of BIM is not substantially disruptive to the way projects are being developed, coordinated, built, and operated. Rather, BIM is a key to enhancing existing processes by allowing construction practitioners to process information more rapidly and make important decisions regarding project performance based on accurate information. However, the guidelines for USC, the City of New York, and Singapore recommend specific full-time positions to oversee the management of the BIM model and the process associated with it (e.g., BIM Facilitator/Engineer, BIM Trade Coordinator, etc.). Post-secondary institutions, including the University of Alberta's F&O, should acknowledge the importance of BIM-facilitating roles and consider including these roles in its projects' contracts.

Table 3 Documents reviewed within research scope

Name	Country	Release Date	Organization Type	Organization Name	Design	Construction	Operation	Energy Modeling	Procedures	Implementation	Legal	Interoperability

3.2.3 Which software to use (use of open or closed architecture application approach)

Figure 2 depicts the recommended working platforms and file-delivery format based on the reviewed guidelines. The importance of defining the working platforms and file format upon delivery arises from the need to eliminate the dependence on specific software vendors, which is substantial for the integrity of public bidding and contracting process.

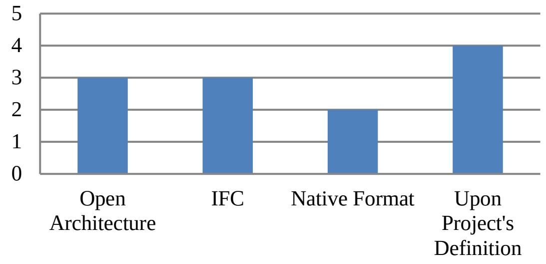

Figure.2 Summary of recommended work platforms required by guidelines

An intriguing finding from this study is that, although most guidelines encourage the use of open file formats for project coordination, several institutions require specific file formats for submittals. The authors believe this is since these institutions have obtained licenses and personnel training for specific software companies. To overcome this potential barrier, the University of Alberta's F&O can adopt a provision from the Texas Facilities Commission guideline, which states that, in the case that a consultant or contractor is using a different software than the one used by the client's F&O department, the consultant may provide the software license and necessary training as necessary for the given project. Figure 3 demonstrates the deliverable formats specified in the guidelines reviewed. It is clear that Autodesk products are preferred, along with the requirement for COBie at the Operation & Maintenance stage. This is presumably due to the predominance of these products in the North American market. In light of possible inconsistencies or problems encountered from not using a native file format, further reading in Singapore's guidelines and extra documentation is recommended since they have specific documentation for each of the notable commercial BIM authoring software suites available.

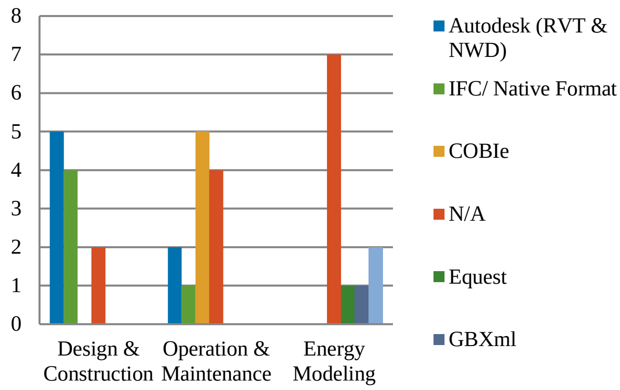

Figure.3 Deliverables format required in the guidelines reviewed

3.2.4 Ownership of the model

Clarification regarding the ownership of the model is a key component for successful implementation of BIM in any institution. Figure 4 summarizes the provisions laid out in the guidelines reviewed regarding this matter. It is noted that institutions with a broad portfolio do not have clear provisions regarding this matter (probably because of the high variability of projects within their scope). Most institutions require full ownership of the model and any related documents, establishing a precedent for the case institution to do the same. For more information about this matter, CanBIM and the State of Ohio's guidelines are recommended for further reading.

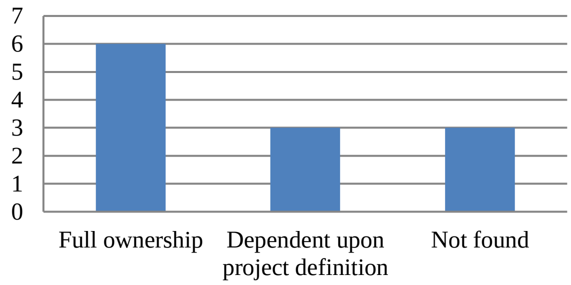

Figure.4 Stances of analyzed institutions regarding ownership of the model

3.2.5 Financial investment incurred from BIM

Manging the cost of BIM is also a cornerstone of its successful implementation. This issue is best characterized in terms of two questions: (1) from a cost perspective, when does it become feasible to implement BIM in a project as opposed to using conventional tools? and (2) how much are other institutions investing in BIM services? (The State of Ohio recommends using BIM for projects with a value of $4M or greater, while Georgia Tech and Indiana University recommend a threshold of $5M.) In order to quantify the potential savings resulting from the use of BIM, Table 5 summarizes the cost incurred from the use of BIM tools and services in consultant fees gathered from the BIM guidelines of Singapore and the State of Ohio. As shown in Table 5, these institutions do not intend to pay any premium for the use of BIM in their projects, but instead reallocate money among each project's stages to account for cost increases due to BIM implementation.

Table.4 Cost incurred from the use of BIM in total consultant fees (Adapted from Building and Construction Authority, 2013 and Ohio General Services Division, 2011)

Project Stage	% change from the use of BIM	
	Singapore	Ohio
Preliminary Design	+2.5%	0%
Schematic Design	0%	+5%
Design Development	+2.5%	+5%
Construction Documents	0%	-10%
Bid and Award	0%	0%
Construction Administration	-5%	0%
Contract Closeout	0%	0%

3.3 Define requirements of BIM guidelines for post-secondary institutions

After performing a comprehensive review of twelve guidelines from various institutions/jurisdictions, the authors conclude that there is a need for the case institution to develop their own guidelines, as no guidelines exist that fully address the expectations of the stakeholders. In this regard, three recommendations are made:

- The guidelines should span BIM uses and implementation during all project phases as per the project's lifecycle breakdown followed in the practice of the case institution.
- As per the guidelines reviewed, the case institution's guidelines should incorporate the following:
    - **BIM Execution Plan:** a document demonstrating which tools, responsible personnel, and strategies are employed by the Design Team and/or General Contractor regarding BIM tools.
    - **BIM Objective & Responsibility Matrix:** a document intended to define the level of detail of BIM objectives according to the design stage and personnel responsible for developing the model.
- The operational stage of a facility represents the largest proportion of cost in its lifecycle. Hence, the BIM guidelines should also consider the use of BIM to reduce the operational cost of the facility.
- The guidelines should clearly address the ownership of the models and other legal aspects of BIM implementation and use in the institution's regular practice.

These recommendations can be applied to public post-secondary institutions with similar responsibilities as the University of Alberta.

Development of Web-based BIM Models Inspection and Modification Management System for Supervisions

Pao-Tsu Hsiao and Yu-Cheng Lin

Department of Civil Engineering National Taipei University of Technology, Taiwan

E-mail: j01425367t@gmail.com, yclin@ntut.edu.tw

Abstract –

The building information modelling (BIM) approach, which is utilized to retain information in a digital format, facilitates easy information updating and transfer in the three-dimensional (3D) CAD environment. When the application of BIM models are adopted in the project, the inspection and and the inspection and modification records of BIM models are necessary to be communicated and managed effectively. However, emails, one of the most convenient ways, is selected and adapted as a communication tool among BIM manager, BIM engineers, and supervisions during the BIM models inspection and modification process. Also, it cannot record and manage the BIM models inspection and modification information and results effectively during the process. Therefore, this study develops a web-based BIM models inspection and modification management system integrated with workflow management. Concepts for supervisions to enhance BIM models inspection and modification work efficiency. The proposed system is applied to a case study of a building project in Taiwan to verify its efficacy. Finally, the study identifies the major benefits, limitation, and facing problems throughout the case study.

Keywords –

BIM; Building Information Modeling; Workflow Mangement; Web-based System

1 Introduction

Development of information communication technology(ICT) arouse the modern architecture, engineering, and construction (AEC) industry upgrading to Informatization. Researchers have been investigating the components and repercussions of building product models[1].Building Information Modeling(BIM) as a new term appeared in 2006 Autodesk new product description[2]. From conceptual to descriptive in nature, research or industry bodies as well as commercial software vendors import BIM into advanced study and practical applications. BIM is becoming mature due to developing collaboration platforms and related BIM uses. So stakeholders focus to manage BIM models information better than before.

Nowadays Cloud-based collaboration platforms have solved the interoperability of multi-disciplinary team. All of them have BIM models collaborative function corresponding to specific stakeholders. But this kind of operating mode have not been implemented in traditional inspection yet. Currently, supervision still inspects construction company BIM models in construction phase by email approach, a unilateral delivery method, which is lacking of communication with each other and leads to dispersing BIM models information. Therefore, the current traditional BIM models inspection must be improved, and also modifiable management workflow between supervision and construction company.

To address the above problems, this study expects to integrate BIM models with workflow management and web-based technology to develop an inspection and modification system of BIM models. It can improve the workflow management of inspection and modification for BIM models, and interactive coordination efficiency of supervision and construction company. Furthermore, supervision may utilize this system to control BIM models status in process. Through BIM models inspection and modification management system, supervision can proactive manage BIM models in the construction phase and confirm BIM models status in workflow. The system will also promote the consistency, correctness and completeness of BIM models information in the inspection and modification workflow.

2 Literature Review

Building information modeling (BIM) is an emerging technological and procedural shift within the Architecture, Engineering, Construction and Operations (AECO) industry[4], then BIM is not just a technological change, but also a change of process[5]. A set of interacting policies, processes and technologies are generating a “methodology to manage the essential building design and project data in digital format throughout the building's life-cycle”[3].

Establishing the goal of each phase in the building’s life cycle play an important role in BIM application. Each phase of milestones need to deliver documents, meeting records and signing contracts. Besides, milestones would separate design, construction and operation phase. The content of policy decision must be finished at this stage and the promise must be fulfilled at next stage[6]. Therefore, there is need for a framework that positions BIM as an ‘integration of product and process modelling' [7] and not just as a disparate set of technologies and processes.

Tien-Hsiang Chuang et al.(2011) indicate that BIM desktop applications can only integrate information on-site. Difficulties remain in obtaining and updating information from other sites, which restricts communication and information distribution between different sites. The study utilize the concept of software as a service (SaaS) and cloud computing in order to develop a visual system for BIM visualization and manipulation. This system cannot only visualize three-dimensional (3D) BIM models,but manipulate 3D BIM models through the web without the limitations of time or distance. Therefore, the system can facilitate communication and distribution of information between related participants in order to manage projects effectively and efficiently[8].

Rong-Chin Kuo et al.(2014) describe current BIM integrating, exchanging and managing information in BIM collaboration. Across disciplines have been major challenges in the AEC industry. This research designed and constructed a “BIM collaboration cloud platform” is based on Microsoft virtual desktop infrastructure (VDI). The platform benefits of the advantages of cloud computing which helps facilitate the integration of information across disciplines during the design and construction phase[9].

Zhiliang Ma and JiankunMa et al.(2017) indicate that existing collaboration platforms may be unable to support the collaboration among multiple participants and specialties due to this characteristic. The study formulates the application functional requirements for such a BIM-based collaboration platform by analysing case studies of integrated project delivery(IPD) projects. And then their conclusions indicated that a dedicated BIM-based collaboration platform is necessary. Formulated application functional requirements can be used in the development of such a platform or for customizing an existing commercial collaboration platform to improve the support of IPD projects[10].

3 System Development

Web-based BIM models inspection and modification management system includes three-tier framework : BIM models inspection and modification management and BIM model tracking mechanism.

3.1 System Framework

The system primarily assists BIM models inspection and modification between supervision unit and construction company. In order to dynamic communication in the workflow the study integrates BIM models inspection and modification management and three-tier framework, supplemented by permissions check. Furthermore, supervision unit may monitor the progress of BIM models inspection and modification status via configuring BIM model status as well as BIM model tracking mechanism for effective managing BIM models (see Figure 1).

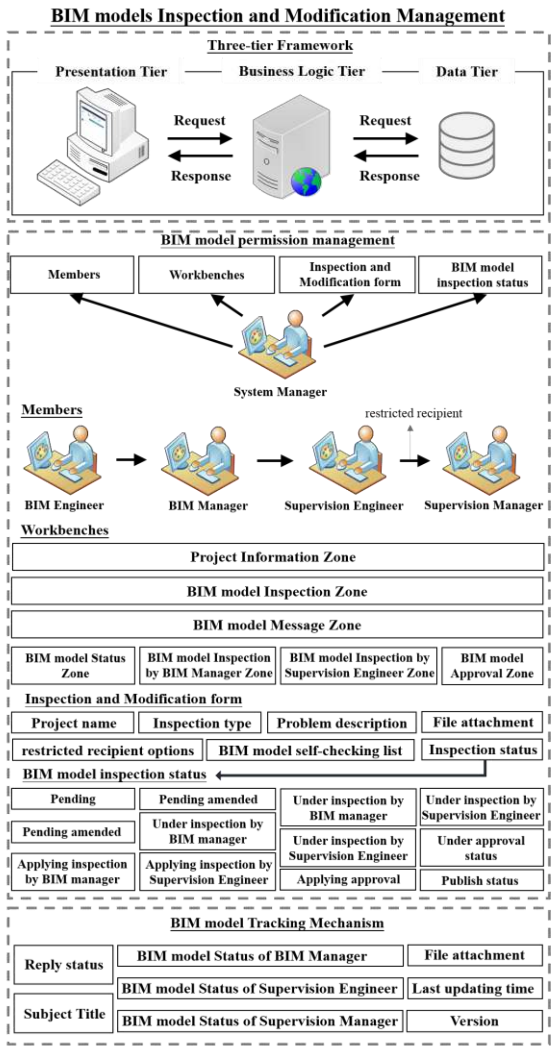

Figure 1 The Framework of BIM Models Inspection and Modification Management System

3.2 System Workflow

The main purpose of the system provides supervision unit the wok flow of BIM models inspection and modification to manage the AEC models of a construction company during the construction phase. Moreover, the system utilizes the same form throughout the work flow of the system for guaranteeing the correctness, completeness and consistency of inspective and modifying information (see Figure 2).

1. After BIM engineer has finished AEC models, logging in web-based BIM models inspection and modification management system, the BIM engineer get into BIM model inspection zone completing the inspection and modification form. In order to properly manage AEC BIM models uploading in a file attachment method, the format of BIM models allows txt, pdf, doc, jpg, png, nwc, nwd format, and then must get standardized name of the file. When BIM engineer submit the form at first time, the status of BIM model will display "pending" status.
2. If BIM manager has received the notification in BIM model inspection, the inspection of the form will start related BIM models. If BIM model inspections were passed by BIM manager, BIM models status of the form will ask for applying inspection status by supervision engineer. In case they were rejected by BIM manager, BIM models status of the form will be asked for modification of BIM engineer, pending amended status by supervision engineer.
3. When supervision engineer has received the notification of BIM model inspection then supervision engineer started to inspect the form and related BIM models. If BIM model inspections have been passed by supervision engineer, BIM models status of the form will be ask for applying approval status of supervision manager. If they were rejected by supervision engineer, BIM models status of the form will be ask for under inspection by BIM manager.
4. When Supervision manager receive the notification of BIM model approval then start to inspect the form and related BIM models. If BIM model inspections are passed by supervision manager, BIM models status of the form will become publish status update information of BIM models for owner and supervision unit. Otherwise, if they are rejected by supervision manager BIM models status of the form will proceed to under inspection by supervision engineer for reinspection.

3.3 BIM models inspection and modification management

BIM models inspection and modification management consists of three-tier framework, BIM model permissions management, and BIM model tracking mechanism, as follow:

Three-tier framework consists of Pesentation Layer, Business logic Layer, and Data Layer, as follow:

- Presentation Layer

This layer mainly transports the system members requestments to Business logic Layer and obtains Business logic Layer's output to display to related members. According to permissions of the system members to user's interface via Bootstrap for allowing supervision unit and construction company to utilize the system by computer or mobile device.

- Business logic Layer

This layer provides the web service for the BIM models inspection and modification by Drupal content management system and Apache HTTP server transporting the request of the presentation layer to data layer and extracts information from it. And transports the information of data layer to presentation layer.

- Data Layer

The system manages database and data backup via phpmyadmin. This layer stores all of the related system information.

BIM model permissions management consists mainly of members, workbenches, inspection and modification form and BIM model inspection status of BIM models inspection and modification management system. The workbench of system includes Member Management Zone, BIM model Inspection Zone, BIM model Status Zone, BIM model Inspection by BIM manager Zone, BIM model Inspection by supervision engineer Zone, BIM model Approval Zone, BIM model Message Zone, and Project Information Zone. Each workbench has specific rules to control system permissions. But all system members have access to project information zone, BIM model inspection zone and BIM model message zone.

The system has four kinds of members：BIM engineer, BIM manager, supervision engineer, and supervision manager, as follow：

1. BIM Engineer: This member mainly fills out the inspection and modification form and has BIM model status zone alone for BIM model condition in inspection and modification progress.

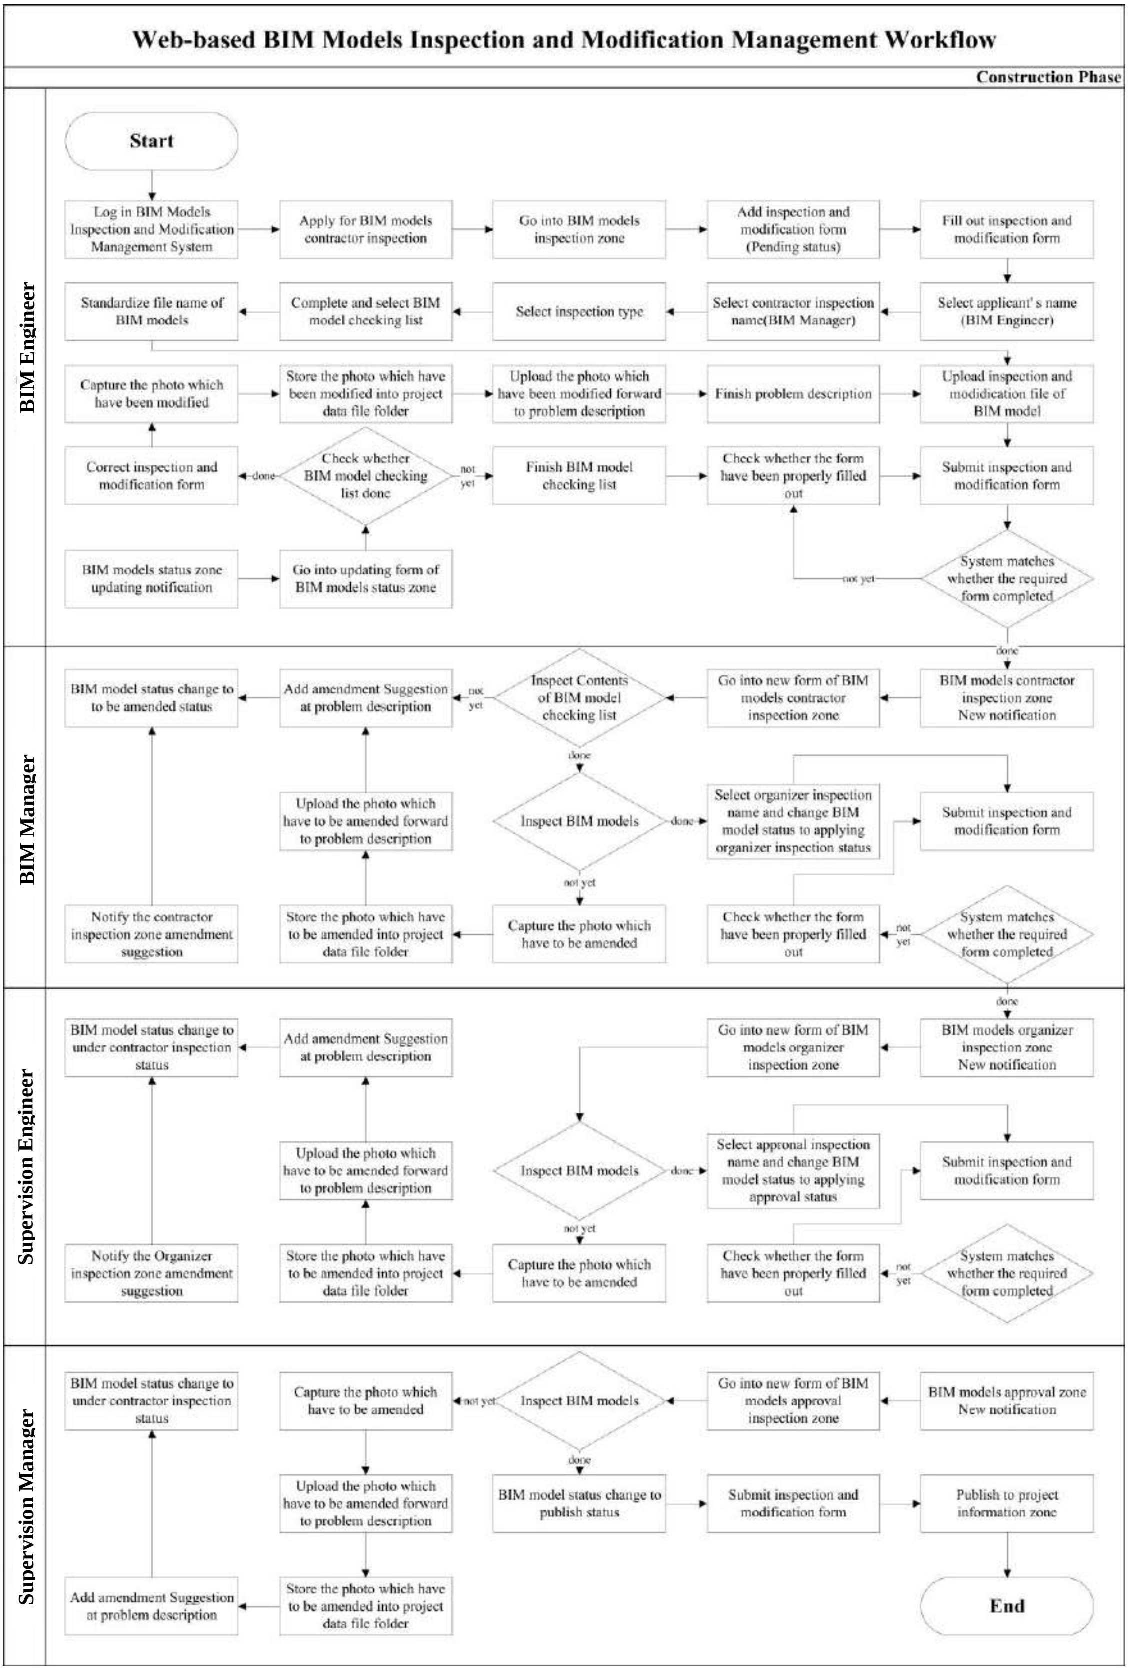

Figure 2 Web-based BIM Models Inspection and Modification Management Workflow

2. BIM Manager: This member primarily inspects BIM Engineer’s BIM model and has BIM model Inspection for implementing models or giving advice.
3. Supervision Engineer: This member inspects BIM Engineer’s BIM model being received by BIM manager and has BIM model inspection for implementing models inspection or giving advice.
4. Supervision Manager: This member primarily inspects BIM Engineer’s BIM model having received from supervision engineer and has BIM model Approval Zone for implementing models approval or giving advice.
5. System manager: This member primarily sets up the system, which masters members registeration and system permissions management before the project starts.

The content of inspection and modification form includes project name, BIM model inspection status, restricted recipient options, inspection type, BIM model self-checking list, problem description and file attachment. Especially, the name of file attachment is according to PAS1192-2:2013 published by British(as shown in Figure 3) .

Figure 3 The name of file attachment in the system

BIM model inspection status consists of pending status, pending amended status, applying inspection by BIM manager status, under inspection by BIM manager status, applying inspection by supervision engineer status, under inspection by supervision engineer status, applying approval status, under approval status and publishing status. According to permissions configuration, both system member and their workbenches have particular BIM model status before the project starts.

3.4 BIM model tracking mechanism

Permits each system member clear rights and efficient management is according by each permission of system members for clear rights and efficient management. BIM model tracking mechanism has eight kinds of functions including reply status, subject title, BIM model status of BIM Manager, BIM model status of Supervision Engineer, BIM model status of Supervision Manager, file attachment, last updating time, and version, as follow:

1. Reply status : When inspection and modification form has been changed, this column will display two kinds of symbols, one is “New”, another is “updated”. New symbol will display to each members, when they receive the form for first time, and updated symbol will show to all the system members when someone modifies or adds suggestions(as shown in Figure 5).
2. Subject Title : The content of the column shows the name of inspection and modification form via BIM engineer applying.
3. BIM Model Status of BIM Manager : The column shows the result of BIM model status which has been changed by BIM Manager. BIM Model Status of BIM Manager has four items, including pending amended status, under BIM manager status, applying inspection by supervision engineer status, and pending status.
4. BIM Model Status of Supervision Engineer : The column shows the result of BIM model status which has been changed by Supervision Engineer. BIM Model Status of Supervision Engineer has three items, including under inspection by BIM manager status, under inspection by supervision engineer status, and applying approval status. These three items represent three situations. When Supervision Engineer choose under inspection, BIM Manager must inspect again and then choose the BIM model status. When Supervision Engineer choose under inspection, it means that the form is inspected. When Supervision Engineer choose applying approval status item, Supervision Manager must inspect and then choose the BIM model status.
5. BIM Model Status of Supervision Manager : The column show the result of BIM model status which has been changed by Supervision Manager. BIM Model Status of Supervision Manager has three items including under inspection by supervision engineer status, under approval status, and publish status. These three items represent three situations. Under inspection by supervision engineer status item means that the form needs to be inspect again. Under approval status item means that the form is being inspected, and publish status item means that has been notified every system member.
6. File attachment : The file of BIM models inspection and modification management system is mainly nwc format because it commonly used to view and discuss BIM model.
7. Last Updating time : The column primarily provides the newest updating time. System members inspect and modify early to improve efficiency between members and shorten the period of inspection amd modification for proactive management.
8. Version : The column indicates that the sum of inspection and modification and allows time

control by Supervision unit and applies related knowledge management in the future.

4 Case study

4.1 Description of the case study

The present study used Autodesk Revit 2017 developing the proposed BIM model and converting rvt to nwc format. And then, the system as BIM model inspection and modification platform exists between construction company and supervisions. The case type chose construction phase of medium building engineering to test the system benefits and limitations, because of general and ordinary scale.

4.2 Implementation

The case building that is examined in the present study is construction phase of National Taipei University of Technology, Sixth Academic Building. First, BIM engineer converts the built rvt format BIM model to nwc format, and furnishes inspection and modification form then applying inspection. Second, BIM manager receives notification of BIM model inspection by BIM manager zone. When the form passes, BIM manager turns the BIM model status to apply inspection by supervision engineer status, on the contrary turn the status to pending amended status. This moment the reply status column of BIM engineer's BIM model status zone display new update message. BIM engineer utilizes this zone to modify the BIM models and gets the latest inspection status(as shown in Figure 4). Finally, by repeatedly modifing and inspecting the BIM model, passing the inspection of BIM engineer, supervision engineer and supervision manager, and then publishing the BIM model information to project information zone by supervision manager for renewing the latest information to all members in the system.

4.3 Discussion

The system solves many of practical problems, for example BIM engineer may transmit BIM models to wrong recipients, BIM manager or supervision unit's members may inspect incorrect models because lacks version control, and all members cannot understand what situation BIM models inspection are. So the system provides some solutions as follow:

- The inspection and modification form of system limits authors and recipients via fixed button items to avoid wrong submitting.
- The system utilizes BIM model tracking mechanism to monitor BIM model status and centralize BIM model information, for example versions and BIM model status of all members.
- Through web-based BIM models inspection and modification management workflow clear defines responsibilities of supervision unit and construction company for more efficient and higher quality production.

However, the system handles many of practical problems above. Some limitations and difficulties still existence as follow:

- The system only designs photos uploading and text editing for describing BIM model, it cannot operate BIM construction management software online. System members have to view, rotate, and markup models by their own BIM construction management software.
- The system status changes by permitted members presently, it is inconvenient because members must change status by themselves. In the future, the system may optimize for automation of BIM model status changes.

5 Conclusion

BIM technology has already developed the BIM modeling mode by changing design model to construction model. But Supervision unit cannot control the status of BIM model's modification and inspection during construction BIM modeling process, as well as construction company cannot timely obtain the result of BIM models approval and the suggestion of the unit concerned. In addition, supervision receives the file of BIM model by papers, emails, FTP, or cloud-based platform which are one way delivery, and the whole procedure lacks permission of management.

To improve the efficency and workflow management of BIM models inspection and modification between supervision unit and construction company. The study develops Web-based BIM models inspection and modification management system, integrating BIM models inspection and modification management and tracking mechanism with permission management and dynamic communication method.

1. For submitting BIM models inspection, Web-based BIM models inspection and modification management system proposes permissions management solution. It helps supervision unit managing BIM models information and actively controlling inspecting progress.

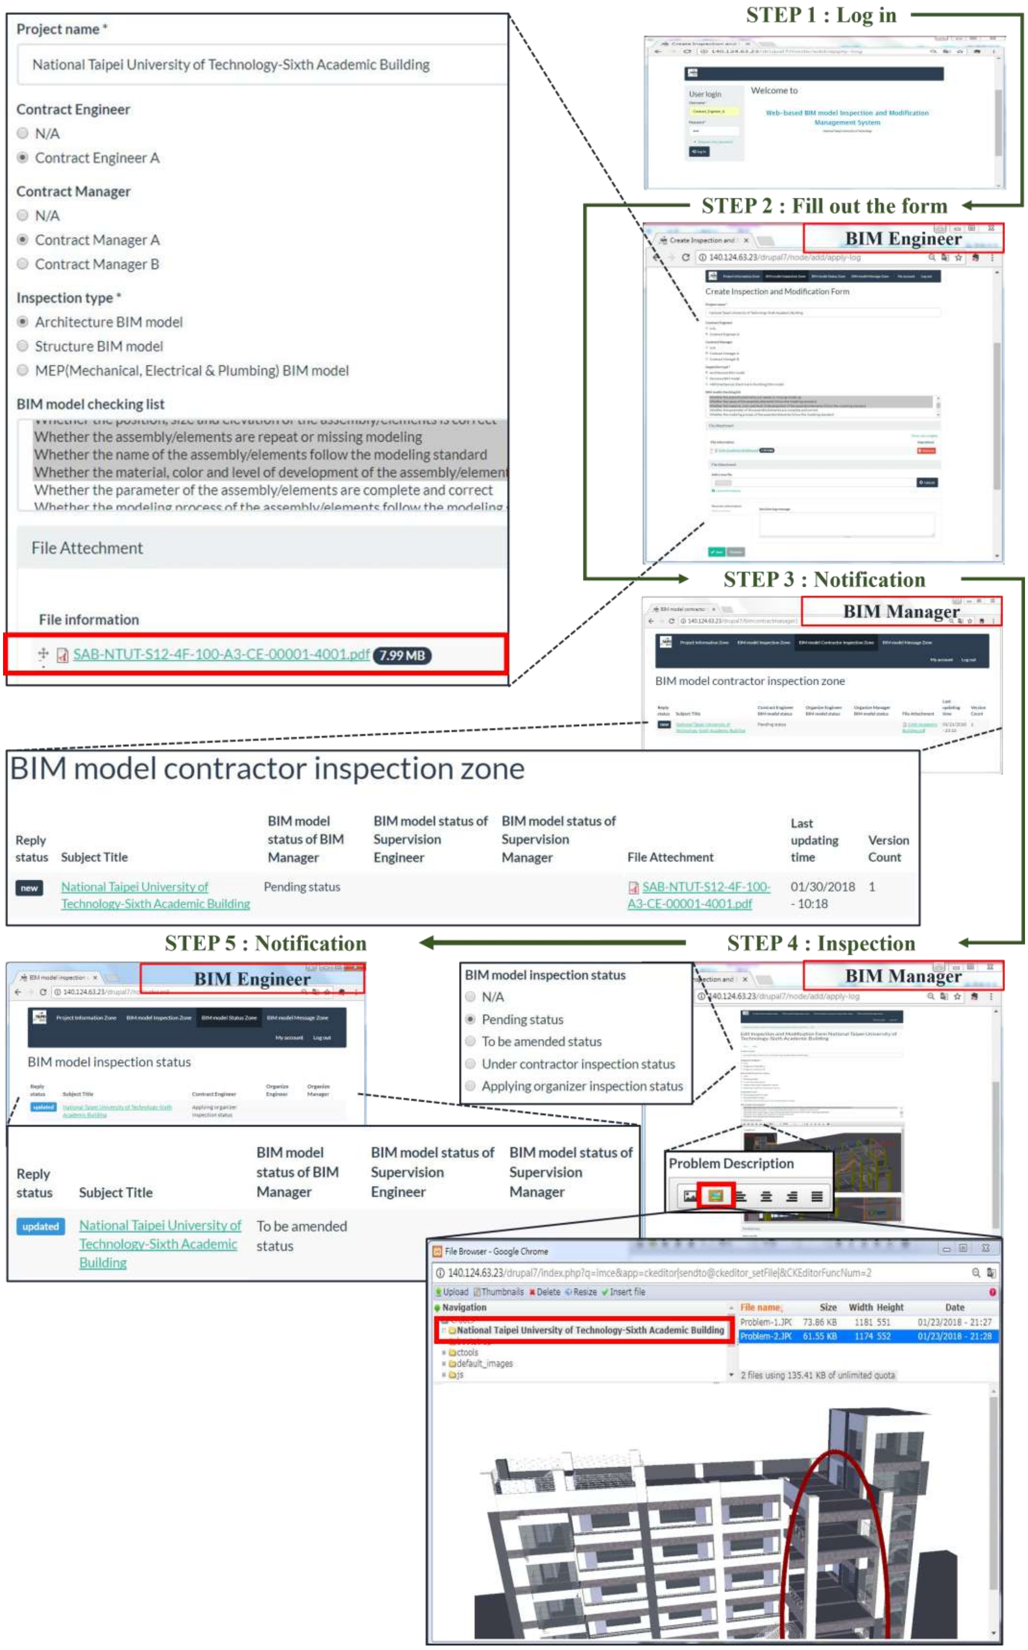

Figure 4 Operation of the BIM model inspection and modification management system

2. BIM models inspection and modification management system supplements traditional inspection workflow. BIM manager, supervision engineer and supervision manager inspect BIM models by single inspection and modification form. It helps improving the correctness, completeness and consistency of BIM models information.
3. BIM model self-checking list helps BIM engineer examining models and providing other members initial inspection. Supervision unit can obtain error-prone items in the list at the end of the project, for next related project inspecting focus.
4. BIM model message function strengthens communication and the efficiency of BIM models modification among BIM engineer and BIM manager, and then enhances BIM engineer the site experiences.
5. BIM model tracking mechanism provides active BIM models inspection and modification management in the construction phase. Let all members understand what present BIM models inspective phase is now and which version is.
6. BIM model developing process information will be stored in system’s database, analyzing the amendment suggestion and feedback to inspection and modification form to adjust the form item for assisting construction phase BIM modeling and BIM knowledge management.
7. Frequently, BIM models have variety of elements and components in the construction. The numerous number of inspection and modification forms will be submitted, so we need to visualize the inspective status for better management.

Classification of Images from Construction Sites Using a Deep-Learning Algorithm

Daeyoung Gil, Ghang Lee*, and Kahyun Jeon

Department of Architecture and Architectural Engineering, Yonsei University, South Korea
E-mail: rlfeodud@gmail.com, glee@yonsei.ac.kr, jeonkh0310@naver.com

Abstract –

Field engineers take and collect several pictures from construction sites every day, and these pictures serve as records of a project. However, many of these images are loaded to and remain on computers in an unorganized manner because tagging, renaming, and organizing them is a time-consuming process. This paper proposes a method for automatically classifying construction photographs by job-type using a deep-learning algorithm. The first goal of this study is to classify construction images according to 27 job-types based on OmniClass Level 2. Google Inception v3—a deep learning algorithm used in this study as an image classifier—was trained using 1,208 construction pictures labeled by job-type. To improve the performance of the classifier, the optimized number of trainings was determined by examining the changes of accuracy and cross-entropy during trainings. The first result shows the incidence of several trainings over 50,000 was not meaningful. The retrained Google Inception as a construction image classifier was validated using a total of 235 images. The validation result shows that the classifier demonstrates an accuracy of 92.6% in classifying inputs properly and an average precision of 58.2% in correct classification. This means that retrained classifier can classify approximately nine out of every ten images correctly and that the deep-learning algorithm has high potential for use in the automatic classification of images from construction sites.

1 Introduction

Pictures taken by field engineers on a construction site contain various information about the site. From a daily report of construction progress to the construction method implemented for each project, pictures have an important role in project documentation, and enormous amounts of pictures are taken to establish a visual record. However, because thousands of pictures are taken for construction projects, the pictures are usually stored in a computer in an unorganized manner after a project has been completed. To properly utilize the information available from these pictures, the pictures must first be classified before they are stored.

This paper proposes the use of a deep-learning algorithm to automatically classify pictures from construction sites according to the job-type that each picture contains using a deep-learning algorithm. After AlexNet [1] won the first prize at ILSVRC 2012 (ImageNet Large Scale Visual Recognition Challenge) using a convolutional neural network (CNN), CNN became the most popular deep-learning method in image classification. Since then, the field of image classification has been developing rapidly. Through the constant development of image classification algorithms, recent studies have reached 96% accuracy in image classification [7].

This study uses Google Inception v3—the latest CNN developed by Google [2]—as an image classifier to automatically classify construction pictures by job-type. To test the performance of the trained classifier, 1,208 pictures were used for training, and 27 images were used for validation.

This paper is divided into five sections. The second section presents a review of previous studies related to this research. The third section describes the overall design of the research and, section 4 reports the experiments and the analytical results. The final section reports the paper's conclusions.

2 Background

2.1 Image Classification on Construction

Several studies have been conducted regarding how

* Corresponding author

to extract information from images of construction sites. A recent study related to image processing focused on object detection from pictures of a construction site. Chi and Caldas [9] suggested a way to find objects from images using an artificial neural network (ANN), and Zhu et al. [4] proposed a method of finding concrete area in a picture using parameter optimization. In addition, Wu et al. [15] used image filtering in order to find specific objects from construction images.

Currently, however, meaningful data is generated from images using the previously developed technique. Kim et al. [3] derived information regarding construction progress from construction images by combining project schedule data and filtered images. Also, Kim et al. [16] suggested a method of measuring the construction progress that uses the 4D information of a given building. More recently, adopting deep-learning, Fang et al. [10] proposed a way to detect non-hardhat users in a construction site. Like the above two studies, not only detecting object from images, but also extracting data that can be useful is the main problem of recent studies. Thus, in this study, we extract the job-type information from construction pictures and use it to classify those pictures as a standard using a deep-learning algorithm.

2.2 Deep learning

In 2012, an image classifier constructed with a deep-learning algorithm was introduced at ILSVRC 2012. The name of the algorithm was AlexNet [1], and it was composed of a CNN with eight layers. With a 16.4% error rate, it surpassed its competitors, whose error rates were over 26% on average, and won the first prize. Since then, CNN has become prominent in the field of image classification, and algorithms composed of CNNs show high accuracy nowadays [5][6][7].

The major difference between deep learning and conventional machine learning based on image processing is not only the high accuracy of image classification but also the ability to conduct feature extraction. The former requires a pre-process of image filtering or feature extraction, whereas a deep learning algorithm can conduct feature extraction automatically by using a huge amount of training data [8]. Although deep learning is being criticized for being a black box approach, its implementation process requires a clear goal first, a deep learning network design, and data collection and analysis based on the goal. Moreover, a considerable amount of programming and optimization efforts is required.

2.3 Google Inception v3

In general, when the structure of a neural network deepens and widens, the performance of the network improves. However, the likelihood that overfitting and vanishing will occur also increases. To prevent overfitting and vanishing, GoogleNet [5] is designed with multiple (22) concatenating layers. Based on its structure, GoogleNet won the first prize at ILSVRC 2014 with a 6.7% error rate. To classify images, we used Google Inception v3 [2], which is developed from GoogleNet. Compared with the previous version, Inception v3 has an improved network structure.

When supervised learning is implemented, both images and label data are needed. The label data indicates what information each image contains. Therefore, in order to use this network in our research, we must retrain the network with labelled pictures that have been prepared for retraining in advance. Using the pictures from the training dataset with label data, the classifier learns each picture and label data in a pair. For example, if an image is given to the classifier after retraining a similar picture with a "Foundation" label, it may determine that the input image is about "Foundation".

3 Research Method

Figure 1 describes the overall research flow. First, pictures from construction sites are gathered for training and validation of the image classifier: Google Inception v3. One of strengths of Google Inception v3 is that it has already pre-trained with a very large set of various types of images from ImageNet [12]. Google Inception v3, however, should be "retrained" with an additional set of images if it is used for a new purpose [13]. Thus, the second step is to retrain Google Inception v3 with construction images labeled by job type so that it can be used as an image classifier for construction pictures [13]. During the retraining process, the classifier learns which image features are associated with which job type.

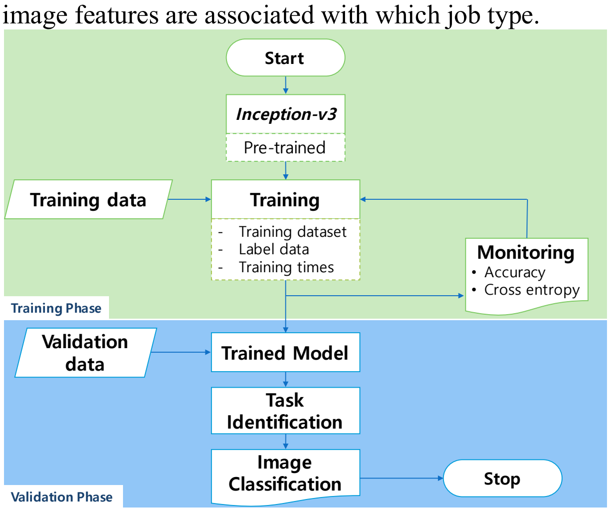

Figure 1. Overall flow of research

At first, we optimized the number of training times with the given training dataset before validating the classifier. Then, after the retraining procedure with the optimized training times was conducted, new images from the validation dataset were inputted into the classifier. Comparing the results, we checked the accuracy and precision of the classifier.

In this study, OmniClass was used as a standard for labeling pictures by job-type. OmniClass is system for classifying the type of construction industry [14]. According to OmniClass, there are 16 tables that can be used to classify the type of industry, and we chose Table 21 – Elements. Originally, there are 29 categories in that table, but we eliminated two categories because they have ambiguous definitions: Integrated Automation and Facility Remediation.

3.1 Training dataset preparation

Because the input image should be classified according to the job-type of construction, we set the 27 standards referring to OmniClass Level 2 categories. After the standard of construction elements was classified according to OmniClass, prepared pictures of the training dataset were labeled by each adequate category. A total of 1,208 pictures in 27 categories were used as construction job-types and the training dataset, and 44 pictures on average were distributed for each category.

4 Experiment & Result

To validate the module, we conducted two different experiments. First, we retrained the classifier 400,000 times with 1,208 pictures in order to find the optimized training time. It is ideal to train a very large number of pictures many times, but, in reality, it is challenging to acquire a large number of pictures and a long training time. Thus, observing the training graph, we tried to determine the optimized point of the training times using a given number of pictures. Second, after retraining the classifier again with the optimized point, we put new images that were not used for retraining into the classifier. Through the two experiments, we yielded a retrained classifier that was optimized and how well it classifies images accurately and precisely.

4.1 Optimization in training times

We used the stochastic gradient descent (SGD) algorithm for the optimization process. SGD requires training of the classifier with the same set of data multiple times to progressively fit the classifier to the training dataset. After the trained classifier is fitted well to the training dataset as the training time increases, it can classify new input data based on the optimized parameters inside the classifier [18]. Thus, training should be repeated for fitting with the same dataset. In general, the performance of a classifier improves as the training time increases. However, too much training can cause an overfitting problem, which worsens performance. Training also takes much time. To maximize the efficiency of the training process, we retrained the classifier 400,000 times and looked for the optimized point. During the retraining, the accuracy value when random data are inputted and the cross-entropy data are extracted, and they were used to assess performance.

4.1.1 Accuracy

Giving the classifier random data during the retraining process, we extracted accuracy data (Figure 2). The average accuracy refers to how well the classifier distributes the random input data into correct categories. In this process, the input data is not an image used for retraining but the randomly created image that has label information.

Figure 2. Accuracy (y-axis) changes according to the number of trainings (x-axis). Average accuracy (thick line) first rises dramatically but then hardly changes after the training time exceeds 50,000.

The accuracy value initially increased, but after about 50,000 times of training, the increasing stopped and the value started to fluctuate. With a value of 0.770, the average accuracy is the highest with a training time of 36,700. Figure 2 shows that conducting more than 50,000 trainings is not meaningful in terms of efficiency.

4.1.2 Cross-entropy

Figure 3. Cross-entropy value (y-axis) initially decreases (x-axis) but gradually increases as the training time exceeds 50,000.

In information theory, cross-entropy is an index that shows the difference between two probability distributions. It is well used for optimization problems and machine learning as a loss function. For one layer, when we suppose p_i represents the probability of the true label and q_i represents the distribution of the predicted value, we can define the cross-entropy loss $H(p,q)$ as follows [17]:

$$H(p,q) = -\sum_i p_i \log q_i$$

However, as we have N layers in the classifier algorithm, we need the averaged loss value J so that we can infer the loss of the whole layers. Then, J can be calculated as follows:

$$J = \frac{1}{N}\sum_{n=1}^{N} H(p_n, q_n)$$

In this study, p_i indicates the value distribution of the classifier in the retraining process, and q_i indicates that of the training dataset. Then, the value J represents how different the distribution of the classified output is from that of the original training dataset when random noise data are inputted during the retraining process. Therefore, the low value of cross-entropy indicates a well-trained model, and it is utilized as a loss function in the optimization problem in a direction that minimizes its value [11]. Therefore, a low cross-entropy value indicates that the training was done well.

The result graph (Figure 3) shows that the minimum cross-entropy value, 0.9561, occurs with 36,700 training times and starts to increase gradually after about 50,000 training times.

4.1.3 Determining optimized point

When it comes to accuracy results, the performance of the classifier does not change after the training times exceeds 50,000 although there is some fluctuation. However, when the result of cross-entropy is considered with accuracy together, it is recommended to select an optimized training time that is between 35,000 and 50,000. In this study, we retrained the classifier 37,000 times and conducted further research.

4.2 Validation

After retraining the classifier with optimized training times, validation of whether the retrained classifier works well. In this study, the validation process was implemented by inputting new images that were not used for training. Eight images on average for each category were prepared, so a total of 235 images were inputted to the classifier and some example images are shown in Figure 4.

The result is shown in Figure 5. Categories on the x-axis are the labels of input images, and categories on the y-axis are those for labels created automatically. The numbers in the cell indicate the averaged probabilities of the input images having the label of the y-axis when the images labelled with the categories on the x-axis are inputted. The probability numbers are used to indicate precision, and their sum on each column should ideally be 1.00. However, some of them do not reach 1.00 because probabilities below 0.05 are eliminated during the process of being averaged. The yellow cell also indicates the highest number in each column, and the classifier defines the image as the label on the y-axis of the cell at that time.

Figure 4. Example images used for validation

For example, if the input images are classified arbitrarily, the numbers of every cell should converge to 3.7%, and the output labels should be determined randomly. However, when the unlabeled images that

Resulted Categories \ Label of input images	Foundation	Subgrade enclosure	Slab on grade	Water and gas mitigation	Substructure related activity	Superstructure	Exterior vertical enclosure	Exterior horizontal enclosure	Interior construction	Interior finishes	Conveying	Plumbing	HVAC	Fire protection	Electrical	Communication	Electronic safety and security	Equipment	Furnishings	Special construction	Demolition	Site preparation	Site improvement	Liquid and gas site utilities	Electrical site improvement	Site communication	Miscellaneous site construction

Figure 5. Distribution of averaged precision (numbers) and resulted labels of job-type (y-axis) when the original label of input images (x-axis) is given. The numbers in yellow cells indicate the maximum precision of each column

should be classified under "Foundation" are inputted into the classifier, they are classified under the correct category with 31% precision. They could be classified under the "Conveying" category with 27% precision, but it is not considered because job-type inferring only follows the category with the maximum precision.

The classifier shows 92.6% accuracy, and the average precision on correct data is 58.2%. Among the 27 categories, 25 categories were classified properly and two categories were classified incorrectly. While the result of "Communication" is close to those of the adequate categories, that of "Slab on grade" has less precision than 12%. Also, the precision of some job-types is distributed to other job-types that have similar visual characteristics. This indicates the confusion that can occur due to human error can be similarly occurred by deep-learning, and it can be fixed to some degree by complementing more featured images or combining those categories.

5 Conclusion

Although there are lots of pictures taken from construction sites, not enough studies to manage them are conducted yet. We propose a method of classifying pictures taken from construction sites using deep-learning algorithm in order to automate the process.

The performance test shows that a deep-learning algorithm (Google Inception v3) can automatically classify construction pictures into OmniClass Level 2 with more than 90% of accuracy when it was trained with 1,208 images. The major contribution of this study is on suggesting a method of automation in documentation. The result shows that the classifier with deep-learning can do some of documentation task instead of human only after retrained with pictures taken in advance.

In fact, recognizing the process of optimization when a deep learning algorithm is used is difficult. However, it is only based on complex mathematical calculation, not on the black box totally [19][20]. For the appropriate result from deep learning to be obtained, the algorithm should be designed first, and a large volume of data for training should be arranged well. This study used over 1,400 images for training and validation, but more reliable results can be derived if a larger number of images were used during the training and validation. Moreover, this study shows that an automated construction-picture classification method solely based on CNN has room for improvement. This paper reports the first step toward developing a reliable classifier for construction work by using deep learning. We are developing it further to improve its reliability. We are planning to develop a new algorithm based on a semantic approach and deep learning (CNN) to improve performance in terms of precision and accuracy with the use of a larger number of construction pictures.

Abstract: Frozen soils are encountered on construction site in the polar regions or where artificial frozen ground (AFG) method is used. Thus, efficient ways to monitor the behaviour and potential failure of frozen soils are on demand. The advance in thermographic technology presented an alternative solution as the deformation occurred in frozen soil would generate inter-particle friction heat, and hence increase in temperature. In this research, uniaxial compression tests were conducted on cylindrical frozen soil specimens of three types, namely clay, sand and gravel. During the tests, the surface temperature profiles of the specimens were recorded by an infrared video camera. The thermographic videos were analysed, and the results shows that temperature increase caused by frictional heat can be observed in all three frozen soil specimens. Therefore, such temperature increase can be deemed as an indicator for the potential failure of frozen soil and such method is applicable for monitoring purpose.

Key words-
Frozen soil; Infrared camera; Crack

1 Introduction

Historically, human has been living and building structures on frozen ground in arctic area where the annually average temperature is below the freezing point of water. And artificial frozen ground (AFG) method has gained its popularity as a technique to stabilise soil during excavation recently. Due bonding effect of ice, frozen soil is more rigid and stronger than normal soil and may demonstrate mechanical behaviour similar to concrete. The crack initiation and propagation in concrete has been studied by many researchers, but few studies are focused on cracks of frozen soil.

As crack occurs, there is relative movement of soil particles around the crack, and hence frictional heat. The frictional heat may cause temperature increase, which can be observed using thermographic devices such as an infrared camera.

Researchers successfully used infrared camera to detect phenomenon with temperature changes, such as oil product spreading on water surface [1], wild fire [2], and wind flow[3].

Specifically, thermographic technique has been applied to defection in structures. Seo and Choi [4] detected crack formation in pillars using infrared camera. Though in some cases, the defection does not generate temperature change when the structure is at rest. When heated by external source, defections will show different temperature comparing to the rest of structure. Broberg [5] used infrared camera to detect defection in welds based on temperature difference between defection and its surrounding surface while the weld was heated by a flash lamp as an external IR source. Štarman and Matz [6]observed the propagation of artificially generated thermal pulse the in steel bars using infrared camera to locate the presence of cracks.

2 Thermal graphic imaging

Infrared is an electromagnetic radiation emits by all body above 0 K. The characteristic of the radiation depends on the temperature of the body so that the temperature of the body can be determined by the measured temperature. When an object is photographed using the infrared camera, the infrared radiation energy emitted by the object is received by the sensor of infrared camera and simultaneously converted to electronic signal. Then the electronic signal is processed by the controlling software to generate the thermal graphic image or, in short, thermograph.

Although to measure the absolute value of temperature with high precision using infrared camera requires robust and sophisticated calibration and strict control over atmospheric condition, the change in temperature can be detected remotely and non-intrusively on a large or small scale desired in specific scenario. Additionally, the thermograph also provide 2D geometry information which cannot be provided by other types of thermal sensors. Therefore, infrared camera is used in this research to detect crack formation in frozen soil in this research.

3 Experimental apparatus setup

In this research uniaxial compression test are conducted on frozen soil specimens while the specimens are subjected to an infrared camera. The arrangements of the experimental apparatus are shown in Figure 1.

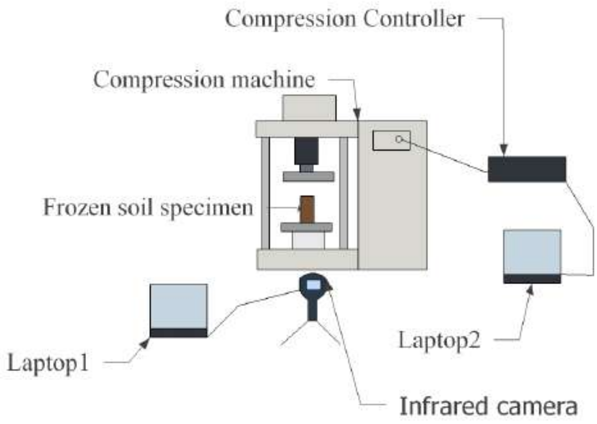

Figure 1. Experimental apparatus setup

The infrared camera is place approximately 1 m in front of the compression machine. The load is recorded at a frequency of 10 Hz. The Time-load curve is visible simultaneously on the laptop2 controlling the compression machine. The uniaxial compression test is terminated when the specimen fails or the lift of piston reached its capacity.

3.1 Specimen preparation

Three cases of soil category are considered in this study, namely clay, sand and gravel. For the clay specimen. The undisturbed clay sample extracted from 3 meters depth is cut into a cylinder of 100 mm (diameter) by 150 mm (height). And then submerged in a water tank for 24 hours to reach saturation. Afterwards it is put in the freezer for at least 24 hours. For the Sand and gravel cases, the soil particles and water are poured into moulds iteratively to make sure the specimen is fully saturated and composition relatively uniform across the height. Then they are frozen in a freezer before removed from the mould. Afterwards, the specimen are again stored in the freezer for 24 hours before test. Figure 2 shows process to make the frozen sand specimen.

Figure 2. Preparation of frozen soil specimen

Due to mechanical disturbance during the removal of the specimen, the height of sand and gravel specimen are not strictly controlled. The geometric information of specimens are shown is Table 1Figure 3 and the photos of specimens taken before the uniaxial compression tests are shown in Figure 3.

Table 1. Geometry of specimens

Material	Height (mm)	Diameter (mm)
clay	150	100
sand	171	100
gravel	179	100

(a) (b) (c)

Figure 3. Frozen clay (a) sand (b) and gravel (c) specimens before uniaxial compression tests

3.2 Infrared camera

The infrared camera used is Flir E60.When an object is photographed using the infrared camera, the infrared radiation energy emitted by the object is received by the sensor of infrared camera and simultaneously converted to electronic signal. Then the electronic signal is processed by the Flir R&D controlling software to generate the temperature profile. The exported results file consists sequence of thermographic photos taken at a frequency of 30 Hz and resolution of 320*240 pixels. Each pixel in a frame has its temperature measured. The exported thermographic files are analysed using software Flir Research IR. The thermal sensitivity is 0.05°C and accuracy is ±2°C.

4 Result and Analysis

Due to lack of pre-existing knowledge of what and how a crack would appear in thermograph of frozen soils. The thermographs were carefully examined frame by frame. The qualification of a crack can be qualitatively described as follows:

- Significant temporal temperature variation, comparing to the immediate surrounding area (baseline), occurs at certain spots of relatively small area.

- The temperature variation initiates within the specimen surface and is not transmitted from the interface between specimen and ambient environment.
- The temperature variation is sustained more than 1 frame, which disqualifies those false positives caused by random flocculation in measured value of temperature.
- The temperature variation is not caused by mass transportation i.e. movement of disintegrated soil particle or water flow thawed from ice.

4.1 Crack in frozen clay

As shown in the load-time curve in Figure 4, the load peaks at 96.30 s after test started.

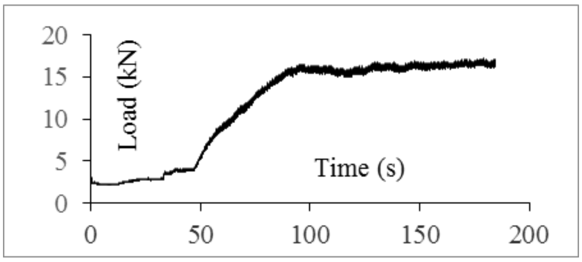

Figure 4. uniaxial load-time curve of clay specimen

After 96.30 s, temperature of certain points on the specimen surface appears to increase at a slightly higher rate than that of the rests. One example is indicated in **Error! Reference source not found.** as the crack point. A baseline point about 4 mm downwards of the crack point is selected to mitigate the effect of measurement error and the effect of heating from the ambient atmosphere on the variation of temperature.

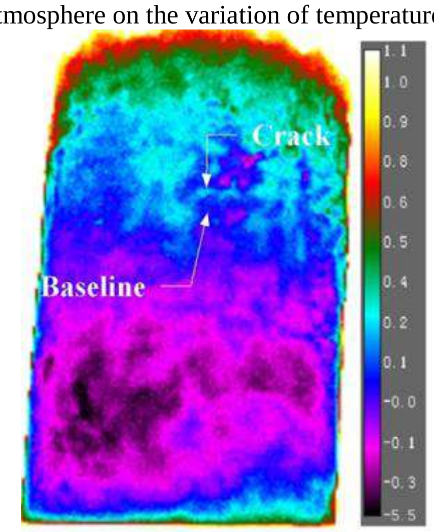

Figure 5. Temperature profile of clay specimen

The temperature-time curve for the crack point and baseline point are plotted in Figure 6. Disregarding the random flocculation, from 105 s to 123s seconds, the T increases from -3.02 °C to -2.41 °C. The temperature increase at crack point is further verified by the temperature profile along a line approximately perpendicular to the crack as shown in Figure 7. Temperature profile at the start of the test (0 s), immediately before the crack occurs (105 s), and after the crack forms (125 s), are plotted. Before the crack occurs, there is no significant difference in temperature between potential crack point and the rest. After the crack is formed, the temperature at the crack point is 0.57°C higher than those at points not influenced by the crack.

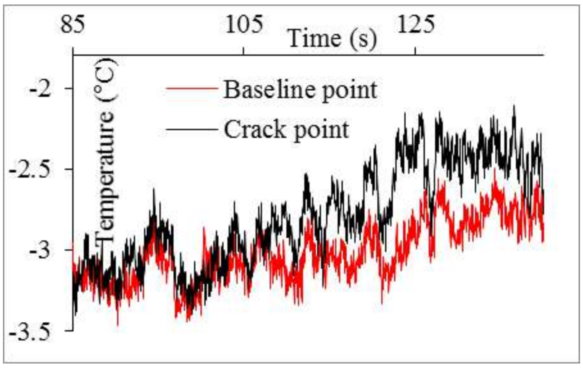

Figure 6. Temperature-time curve of crack point and baseline

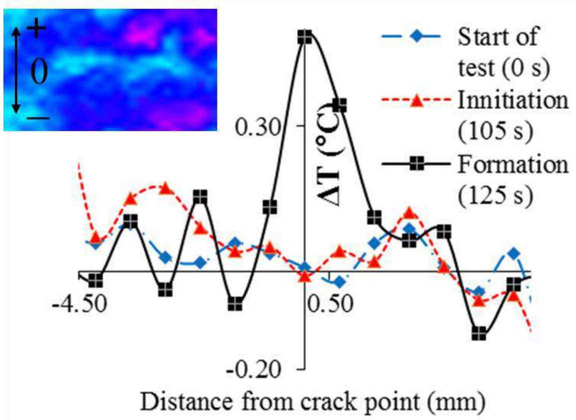

Figure 7. Temperature profile along a measurement line approximately perpendicular to the crack (the position of the measurement line is marked on the temperature profile attached on the top left)

4.2 Bulge effect in frozen sand

Although there is no individual crack observed in the sand case. As the frozen sand specimen is compressed, the. The expansion in radial direction, which we call bulge, becomes significantly visible after yield and the phenomenon can also be correlated to temperature variation. The temperature of three representative points located at upper part (U.), lower left part (L.L), lower right part (L.R), and average temperature of a square area (S.) are selected to demonstrate the effect of bulge on temperature. The locations are indicated in Figure 8.

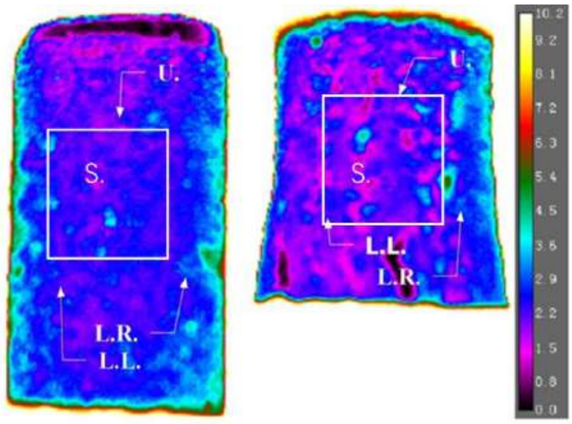

Figure 8. Temperature profile of frozen sand specimen at start (left) and end (right) of compression test

.

The temperature and load curves are plotted together in Figure 9. As the bulge of the specimen becomes obvious after yield (64.9 s), the temperature of every single point of specimen surface demonstrate 4 simultaneous impulsive increase initiating at 66.80 s, 88.30 s, 99.53 s and 110.30 s respectively. Impulses are not observed at points outside of the specimen surface, which means these impulses are not measurement error. The magnitude of ΔT for the impulses ranges from 0.37 to 0.95 °C.

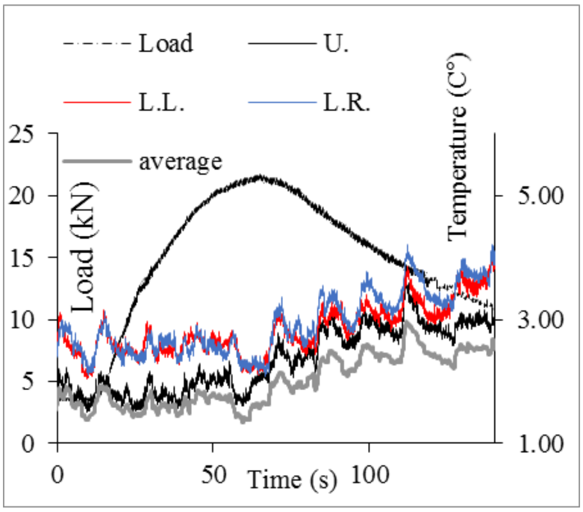

Figure 9. Load curve and temperature-time curve of sand specimen

4.3 Cracks in frozen gravel

Two types of cracks are observed during the compression test of the gravel specimen. The cracks, which occur in-between gravel particles, cause increases of temperature at crack point. Such cracks are noted as I1, I2 I3, and I4 following the initial of the word ‘increase’. Temperature decrease at crack point is observed for cracks occur within ice block. Such cracks are noted as D1, D2, D3, D4, D5 and D6 following the initial of word ‘decrease’. The ideal temperature variations for cracks of type I and D are illustrated in Figure 10. When cracks occur between gravel particles, the inter-particle friction generates heat. But those friction is relatively negligible between ice surfaces due to its smoothness. Even though there were heat generated around ice particles. The heat would probably be consumed by melting of ice rather than cause temperature increase. The temperature decrease is due to the temperature gradient from the surface to the inner core of specimen. When crack widens, the inner surface of the specimen, the temperature of which is lower comparing to the outside, is exposed to the camera. The location of these two types of cracks are indicated Figure 11.

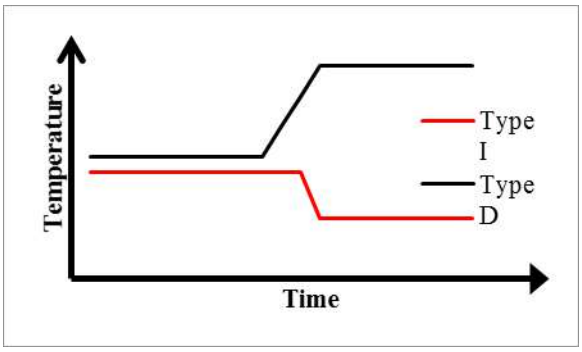

Figure 10. Ideal temperature-time curves of crack type I and type D

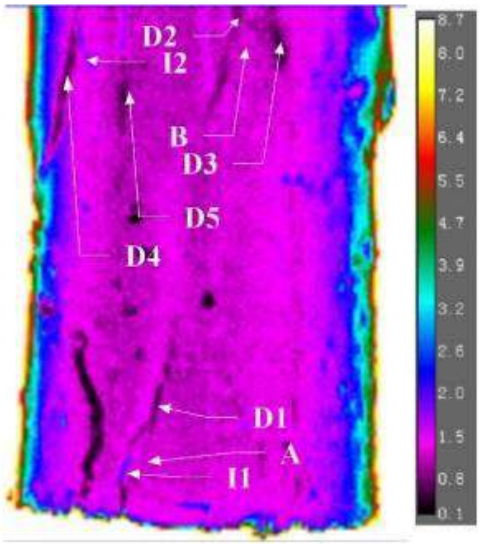
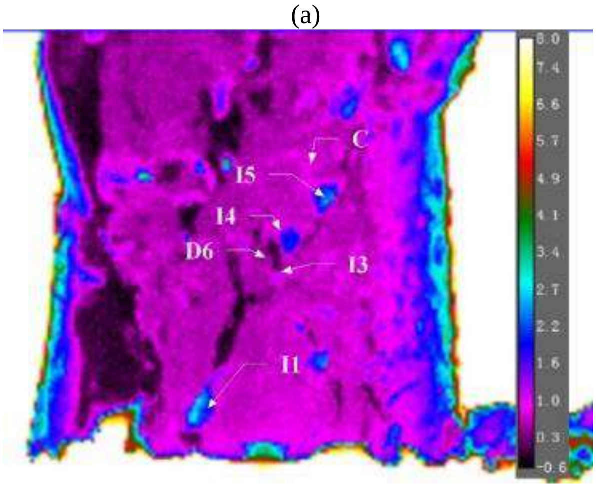


(a)



(b)

Figure 11. Locations of cracks before plastic deformation (a) and after plastic deformation (b)

Temporal variation for crack I1, D2 and D5 are Shown in Figure 12. Crack I1 occurs at the time of yield. Before crack initiates, temperature of the crack point is relatively constant and approximately equals to the temperature of baseline. The T-t curve of crack point deviates from that of the baseline since t=126.33 s. From t= 126.33 to t=128.80s, the temperature at crack point increase by 0.6 °C while that at the baseline is relatively stable. After the crack is formed the temperature at the crack is relatively steady from 128.90 to 135.33 s but subsequently decreases due to the decrease of load. Crack D2 forms at the transitional point between stress softening and plastic deformation, which takes less time than the formation of crack I1. It is compatible with the common sense that the ice is very brittle and there was little friction. The magnitude of temperature decrease is not as important as the temperature increase for crack between gravel particles as the decrease only show how deep the crack develops into the specimen. The crack I5 occurs along the global failure surface during plastic deformation. The crack occurs at 265 s with a temperature increase of 0.51 ° C. After the relative movement between two parts of specimen on each side of the failure surface starts at 280 s the temperature increase takes 3 steps, which is corresponding to the steps of relative movement along the failure surface observed in the video. The load, and hence the stress within the specimen, is less than those previously during the elastic stage when I1 occurs. But the relatively movement along the global failure surface is more intense. Thus, both the rate of increase and total amount of increase in temperature is larger. From 280s to 315s, the temperature increase due to friction along the global failure surface is 2.66 °C.

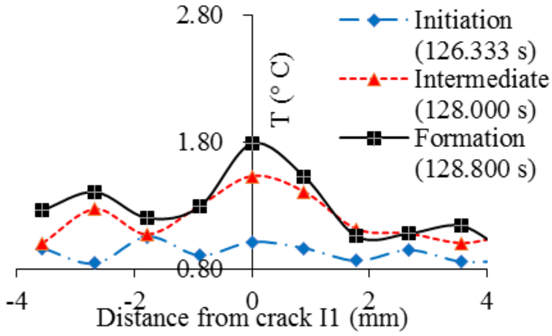
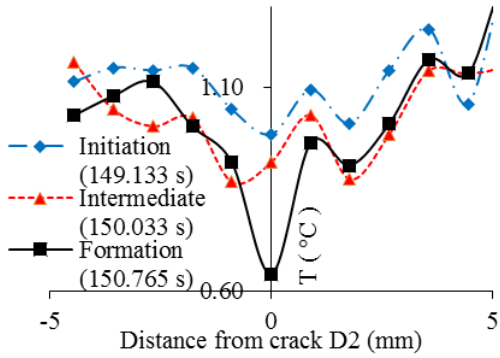
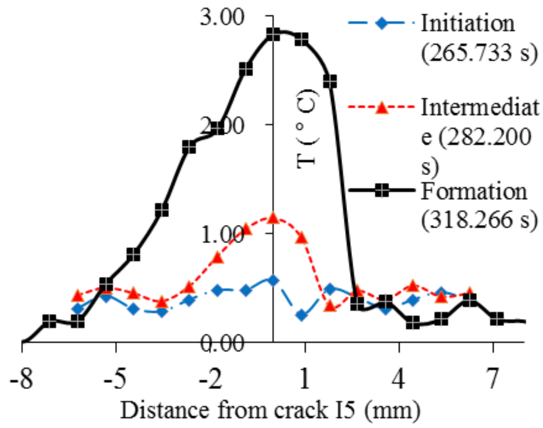
Figure 12. Temporal temperature variation at crack I1, D2, and I5 and their respective baseline A, B, and C.



(a)



(b)



(c)

Figure 13. Temperature profile across crack I1, D2, and I5 during its formation

The spatial temperature distribution across I1, D2, and I5 are also plotted to demonstrate the increase during the formation of crack in Figure 13. ΔT_{I1} is defined as $\Delta T_{I1} = T_{I1} - T_{average}$,where T_{I1} is the temperature at crack I1 at formation and $T_{average}$ is the average at the immediate surrounding area of crack I1.In the same manner, the time t_i, when the crack is fully developed, and ΔT_i is recorded for cracks I2, I3, I5, D1, D3, D4, and D6. After a crack has formed, the temperature may still vary subjected to the change in stress-strain condition. Thus the ΔT for crack I1 at stress-softening stage (noted by the initial 's' as subscript in $I1_s$) and plastic stage (noted by the initial 'p' as subscript in $I1_p$) and ΔT for Crack I2 at plastic stage are also calculated.

The serie of $(t_i, \Delta T_i)$ are plotted together with load-time curve in Figure 14. During the elastic stage, only two cracks, I1 and D1, occur slightly before yield (128.9 s). As the load decreases during the stress-softening period, the ΔT at crack I1 also decreases. A series of crack consisting 4 type D and 1 type I occur just before the transition to plastic deformation at 162.0 s. Afterwards, the load is relatively constant as the compression reached its plastic stage and no crack occurs until t=265 s, when the cracks later forming the global failure line initiates. From t= 265 s to t 300s, the global failure surfaces gradually grow by connecting these individual cracks and the temperature along it generally increases. The total temperature increases at this series of cracks are all above 2.1 °C.

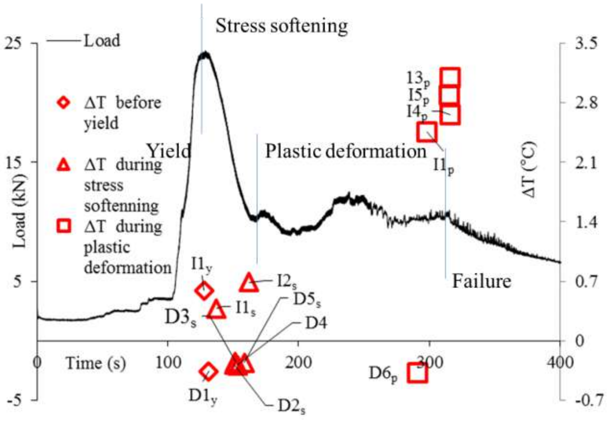


Figure 14. Load-time curve with magnitudes of temperature change at cracks

5 Conclusion

In this research, the thermographic profile of frozen soil specimen under uniaxial compression test is studied. For all 3 cases, abnormal temperature variations on specimen surface due to inter-particle friction occur are observed.

1. In frozen clay specimen, the temperature increases at cracks are identified only after plastic deformation occurs
2. For the frozen sand, simultaneous temperature increases are observed on the entire specimen as it bulges at plastic stage.
3. In frozen gravel, temperature change are observed at cracks before and after yield. For cracks in ice particles, temperature decreases due to change in geometry. For cracks in gravel particles temperature increases due to inter-particle friction.

6 outlook

In this research, the identification of temperature change induced by friction is achieved after the thermal-videos are manually examined for multiple times and the temperature variation at manually selected points are analysed. Such manual observation and analysis are time-consuming and not efficient enough for real-time monitoring. Thus, the application of this method for monitoring on-site requires significant improvement in efficiency in the future.

Abstract

There is a necessity to expand the supply apartment houses for the vulnerable classes. In addition, it is required to manage the assets for public rental housing to improve economic efficiency, such as improving the residential environment to prevent the surge of maintenance expenses due to deterioration. Therefore, it is necessary to supply modular apartment houses that can be constructed with low construction cost in a short period of time. This study aims to derive factors that have the greatest impact on assets in the maintenance phase, and determine the priority of them as part of basic research for efficient asset management of modular construction project. The optimum maintenance cycle and rate are applied as weight factors through a proper formula. As a result, wire rope & pulley, monitoring box, record device, CCTV and information signs are the highest priorities of long-term maintenance contents in economic aspects. In addition, mortar finishing has a high applicability.

Modular; Apartment House; Asset Management; Influence Factor; Maintenance

1 Introduction

1.1 The Background and Purpose of Study

In South Korea, the residence rate of domestic recipients of basic living is 40.2%, but the supply ratio of public rental housing is only 32.9% [1]. Therefore, it is necessary to expand the supply for the vulnerable classes. Also, the increasing number of one and two family members has led to a change in the area of the apartment house. In addition, it is required to manage the assets for public rental housing to improve economic efficiency, such as improving the residential environment to prevent the surge of maintenance expenses due to deterioration [2]. Therefore, it is necessary to supply modular apartment houses which can reduce life cycle cost, particularly in maintenance phase.

The ultimate goal of this study is to create a decision support model for optimal asset management of modular apartment housing. As a first step to achieve the goal, this study aims to derive factors that have the greatest impact on assets in the maintenance phase, and determine the priority of them as part of basic research for efficient asset management of modular construction project comparing to conventional (reinforced concrete) construction project.

1.2 The Scope and Method of Study

The subject of this research was limited to apartment houses constructed by modular construction method. The scope of this research was limited to financial assets except for other type of assets such as human assets and intellectual assets. The scope of period was also limited to maintenance phase. The reason was that the characteristics of modular construction are the most visible in maintenance phase. One of the influential advantage of modular construction is that the module or its components can be easily changed(repaired) and reused.

Figure 1. The sequence of this study

This research was conducted in the following sequence, as shown in Figure 1. First, the previous studies of modular apartment houses in asset management aspects involving domestic and overseas literature review were investigated. Second, general long-term maintenance items of apartment houses were derived. Following that, weight factors and importance factors for each item were assigned. Once this was done, priority for each item was derived. The final step is that long-term maintenance items between conventional and modular houses were compared and analyzed.

2 Literature Review

2.1 Previous Studies

The previous studies related to modular apartment houses in asset management aspects are shown as Table 1.

Table 1 Major research related to modular apartment houses

Author	Title	Main Content
Kim (2011) [3]	Economic Feasibility Study on the Unit Modular Fabrication Method According to the Life Cycle Costing Methodology	Proposing an economic feasibility forecasting model and to apply the model for method of unit modular construction
Kim (2013) [4]	An Economic Analysis of Modular Method for the Urban-type Housing	Conducting an economic analysis by calculating cost and profit by construction method in order to provide basic data for establishing directions for the projects in the future and making decisions
Bang (2014) [5]	An Economic Analysis of Steel Framed Modular Housing: Compared with Case of Urban Type Living Housing of Wall-slab	Analyzing the economics of modular house to vitalize the constructed residential building by modular method and to develop the modular method
Lee (2015) [6]	A Study on Comparative Analysis of Modular Architecture for Movable Accommodation	Proposing demand sensitized movable modular building in order to reduce the financial burden

In fact, one of the advantages of modular construction is reducing construction cost by fast construction. So many studies on the economic analysis of modular apartment houses have been carried out, but the majority of studies have only considered details of construction cost and indirect cost. However, it actually costs more than the conventional method since the infrastructure is not yet built up in South Korea. Therefore, LCC analysis including the details of the modular construction in maintenance phase is needed.

2.2 Introduction to Modular house

2.2.1 General Meaning of Modular house

Modular Construction can be defined as a construction system where volumetric components forming a completed part of a building are produced off-site and transported to the construction site for installation [7].

There are two types of modular construction. One is Permanent Modular Construction(PMC) and the other is Relocatable Buildings(RBs). Permanent Modular Construction “PMC” is an innovative, sustainable construction delivery method utilizing offsite, lean manufacturing techniques to prefabricate single or multi-story whole building solutions in deliverable module sections. PMC buildings are manufactured in a safe and controlled setting, and can be constructed of wood, steel, or concrete. The structures are 60% to 90% completed in a factory-controlled environment, and transported and assembled at the final building site.

A Relocatable Building(RB) is a partially or completely assembled building that complies with applicable codes or state regulations and is constructed in a building manufacturing facility using a modular construction process. Relocatable modular buildings are designed to be reused or repurposed multiple times and transported to different building sites. [8]

2.2.2 Characteristics of Modular Construction

There are four major characteristics of modular construction.

① Fast

The modular construction is based on the dry method, so it is possible to carry out the module production at the factory and the foundation work on the site at the same time [9]. Therefore, the modular construction can be constructed in the rainy season and the winter season, so the construction schedule can be reduced by 50-80% compared to the conventional construction method [10].

② Increasing profit

Compared to the conventional construction method whose labor cost is 50% of the total construction cost, the modular construction costs 20% for the labor cost and 80% for the material and equipment cost. Thus, it is expected that higher profitability as high-function and valuable products [11].

③ Eco-friendly

Since most of the housing materials are produced at factories, the effect of noise and dust reduction is outstanding by minimizing the site construction when it is constructed close to existing building [1]. From a lifecycle perspective, carbon dioxide and construction waste can be minimized during construction, use and disposal [9].

④ Improving quality

Modular construction is able to move and reuse due to the standardized design of materials and module [10]. It is also possible to maintain the uniform quality of the house as the materials are produced indoors [1].

Among these characteristics, the most effective properties in Korean construction industry is that materials or modules can be easily changed(repaired) and reused. It is because that there is less advantages of cost saving in construction period.

3 Influence Factors

3.1 Long-term Maintenance Items

According to the previous research, the LCC items of apartment house are largely classified into 'Planning Cost', 'Design cost', 'Construction Cost', 'Operation & Minor Maintenance Costs', 'Utility Costs', 'Long-Term Maintenance Costs', and 'Remaining Value & Removal Costs'. When considering the whole lifecycle, the most critical item is long-term maintenance costs.

Table 2 represents the criteria for establishing long-term repair plans according to Enforcement Rule of the Multi-family Housing Management Act in Statutes of the Republic of Korea [12].

Table 2 Criteria for establishing long-term repair plans

Category	Component	Content
Exterior building	Roof	Mortar finishing, Polymer coating waterproofing, Polymer sheet waterproofing, Metal shingle roofing, Asphalt shingle roofing
	Outside	Stitching, Water-based painting
	Outside window	Door (automatic door)
Interior building	Ceiling	Water-based painting, Oil-based painting, Synthetic resin coating
	Inside wall	Water-based painting, Oil-based painting, Synthetic resin coating
	Floor	Underground parking (floor)
	stairs	Non-slip stairs, Oil-based painting
Electricity, digestion, elevator and intelligent home network equipment	Spare power (self-generated) facility	Generator, Switchboard
	Substation	Transformer, Incoming panel, Switchboard
	Automatic fire detection system	Detector, Receiver
	Fire extinguishing system	Fire Pump, Sprinkler head, Digestion water pipe (steel pipe)
	Lift & elevator	Machinery, Wire rope & pulley, Control board, Governor, Door opening / closing device
	Lightning protection equipment & outdoor light	Lightning protection equipment, Security light
	Communicating & broadcasting facilities	Amplifiers & speakers, Broadcast receiving facility
	Boiler & machine room	Power tables
	Security facilities	Monitoring box, Record device, CCTV (closed circuit Television) camera & intrusion detection facility
	Intelligent home network equipment	Home network device, Complex common system equipment
Water supply, gas, drainage and ventilation equipment	Water supply equipment	Feed pump, High water tank (STS, synthetic resin), Supply pipe (steel pipe)
	Gas equipment	Pipe, Valve
	Drainage	Pump, Drain pipe (steel pipe), Waste water pipe (cast iron), Waste water pipe (PVC)
	Ventilation equipment	Extractor fan
(Water) Heating equipment	Heating equipment	Boiler, Water supply tank, Boiler pipe, Heating circulation pump, Heating pipe (steel pipe), Automatic control device, Heat exchanger
	Hot water supply facility	Circulation pump, Hot water tank, Hot water pipe (steel pipe)
Outdoor (welfare) facilities	Outdoor (welfare) facilities	Asphalt pavement, Fences, Children's play facilities, Paving block, Septic tank, Drain & manhole, Entrance, Roof at access road to underground

	parking lot, Bicycle storage, Parking breaker, Landscape facilities, Information signs

Each content has optimum maintenance cycle and rate. These two elements are applied as weight factors in this study on the assumption that the general maintenance period of apartment houses is approximately 50 years [13]. The method of applying weight factors is shown in the formula below.

$$\text{Result value} = Z \times \frac{y}{100}$$

$$Z = \frac{50}{x} - 1 \text{ (when } \frac{50}{x} \text{ is an integer value)}$$

$$Z = \text{natural number of } \frac{50}{x} \text{ using truncate function (when } \frac{50}{x} \text{ is not an integer value)}$$

When x : maintenance cycle (year)
y : maintenance rate (%)
Z : number of repair times

The maintenance cycle (year) is substituted to number of repair times in 50 years, and it is mulipied by the maintenance rate. Some of contents are classified into the method of repair such as partial repair (pr), full repair (fr), full replacement (fm), and full painting (fp). For easy understanding, exterior building category was an example, as shown in Table 3.

Table 3 An example of applied formula

Content	Maintenance cycle (year)	rate (%)	method	Z	Result value
Mortar finishing	10	100	fr	4	4
Polymer coating waterproofing	15	100	fr	3	3
Polymer sheet waterproofing	20	100	fr	2	2
Metal shingle	5	10	pr	9	0.9
roofing	20	100	fm	2	2
Asphalt	5	10	pr	9	0.9
shingle roofing	20	100	fm	2	2
Stitching	25	5	pr	1	0.05
Water-based painting	5	100	fp	9	9
Door (automatic door)	15	100	fm	3	3

3.2 Priorities of Long-term Maintenance

If all contents are analysed in the same way as above, they can be prioritized as shown in Table 4. It represents top 20 items among all the long-term maintenance contents.

Table 4 long-term maintenance contents ranked top 20

Ra -nk	Content	Result value	Mainte -nance method	Applic -ability in modular
1	Wire rope & pulley	9	fm	N
1	Monitoring box	9	fm	N
1	Record device	9	fm	N
1	CCTV (closed circuit Television) camera & intrusion detection facility	9	fm	N
1	Information signs	9	fm	N
6	External water-based painting	9	fp	N
6	Ceiling water-based painting	9	fp	N
6	Ceiling oil-based painting	9	fp	N
6	Ceiling synthetic resin coating	9	fp	N
6	Inside water-based painting	9	fp	N
6	Inside oil-based painting	9	fp	N
6	Inside synthetic resin coating	9	fp	N
6	Stairs oil-based painting	9	fp	N
14	Boiler pipe	5	fp	N
15	Underground parking (floor)	4.5	pr	N
16	Home network device	4	fm	N
16	Feed pump	4	fm	N
16	Extractor fan	4	fm	N
16	Drainage pump	4	fm	N
16	Mortar finishing	4	fr	H

If the result values are same, the maintenance method would become the standard of rank. The order is full replacement(fm) > full repair(fr) > full painting(fp) > partial repair(pr). Additionally, the applicability in modular houses was considered whether highly(H) or normally(N) applicable. Only ‘mortar finishing’ has a high applicability in modular construction. The reason is that it can be fully repaired or replaced as a module. It was difficult to find clear difference of long-term maintenance items between conventional and modular construction. However, table 4 is a result of fundamental research to derive influence factors on modular residential asset and represents top 20 long-term maintenance contents. As the research continues, the ranking items will support to decide the prior scope of economic analysis on modular maintenance asset. Since there are too many considering economic maintenance items, the prior influence factors are needed.

4 Conclusions

In this study, research was carried out to derive influence factors which are long-term maintenance items of apartment houses. Also, the priority of items was derived through assigning weight factors. However, most of prior items have little difference between conventional and modular construction.

On the whole, more considerations and weight factors are needed. The maintenance method should be weighted as a number and included in applied formula according to objective criteria. Also, construction materials or works should be repaired as a whole unit such as wall and floor itself, not separately. For instance, roof can be replaced as a module in modular construction if mortar finishing, polymer coating waterproofing and metal shingle roofing are needed to repair simultaneously. Even though a module is installed as one room at construction site, it is possible to replace each part in maintenance phase. This is because modules are made up of bundles of individual components such as exterior/inner wall, ceiling and window.

In addition, this study was focused on repair of long-term maintenance items. In order to highlight 'reuse' which is strong advantage of modular construction, considered period or phases should be increased. If the remaining value and removal phase are considered, there must be lots of items which have high applicability and strength to modular construction.

It was so hard to analyze influence factors on modular residential asset with scarce economic information. This study was the first step to manage modular residential asset. In conclusion, it was meaningful study as a leading research. Therefore, the results of this study will lead to a study on asset management of modular houses in the future.

Automatic traveling method for the self-propelled Tunnel Inspection System

Nobukazu Kamimura[a] , Satoru Nakamura[a]

[a]Institute of Technology, Tokyu Construction Co.,Ltd.
E-mail: kamimura.nobukazu@tokyu-cnst.co.jp

In recent years, road tunnels in Japan with severe aging are obliged to check periodically. But there are problems such as lack of engineers and inspection cost.

In order to solve these problems, we are developing a tunnel full-section inspection system.

In this system, inspection devices are arranged at the upper and both side parts. The lower part is protective frame vehicle with portal frame shape secured space through which the vehicle can pass. Although this system travels in a limited space, the position of the inspection device in the tunnel transverse direction is particularly important. Moreover, tunnel is a special environment that the GPS cannot be used, and feature points are few.

Therefore, we examined the automatic traveling control method suitable for this system and carried out driving tests.

As a result, it is confirmed the automatic travel control method using the magnetic sensor and guide are effective for this system.

Keywords –
Automatic operation; Magnetic sensor; Road tunnel

1 Introduction

Approx. half of road tunnels in Japan are over 40 years from the construction and aging is serious. Under such circumstances, due to the collapse of the tunnel ceiling board that occurred in 2012, periodic inspection every five years was obliged. In road tunnels, there are problems such as the shortage of engineer and the inspection cost. This tendency is particularly noticeable in road tunnels in country areas.

In order to solve these problems, we are developing a tunnel full-section inspection system (hereinafter, called this system) aimed at efficiently inspecting road tunnels. The final goal is to use this system for inspection instead of engineer.

The concept of this system is shown in Figure 1. Inspection equipment is arranged at the upper part and both side parts, and at the lower part it consists of a self-propelled portal frame secured space through which the vehicle can pass. Then, these inspection devices are moved to a predetermined position for inspection. The target value of the traveling position accuracy depends on the clearance with the tunnel that the frame and inspection device can tolerate. In this system, the tolerance of traveling position is within ± 75 mm in the tunnel transverse direction. Also, it is desirable that the operation during traveling is as simple as possible. Therefore, we consider mounting an automatic traveling control method in this system. The method can travel along a tunnel linear shape with keeping acceptable traveling position.

The environments of inside the tunnel are follows. Global Positioning System (GPS) cannot be used, and there are relatively few feature points with relatively monotonic shape. Therefore, we compare and study the sensing technologies used for various automatic driving control currently in practical use. And we select a control method considered to be suitable for this system. Then we conduct driving test with control method, and evaluate traveling accuracy.

In this paper, we report on the results of examination of these automatic traveling control methods and the evaluation results of driving accuracy by driving test.

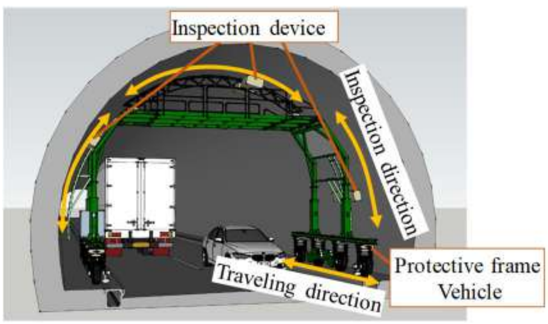

Figure 1 Concept of Tunnel Inspection System

2 Outline of Tunnel Inspection System

The actual machine of our system, which we produced, is shown in Figure 2, and the details of systems are as follows.

1. Crack inspection device: To replace the visual inspection from inspector. Automatic detection of cracks on concrete surface by light sectioning method with color image.
2. Hammering inspection device: To replace the hammering inspection from inspector. By hammering the concrete surface with the same force as inspector, the deformed of the surface layer is automatically found by the hammering sound.
3. Variable Guide Frame (hereinafter, called as VGF): Rail that moves the inspection devices in the transverse direction. In order to avoid an obstacle, it can be deformed into an arbitrary shape.
4. Protective frame vehicle: Travel the inspection system to a prescribed inspection position while securing a space through which the vehicle can pass. An inspector can ride on the upper stage, and it is effective when the inspector approaches the upper part of the tunnel. In turning traveling (minimum turning radius is R50(m)), it is assumed that the speed difference is given to the left and right driving wheels, and steering operation for adjusting the direction of the wheels is unnecessary. Since the device size can be adjusted by exchanging this frame, it is possible to deal with tunnels of various sizes. Table 1 shows main specifications of this system.

Figure 2 Actual machine of Tunnel Inspection system

Table 1 Specification of Tunnel Inspection System

Specification	
Inspection Speed (m/h)	25
Traveling speed (m/min)	Max 10
Turning diameter (m)	Min R=50
Weight (kg)	4.000
Length (m)	5.000
Width (m)	7.500 (Adjustable)

3 Automatic traveling of the protective frame vehicle

3.1 Travel accuracy and driving environment

This system aims to move the inspection device to a predetermined inspection position while traveling in the tunnel. In particular, the positional accuracy in the tunnel transverse direction is important. And its target tolerance is set to be within ± 75 mm that the frame and inspection equipment can tolerate.

On the other hand, the features in the tunnel are as follows.

1. It is not possible to grasp own position by GPS.
2. It is a relatively monotonous shape with few feature points.

Furthermore, since the vehicle width is large, the blind spot of the operator is large, and the traveling operation relying on the visual confirmation is high in risk. Therefore, we should consider automatic traveling control method to travel accurately in the tunnel.

3.2 Sensing method used for automatic traveling control

Currently, various sensing technologies for automatic traveling control exist. So we compare them and consider methods that are considered to be suitable for this system. The comparison result is shown in Table 2. From this result, it is considered that the magnetic guide sensing technology is suitable for the automatic traveling control of this system.

Table 2 Comparison of sensing method for automatic traveling control

Type	Technology	Issues	Cost	Eval
GPS	Positioning estimation by GPS	GPS signal cannot be received	Mid	Poor
SFM (Structure from Motion)	Positioning estimation from acquired image	Error due to few feature points	Mid	Poor
LiDAR	Measure the forward shape with electromagnetic waves	Need high-spec PC for calculation	High	Average
Laser ranger	Measure distance between tunnel wall and frame	Error due to equipment (ex. road signage, fire hydrant)	Low	Average
Magnetic guided	Scan the position of the magnetic guide and calculate the deviation	Magnetic guide installation required	Low	Good

4 Evaluation of Magnetic Guided Type Automatic Travel Control

4.1 System configuration of magnetic guided automatic traveling

As a result of 3.2, we decide the magnetic guided sensing technology is suitable for this system. This control method is installed in this system and we conduct driving test. The configuration of control system is shown in Figure 3, the mounting appearance is shown in Figure 4, and the specifications of control system are shown in Table 3.

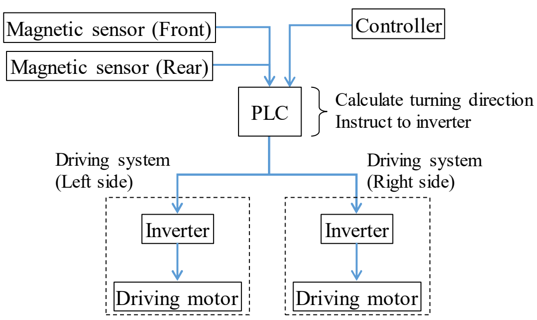

Figure.3 Control System Configuration

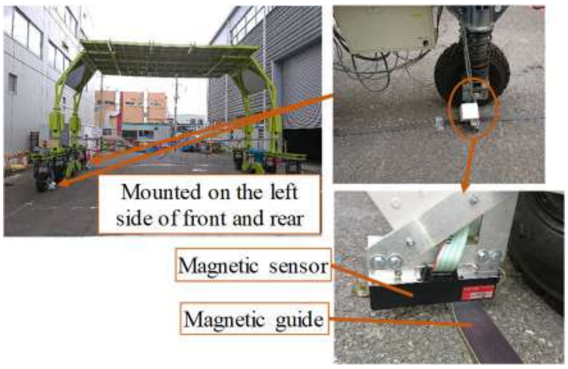

Figure 4 Appearance of magnetic guided sensor

Table 3. Specifications of control system

Equipment	Model	Manufacturer
Magnetic sensor	GS-115	MACOME
Magnetic guide	MGL-50-25	CORPORATION
PLC	KV-N14AT	Keyence

4.2 Driving Test with Magnetic Guided Automatic Travel Control

A driving test of a protective frame vehicle with a magnetic guided automatic traveling control is conducted. The results are shown as follows.

4.2.1 Conditions of driving test

The conditions of driving test are shown in Table 4. And the laying situation of the magnetic guide as the driving target is shown in Figure 5. The driving road is a flat asphalt pavement surface in a dry state.

Table 4 Conditions of driving test

Driving mode	Driving direction	Driving speed	Number of driving
Intermittent Every 40 cm	Forward / Backward	10m/min	Every 3 times
Continuance	Forward / Backward		

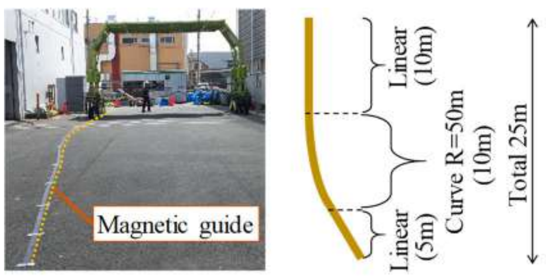

Figure 5 Magnetic guide laying situation

4.2.2 Measuring method of driving locus

In this test, automatic tracking type Total Station (hereinafter, called as TS/ST15P and ST16, Leica) is used for measurement of the magnetic guide position and the driving locus. Particularly the measurement of the driving locus, the TS target is located on front and rear of the magnetic sensor side. And the measurement is performed continuously using two TSs. This measurement method is shown in Figure 6.

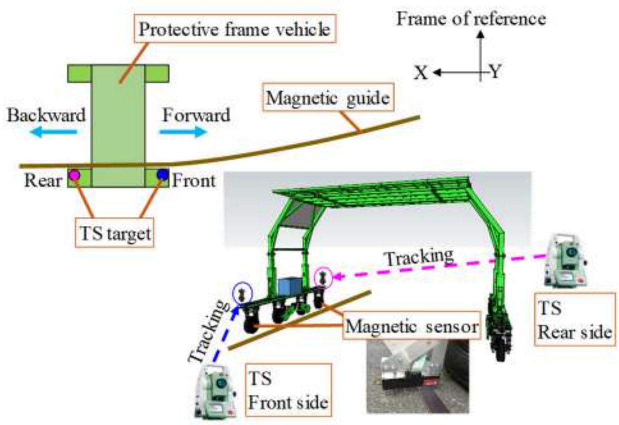

Figure 6 Measuring method of driving locus

4.2.3 Test results

Figure 7 shows the result of comparing the magnetic guide position and traveling locus in this test (excerpt of the first driving result). The numerical value in the graph indicates the maximum deviation amount (right and left with the magnetic guide position as the center) and its position.

Magnetic guide of this test is combining the linear part and the curve part (Turning radius R=50m). As a result of the automatic driving test with the magnetic guide control, the maximum deviation amount from the magnetic guide is 79mm. The large deviation points are before and after turning area. No difference is confirmed by running conditions (continuous driving / intermittent driving, forward / backward).

In this test, since the deviation amount is almost within the target. It is considered that the magnetic guided automatic travel control can be used for this system.

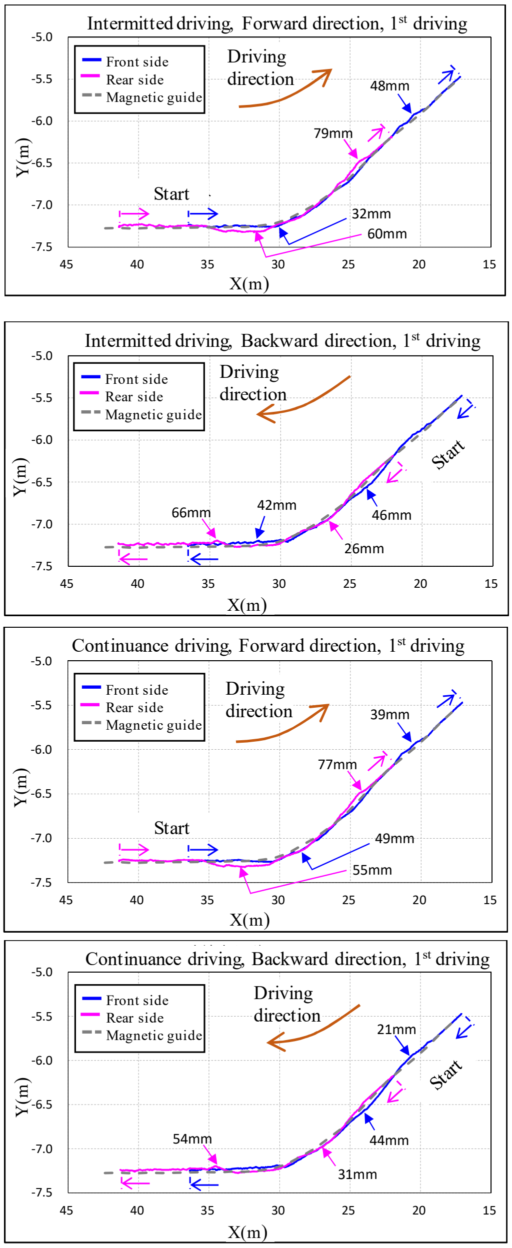

Figure 7 Comparison of magnetic guide and driving locus

5 Implementation of magnetic guided automatic traveling control system

Magnetic guided automatic traveling control system confirmed effectiveness is mounted on actual machine. Installed system configuration is shown in Figure 8, and detail of magnetic guide is in Figure 9. The main improvements based on test results are as follows.

1. Increase number of sensors (From one side to both sides): To improve the accuracy of traveling control by sensing magnetism on both sides.

2. Add the distance guide: This system should stop at every 40cm at inspection. Therefore, a marker is incorporated in the magnetic guide as a stop target.
3. Magnetic guide indicator: An indicator is added in operation interface. Operator can check the deviation amount of each magnetic guide.
4. Output of running position and deviation amount: For grasping position information, the position in the traverse direction is calculated from the deviation amount of the four magnetic sensors. The traveling distance is calculated from encoder count. And these information are output to inspection system.
5. Magnetic guide installation method: The magnetic guide is installed in the tunnel at the timing of inspection. The installation position is set to a certain distance from the tunnel wall surface, and it is installed simply and accurately with a JIG. Also, magnetic guides are connected by connecting 1 m straight lines. Since it is possible to handle all straight and curved sections, it is not necessary to prepare multiple types of magnetic guides.

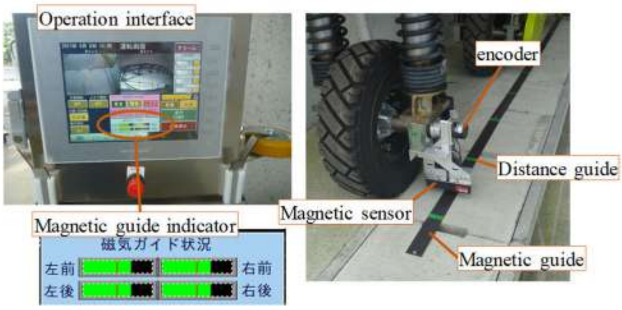

Figure 8 Installed system configuration

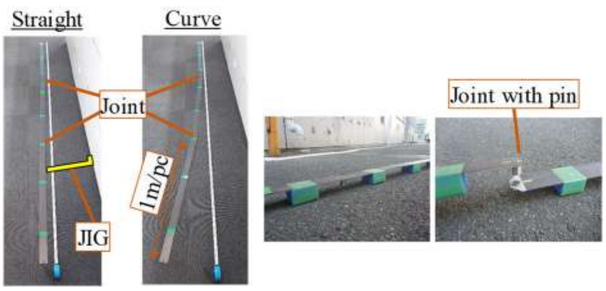

Figure 9 Detail of magnetic guide

6 Conclusion

In this paper, we evaluated the automatic traveling control method of the tunnel full cross section inspection system. As a result, it is found that the automatic traveling control method using the magnetic guided is effective and reasonable.

In the future, we will try to optimize the frame structure and the turning method by measuring the twist of the frame during turning and structural analysis.

In addition, it is now supposed to complement self-position information that is detected only by a deviation from the magnetic guide. Since we will study a system that measures the distance between the entire frame and the tunnel wall surface at several places.

With these improvements, we aim for practical application of this system.

This work was supported by Council for Science, Technology and Innovation, " Cross-ministerial Strategic Innovation Promotion Program (SIP), Infrastructure Maintenance, Renovation, and Management". (Funding agency: NEDO)

Abstract

Building Information Modelling (BIM) has been indicated as the right tool to provide the construction industry with the productivity boost that has been lacking in the last 40 years. This momentum finds its highest fulfilment in the support provided by BIM models to knowledge management and the automation of process. However, the management of information flow is still far from its automation breakthrough and, as far as operation and maintenance are concerned, knowledge about procedures is often incomplete. Moreover, processes are often do not undergo optimisation and the individual steps to be performed are not communicated, but in facility management (FM) the transmission of know-how is fundamental particularly because some operations are dangerous or risky. In this framework, Mixed Reality (MR) represents a powerful means to communicate the correct data concerning both geometric features to be considered and the standard procedure to be followed. The aim of this paper is to investigate the possibility of exploiting the benefits provided by these technologies to achieve automation in the transmission of information and optimisation of procedures, improving efficiency and productivity thanks to a better understanding of the operations to be carried out and the reduction of errors. With the support of a head-mounted display (HDM) device with a see-through screen capable of presenting 3D virtual objects, this research tries to combine information from a BIM model with reality to study the benefits for maintenance personnel.

Keywords –
Mixed reality, BIM, Operation and Maintenance

1 Introduction

Facility Management is the phase in the entire building life cycle with the highest costs and yet to date little attention is still being paid to it. Nevertheless, there would be plenty of room for improvement for various aspects of operations and maintenance. The possibility of performing assisted diagnoses, automatically detecting components, avoiding surveys for the collection of information are all scenarios that offer great opportunities for improvement, particularly in terms of automation, since the automation of procedures is the benchmark for the improvement of efficiency and productivity. This research starts from an analysis of the needs which are still not being satisfied in the maintenance industry. Once the goals are established, the aim is to test the effectiveness of a system that collects together some technologies that, when considered separately, have already been demonstrated to increase efficiency in the construction industry. The BIM paradigm, which is rapidly spreading and establishing itself as a guarantee of efficiency, cloud systems for data management and mixed reality, which is the most interesting version of virtual reality since it allows human interaction with the digital environment created. This work aims to demonstrate the feasibility of this system and lay the foundation for its implementation by analysing its architecture and identifying all its components. Finally, on the basis of the needs identified, three scenarios the system could be used to bring benefits to and improve efficiency by reducing time and costs are proposed.

2 Scientific Background

The operational phase of a building is the main contributor to the cost of the building's life-cycle. Studies show that this cost is five to seven times higher than the initial investment costs and three times the cost of construction [1]. It is, therefore, crucial to identify increasingly efficient methods for managing the life-cycle of buildings.

At the same time, Building Information Modelling (BIM) has become the new international benchmark for improved efficiency and collaboration in the different phases of the life- cycle of a building [2].

One of the first necessities when performing commissioning or preventive and corrective maintenance is to identify building components (equipment, materials and finishes) and related information for quick identification and solution of possible problems [3].

Several studies state that building maintenance requires a comprehensive information system that captures / retrieves information about those components that may need intervention [4].

But building inspections are time and cost consuming, both with regard to on-site surveys and, even more, the subsequent BIM modelling of the data collected. In this regard, several researches have been initiated to facilitate this task by finding faster methods to retrieve information and communicate results, while other studies are focusing on the possibility of reaching automated reconstruction of 'as-built' building models [5, 6, 7].

After the surveying phase, one of the biggest challenges in the construction industry today is information management, both in the construction phase and in the building management phase. In order to manage buildings a huge variety of information are necessary [3]. As regards variety, to take maintenance decisions, facility managers require the integration of various types of information and knowledge created by the different members of a construction team such as maintenance records, work orders, causes and knock-on effects of failures, etc. Moreover, when it comes to information, besides the data that can be collected or the individual technical specifications of the various components of the building, a further aspect that needs to be kept in mind is the knowledge created from maintenance operations such as the lessons learnt from the investigation of the causes of failure, the reasons for choosing a specific maintenance method, the selection of specialist contractors, ripple effects on other building elements [4]. This knowledge also includes the fundamental know-how to train new personnel and therefore should be captured/retrieved in sufficient details. However Building Information Modelling is not tailored to individual processes and this makes it very difficult to enter the aforementioned kind of information if not already considered by the IFC structure [5, 8].

Cloud database systems represent a tool for connecting information of different disciplines that is not placed in building models and information related to processes [8]. Furthermore cloud computing has the ability to support construction projects in the sharing of documents and information despite the fragmentation of the construction industry [9, 10]. In particular, the power of cloud computing lies not only in making the sharing of documents and information possible, but also in improving it and allowing it to be exchanged in real time. [11,12] In fact, one of key challenges in operation and maintenance processes is always the need to have sufficient information about products readily available.

The Cloud-BIM system not only provides an information display service, but also provides information manipulation services for users located anywhere and at any time [13]. A link from BIM models to FM databases could help detect and diagnose construction equipment based on the necessary information such as specifications and maintenance history, which could be automatically associated with the equipment located and delivered to the staff on site [2]. Effective and immediate access to information during operations minimises time and labour and helps avoid ineffective decisions made in the absence of information [14].

This system for the management of large information flows can also find the necessary support for on-site visualisation thanks to a head mounted display that supports mixed reality. Starting from the definition by Milgram and Kishino [15] of mixed reality as a "spectrum of reality" ranging from pure "reality" (seen by a user without computer intervention) and pure "virtual reality" (a computer-generated environment where the user has no interaction with the physical world), it can be said that MR is any environment that incorporates aspects of both physical reality and computer-generated reality, for example, by overlapping virtual objects over a user's field of view of a real space. As far as augmented reality (AV) is concerned, it is a predominantly real environment with some virtual elements. Milgram et al. also gave other details about MR, which is also defined as a special class of Virtual Reality-related technologies for creating environments wherein real world and virtual world objects are presented together in a single display [15].

Thanks to these characteristics, mixed reality has already found application in on-site support to operators, especially with regard to the need for a good training of operators and access to large amounts of information about equipment management . In these circumstances, in fact, the capability of AR to involve construction personnel in increased workspaces allows a user to work with the true 3D environment while visually receiving additional computer generated or modelled information about the activity in progress. Mixed Reality can improve the user's perception of the real environment, showing information that he could not directly acquire without help [16].

Despite the great successes of BIM-based VR and cloud computing in improving the performance of AEC activities, it is still necessary to examine methods and systems to integrate both BIM virtual reality and cloud computing for advanced project communication among remote project stakeholders with a shared immersive virtual experience [11].

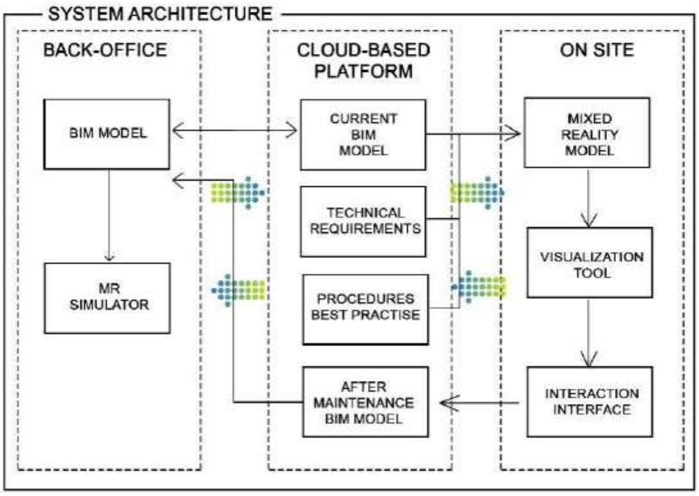

Figure 1. System Architecture

Indeed the research presented in this paper is mainly focused on:

- integrating the BIM virtual model, the real environment and operators;

testing the mixed reality approach in three novel scenarios (inventory/survey support, diagnosis, remote support to operations).

3 Research Methodology

This research starts from the study of FM needs. The identification of these challenges leads to a huge set of data requirement which become the starting point for the creation of a BIM model of the building. Following a survey with maintenance expert personnel additional information and procedures are collected. Since the management of all the maintenance data must be real time, therefore fast and efficient, the study foresees the use of cloud platforms for the management of large amounts of data and consequently the creation of interfaces between the model and virtual data. Finally to verify the proposed approach, simulations of the three different scenarios are carried out with both preliminary and real world test.

3.1 Requirement analysis

In literature it is widely recognised that FM includes and involves multi-disciplinary activities and, as a consequence, has extensive information requirements. [2] Operation and maintenance are a substantial part of the FM and can be related to structures or facilities which may be very different from each other. Many references about the most important needs to be met in order to best perform maintenance interventions can be found in literature.

In this research the analysis will be enhanced by also considering the opinions of experts in the maintenance sector.

In literature, requirements can be split into:

aided document/information retrieval

components localisation

procedure management automated support

personnel training

automated identification and modelling of components

Aided document and information retrieval is based on the use of BIM software for modelling buildings. The digital model of a building could, in fact, contain information on the maintenance operations carried out, the level of deterioration and technical specifications, making this data easily retrievable and providing an immediate localisation in the building. Furthermore, the digital model could be supported by cloud data storage systems for procedures or extended information that cannot be inserted into the model. [17,18,19]

In literature, research attempting to identify, in a more or less detailed way, the information needed for buildings maintenance management can also be found. This depends largely on the type of facilities and on the operations to be carried out. Among the necessary data, Hamledari et al. indicate the details associated with the inspection process, such as the person/organisation responsible, defects, as-built type, as-designed type, data capture tools, time/date of the inspection, the inspector's notes and the images captured [20]. Gao et al. begin, instead, from a more detailed analysis of the components to be detected on-site, starting from the OmniClass classification and integrating it with data fields in a COBie worksheet [21].

A further informative requirement concerns the localisation of the component which is an expensive activity in terms of time and effort. Conventionally, maintenance personnel on-site rely on paper-based blueprints or on their experience, intuition and judgment in finding and locating equipment,such as HVAC systems and electrical, gas and water lines, which are usually in places that are not easily visible, e.g. above ceilings, behind walls or under floors. This task becomes of great importance especially during an emergency, or when newly assigned personnel takes over responsibility for the facility or when the equipment has been replaced or removed. Also in this case, the BIM as-built model can be of great help, also considering the clear visualisation that the 3D model provides. [2,22]

It is crucial to organise and have information regarding also the procedures to be followed always available : which maintenance and repair works must be performed, when these works must be done, how work can be undertaken safely and which works are most needed. [17]

These initial information requirements are all included in the training of personnel, who are currently managed through presentations, on-site visits, hand-hand demonstrations and self-study, which requires intensive preparation, takes a long time and depends largely on the skills and experience of the trainers. [2] This would certainly benefit from organised data management and advanced visualisation and support tools. [23,24]

Lastly, the real geometry of buildings often differs from the original plans and for this reason the reconstruction of a precise 3D model is a common requirement. The efforts in automated modelling have so far focused on the segmentation and recognition of large structural components and more strongly for the exterior rather than for internal components. However, modelling should also include small-sized indoor items for different purposes (scheduled maintenance, storage and documentation, FM, security, feeding of building information models). In addition to this, recent research focused more on capturing geometric data rather than semantic representations of buildings and feeding point cloud data into BIM software [5, 25, 26, 27, 28, 29] This requires, on the one hand, a certain work of interpretation of the data collected, on the other hand, it omits a series of information that goes beyond the geometry of the elements and which is necessary for process management. In general, although this proves to be a demanding task, so far relatively few studies have turned their attempts to reduce modelling/ conversion efforts from construction data acquired into BIM objects with a high semantic meaning. [23,24,30]

3.2 System architecture

This research proposes a framework that integrates the information flow from office to operation site and vice versa. The architecture of the system proposed is actually composed of three different fields of action: the back-office, a cloud-based platform for big data management, and the operation site (Fig.1).

Starting from the back-office, this is the place where operators work. They have access to all the documents (BIM model, data sheet, etc.) and give support to the operators on site. The back office contains also the BIM model and the MR simulator necessary to enrich the virtual environment.

The cloud-based platform is the place where the BIM model updates are shared. At first, the model of the current state is shared, so that the information packages and procedures can be connected to objects. Then, following the maintenance operations, also the updated BIM model is shared to allow the back-office model to be updated.

The on-site part of the system makes available equipment to provide the technician with the MR view, the visualisation of the virtual reality on top of the real one and an interface that allows the interaction and transmission of information to the cloud system.

3.3 Cloud-based Platform

The BIM model of a building needs a deeper range of information in order to be usable for MR applications. All this information can be integrated through cloud systems for big data management. The choice of the use of a cloud based platform to support data flows depends on the need of having a schema that allows fast and efficient queries among data coming from different technologies or with different purpose and, as other researches have shown, IFC is not a suitable choice for real-time applications [3]. The maintenance operation data to be included in a cloud system concern, on the one hand, a specific in-depth analysis of the components, containing all the technical information necessary for the interventions, and, on the other, the procedures that the personnel must follow to complete the operations.

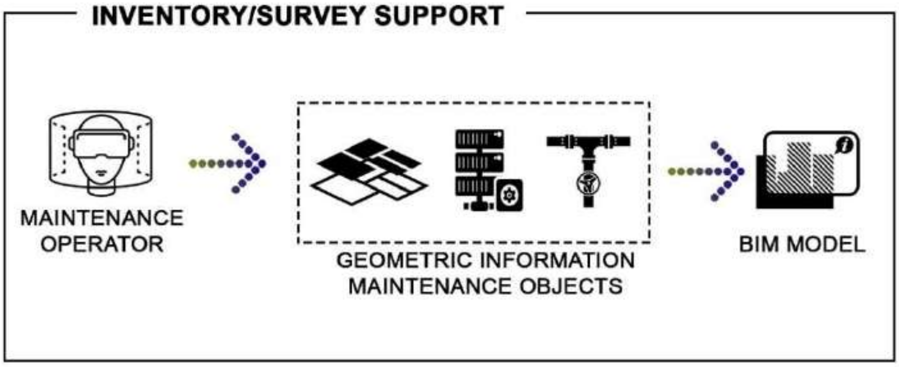

Figure 2. Inventory/survey support scenario

3.4 Design of workflow management

The information data will flow through the different components of the system by means of the cloud platform. Depending on the applications, it will be decided how and which interfaces to use to guarantee interoperability and allow the different users (back-office operators, designers, technicians) to collaborate. The flow will move in both directions, from the office to the site and vice versa, thus allowing a continuous exchange of data, which will make it possible to have continuously updated documents and the perfect knowledge of the asset status.

3.5 Development of on-site technology

The on-site part of the system proposed is developed with the support of a head-mounted display device with a see-through screen capable of presenting 3D virtual objects on top of existing physical surfaces. [31] This technology enables maintenance personnel to interact with the building and with virtual building objects, thus, pushing mixed reality towards a necessary goal so as to promote its widespread use [11].

The MR functions provided by this device include the possibility of displaying virtual objects and performing automated localisation in the building without markers.

This interaction brings also the possibility of capturing real-time data (e.g. updating maintenance operation results) which, in turn, allow constant updating of the model leading to having the updated version of the digital building all the time.

3.6 Preliminary and real world test

The tests to determine the reliability of the system will be performed, at first, in a predefined environment, the basis for the creation of the system itself. This experiment will have the purpose of calibrating the system and verifying the system's main functions based on the intervention scenario taken into consideration. Secondly, the test will be carried out in the real world, in a new environment. That is where the possible sources of interference will be evaluated and the remote support function will be tested.

4 Three interventions scenarios

Following the requirement analysis, as far as the management of maintenance operations, scenarios with criticalities only partially solved have emerged. These are the usage scenarios which are the basis of three frameworks that have been developed for information flow management and on-site support.

4.1 Inventory/survey support

Existing building data collection is the necessary basis for asset maintenance management and it is a challenging step. Recovering all the necessary information on all the elements of a building could indeed be difficult or sometimes impossible [19,24]. A series of new or more advanced technological applications are emerging to make information acquisition faster and more efficient (Scan-To-Bim for small building components), but often these applications are not related to the creation of a BIM model [30]. The first intervention scenario is therefore the automated acquisition of data on the status of fact (Fig. 2). To make the creation of a BIM 3D model of the building as automated as possible, this collection of data should be based not on point clouds or generic surfaces but on objects, which are the basic elements of BIM digital modelling.

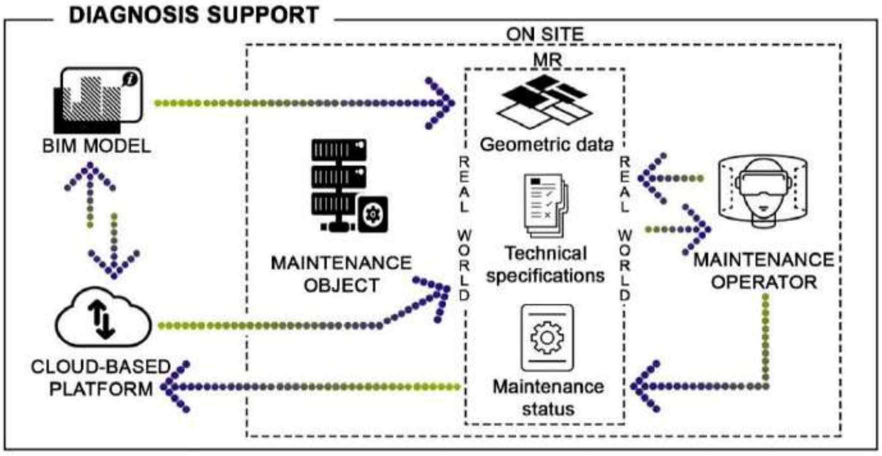

Figure 3. Diagnosis support scenario

In order to allow this type of recognition, it is essential to identify the objects' relevant features that will allow the operator to perform the recognition. This type of analysis involves the adoption of a precise and codified classification that makes it possibloe to detect all the elements involved in maintenance operations, at the same time collecting also the information necessary for the subsequent operations. The innovative contribution of this research work lies in its aim to provide a more efficient object inventory and a more rapid conversion of the elements identified during inspection into BIM elements by adding not only geometric but also semantic data and trying to minimise the post-collection work of the data acquired.

4.2 Diagnosis support

The second scenario this system could bring benefits to is that of diagnosis (Fig. 3). The prime set of information functional to diagnosis is undoubtedly the geometric one. Correct and immediate localisation of the objects on which it is necessary to operate certainly allows a reduction of possible misunderstandings, also thanks to the mixed reality display viewer that avoids having to rely on paper documents, thus making the possibility of error lower, keeping in mind that the overlapping of a virtual reality allows maintenance personnel to see hidden things (e.g.

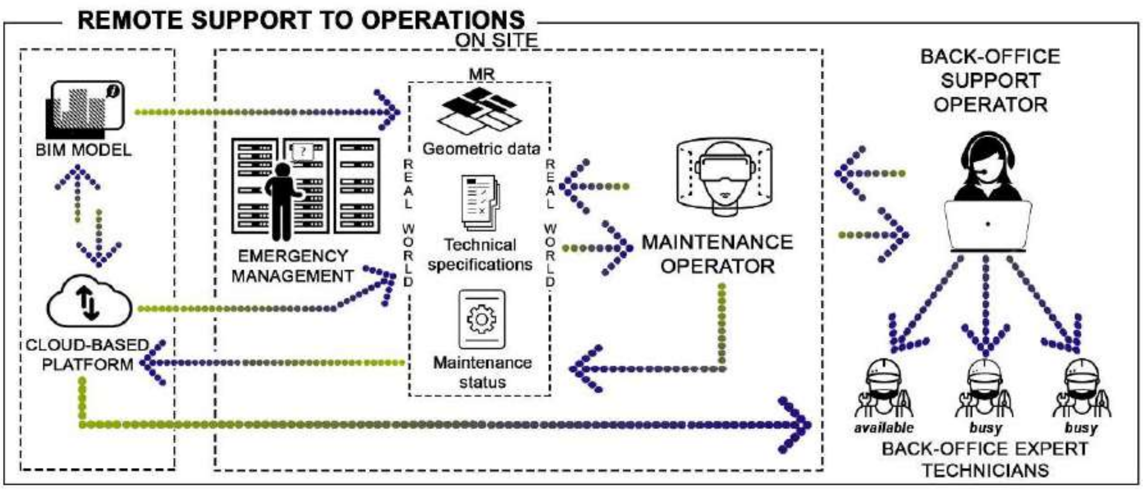

Figure 4. Remote support to operation scenario

steel in the concrete or cable paths in the walls or behind the floor). In addition to geometric data, there are also technical specifications and descriptions of components to be updated and stored and procedures to be followed in the operations. All these data start from BIM and cloud databases and can then be visualised thanks to a head-mounted display and be immediately available on site.

4.3 Remote support to operations

The last scenario taken into consideration is that of on-site operatios support from back-office (Fig. 4). Sometimes it is not possible to reduce maintenance operations to a standard procedure displayed as an object property. Therefore, in case of emergency, a standard procedure to be performed is not always available. These are the circumstances in which back-office support can be fundamental.

Moreover, sometimes not all information can be displayed automatically, because it would result in having a large amount of bulky data to be handled on site. In this case, remote support can be of great help for all the information that would be complicated/ difficult to find automatically, which is more efficient than asking a colleague working remotely (e.g. the pieces out of production in stock).

5 Conclusion

The aim of this research project is to provide support for the operation and maintenance phase during building life-cycle. This study focuses on the possibility of a combined use of three big technologies, the BIM paradigm for data management, a cloud-based system for managing information flows and mixed reality, to obtain an interaction between operators, digital model of the building and information flow.

A data set, not covered by this project, that could be developed in the future is that related to the building functional data and therefore the management of on-site safety, an issue that is always very important, since it aims at reducing risks at the workplace.

Abstract

This contribution aims to increase quality level of organization applying the EFQM (European Foundation for Quality Management) excellence model. It provides analysis of current quality management trends, defines EFQM model structure a criteria and possibilities of its introduction in construction companies all over the world. The purpose of this contribution is also proposal of electronic manual and automated system of evaluation the criteria and sub-criteria of EFQM model by company management and also by external auditors.

Selected scientific methods of problem solution can be divided into two main groups: empirical and logic (scientific analysis and synthesis). An empirical method is applied to an electronic survey that aimed to determine knowledge of the EFQM model and its use in practice among organizations operating in Slovakia. The logical method was utilized for the problem solving analysis and synthesis. Methods of scientific analysis was used to evaluation of the current issue of quality management level and EFQM implementation in construction sector, analysis of criteria and sub criteria of the EFQM model, exploring the possibilities of applying the EFQM model in construction organizations and examination of existing systems of assessment under the EFQM model. Synthesis allows to know the object as a single whole and is the basis for correctly decisions. Scientific synthesis method was used during the process of definition of methodology for application of the EFQM model, creation of electronic manual for the development and improvement of the EFQM model in the construction, design an electronic evaluation of construction company quality management level, defining the benefits of the EFQM development and implementation in the organization, creation of documents and forms within the individual criteria of the EFQM model.

Research work results in the form of its own methodology and electronic manual allow to construction organizations effectively introduce and implement EFQM model requirements to practice in a relatively short period of time with aim to constantly improve its performance towards excellence. Defined methodology suggests and explains the sequence of steps towards EFQM model applying, the electronic manual describes all of EFQM model sub-criteria and provides concrete suggestions and solutions to meet them. In the manual there is also automated electronic assessment system for construction organizations included.

Application of the methodology and manual on concrete company enabled in a short time to evaluate its quality management level, identify opportunities for improvement and also implement concrete improvement steps in necessary areas. Theoretical results in terms of current state analysis will find its application in educational process, science and common practice. Created methodology and automated evaluation system can be applied in different construction organizations introducing EFQM model and to utilize acquired knowledge to further research this issue.

Keywords –

Management level; Model of excellence; Construction company

1 Introduction

The EFQM excellence model is an European model based on Total Quality Management – TQM. It is designed for all organizations that are interested in continuous improvement and progress towards excellence. The main purpose of the EFQM model is self-assessment of the organization in order to achieve continuous improvement of quality. It helps identify strengths and opportunities for improvement and encourages solutions. It allows for an independent view on the organization and its functioning. [1,2]

The EFQM model is a basis for assessment and evaluation of a business aspiring to receive the

European Quality Award (EQA), but also the National Quality Award of the Slovak Republic. In order to win the EQA, the model must be applied for at least three years and yield the corresponding results.

The EFQM model may be used in any business as well as any government organization (however, the Common Assessment Framework – the CAF model is specially designed for public administration) [8]. There are several literature sources, which describe the structure of EFQM model and offer methodology, how to implement and evaluate it, but for customers are very brief and hard understood. [2,4,5,6,7,8,11,12] Therefore we decided in our research work to propose integrated electronic manual, which will offer to construction company complex and total information concerning the implementation and evaluation of all criteria of EFQM model. Our electronic manual contains total 9 criteria, 32 sub-criteria and 121 sub-sub-criteria of EFQM model. [6,8]. Users of this manual can self-evaluate own activity in a given sub-criterion and using automated system (software) determine point value of quality level (see next chapters).

2 EFQM Model Structure and Features

The EFQM model was created by the European Foundation for Quality Management (EFQM), which was founded in 1988. Its establishment involved fourteen large European corporations. [5] The aim of the foundation was to create a model based on Total Quality Management (TQM) in order to achieve excellence in European companies and make them competitive in comparison with the U.S. and Japanese companies in the global market. Society-wide recognition of quality in the USA (Malcolm Baldridge National Quality Award) and Japan (Deming Application Prize) proved that the application of TQM models delivers measurable business results to organizations [9,10]. The EFQM model first appeared in 1991 and it was called The European Model for Business Excellence. [4] It was innovated in 1999 and it became more universal and applicable in a larger number of organizations. For public administration, the CAF (Common Assessment Framework) model was developed. It was launched in 2000 and revised in 2002. The EFQM model is based on 9 criteria: leadership, policy and strategy, people, partnerships and resources, processes, customer results, people results and key performance results [6,13]. The first 5 criteria are enablers (what the organization has got) and the remaining 4 criteria are results (what the organization achieves). All criteria are divided into sub and sub-sub-criteria. The structure of the model, together with score for each criterion is shown in Figure 1. The direction of arrows shows the dynamic nature of the model. Innovation and learning help improve enablers, which leads to improved results. This process is continuous. Criteria and sub-criteria of the model are very sophisticated and deal with all areas of the organization, even with the environment surrounding it. The model emphasizes the ethical principle crucial for those who are exceptional.

ENABLES (500 points)
1. Leadership (100 points)
2. People (100 points)
3. Strategy and Policy (100 points)
4. Partnerships and resources (100 points)
5. Processes, products and services (100 points)

RESULTS (500 points)
6. People results (100 points)
7. Customer results (150 points)
8. Society results (100 points)
9. Key results (150 points)

Figure 1. EFQM model structure

3 Survey concerning the EFQM Model Implementation

The survey concerning the EFQM model implementation has been carried out during three months in year 2017 by the form of electronic and anonymous questionnaire. There were surveyed 180 construction companies in Slovakia of all sizes. The questionnaire completed 36 of them.

The issues were identified about whether the model has been applied for excellence in the organization, the purpose of its application (or the reasons not to apply it), as well as interest of the construction company to introduce the EFQM model in the future. Graphical interpretation of some of the responses is shown in Figure 2.

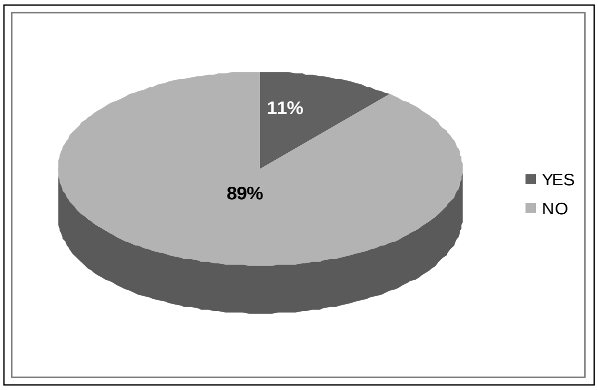

Figure 2. Application of the EFQM model at present or in the past in surveyed companies

The results obtained by survey shows that the EFQM excellence model and its application in practice in Slovakia are still relatively new, unexplored issues. Most companies do not exclude its application in the future, but they need much more necessary information about this model and effective training process. The solutions contained at this contribution can be helpful for the performance of the EFQM model to organizations, which have aims to continually improve their quality management level and implement maximum positive effects in future activities.

3.1 Analysis of EFQM model application in construction companies

The study of the EFQM model through consultations with trainers in the area of Quality Management and our own knowledge concerning this area of interest made us aware of areas for improvement and problems currently faced by Slovak companies striving for excellence when implementing the EFQM model. Application of the EFQM model in Slovak organizations is currently not a very frequent activity. Although the model seems simple, its application is a complex process in terms of time and resources. The EFQM model can be described as a higher form of quality management in organizations. It is starting to be implemented mostly by organizations, which have successfully passed the introduction and certification of the Quality Management System (QMS) according to ISO 9001 and look for other ways how to improve the quality of their products.

However, the management in most organizations fails to realize that this approach to improving the quality is not as simple as it seems at the first sight. Although the nine main criteria of the EFQM seem like they were encountered when building the QMS, the EFQM model contains a series of sub-criteria (32), which require a very detailed description of the functioning of the organization and many of the sub-criteria are often misunderstood by the management. Thus, the enthusiasm with which the management welcomes the introduction of the EFQM model begins to fade when the model is implemented in practice. A deeper study of the EFQM model makes directors come to conclusion that the whole process is too bureaucratic. Organizations often meet the EFQM requirements, but fail to record their results sufficiently and as required. When aspiring to the National Quality Award of the Slovak Republic or the European Quality Award, the company has to prepare a self-assessment report according criteria of the EFQM model. The preparation of the self-assessment report is an extremely complex and time-consuming process and requires involvement of key employees from all areas of business. Incorrect definition of processes and results in the self-assessment report may result in a low score of an otherwise successful organization from the professional EFQM auditors. This leads to disappointment, conflicts and rejection of the whole process.

The path towards excellence according to the EFQM model is a long-term process that must be upheld by the whole business from the top management to the last employee. If only the top management desires the introduction of the EFQM model and then delegates the application duties to employees – failing to properly explain its effects – it encounters resistance and the process is doomed.

The current competitive environment in the global marketplace requires organizations to continuously improve quality. This applies not only to products, but also to processes and management. Today, it is often not enough to satisfy customer needs, but it is necessary to exceed them. This requires excellence in organizations.

The EFQM excellence model understanding and effective implementation is one of the tools that can help organizations on their path of improving and achieving a lasting success.

4 The EFQM Model Application Methodology

During the research work in this area, we propose a methodology for application of the EFQM model, which is proposed especially for manufacturing organizations, which have developed and implemented Quality Management System (QMS) according to standards ISO 9001 and plan further development and improvement of the existing management system using the model EFQM. Steps of the methodology are illustrated in Figure 3.

The methodology is designed in conjunction with manual and automated self-assessment system to enable the organization to apply the EFQM model in less time and evaluate their performance level and effectiveness by more transparent way. The methodology enables to get an idea of what is necessary to do in the process of EFQM model application. The actual implementation of the methodology and the manual is designed to avoid confusion and unnecessary complexity requiring to start again and resulting in the time loss.

4.1 Used scientific methods

Selected scientific methods of problem solution can be divided into two main groups: empirical and logic (scientific analysis and synthesis). Empirical methods are applied to an electronic survey that aimed to determine knowledge of the EFQM model and its use in among organizations operating in Slovakia. The logical method was utilized for the problem solving analysis and synthesis. Methods of scientific analysis were used to evaluate the current issue of quality management level and EFQM implementation in construction sector, to analyse criteria and sub-criteria of the EFQM model, to explore the possibilities of applying the EFQM model in construction organizations and to examine the existing systems of assessment under the EFQM model.

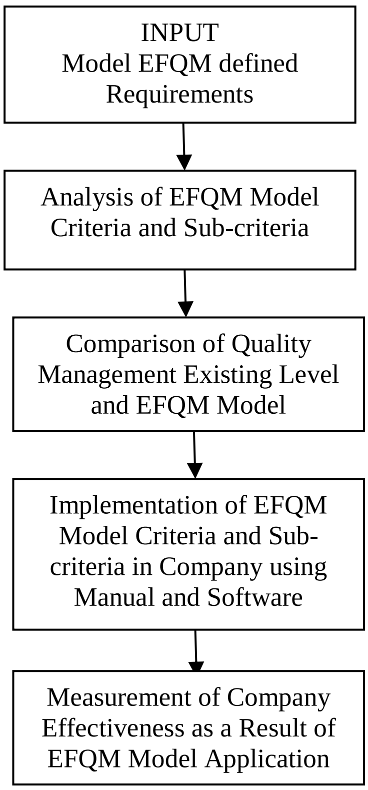

Figure 3. Steps to apply EFQM model in construction company

Scientific synthesis method was used during the process of EFQM model development and implementation including the creation of electronic manual and during the process of automated evaluation system of construction company quality management level.

5 Electronic Manual for the EFQM Model Application

Electronic manual is designed on the basis of the EFQM model criteria and sub-criteria requirements and helps organizations to understand and apply the EFQM model and evaluate their own performance and effectiveness in a shorter time. The structure of the proposed manual consists of these main parts:

- the analysis of EFQM model requirements defined by criteria and sub-criteria and determine the existing quality level of the organization and opportunities for improvement,
- self-assessment system of organization quality management level using the criteria and sub-criteria of the EFQM model by electronic automated system.

5.1 The Evaluation System of EFQM Model Criteria

The EFQM model consists of prediction and result parts. For each of them is in the manual suggested a specific method of evaluation. In this paper we provide an example evaluation of prediction part of the EFQM model. In the process of self-assessment of the organization is for each of the manual requirements of prediction part of the EFQM model selected phase of applications based on the Deming cycle - Table 1 and the performance level -Table 2.

Table 1. Evaluation of EFQM model application level in organization

Activity is:	Description	Evaluation %
P (planned)	Organization plans the activity to apply	10
D (done)	Activity is implemented	15
C (checked)	Organization checks the effects	20
A (acted)	In a case of positive effects activity is used in practice	25
B (benchmarked)	Organization compares the activity with best organization in market	30

Table 2. Level of EFQM model sub-criterion fulfilling in a given phase of application

Level of fulfilling	Description
0	There is no evidence to fulfil the requirements
0,25	There exist indicators of compliance requirements
0,5	Partial evidence of requirement fulfilling
0,75	Significant evidence of requirement fulfilling
1	Clear evidence of requirement fulfilling

The selected phase applications and performance levels are the basis for calculating the assessment for the achievement of the criterion and sub-criterion requirement. Position in the current phase of the application assumes management of the previous phases. If the company in meeting this requirement found for example in phase "act" with the degree to 0.5, the overall percentage achieved in meeting this requirement are:

$$\underset{\text{PLAN}}{1x10} + \underset{\text{DO}}{1x15} + \underset{\text{CHECK}}{1x20} + \underset{\text{ACT}}{0,5x25} = 57.5\ (\%) \qquad (1)$$

By this way is calculated the percentages evaluations for all requirements. The percentage evaluation of each sub-criterion is the weighted average of achieved percentage values for each of its requirements, and a set of weights represents the coefficients of importance.

$$P_{K_iS_j} = \frac{\sum_{r=1}^{n} P_{K_iS_jR_r} . d_{K_iS_jR_r}}{\sum_{r=1}^{n} d_{K_iS_jR_r}} \qquad (2)$$

where P_{KiSj} is achieved percentage evaluation of j sub-criterion in i criterion,
r = 1,2...n – number of requirements in criterion K_i and subcriterion S_j,
d_{KiSjRr} is coefficient of importance for r requirements of j sub-criterion in i criterion.

Each of the criterions of the EFQM model has a defined maximum point value which can be achieved. It is evenly distributed among the individual sub-criteria.

The resulting number of points for the sub-criterion we obtain by multiplying of the achieved percentage value by maximum number of points. Generally we can for any criterion express:

$$B_S = B_{max} \cdot \frac{P_s}{100} \qquad (3)$$

where B_S is achieved score in evaluated sub-criterion,
B_{max} is maximum score which can be in a given sub-criterion obtained,
P_S is achieved percentage evaluation for given sub-criterion

The resulting score for each criterion is the sum of achieved point value of its individual sub-criteria. The total achieved point value concerning the enablers is the sum of achieved points for criterion 1 to 5. The maximum possible score can be 500 points (see enablers - Figure 1).

5.2 Electronic Evaluation of the Proposed Solution

Electronic solution of proposed evaluation system is realized by using Microsoft Excel Program. The aim was to design and develop an automated system using computer technology, which would on the basis of defined requirements in electronic manual and in evaluation system allow easy, fast and comfortably realize evaluation of business performance and effectiveness, as well as clear and understandable display output of the evaluation process. Entering of inputs is handled through a questionnaire form, by selection of predefined options from "drop down menu" (dropdown list). The user does not perform any calculations, nor inscribe the input values. The results are updated immediately after any change in input data.

The selected values the user can change at all time during the evaluation process shown in Figure 4. Sheets “enablers” in Figure 5 and “results” in Figure 6 clearly show achieved percentage scores for each sub-criteria and requirements, and from these values is automatically calculated score for sub-criteria, and all criteria of “enablers” and “results” sections. Changes of point values are automatically transferred to the sheet EFQM - assessment, in which is a graphical view of the structure of the EFQM model with the nine criteria and the corresponding percentage and scoring for each of them for the “enable” and “result” part and also total assessment of all criteria.

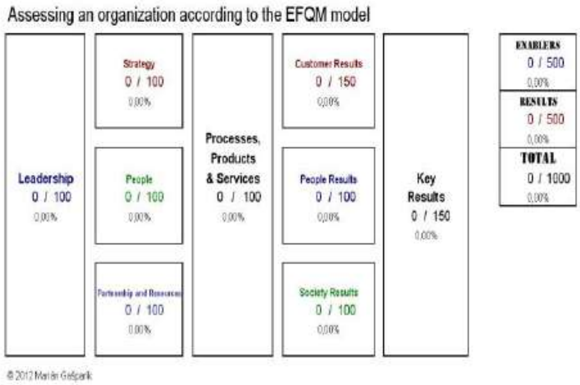

Figure 4. Software illustration of EFQM model basic structure (starting level of criteria evaluation)

5.3 Application of the Proposed Methodology and electronic Manual into Construction Company (2)

Application of the proposed methodology and the electronic manual was made for a construction company in Slovakia. During our cooperation we offered to the company basic training process concerning the EFQM model development and application and electronic manual for self-evaluation according to EFQM model criteria.

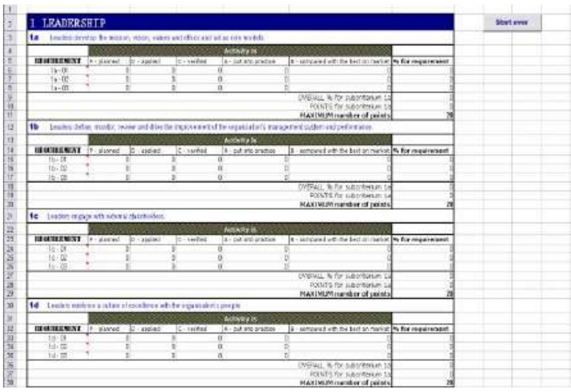

Figure 5. Software illustration of EFQM model part „enablers“

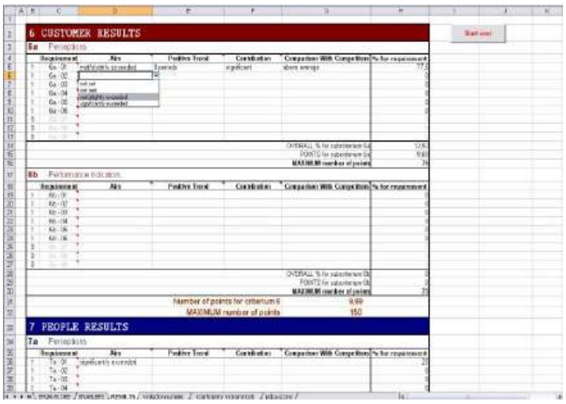

Figure 6. Software illustration of EFQM model part „results“

Process of self-evaluation was realized using our software for automated evaluation quality management level in company according to EFQM model criteria. By application of the higher described methodology and electronic manual and the company during 1 year showed improvement in all criteria of the EFQM model in Figure 7. Our cooperation will continue and we assume more dramatic improvement next 1-2 years after implementation next actions especially in production process. Quality of construction processes at this model company was increased by implementation of research activities described in [15, [16] and [17].

Model EFQM is useful to implement after development and implementation of Quality Management System (QMS) according to ISO 9001. QMS represents very good basis for application of higher quality management philosophy, like TQM, KAIZEN or model EFQM.

6 Conclusion

Research work described at this contribution results in the form of its own methodology and electronic manual allows to construction organizations effectively introduce and implement EFQM model requirements to practice in a relatively short period of time with aim to constantly improvement its performance towards excellence.

Defined methodology suggests and explains the sequence of steps towards EFQM model applying the electronic manual describes all of EFQM model sub-criteria and provides concrete suggestions and solutions to meet them. The part of manual there is also automated electronic assessment system for construction organizations which was verified in real company. Application of the methodology and manual enables in a short time to evaluate company quality management level and to identify opportunities for continually quality improvement.

The main results of our research activity are:

- creation of a new electronic manual for implementation and evaluation of EFQM model criteria and sub-criteria in construction company,
- the definition of mathematical models for automated evaluation of EFQM model criteria,
- the proposal of own software for automated evaluation of quality management level for company using EFQM model,
- continually improvement of construction company quality management level in all areas of its activities.

Model EFQM is an effective tool for continual improvement of organization quality, which leads not only to higher level of quality management, but also to customer satisfaction, success at national and world market and to increasing the culture of whole organization.

This paper was prepared during research work at international project ERASMUS+ PROGRAMME, Project Number: TAP-573738-EPP-1-2016-1-PS-EPPKA2-CBHE-SP.

Abstract -
In Japan, deterioration of many tunnels and bridges have become a serious problem. Moreover, engineers that manage them are insufficient due to aging. Therefore, we developed an under-actuated hammering robot that can imitate hammering sounds of inspection workers. When we use this robot, workers can detect concrete defects by using their experiences. For example, if we attach a video camera or microphones to this robot, they can detect defects as before at remote locations. Furthermore, it can contribute building high accurate automatic inspection systems by learning hammering sounds of inspection workers. Therefore, we developed an under-actuated hammering robot that can imitate hammering sounds of inspection workers. In this paper, we described these systems using this robot. To verify usefulness of these systems, we conducted experiments using a concrete test block and compared the results of an inspection worker with this robot. As a result, we confirmed that this experiments showed the results of this robot is similar to its of an worker.

Figure 1. The hammering test by inspection workers

1 Introduction

In Japan, deterioration of many tunnels and bridges have become a serious problem. Moreover, engineers that manage them are insufficient due to aging. For this reason, it is desired to develop innovative inspection techniques such as robots and implement on site.

Inspection of the concrete structure are using nondestructive test mainly. There are visual inspection and hammering test and so on in that test. Visual inspection is useful to inspect cracks of the concrete surface. For example, systems that find out concrete cracks using a CCD camera or others are actually implemented on site[1][2].

Hammering test is useful to find out defects inside the concrete. For example, the hammering test by workers as shown in Figure 1 is a popular method. In this method, the worker hammer the concrete surface and assesses condition of the concrete from hammering sounds. Another method is that the Schmidt rebound hammer is widely used in the concrete inspection[3]. However, the method takes much time to inspect a wide range. To improve the efficiency of these work, there are researches to find out defects inside the concrete. There are a robot named "Sonic Meister" using an industrial manipulator and impact unit with five hammers[4][5]. This system can obtain hammering sounds at 0.2 s intervals by controlling these hammers successively. However, this system is large and requires eight-ton truck. There are a inspection method using the non-contract laser measurement technology[6]. This technology enables high speed inspection and automation. However, the technology requires high position accuracy in order to irradiate the concrete surface with the laser. The laser may hurts the eyes of workers.

To consider these results, we examined a mobile hammering robot based on the hammering testing method. When we use hammering robot that can imitate hammering sounds of inspection workers, they can detect concrete defects by using their experiences. For example, if we attach a video camera or microphones to this robot, workers can detect its at remote locations as before. Furthermore, it can contribute building high accurate automatic inspection systems by learning sounds of inspection workers.

Therefore, we developed an under-actuated hammering robot that can imitate hammering sounds of inspection workers[7]. This robot and a example of the system as-

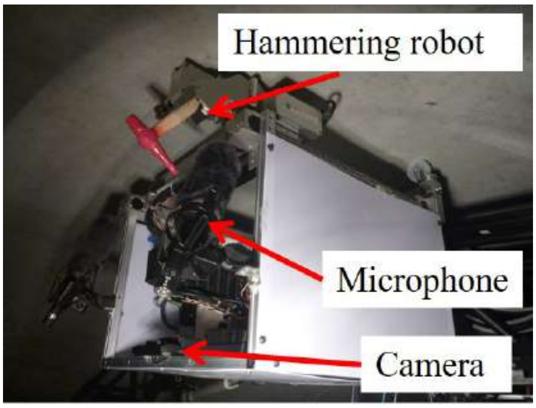

Figure 2. The hammering robot

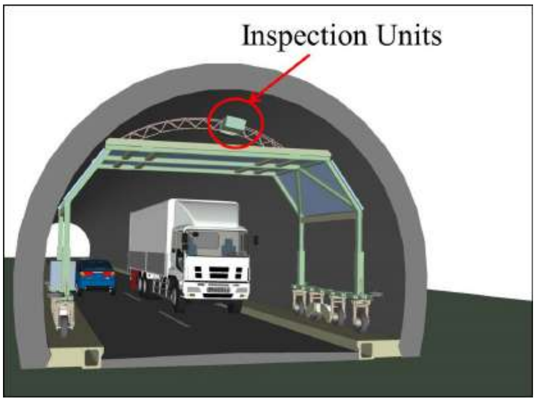

Figure 3. An image of the tunnel inspection system using the hammering robot

sumed to mount it are shown in Figure 2.

In this paper, we described systems using the hammering robot and the results of experiments to verify usefulness of them.

2 Concrete inspection system

There are concrete inspection systems using the hammering robot. For example, we have assumed a tunnel inspection system such as Figure 3. This system will equip the robot and can inspect tunnel automatically by using vehicles. This robot has a camera and microphones and can record image of concrete surfaces and hammering sounds. As a more simple system, you can attach this hammering robot to the tip of a pole.

In this system, we have thought that there are two ways to detect concrete defects. The first way is that inspection workers use measured data "Type-A". For example, inspection workers can detect concrete defects at remote locations by using data sent from this inspection system. The second way is that systems learn this data by the

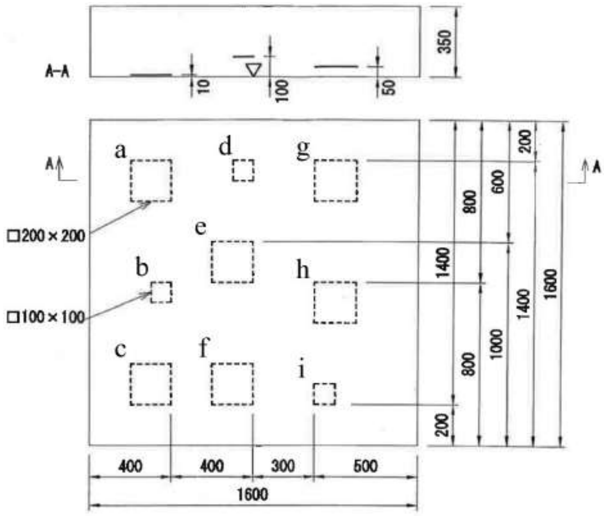

Figure 4. Drawing of the concrete test block

ensemble learning method to detect automatically "Type-B"[8]. If hammering sounds of this robot is similar to inspection workers, we can collect reliable learning data by using hammering sounds of inspection workers. To verify usefulness of these systems, we conducted hammering experiments assuming these systems.

3 Hammering experiment

In this experiment, we verified usefulness of these systems comparing the results of assuming Type-A with the results of previous works by expert inspection workers. If Type-A is useful, we can verify that sounds of the robot are similar to inspection workers. Therefore, this robot is also useful with Type-B.

3.1 Concrete test block

The concrete test block which is used in this experiment is shown in Figure 4. In this block, there are some artificial cavity which are shown as Table 1 simulating defects.

Table 1. Specification of the defect

Defect	Area[mm2]	Depth[mm]	Thickness[mm]
a	200×200	10	1
b	100×100	10	1
c	200×200	10	20
d	100×100	100	1
e	200×200	100	1
f	200×200	100	20
g	200×200	50	1
h	200×200	50	20
i	100×100	50	1

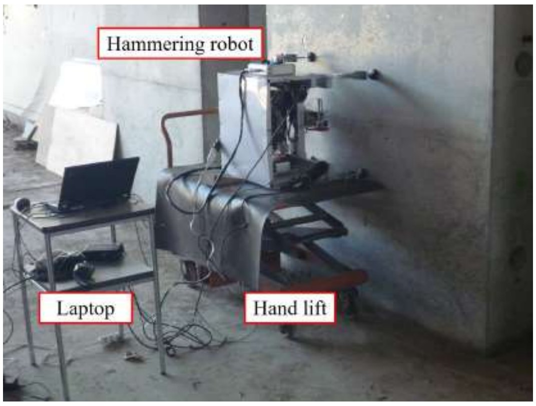

Figure 5. Appearance of a test using the robot

Figure 6. Appearance of a test by an expert

3.2 Hammering device

Figure 5 is a device with the hammering robot we developed. This device can hammer the concrete surface at equal intervals because it can move a hammering robot at the same speed. When this device fixed, the robot can move within 300[mm]×300[mm] area. This device has a camera and microphones and can record images of concrete surfaces and hammering sounds. This hammering robot have equipped with a hammer weighing 100g using by many inspection workers.

3.3 Experimental method

First of all, we described about hammering tests by the robot based on Type-A. In this tests, we used a device such as Figure 5 and hammered the surface of a concrete test block. The hammering interval was set to 25mm. The height of this device was adjusted using hand lift. We recorded images of concrete surfaces and hammering sounds by this device. Furthermore, we prepared an expert inspection worker who had not know the position of defects. An expert detected defects using this data at a later date. In this process, an expert had not know where these image are on the test block.

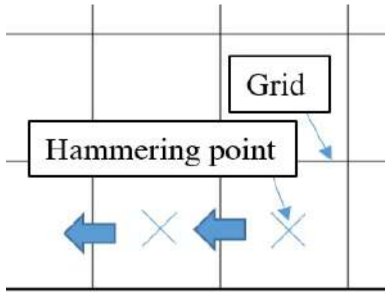

Figure 7. Hammering points

Secondly, we described about hammering tests by inspection workers. An inspection worker was the same as an expert who detected defects in Type-A. He used a hammer weighing 100g that he always use. We displayed grid which size is 25mm on the concrete test block by the projection mapping such as Figure 6. He hammered at the center of each grid such as Figure 7. To compare quantitatively, we adjusted the position of grid to hammer the same place as Type-A.

3.4 Evaluation method

We recorded positions detected defects and qualitatively compared. Furthermore, we recorded the number of grids $P[points]$ detected defects, and quantitatively compared by detection rate of defects $R[\%]$. When inspection interval is $D[mm/points]$, defect area $S[mm^2]$ is written by,

$$S = P \times D^2. \tag{1}$$

If defective area in a concrete test block (Figure 4 or Table 1) is $S_0[mm^2]$ and it detected in this experiment $S[mm^2]$, detection rate R is written by,

$$R = \frac{S}{S_0}. \tag{2}$$

We compared the results of the robot and an expert using this detection rate.

3.5 Experimental Results and Consideration

The result of defective area by the robot based on Type-A is shown as Figure 8. An expert were able to detect defects a, b, c, g, h from images of the concrete surface and hammering sounds of this robot. This experimental result showed that it is difficult to detect defects of depth is 100mm. Moreover, it is difficult to detect defects of area is 100[mm]×100[mm] even if depth of defects are 50mm. Similarly, the result of defective area by an expert is shown as Figure 9. As shown in Figure 9, he were able to detect

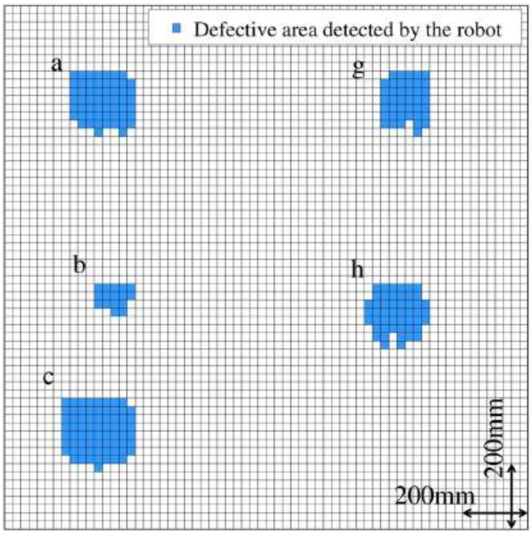

Figure 8. Defective area by the robot (25mm)

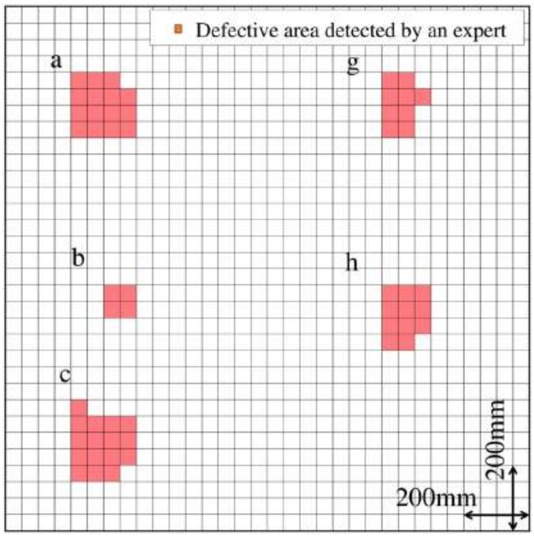

Figure 11. Defective area by an expert (50mm)

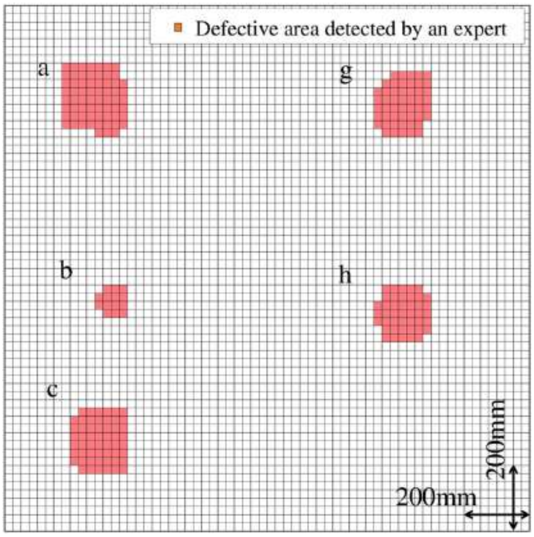

Figure 9. Defective area by an expert (25mm)

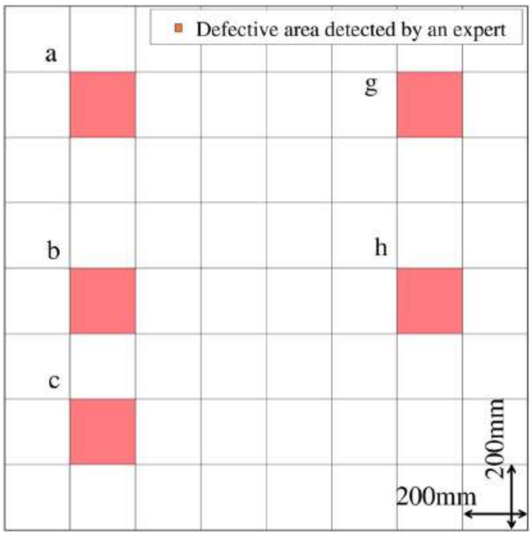

Figure 12. Defective area by an expert (200mm)

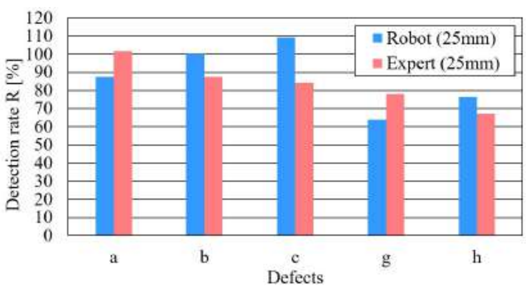

Figure 10. Detection rate

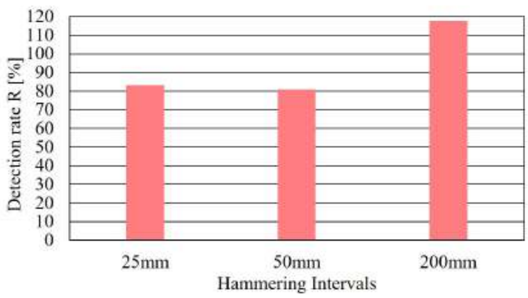

Figure 13. Detection rate of an expert

the same position of defects as the robot. As a result of qualitatively comparing, the results of defective area by the robot and an expert are similar. Therefore, we verified usefulness of our concrete inspection systems using the hammering robot.

We compared these results quantitatively using Equation (2). As shown in Figure 10, the robot can simulate an expert within ±15% at defects of a, b, g, h. We think that it is not a problem although there is a difference of about 25% at a defect of c. Because the robot detected a defect wider than an expert of it.

In this paper, we conducted hammering tests at 25mm interval. In fact, the more this distance larger, the more inspection speed large. Therefore we conducted hammering tests 50mm interval and 200mm interval by an expert. This result is shown as Figure 11 and Figure 12. Both tests could be detected a, b, c, g, h as in the Figure 9. Moreover, detection rate at whole defects is shown as Figure 13. As shown in Figure 10, the difference between 25mm and 50mm was within 3%. However, 200mm detected defects about 35% wider than 25mm and 50mm. This experimental results showed that hammering inspection at 50mm intervals is useful for accurate defective area. We think that it is useful to inspect at 200mm intervals and then inspect a detailed at 50mm at the defective area.

4 Conclusion

In this paper, we described usefulness of the way to detect concrete defects by an expert inspection worker using sounds of the robot. To verify usefulness of this system using the hammering robot, we conducted hammering experiments using a concrete test block at 25mm interval. As a result of the experiments, the results of defective area by the robot and an expert are similar. Moreover, the experimental results showed that the robot can simulate an expert within ±15% at almost defects. Therefore, we think that inspection workers can detect concrete defects using data sent from this robot. In addition, we think that they can automatically obtain inspection results using this robot that adopted the ensemble learning. method.

We also conducted hammering tests at 50mm, 200mm intervals by an expert to improve inspection speed. As a result of the experiments, the difference between 25mm and 50mm was within 3%. However, 200mm detected defects about 35% wider than 25mm and 50mm. We think that it is useful to inspect at 200mm intervals and then inspect a detailed at 50mm at the defective area.

Abstract –

Hoisting an object with two crane hooks is sometimes applied when the pitch attitude of the hoisted object is necessary to be adjusted. The pitch attitude can be manipulated by changing the length difference of the two crane cables that connect the object with two hooks at two different positions. However, this twin-hoisted approach is impractical for crane operators who must be highly experienced and capable of adjusting the crane based on their visual measurement. This implies that the safety of workers and operation efficiency may rely on the physical and mental state of the operator. Furthermore, for the automation of the hoisting process, the method to precisely adjust attitude is required. In this research, a numerical study is carried out by a model that enables the attitude manipulation of a twin-hoisted object. By specifying a pitch attitude and lifting height of the object, the model can take the geometrical limitations of hoisting process into consideration and then determine the lengths of the two crane cables in real-time. In this study, the developed model is validated using a mobile crane both through a virtual environment and a lab-scale experiment. The proposed model not only can be implemented with a guiding interface established to guide crane operators in real time but also contributes to the development of automated crane control method.

1 Introduction

Conventionally, if the manipulation of the pitch attitude of a hoisted object is necessary, three approaches can be applied. The first approach is to hang the object with one crane using one single cable. This requires nearby workers adjusting the pitch angle of the hoisted object. The second approach is to hang the object by two cranes. These cranes hang each sides of the object and adjust its pitch angle through changing the length of their cables. The last approach hangs the object with two cables on one crane. By using both cables of the main boom and the auxiliary jib, adjustment can be achieved similarly to second approach. However, the former two approaches are limited in many ways. The first approach requires space for workers to adjust the attitude of the object. This may be hazardous when the attaching point is located high where there are only uncomplete structures for workers to stabilize themselves. Moreover, the object hanging in the air can also pose dangerous to nearby workers by striking them [1]. As for the second approach, requiring an additional crane implies that extra space and rent are needed. This may increase the total cost of the project and hinder its progress as well. Moreover, the coordination of the two cranes may be troublesome when attempting to reach the desired attitude by respectively changing the length of their cables.

While the first and the second method face those issues, the third method avoids them. As a result, demands on controlling the pitch attitude with the third approach is reported to be rising [2]. Furthermore, similar approaches in the field of manufacturing have been developed. Sawano et al. proposed a power-assisted attitude control system that hangs an object with one cable and a linear cylinder. In their study, the attitude of the object can be controlled through expanding and contracting the cylinder [3]. Hence, we aim to further improve the third method for a better controlling of the pitch attitude of the object hung by a crane.

Although the third method has some advantages over other methods, it still has a few disadvantages. This practice relies heavily on the experience of the crane operator. Also, the operator has to estimate the angle of the object by sight, which is not intuitive and precise. In the case that the operator cannot see the object, a voice guidance from other workers is needed. However, this may be sometime confusing to the operator. In addition, if an autonomous crane control system is to be developed, a precise approach to determine the pitch attitude will be necessary.

Therefore, we propose a numerical model to aid the manipulation of the pitch attitude using one crane and two cables. The telescopic boom of crawler cranes and a beam-type object are selected in this model. Formulas are also developed basing on the geometry of the crane and the hoisted object. By specifying the desired attitude, the corresponding lengths of the two cables can be obtained. Then, the cables of the crane are adjusted without changing the posture of the crane. An assigned attitude includes the pitch angle and the height of the hoisted object. As a result, a desired pitch attitude at a certain elevation can be reached. Finally, we inspect the validity through a virtual experiment and a lab-scale experiment.

2 Numerical Model and Formulas

The model considers the geometry of a crane to calculate the proper length of the crane cables to achieve specified pitch attitude of the object hoisted. In our study, A mobile crane with a telescoping boom and an auxiliary jib attached on the top of the boom is considered. A simplified mobile crane is illustrated in figure 1 with a set of parameters representing the geometry of the crane. As the figure shows, l_1, l_2, a and b respectively represents the length of the main cable, the length of the auxiliary cable, the distance between the left hooked point on the object to the center of mass of the object and the distance between the right hooked point on the object to the center of mass of the object. The distance between the sheaves of the main boom and the auxiliary jib is assigned as D. The angle of elevation of the auxiliary jib, main cable, auxiliary cable and the object are respectively defined as φ, α, β and θ. Furthermore, we defined a set of constraints to these angles. That is, $0° \leq \varphi \leq 90°$, $0° \leq \alpha \leq 90°$, $90° \leq \beta \leq 180°$ and $-90° \leq \theta \leq 90°$. This is to prevent unreasonable attitudes of the system.

The aim of the model is to obtain the length of the cables, l_1 and l_2, when a certain pitch angle θ and the vertical length $l_1 \sin\alpha$ of the main cable are assigned. Here we assume that the height of the main boom sheave is readily known, thus setting the vertical length of the main cable is equivalent of setting the height of the object. In this regard, we view D, a, b and φ as known parameters. On the other hand, the angle of the two cables, α and β will be calculated in the process as well. Therefore, a set of attitude calculation formulas are proposed.

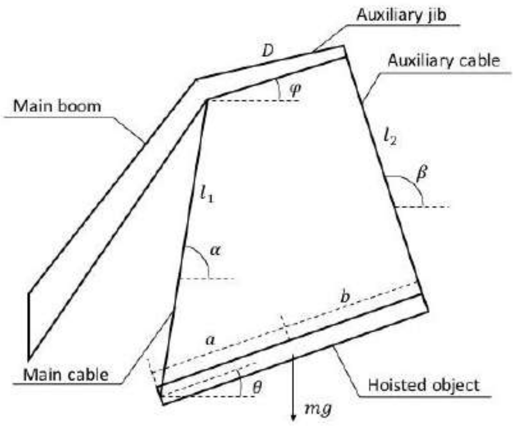

Figure 1. Simplified crane geometry

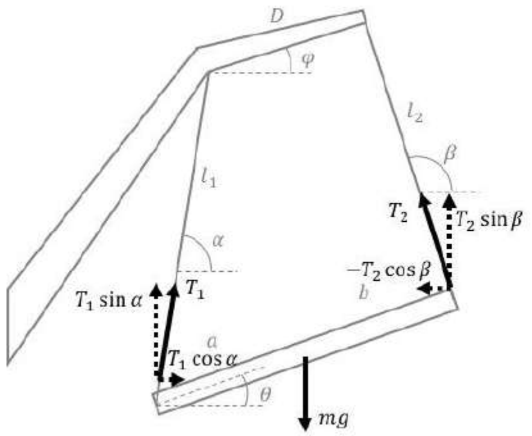

Figure 2. Forces acting on the object

Here we illustrate the formulation of the attitude calculation formulas of the model. The forces acting on the hoisted object in mechanical equilibrium are shown in figure 2. T_1 and T_2 are the tension of the main cable and the auxiliary cable. mg is the gravitational force acting on the hoisted object. Since the object is in mechanical equilibrium, vertical and horizontal forces in the system balance each other. Therefore, we can yield:

$$T_1 \sin\alpha + T_2 \sin\beta = mg \text{ and} \tag{1}$$
$$T_1 \cos\alpha + T_2 \cos\beta = 0. \tag{2}$$

In addition, the hooked points on the left and right side of the object are free to spin. This indicates that the moment on both side should be zero in mechanical equilibrium. Therefore, we can yield:

$$T_1 = m \cdot \frac{b}{a+b} \cdot \frac{\cos\theta}{\sin(\alpha-\theta)} \text{ and} \tag{3}$$

$$T_2 = m \cdot \frac{a}{a+b} \cdot \frac{\cos\theta}{\sin(\beta-\theta)}. \tag{4}$$

From Equation (1), (2), (3) and (4), we obtain a relationship between α and β:

$$\tan\alpha = \frac{a+b}{a} \cdot \tan\theta - \frac{b}{a} \cdot \tan\beta. \tag{5}$$

From the geometry relationship between the vertical distance of the upper and lower ends of D, l_1, l_2 and $(a+b)$, we get:

$$l_1 \sin\alpha = l_2 \sin\beta - D\sin\varphi + (a+b)\sin\theta. \tag{6}$$

Similarly, from the geometry relationship between the horizontal distance of the upper and lower ends of D, l_1, l_2 and $(a+b)$, we get:

$$l_1 \cos\alpha = l_2 \cos\beta - D\cos\varphi + (a+b)\cos\theta. \tag{7}$$

Finally, through Equation (5), (6) and (7), we yield:

$$\begin{aligned} & l_1 \sin\alpha \\ & = \Bigg((a+b)\sin\theta - D\sin\varphi \\ & + \big((a+b)\cos\theta - D\cos\varphi\big) \\ & \cdot \left(\frac{a}{b}\cdot\tan\alpha - \frac{a+b}{b}\cdot\tan\theta\right)\cdot\sin\alpha \Bigg) \\ & \div \left(\sin\alpha + \cos\alpha\cdot\left(\frac{a}{b}\cdot\tan\alpha - \frac{a+b}{b}\cdot\tan\theta\right)\right) \end{aligned} \tag{8}$$

By inputting a set of known value of D, a, b and φ and assigning a set of $l_1 \sin\alpha$ and θ, a set of αs satisfying the constraint of α can be obtained through Equation (8). In addition, the corresponding l_1s can also be calculated. Through Equation (5), a set of corresponding βs can be obtained. By checking if β meets its constraint, we can get the only set of α and β. With the particular set of α and β, l_1 and l_2 can be calculated through Equation (6) or (7). In this study, the process of finding l_1 and l_2 is carried out by Matlab.

3 Experiment and Result

To examine the validity of the proposed model and formulas, we conducted several tests with a virtual crane. In the tests, we specified 6 different attitudes of the hoisted object. Which are, respectively, 1. $\theta = 30°$, $l_1 \sin\alpha = 30cm$, 2. $\theta = 45°$, $l_1 \sin\alpha = 30cm$, 3. $\theta = 60°$, $l_1 \sin\alpha = 30cm$, 4. $\theta = -30°$, $l_1 \sin\alpha = 30cm$, 5. $\theta = -45°$, $l_1 \sin\alpha = 30cm$ and 6. $\theta = -60°$, $l_1 \sin\alpha = 30cm$. First, we calculated the corresponding set of α, β, l_1 and l_2 basing on the formulas through Matlab. Then, we adjusted the l_1 and l_2 of the virtual model according to the result of the previous calculation. Finally, we compared the resulting αs, βs, l_1s and l_2s. In addition, tests are also conducted with a lab-scale crane shown in figure 3. The feasibility of applying our method was expected to be inspect through these tests.

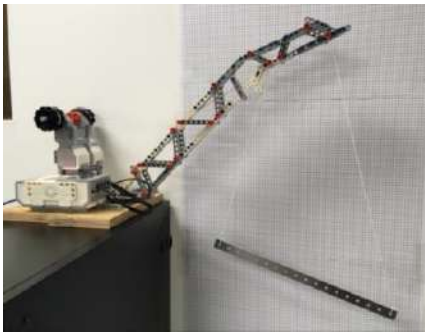

Figure 3. Lab-scale crane

In both virtual and lab-scale tests, the geometry parameters of the crane models are set identically as follows: $D = 9.7cm$, $\varphi = 26.04°$, $a = b = 13.65cm$. The corresponding αs, βs, l_1s and l_2s calculated basing on our formulas are listed in table 1.

Table 1 The calculated corresponding αs, βs, l_1s and l_2s

Attitude	$\alpha(°)$	$\beta(°)$	$l_1(cm)$	$l_2(cm)$
1	75.8	109.6	30.9	21.9
2	79.0	107.7	30.6	15.7
3	84.0	99.5	30.2	10.8
4	97.7	99.9	30.7	48.6
5	81.6	96.5	30.3	53.9
6	86.4	93.0	30.1	58.0

In the virtual crane test, we built a crane in Unity 3D, which is a physic engine as well as a game engine. We adjusted the length of the cables to the calculated l_1s and l_2s of the six specified attitudes in the virtual environment. Then, we measured the resulting θs and $l_1 \sin\alpha$s as well as αs and βs. Noted that we did not precisely set the lengths to the precise numbers but manually adjust them to simulate the crane operating process. Thus, slight difference of l_1s and l_2s between the calculated result and experimental result can be noticed. The result of the virtual test is list in table 2.

In the lab-scale crane test, we built a crane boom and an auxiliary jib attached on its top with LEGO Mindstorms EV3. We also adjusted the length of cables l_1 and l_2 and measured the resulting θs and $l_1 \sin\alpha$s as well as αs and βs. Similarly, we did not precisely set the length but manually adjust their lengths. Thus, slight difference of l_1s and l_2s between the calculated result and experimental result can also be noticed. The result of the lab-scale test is list in table 3.

Table 2 Result of virtual test

Attitude	$\theta(°)$	$l_1 \sin\alpha\,(cm)$	$\alpha(°)$	$\beta(°)$	$l_1(cm)$	$l_2(cm)$
1	29.4	29.8	74.8	108.6	30.9	21.8
2	46.1	30.3	79.1	106.4	30.8	15.5

	Lab-scale Test	7.8%	12.1%	20.6%	0.9%
5	Virtual Test	0.8%	0.4%	1.5%	0.7%
	Lab-scale Test	14.5%	10.1%	1.7%	1.9%
6	Virtual Test	0.6%	0.5%	0.2%	0.3%
	Lab-scale Test	10.4%	9.8%	1.6%	2.3%

4 Discussion

The gap of the geometry parameters between the results calculated through the formulas and the results obtained through the tests is listed in table 4. The gaps between the θs of the virtual tests and the calculation are less than 2.5%. Also, $l_1 \sin\alpha$s, αs and βs of the virtual tests also show matching results with gaps no more than 1.5%. This indicates that the corresponding l_1 and l_2 calculated through proposed model and formulas are able to form the specified attitude. On the other hand, the results of the lab-scale tests show larger gaps. However, since the main purpose of the lab-scale tests are not evaluating the formulas, precise measure methods were not applied. Therefore, we believe this is because of the errors of the measurement of these parameters. Also, deformation of the crane boom caused by weight was noticed and may also lead to the inaccuracy of the attitude of the object.

We observed several facts during the lab-scale tests. 1. Some geometry constraints are necessary to be added into our model. 2. The swaying pattern of a twin-hoisted object is complicated. 3. Physical factors are necessary to be considered. For the first observation, we noticed that the hoisted object may strike the crane boom in certain critical condition. This is especially likely to occur when the length $(a + b)$ of the object is sizable or the object is close to the boom. Therefore, geometry constraints are needed to avoid collisions between the object and the boom. For the second observation, we noticed that the swaying of the twin-hoisted object is apparently different from single-hoisted objects.

Referring to the study of Maleki et al., a two-mode oscillation occurs when a motion perpendicular to the boom is performed with unequal cable lengths [4]. Reduction of the oscillation may be needed to allow more rapid operation and further applications. Finally, for the third observation, we found that deformation of the boom caused by weight can affect the accuracy of the resulting attitude. This issue should also be considered to allow a precise control of the hoisted object.

Although several problems were observed in the tests, the proposed method is still able to provide useful indication to adjust the cable lengths for an assigned pitch attitude of the hoisted object. Also, we believed that allowing users to assign the height of one side of the beam-type object is considerably convenient. In a case of attaching a beam to the structure, the operator may first lift the beam horizontally to the desired height near the attaching point on the structure. Then, he or she can adjust its attitude without changing the height of the attaching point on the beam. Consequently, the effort and time of readjusting the height of the beam can be saved.

5 Conclusion

A numerical model of a twin-hoisted beam-type object hoisted by a crane is proposed. In the model, the object is hoisted by a main boom and an auxiliary jib attached on the boom with two cables. Formulas are also proposed to calculate the corresponding cable lengths which can lead to specified attitude of the object under certain conditions. Furthermore, several issues were observed in lab-scale test, which indicate several necessary enhancements to further improve the safety and precision of such practice. Finally, the results of our tests suggest that the proposed model and formulas are capable to aid the manipulation of the pitch attitude of the hoisted object using one crane and two cables. Future works can be focused on implementing the proposed method on real cranes, while simultaneously addressing the observed issues.

Abstract – Product development for commercial façade systems is a complex procedure. Since the Grenfell Tower disaster in London in June 2017, the import, use and sale of polyethylene core Aluminum Composite Panels (ACP) has been reduced. This encourages research on development of new façade systems using advanced production techniques such as additive manufacturing and CNC milling. The aim of this paper is to analyze the two techniques considering principles of design for manufacturability and assembly (DfMA). Results show that in advanced manufacturing of façade elements, a large percentage of project budget is related to acquisition costs for equipment such as CNC machins and 3D printers. Despite these high costs, non-traditional manufacturers are likely to see return of investments over future development projects for the modular façade systems.

1 Introduction

Complex façade systems are increasingly used in construction of iconic buildings. Such façade systems often utilize hyperbolic paraboloid surfaces to maximize aesthetic attraction. While traditional site-built construction is unable to deliver such levels of complexity, off-site prefabrication of façade modules provides an optimal alternative [1].

Modern manufacturing techniques such as 3D printing and CNC milling can further increase the efficiency of façade prefabrication [2]. Coupled with principles of design for manufacture and assembly (DfMA), such manufacturing-led initiatives have the potential to optimize product development in modern construction.

The focus of this research is on production of modular façade systems with hyperbolic paraboloid surfaces. Such façade production includes off-site prefabrication of modular corner façade surfaces, modular straight façade surfaces, and modular curved façade surfaces (see Figure 1). The elements are to be held together by interlocking mechanisms. The aim of modular prefabrication is to allow the production of robust combinations of various façade patterns for clients.

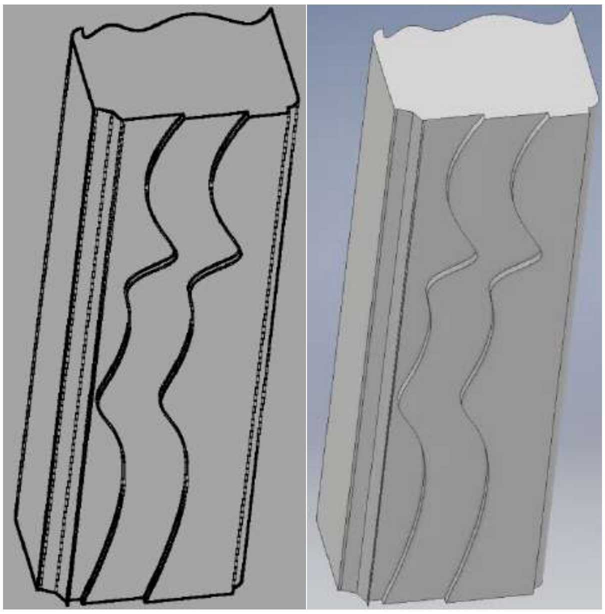

Figure 1. Sketch illustration and realistic view of

a complex façade system with hyperbolic paraboloid surfaces

The current paper explains principles of DfMA in modular prefabrication of complex façade systems. Then it reviews the advantages of using advanced production techniques of CNC milling and additive manufacturing. In the remaining part of the paper, a case study approach is used to analyze the cost and time requirements. At the end, concluding remarks are presented.

2 Modular prefabrication of complex façade systems- Design for manufacture and assembly

Modular prefabrication of Principles of complex façade systems is optimized by adopting principles of design for manufacture and assembly (DfMA). This is due to adoption of manufacturing-led and advanced processes in product development [3]. Furthermore, DfMA encourages multidisciplinary collaborations in product development where manufacturing and resourcing constraints are considered in designing parts and assemblies [4].

Successful implementation of DfMA requires parametric modelling software that supports collaborative work of designers, engineers and manufacturing teams [5]. Strong software such as CATIA and DELMIA have assisted off-site manufacturers of building elements to increase efficiencies and productivity [6]. CATIA is a software suite with multiple platforms for product lifecycle management (PLM), computer-aided design and computer-aided manufacturing [7]. DELMIA is also a software suite developed by Dassault Systems and focuses on manufacturing simulation [8].

The construction literature identifies most important principles of DfMA, including:

- Interdisciplinary collaborations in the early-stage design. Previous research shows that at least 80% of total project costs are committed during concept design stage [9, 10]. Project cost, time and quality of delivery will be optimised by involvement of design engineers, off-site manufacturers, assembly and on-site teams in early concept decisions [11]. This involvement also minimises the amount of rework or re-entrant flow, which is a key source of waste in construction projects [12, 13].

- Addressing past issues related to manufacturability and assembly. Design attributes in future projects are informed by challenges in previous projects. This way, issues that have caused difficulties for manufacturability and assembly will not be repeated [14, 15]. Past issues should be recorded in DfMA and CE knowledge repositories and properly addressed in future designs [16-18].

- Considering constraints in off-site and on-site construction. This DfMA principle optimises product design and process development so that both off-site and on-site limitations are satisfied [19]. Previous research has observed and analysed many cases in which desig of building components has been problematic in terms of transportation [20], crane operations [21], and safety of operations [22].

- Standardisation of design attributes. Excessive variation in design complicates manufacturing and assembly [12, 23, 24]. Some initiatives can minimise errors in assembly and installation such as designing paired parts instead of left/right hand parts [25]. Furthermore, paired-part designs support economy of scale in the supply chain by doubling purchasing volume when compared to mirror image parts [26, 27].

3 Prefabrication of complex façade systems- CNC milling

CNC milling can be used to produce required moulds for prefabrication of façade modules and panels, as well as the panel interlocking mechanisms [28]. The primary justification of using CNC milling at the prototyping stage is the ability to use CNC milling while transitioning from prototyping to final production [29]. Essentially, the ease to scale from prototype size to production size makes CNC milling an attractive approach. Furthermore, the basic skill sets required by CNC machining allows for cost-effective workers to be employed [30].

To enable the optimal production of façade systems using CNC milling, the workflow and product requirements must be understood and implemented. In order to determine the necessary activities for the project and the activity sequence, the following workflow needs to be analyzed and evaluated:

The workflow for CNC production includes design, program, setup, manufacture, assemble and evaluate.

- **Planning:** Throughout the planning process, product development teams identify the objective, specifications and requirements for the project. It is within this stage that risks, challenges and restrictions are identified, as well as establishment of scheduling and product plan outline.

- **Design:** The Design process for CNC requires the use of a 3-dimensional design definition that is constructed in CAD. Generated data can be complex and requires the time and labor of a CAM programmer. However, to initiate the design phase detailed engineering drawings must be provided to the CAM programmer and also CAD data must be reviewed considering DfMA requirements.
- **Program:** The program phase is the process of defining the machine operations. At this point, CAD data is imported into CAM programs, so the manufacturing process can be manually defined. The main components of the machine that must be defined are parts interlocking mechanisms, required number of machine passes, necessary cutters, and feed rates. As each façade design is unique, these decisions are made on a feature-by-feature basis.

- **Setup:** For CNC façade moulds, the set-up process is reasonably quick for machine operators. However, when there are multiple setups because of holes or pockets in moulds, processes need to be constantly repeated that will add time implications to the project. The setup process, however, requires machine operators to load required cutters onto machines and then fixture work pieces.

- **Manufacture:** Using 3-axis CNC, work pieces are repositioned to cut upon faces that are not in the original orientation for facilitating access by cutters. In order to reposition, the operator has to reorient and re-fixture the work piece. Due to the nature of CNC production, time is impacted by the volume of materials subtracted and the removal rate. Such rates are then impacted by specific tolerances and part thicknesses.

- **Assemble:** Depending on the required form of façade moulds, there are mandatory secondary operations after the CNC milling.

- **Evaluate:** Production process is reviewed by the evaluation process when comparisons to the initial design plan is conducted. Evaluation analyses the efficiency of time, cost and quality to determine if the CNC system will be substitute for the production of moulds in manufacturing façade modules.

The activity selection process in this research is based on the aforementioned stages to identify the sequence and flow of detailed project activities. The activity sequence has been identified below in the work breakdown structure illustrated in Figure 2.

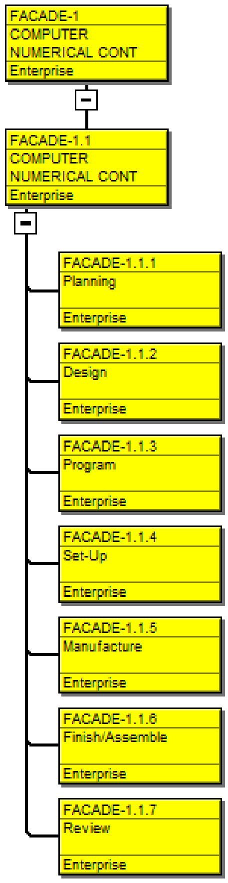

Figure 2. Workflow for manufacturing façade moulds using CNC- Developed in Primavera P6

4 Prefabrication of complex façade systems- Additive manufacturing

Additive manufacturing or 3D printing can be used to create prototypes of façade elements such as small interlocking mechanisms for modules. The applications of 3D printing generates benefits over standard processes during the production of curved elements façade modules where expertise and time are required to form materials into hyperbolic paraboloid surfaces [31].

To further mimic the characteristics of real material, different filaments can be utilized to create similar forming processes. Filament typically utilize a mixture of plastic (usually PLA) and other fibres. As such, they can undergo similar finishes to façade materials such as sanding and staining. The risk of utilizing commercial fibres in 3D printing is reduction of strength and flexibility compared to real-life scenarios. However, as the prototypes are primarily used for design validation and not for structural or endurance testing, this risk can be retained.

Key 3D printing considerations include but are not limited to printing speed, thickness of printed layers, extrusion process, retraction setting, variable speed setting, and printing temperature.

5 Case study- Time and cost analysis

Towards the aim of this study and in a similar approach to Liu, et al. [32], a case study method was adopted as it allows retaining a holistic approach towards the research problem at hand [33]. Selected façade production projects in Australia were deemed suitable to analyze time and cost within off-site project settings. A purposeful selection of case studies targeted maximum level of complexity in project production flows. Main factors contributing to project complexity included the hybrid production mode (on-site and off-site), the complex hyperbolic paraboloid surfaces in facade, and complicated design and construction processes across several project modules.

The average durations of the selected projects were calculated using Primavera Project Planner and is equal to 37 working days. The average total cost for a project is $108,240. The project cost has been calculated based on human resource costs and equipment hire. The resources have been distributed amongst activities to reduce costing. Resource costs have been identified in Figure 3.

Resource Name	Resource Type	Price / Unit
Machine Expertise	Labor	$60.00/h
Product Development Team Memeber	Labor	$35.00/h
Product Development Team Leader	Labor	$45.00/h
Designer	Labor	$45.00/h
Engineer	Labor	$65.00/h
Programme Technician	Labor	$60.00/h
Machine Operator	Labor	$42.00/h
Senior Management	Labor	$60.00/h
CNC Machine	Nonlabor	$110.00/h
CAD Software	Nonlabor	$50.00/h
Spindle	Nonlabor	$20.00/h
Cutters	Nonlabor	$5.00/h

Figure 3. Resource costs for manufacturing façade modules- Developed in Primavera P6

Cumulative cost for each WBS level can also be calculated. As can be seen in Figure 4, majority of project cost incurs during the program and set up stages. This is due to engagement of specialized resources in the two stages. These resources include but are not limited to engineers, designers, program technicians and machine operators. The labor intensive nature of aforementioned stages increases the total cost associated with human resources.

Figure 4. Cost and duration analysis for different stages of façade prefabrication

6 Conclusions

Previous work has documented the effectiveness of using prefabricated façade elements in complex construction projects [34, 35]. Such studies, however, have not analyzed the use of modern production techniques such as additive manufacturing and CNC milling for prefabrication of complex façade modules.

Results of the current study show that multi-platform software such as CATIA and DELMIA are capable of increasing effective collaboration amongst product development teams and supporting design for manufacturability and assembly. Product development teams for prefabricated façade projects should be kept fairly small to reduce cost and increase efficiency. To save costs, a single Plant Operator (PltOp) should handle setups for both 3D printing and CNC milling.

In advanced manufacturing of façade elements, a large percentage of project budget is related to acquisition costs for equipment such as CNC machins and 3D printers. Despite these high costs, non-traditional manufacturers are likely to see return of investments over future development projects for the modular façade systems.

Abstract –

Temporary bridges play an important role in disaster relieving operations. However, available workers and limited time are precious resources during a disaster event. The requirement of not only human resource but also construction safety creates a barrier for completing the temporary bridge construction within expected time, which may result in the delayed subsequent rescue operation. To address these issues of worker safety and the worker shortage during a disaster event, an automated beam assembly approach for temporary bridge segment is proposed in this study. The approach includes a framework for temporary bridge construction to be automated assembled by a crane and a construction process based on the framework. The framework and the construction process are examined with both virtual and small-scale models.

Keywords –

Automated construction; Construction safety; Mobile crane control; Autonomous structural connector; Disaster relief

1 Introduction

Temporary bridge is recognized as being considered to be the approach of disaster relieving operation, when a bridge structurally loses its workability. Russell et. al. classified temporary bridges which were portable and rapidly-deployable into four types in 2013 [1]. Those bridges remain the span length and maximum load-carrying capacity of a bridge as a key issue. Therefore, Yeh et. al. in 2015 applied glass-fiber-reinforced-plastic (GFRP) material in a segmental temporary bridge design making it light-weight and reusable [2]. The live load capacity of the GFRP bridge was 5 tons, and the span was 20 meters. However, when taking actual working environment into consideration, the assembly of the GFRP bridge may be difficult. The reason is that not only the weather may not be suitable for construction but also it is hard to recruit sufficient workers on-site.

To clarify the main reason of these problems, we analyzed the video of the process of constructing the GFRP temporary bridge. The hoist and assembly process has been found to be so critical that it majorly controlled the construction progress and the worker safety of the bridge construction. This process put emphasis on the technique of beam assembly.

2 Background

Many attempts have been made with the purpose of automated steel beam assembly. A research team focused on automated construction of high-rise building with a construction factory covering at the top of the building [3, 4]. They developed robotic bolting and robotic transport of steel beam, and tested beam assembly in real construction site. This application created the constraint of architecture design because of the geometrical limitation caused by the working space of the construction factory. In 2016, a research developed an approach helping construction workers assemble steel beam with an automated wire control machine [5]. The research protected workers from assembling steel beams at height, although the pre-installation of the guiding ropes for automated assembly may be risky for workers. Another research tried to remotely achieve steel beam assembly by means of structural connector design and controllable rotation of crane hook [6]. The rotating hook would trigger the opposite rotation of the attached steel beam to finish beam assembly. However, object avoidance during the beam rotation was a challenge for the research.

To address worker safety and shortage during disaster event as well as comprehensive consideration of steel beam assembly using a crane, an automated beam assembly framework for segmental temporary bridges is proposed in the research.

3 Automated Beam Assembly Framework

The automated beam assembly framework identified critical elements for research development and proposed a construction process providing an automated approach utilizing a mobile crane to build up a temporary bridge.

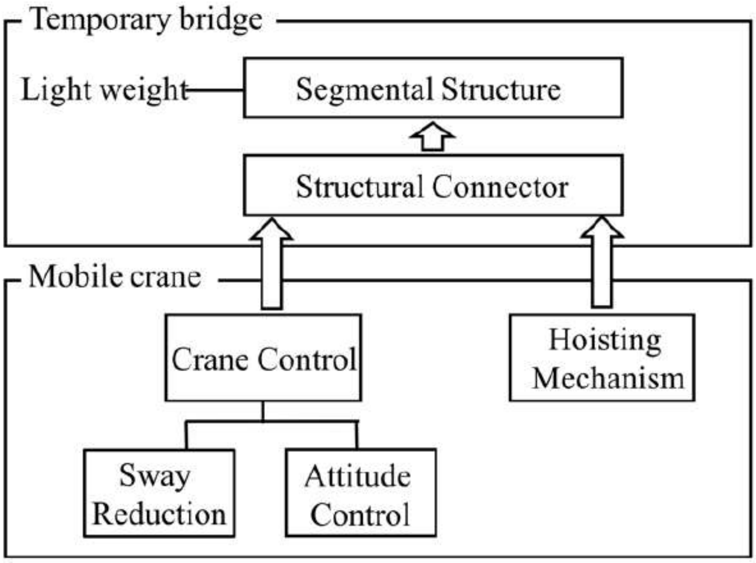

Figure 1. The framework of automated beam assembly

3.1 Elements of the Framework

The critical elements were categorized into two parts: structure and automated process. The structure part, also named Temporary bridge in Figure 1, including segmental structure, light weight, and structural connector, defines the requirement of the material and structural geometry to be used in a construction. The automated process part, also named Mobile crane in Figure 1, considers technical requirement on how a mobile crane finishes hoists and assembly tasks without any worker on site.

3.1.1 Segmental Structures (SS)

The temporary bridge for disaster relieving needs to be constructed within limited time. Therefore, segmental structure becomes an option to satisfy the requirement. Before a disaster occurs, each segment of the temporary bridge can be compactly stored in a container for shipping. The container can be placed near the potential damaged area.

3.1.2 Light Weight (LW)

To have a longer span of a temporary bridge, light weight is one of the important properties. According to the information from officers in Taiwan Directorate General of Highways, 30 meter at least is the common span of the bridge to be repaired after the bridge has been devastated by a disaster. Additionally, lighter weight of the bridge makes more convenient for shipping to the proximity to a valley or a river in a mountain where is often not easily accessible.

3.1.3 Structural Connector (SC)

A structural connector allows two segmental structures to be assembled with each other. The structural connector to realize automated bridge construction focuses on the beam design for autonomous assembly. The designed connector should also consider the construction feasibility when using a crane. In the research, we utilized the connector from our previous research for autonomous beam assembly [7]. The previous research demonstrated the feasibility of the hook-shaped structural connector for autonomous assembly. The design concept was to use a male connector and a female connector to lock themselves autonomously.

3.1.4 Crane Control– Sway Reduction (SR)

Sway reduction is necessary to reduce the magnitude of a sway of a payload. The payload such as a beam with designed connector should be stabilized to a suitable level to execute position control. Finally, the automated attachment of the male connector and the female connector can be executed afterwards.

3.1.5 Crane Control– Attitude Control (AC)

When a connector is at the targeted position, attitude control of the structural component may rotate the male connector to attach the female connector. Taking advantage of the sway reduction and the attitude control, the automated assembly of these two structural components becomes easier.

3.1.6 Hoisting Mechanism(HM)

Before the beam transportation using a crane, the beam should be firmly attached to the crane hook. After the transportation, the beam needs to be conveniently detached from the hook. Without human operation to attach and detach the beam, the automated mechanism of attaching and detaching is necessary.

3.2 Construction Process

The construction process defines each step of the beam assembly and disassembly.

3.2.1 Assembly process

- Step 1: Connect the crane hook to the beam.
- Step 2: Lift up the beam.
- Step 3: Transport the beam to the selected position for assembly.
- Step 4: Adjust the attitude of the male connector to attach the female connector on the bridge.
- Step 5: Release the beam for assembly triggered by gravity.
- Step 6: Lock the beam on the bridge structure.
- Step 7: Disconnect the beam from the crane hook.

3.2.2 Disassembly process

- Step 1: Connect the crane hook to the beam to be disassembled.
- Step 2: Unlock the beam.
- Step 3: Lift up the beam.
- Step 4: Detach the male connector from the female connector on the bridge structure.
- Step 5: Transport the beam to the storage area.
- Step 6: Release the beam.
- Step 7: Disconnect the beam from the crane hook.

4 Experiment & Result

The framework and the construction process were validated by the experiment described in this section. Three assumptions were made in the experiment. (1) If the assembly steps are feasible, the disassembly steps are also feasible. (2) Attitude control rotates the beam in the longitudinal direction. According to the research by Lee et. al. in 2012, the attitude control of a beam is probable to be implemented [8]. In the experiment, we rotated the beam by human operation. (3) Hoisting Mechanism was assumed that it connects to the end of a beam and can be remote controlled. The experiment was tested on-site and also in a virtual model using a commercial physics engine.

4.1 On-site experiment

The first four steps of the proposed assembly process were validated by an on-site experiment. The experiment measured the placement deviation from the targeted position of the hoisted structural component for assembly (Fig. 2). A crane with hydraulic retractable boom with the maximum load capacity of 3.4 tons was used in the experiment. The payload was an approximately 80kg and 1.45m beam. The crane operation was executed by a graduate student in the experiment. The student learnt crane operations from a professional crane operator, and practiced the required operation of the sway reduction before the experiment.

The result of X deviation was 3.03cm in average, and the result of Y deviation was 1.37cm. Figure 3a-1 shows the environment of the experiment. We placed a short beam which is around the center of the picture as the targeted position for beam assembly. The overview of the crane we used and the test environment is represented in Figure 3a-2. Figure b recorded the first four steps of the assembly process. In the experiment, we connected the end of the beam to the crane hook using steel cables (Figure 3b-1). The beam was lift up with an approximate distance of 50cm from the ground (Figure 3b-2). The crane operator transported the beam only by slewing the crane (Figure 3b-3). Figure 3b-4 is the state that the beam was already at the targeted position, the crane operator reduced the sway by manual crane operation, and the operator manually rotated the beam in the longitudinal direction for the attitude control. After the position and the attitude of the beam were stable, the crane operator placed the beam on the ground to measure the placement deviation (Figure 3b-5).

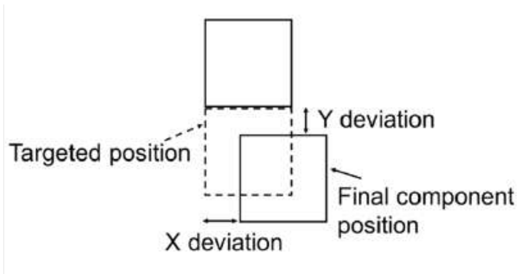

Figure 2. Measurement of structural component deviation from selected target.

Table 1 Placement deviation from selected target

Test	X deviation [cm]	Y deviation [cm]
1	4.0	2.9
2	1.9	0
3	3.2	1.2

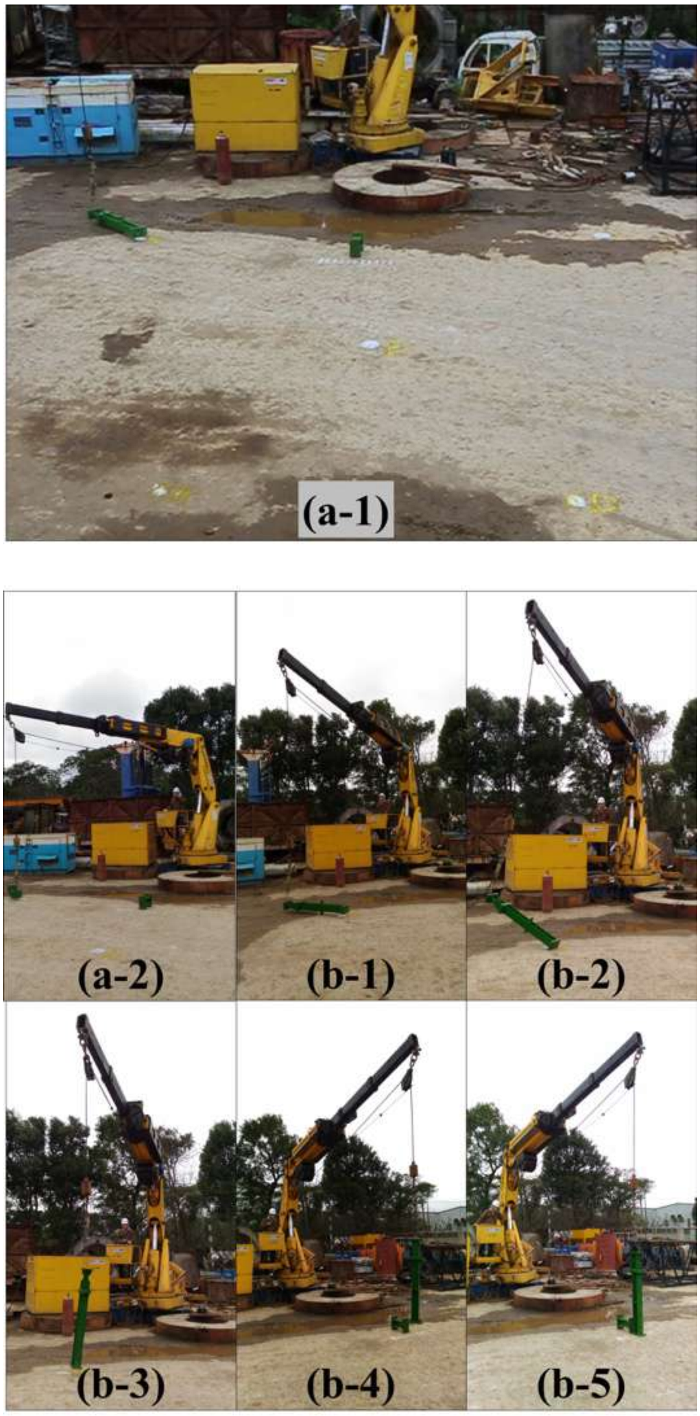

Figure 3. (a) On-site experiment environment. (b) The results of the automated process.

4.2 Virtual model experiment

To validate the step 5, “Release the beam for assembly triggered by gravity”, of the assembly process, we created a virtual structural component and used a virtual mobile crane to simulate the rotation of the structural connector. The virtual model was created on a commercial physics engine, Unity3D. The virtual model successfully demonstrated the step 5 (Fig. 4).

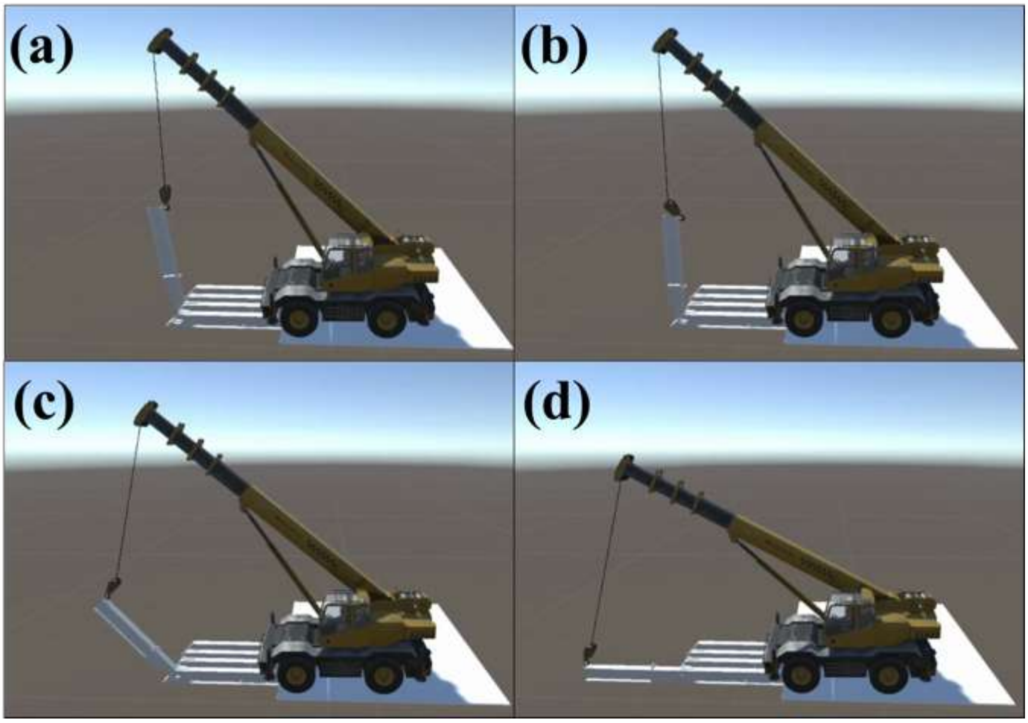

Figure 4. The results of virtual beam assembly by a mobile crane.

4.3 Discussion

The placement deviation from selected target showed the sway reduction made by the student crane operator an unstable performance. The unstable slewing torque generated by the hydraulic system of the crane was the main reason. The hydraulic control system could not keep the same angular velocity of slewing during the transportation of the beam, even the control stick of slewing remained the same inclination level. Another crane control issue was the control limitation of degree of freedom. Only one degree of freedom could be controlled at one time, indicating that the hoisted beam could not move as smoothly as we expected. To minimize the sudden change of the transportation path, we only applied slewing rotation in the experiment.

5 Conclusion

This research tried to clarify the construction process of automated beam assembly and identify key elements for the automated assembly for temporary bridge by a crane. The key elements including structure part and automated process part form a framework presented in the article. We conducted an on-site experiment and a virtual simulation to validate the construction process. The beam placement deviation from the targeted position was found, which can be the reference for autonomous structural connector design. The results showed the feasibility of the proposed framework and the construction process which may contribute to the development of automated beam assembly approach using crane operations. Future research can be focused on crane control including sway reduction and attitude control. It is suggested that the sway reduction for crane operation can be executed after the hoisted beam arrives the expected position. Since it is difficult for the crane hydraulic system to apply stable output force on the hoisted beam, it is easier to apply the sway reduction by controlling the crane boom to follow the motion of the beam. To control the beam attitude for connection, the benefit of controlling two crane hoist lines may be taken into consideration.

Abstract

Robotic systems are increasingly becoming a relevant factor for so-called "made to order" production, as is the case in the construction industry. The aim of this contribution is to provide a basis for a cross-disciplinary discussion on the topic of robotics in the construction industry, in which both technical issues regarding the technical challenges of robotics in the construction industry and how automated building construction can be practically addressed in education and training. Based on case studies and lab experiments, the authors investigated upcoming transformations in shell production by comparing the conventional construction process with proposed processes involving cable-driven parallel robots. The focus is on bricklaying and working methods for the installation of pre-fabricated elements. Based on the prospective changes in construction the impact on vocational education and training will be discussed and influences in current educational frameworks based on automation and robotics will be introduced.

Keywords –

automated building construction, cable-driven parallel robot, bricklaying, site logistics, human-machine interaction, social effect, technology dissemination, vocational education and training, VET

1 Introduction

The Internet of Things and Building Information Modeling (BIM), which has already been used in some construction organizations, are two major areas of digitization in the construction industry [1]. Due to the increasing digitalization in the context of industry 4.0 and the current increasing spread of BIM in the construction industry as well as the constantly growing technical possibilities and the increasing computing power, the application and use of automated building construction systems is currently being pushed forward. Such systems can ultimately include both digital planning and autonomous construction of a building. The changes resulting from digitization will create new jobs, change existing ones, or make existing ones disappear [2]. In the context of this article, the study by Dengler and Matthes (2015) deserves to be considered. The authors discuss which professions could (partially) be replaced today due to the current state of digitalization. It should be emphasized that the current status of digitalization has a similarly high substitutability potential for assistant and specialist occupations. The study concludes that the ongoing digitalization process should be taken more into account in the training of skilled workers in order to counteract the loss of professional groups [3]. It does not deal with the question of whether only a shift in the areas of activity in the occupational groups takes place through digitalization and to what extent possibilities can be created with which the occupational groups can be supported or to what extent current training standards would have to be adapted. This paper aims to provide a first qualitative basis to answer these questions in the context of vocational education and training (VET) in the construction industry. It is not the aim to present new curricula for VET in this field, because setting up new curricula involves a lot of red tape which in turn costs a lot of time. Developments in automation and robotics are currently happening very fast, and therefore the construction industry needs solutions that can be implemented within a short period of time. Therefore, at this stage, the authors are more interested in identifying how new requirements from automation and robotics can be integrated into existing ordinances and framework curricula on short notice. Preferably directly at vocational schools or at the workplace.

2 Methodology

Based on an existing prototype of a cable-driven parallel robot at the University of Duisburg-Essen, the authors used for this research a) simulations and data analysis, b) qualitative case study, c) comparative analysis. The authors carried out analyses regarding the operation of the cable-driven parallel robot within the body shell construction. Based on this, possible influences on existing material and work processes up to changes in the construction site layout are identified (detailed results are published in [4][5][6]).

Consequences for VET are derived from technology, work organization, tasks and responsibilities, work environment and safety, materials management and site logistics. Based on the (partially) new boundary conditions identified in this way, general influences on the technical personnel are worked out in a qualitative analysis and the effects on the field of activity are illustrated exemplarily within the following three occupational profiles.

1: Construction equipment operator - Currently, this occupational group is responsible for the operation and maintenance of construction equipment. It is assumed that this profession will take over the operation of an automated building construction system in the future.

2: Bricklayer - This professional group is massively influenced by the use of an automated building construction system due to a shift of work in their activity areas. In order to counteract the loss of this professional group, it is assumed that further qualification is necessary and advisable.

3: Draftsmen - This professional group is involved in the conception and planning of a building project from an early stage. By using the BIM method draftsmen can have one or more of the following roles depending on their qualification, project size and responsibility: BIM author, BIM user, BIM coordinator. Due to the use of automated building construction systems, the (digital) construction drawings, especially for execution, must be aligned to the use within such a system.

The results of the analysis are compared with the corresponding ordinances and framework curricula of the professions selected as examples, to identify points of contact in relevant learning fields. Finally, it proposes options for the implementation of these options in construction technology education, which could already be implemented in the current situation at the educational institutions (e.g. VET schools).

3 Changes on the construction site using the example of a cable-driven parallel robot

The development of cable-driven parallel robots allows to create large manipulators that even cover the volume of a construction site [4]. It first carries out masonry works, later on other trades, partially autonomously in the structural work. As the cable-driven robot is covering the volume of a complete masonry building, it is potentially suitable for a wide range of construction processes and thus a superior concept to currently existing specialized systems like bricklaying robots. Therefore, the cable robot technology might have a broader impact on the automation of nearly all construction steps and serves as an example of future automated construction and the potential changes in the involved professions. Since December 2016 we are using a demonstrator with the dimensions L/W/H = 12.0 m/1.5 m/5.0 m which is able to assemble bricks into simple wall panels. The capabilities of the prototype will be continuously expanded in the planned follow-up projects, e. g. with automated mortar application (e.g. high-performance adhesives).

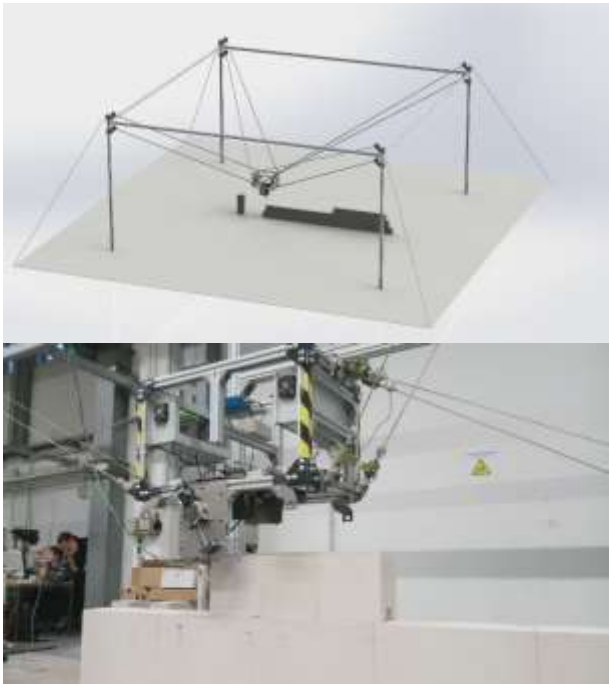

Figure 1. Cable-driven parallel robot for brickwork construction (upper illustration [5], illustration below own picture)

Figure 1 shows the desired long-term concept and a detail of the retractor of the current prototype. The prototype can already be used to investigate many interdisciplinary research questions. Due to the increasing digitalization, the construction industry is changing. Current buzzwords include Industry 4.0, Cloud Computing and Building Information Modeling (BIM). To assess the effects on VET, the changes resulting from the use of a cable-driven parallel robot in brickwork construction are identified below and significant adaptations to the construction site are derived from this. In principle, it must be stated that an automated building construction system is highly sensitive concerning the working process. Changes are common on construction projects and disruptive to labor productivity, in turn leading to increased costs and delayed projects [7][8]. Hence, early recognition of change is important, especially in automated processes. Faulty process sequences or wrong materials, which people must compensate (until now), lead to immediate downtimes during automated building construction. The construction process of the entire shell will be interrupted in the event of disturbances and additional (high) costs will be incurred.

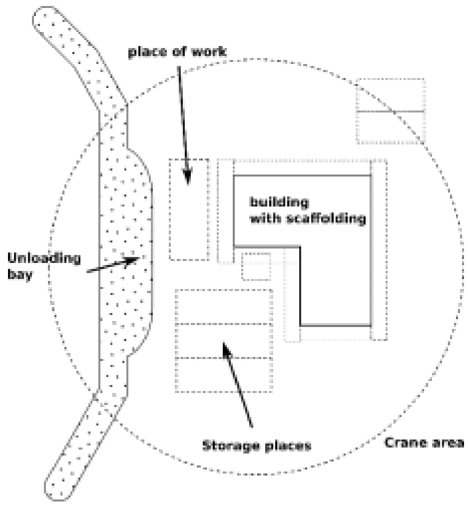

Figure 2. Example of a current construction site layout (based on [6])

Figure 2 shows an example of a current construction site layout without a cable-driven parallel robot and Figure 3 an exemplary construction site with a cable-driven parallel robot. Without a cable-driven parallel robot, a classic layout with tower crane, material storage areas, workshop, scaffolding and construction road is displayed. The construction site with a cable-driven parallel robot (Figure 3) is divided into 3 zones. Zone 1 is the material delivery zone. Here, trucks with the required materials arrive and are unloaded by forklift trucks. Zone 2 is the so-called pre-zone. The materials are stored here and pre-assembled into processable units for the robot. Zone 3 is the working area of the robot. Here, the construction process is largely autonomous. The personnel should not enter this zone while the robot is running as there is a considerable risk of injury. High loads are transported at speeds of several meters per second (the prototype currently transports 6-DF sand-lime bricks at a speed of approx. 0.5 m/s, the current maximum speed is approx. 4.0 m/s). For further details of the technical background of the cable-driven parallel robot refer to [6].

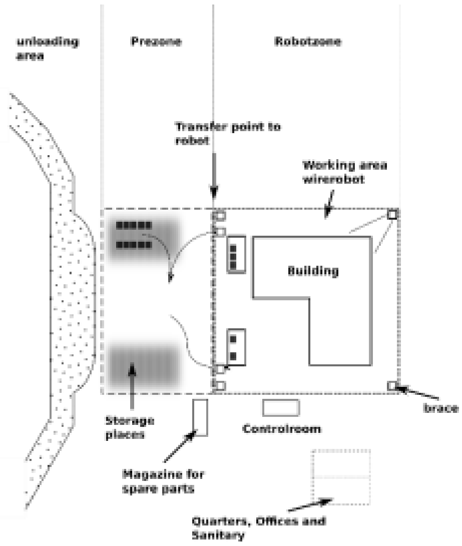

Figure 3. Changes on the construction site (based on [6])

4 Effects on the considered professions

Six different dimensions are considered to assess the effects on the technical personnel:

A: Collaborative working - Change of cooperation through interconnected working towards collaboration.

B: Support through technology- Support of many work steps by (partially) automated systems.

C: Modified construction processes - Changes in processes and office workflows, both in planning and by the introduction of ICT and robotics, especially in execution on the construction site.

D: Interaction with machines - Additional employment in man - machine and machine - machine interaction. The latter must be monitored by humans.

E: Virtual working - Increasing visualization of virtual objects in the real world.

F: Overflow of data - Increasing data must be handled, also in manual work processes.

The dimensions show, that there will be a shift from originally increasingly executive work towards cooperation and collaboration through interconnected working. Besides the other dimensions, which are mainly related to information and communication technology (ICT) issues, the first dimension takes foremost the social effect of automation and robotics into account and therefore the impact of automation on individual and collective level of human interaction. Hence, it investigates mainly the social outcomes of the innovation processes introduced by building automation in construction and workers re-skills effects. These effects are an important influencing part of the human capital, which is one of the basic factors of economic growth in the information, knowledge-based economy as its level of usage determines the innovation component [9]. The influence of automation on social aspects has been addressed since the 1930s (e.g. [10]) and has also become a relevant topic in the ICT community in the 1960s (e.g. [11],[12]) as well as in qualification and training of workers in the 1970s (e.g. [13]), probably driven by the beginning of the personal computer era with the founding of companies such as Apple, Microsoft and others. Nevertheless, the influence of automation in the construction industry seems to be predominantly discussed on technical and economic levels. Even if social aspects impact the whole social structures and changes working culture (e.g. on construction sites or in design teams) this paper deals as a first step mainly with direct changes and impacts on an individual level in exemplary professions. To be able to examine the effects on VET in a first step, the occupational profiles selected exemplary are identified on the basis of the essential activities and influences are localized in the context of automated building construction. The dimensions A-F are related to their effects on the following highlighted fields of activity of the considered occupational profiles ([14],[15],[16]), which are influenced in particular using an automated building construction system.

1: Construction equipment operator - **Set up construction machinery (cm); operate; transport and maintain cm**; carry out repair work on cm; observe safety and environmental regulations; **operate stationary equipment**

2: Bricklayer - **Execute preparatory work**; carry out scaffolding, formwork, erection of scaffolding, formwork, **structures and parts of buildings**; **produce masonry**; produce interior and exterior plaster; install insulation and insulation materials; erect lightweight walls; produce screeds and floor coverings; refine masonry; **produce exterior wall coverings**; carry out demolition and piling work; **operate, maintain and service construction machinery and equipment for building construction**; **quality check of the work carried out**; create measurement of finished work for billing.

3: Draftsmen - **Planning and coordinating work processes; preparing construction drawings for construction planning and execution**; carrying out surveying work; preparing documentation and drawings for presentations; **participating in the preparation of tender documents**; working out building applications in compliance with construction regulations; calculating simple static proofs; preparing accounting drawings and contributing to construction accounts.

As already shown in Figure 2, the construction site layout in particular will significantly change the field of activity of construction machinery operators. This includes the modification of construction processes and the interaction with machines. Recent developments show that construction machines with assistance systems and machine controls are increasingly being used [17]. In earthworks, for example, GPS data and inclination sensors are used to control the guidance of the excavator bucket along a digital terrain model. Other assistance systems, some with 3D control, make it easier, for example, to produce an exact level in road construction. Additionally, there are developments in surveillance, inspection and analysis of the construction progress [18], in the fabrication of wooden structures [19][20][21][22] and steel construction [23][24], too. Current research is also concerned with the unification of real and digital worlds (Augmented Reality Technologies [25][26][27]). To prevent existing underground pipelines and cables from being damaged during the excavation work, they are faded into a display or data glasses, for example. The use of these technologies is increasingly changing the way construction machines are operated on site as well as the planning of their deployment. Hence, the operation of an automated building construction system represents a further change in machine control and is therefore one of the most massive changes which includes almost all considered dimensions. The same applies to the operation of stationary systems. In contrast, transport is also subject to change. However, these are not to be assumed to the same extent as the other activities considered. Overall, it can be stated that in the dimensions "modified construction processes" and "interaction with machines" the strongest influences are to be expected. Since this paper looks at the effects of automated building construction on VET in the light of automated building construction using a cable-driven parallel robot, it is obvious that masonry construction will have a variety of effects. This means that the preparation as well as the construction of the building or parts of it and in particular the construction of masonry is influenced by almost all considered dimensions. A special focus will also be given to the examination of the executed quality. In the future, the bricklayer will be given the task of checking the performance and quality provided by the automated building construction system in a qualified manner and, if necessary, of adapting it by hand. Moreover, it will be necessary to understand, plan and organize the automated production process. Due to the sensitivity of the automated building construction system in the building process (everything depends on the faultless operation of the robot as the leading device), decisions must be made directly on site. Therefore, it is evident that in this field of activity more dispositive work has to be carried out and that, as a result, more and more management tasks will be assigned to this field. In the field of activity of draughtsmen a general approach seems to make sense, since this professional group is involved in the conception and planning of a building project from an early stage. Already in 1986, a modernization of the training content regarding computer-aided drawing and design was implemented in the reorganization of training according to the Vocational Training Act. Other technological innovations in electronic data processing (EDP), such as the incorporation of modern ICT, were included in 2002. Although the above-mentioned amendments go further than in the other two occupational groups considered, further changes can be expected in the observed dimensions. Since, for example, the BIM method considers the project ideally as a multi-professional and collaboratively planned building within its lifecycle, the planning and coordination of work processes is influenced by all dimensions. Due to the use of automated building construction systems, the (digital) construction drawings, especially for execution, must be aligned to the use within such a system for both the construction itself and the validation of the plans regarding the faultless implementation on the building site (e.g. operational aspects as well as data exchange and security issues). This presupposes that knowledge about the changed building processes during the practical implementation of the building construction must be available. The validation of the planning is done advantageously in a virtual building model. In addition, it should be pointed out that technical support for the preparation of tender documents is already integrated in a collaborative manner and therefore an ever-increasing amount of data has to be organized.

4.1 Intermediate results

Based on the qualitative analysis carried out, it can be concluded that the dimension "modified construction processes" has the greatest influence on the considered occupational profiles, followed by the dimensions "collaborative working" and "support through technology". On average, when comparing the considered occupational profiles, the highest influence of an automated building construction system is identified in the group of draftsmen, followed by bricklayers and construction machine operators. Nevertheless, the professional field of bricklayers will experience one of the most massive upheavals through automated building construction systems. For the construction machine operators, it could be assumed that the operation of the new technology could be handled in a similar way as it is currently the case with GPS-controlled construction equipment, for example, in which an introduction/ training takes place. On the other hand, however, it must be noted that an automated building construction system is a comparatively complex system whose operation and maintenance will probably require more far-reaching skills.

5 Consequences for VET

The results of the qualitative analysis are compared with the corresponding ordinances and framework curricula of the professions selected as examples. The German directives on training are structured in specific learning fields (LF) which were examined one by one to identify points of interest. As already introduced above, there is a lot of research on innovations in building construction regarding the use of assistance systems for construction equipment, but these new trends and developments have not yet been incorporated into any amended ordinance or the framework curriculum, especially in the profession of construction equipment operators. Using the example of construction equipment operators [28], five connecting points can be identified in the corresponding learning fields on which the use of an automated building construction system would have an influence leading to additional learning objectives.

LF 1: Setting up a construction site

Knowing automated workflows and processes, ability to plan and evaluate parking and traffic areas for automated building construction.

LF 2: Building a masonry wall

Ability to plan construction of masonry with automation technology (especially planning and checking of relocation plans).

LF 7: Handling of electrical systems

Understand the basic interrelationships and safety in automated electrical systems, integrate data and adapt programming if necessary.

LF 8: Maintenance of engines

Know the tasks and functions of automated technologies.

LF 9: Maintenance of trackside trolleys

Knowledge and ability to implement maintenance and servicing of automated technologies.

In LF 1, further learning objectives must be defined which deal with the changed workflows and processes. Because the construction site layout is fundamentally modified, it is important to be able to plan and evaluate parking and traffic areas for automated building construction. The production of masonry using automation technology should be addressed in LF 2. In this context, it is particularly important to follow on from the already known implementation plans, since the correct planning of an installation sequence is also an essential success factor for the rapid construction of the building when it comes to the automated building construction. When handling electrical systems in LF 7, construction equipment operators should be familiar with the basic interrelationships and safety aspects of automated electrical systems and should be able to integrate the corresponding data into the system.

Furthermore, it makes sense to be able to adapt programming on site, if necessary, as well as to know the tasks and effects of automated technologies in LF 8, and to know and to be able to implement maintenance and servicing of automated technologies to avoid or minimize longer downtimes (LF 9). For bricklayer [29] the modified workflows and processes resulting from the changed construction site layout leads to additional learning objectives similar to construction equipment operation.

LF 1: Setting up a construction site

Similar to construction equipment operator

LF 3: Building a wall of a single-shell building structure, knowledge of the basics of robot-compatible brickwork, e. g. wall connections and masonry connections and the ability to carry them out (e. g. for adaptation and repair work).

LF 7: Masonry walls of a single-layer

Ability to plan, test and optimize masonry of large formats for automatic construction (as a new installation technique), ability to work with digital layouts

LF 16: Fabrication of special wall components

Knowledge about measures for adjusting irregular masonry constructions (e. g. angled brickwork) and ability to implement it manually.

In relation to the specific handicraft activity, LF 3 should deal with the basics of robot-compatible execution of masonry in order to gain knowledge about wall connections and wall integrations which have to be implemented in the context of adaptation and repair work during the construction process. In addition, the bricklayers should be able to plan, test and optimize the masonry made of large-format masonry for automation (as a new installation technique). For this reason, it is recommended to work with digital installation plans in LF 7. As not every brickwork geometry can be created when using an automated building construction system, measures for the adjustment of irregular brickwork constructions (e. g. angled brickwork) should be known in LF 16 as well as the manual implementation in the context of an automated construction site should be taught. With reference to the automated construction site, the group of draftsmen [30] have six essential points of contact.

LF1: Participation in construction planning

Knowledge of data organization and data management in relation to collaboration platforms, planning and implementing data storage

LF 3+4: Development/ planning of foundation

Ability to create 3D/xD models for automated execution and validate third-party models.

LF 5: Planning a basement

Knowledge of the fundamentals of robot-compatible brickwork execution, creating, testing and optimizing installation plans for automated execution.

LF 10a: Preparation of a building permits application

Knowledge about data exchange between different stakeholders, ability to plan and implement data exchange strategies for automated execution, validate data, identify interface problems and propose countermeasures.

LF 11a: Designing an exterior wall

Ability to design external wall constructions for automated execution.

Due to the expected increase in digitally generated and processed data, important aspects that need to be addressed already arise in LF 1. Here, draftsmen should know forms of modelling and design, data organization and data management regarding collaboration platforms as active (and in practice to a large extent responsible) persons. Here, basic types of data transfer, information flows and interfaces should already be addressed to be able to plan and implement data storage and security strategies in practice. In LF 3 and 4, it is possible to extend digital modelling to automated building construction and implement it using practical examples. Furthermore, draughtsmen should be able to understand foreign models and validate their content. In this case, similar to the previous professional profiles, it is also imperative to know the fundamentals of robot-compatible brickwork execution and to have the ability to create, check and optimize installation plans for automated execution. This can be addressed in LF 5. Following on LF 1, the planning and implementation of data exchange strategies for automated execution, the technical validation of data as well as the identification and, if necessary, the first steps to solve interface problems should be considered when creating a building application (LF 10A). Finally, in learning field 11A, the automated execution can also be considered as a topic in the design of an outer wall construction.

6 Conclusion

This study shows that the use of an automated building construction system will lead to far-reaching changes in the entire work organization in the socio-technical field. The investigation provides a first ground for increased consideration of social aspects due to building automation in construction in a variety of areas. It is strongly recommended to conduct further investigations on the social impact of automation and robotics in construction in the social and psychological spheres on different sub-topics and levels. Such research is essential to avoid the development of a parallel and in a long term incompatible workforce. Indications for this are given through current research and development work, which shows that companies are increasingly considering how they can (fully) automate their work, which will lead to further significant changes in all areas of the construction industry in a relatively short period of time. For example, the object-related construction work is almost exclusively carried out by the automated system in the future, which will lead to the following positive causal relationships:

The productivity of the execution performance is increased by the automated building construction system. At the same time, this reduces the physical workload of the site personnel. This in turn leads to an increase in the physiological motivation of the workforce. Furthermore, the changed working conditions lead to more safety at work, which in turn will increase psychological motivation. In addition, the entire construction site organization has to be rethought, both at operational and management level. This means, for example, that tasks, responsibilities and competencies will be transformed due to changed work processes.

The examination of the potential changes within the operative production factors shows that there will be a shift from the executive work on the building itself towards dispositive work (planning, management and organization). The changed roles mean that skilled workers must acquire additional skills, competences and responsibilities as well. As a result, the training concepts and content in VET must be adapted to the new circumstances. The curricula for the operative construction staff must be redesigned in order to increase dispositive work. This paper gives some indications about additional learning objectives related to recent learning fields of existing regulations. To achieve a comprehensive understanding of technology and new working methods, further topics must be included in the curricula, depending on the characteristics of the specific occupation. These are topics from the ICT field as well as management. Although current ordinances or framework curricula do not yet cover such effects in terms of content, it should already be possible to address further learning objectives within the existing learning environments that are necessary for the profession in terms of content and methodology. The results of this study are intended to provide guidance in this respect.

The analysis carried out shows that the incorporation of automated building construction into the various learning fields of the considered occupational profiles appears potentially possible. As the amendment of training guidelines cannot be achieved at short notice, the authors are currently examining options which can be implemented immediately in the current situation in VET schools and companies to address the additional learning objectives independent of existing regulations. First promising approaches are (ICT-supported) group-oriented teaching/learning projects, across-school projects in cooperation with companies or even game-based concepts.

Abstract –

Construction robots must perceive and model their surroundings to compensate for uncertainties in their workpieces. This research investigates a technique to enable the autonomous sensing and modeling of construction objects and features so construction robots can adapt their work plans and perform work. To that end, the Generalized Resolution Correlative Scan Matching (GRCSM) construction component model fitting technique is presented, which registers BIM models to point cloud sensor data. The registration results enable the robot to update its workpiece models to reflect their actual condition. An experiment was conducted in which virtual sensor data was generated for a virtual construction joint, and joint profile models were registered to form a model of the joint. It was found that the GRCSM construction component model fitting technique can be used in combination with a low precision sensor to estimate the pose and geometry of a virtual construction joint with a mean norm positioning error of 1.7 mm. The GRCSM construction component model fitting technique appears promising for the geometric estimation of construction objects, especially for situations involving full automation, detailed construction work, incomplete sensor data, and complex object geometry.

1 Introduction

The construction industry is often considered one of slow change, hazardous conditions, old technology, and stagnant productivity levels. Robotics offers the potential to change that by reducing construction project cost, shortening project lead time, improving construction quality, and improving worker safety [1]. However, the construction industry's adoption of robotics has proven slower than other industries, such as manufacturing. This is largely attributable to technological challenges arising from the unique characteristics of the industry [2].

One such challenge is the construction robot's need to perceive its workpieces and adapt its plan in order to reliably perform quality work. In contrast with construction robots, many manufacturing robots are able to perform work with little or no sensing of their workpieces. This is made possible through tight control over the manufacturing robot, its environment, and its workpiece. Such control enables the robot to neglect stochastic variation and leverage a simple a kinematic chain to estimate its pose (i.e., position and orientation) relative to the point of interest on its workpiece.

However, such control is generally much looser for the construction robot. For example, far greater uncertainty exists in the pose of the construction robot relative to the jobsite due to the robot's need for mobility and the high uncertainty inherent in mobile robot pose estimation methods. Similarly, greater uncertainty exists in the pose of the construction robot's workpieces relative to the jobsite due to loose construction tolerances and high process variation. Additionally, uncertainty exists in the actual geometry of the construction workpiece due to such factors as material variation, material deflection, and process variation. Given the high uncertainties present, the construction robot cannot reliably determine its pose relative to the workpiece through a kinematic chain like the manufacturing robot, but rather, must perceive the workpiece in place.

The objective of this research is to develop a means by which a construction robot can perceive and model the workpieces in its immediate environment so it can ultimately adapt its plan and autonomously perform detailed construction work.

2 Related Work

Past research has been conducted in the sensing and modeling of construction objects and environments. Such researchers employed various sensing and modeling techniques for the purposes of project progress monitoring, as-built documentation, material quantity estimation, material tracking, obstacle avoidance, and object manipulation.

To circumvent the challenges and computational burden associated with fitting models and extracting meaning from dense point clouds, Cho et al. [3] proposed leveraging human cognition to assist in the modeling of a construction environment. In this approach, a human selects a geometric primitive (e.g., cuboid or cylinder) or a complex model (e.g., excavator or bridge) from a database and manually aims a laser rangefinder at strategic points on the physical object to obtain individual point measurements. The selected model is then fit to the sparse point cloud. McLaughlin et al. [4] used the same approach, but developed three additional construction workspace model types: partitions, convex hulls, and tight-fitting bounding boxes. Kim et al. [5] applied the aforementioned partition and convex hull methods for such purposes as obstacle avoidance, accident prevention, and material tracking. However, all such variations of this sensing approach rely on human operation, which is not suitable for autonomous applications.

Kim et al. [6] later demonstrated that convex hull modeling could be used in combination with a more automated form of sensing, flash laser distance and ranging (flash LADAR), in which a 2D array of measurements can instantly be obtained by pointing a flash LADAR sensor in the general direction of interest. The approach was only demonstrated with large objects and coarse models for such purposes as obstacle avoidance, and did not include semantic recognition of the objects it detected. Thus, the approach is not suitable for the autonomous recognition and manipulation of detailed construction components.

Stentz et al. [7] developed an autonomous excavator for excavating soil and loading it into a parked truck. The excavator used laser rangefinders for sensing the soil terrain and a nearby truck. A 2D grid of height values was fit to the terrain data and a parametric truck model was fit to the truck data. The terrain model was used to determine where to remove soil and the truck model was used to determine where to dump soil. The approach reportedly worked well, but was only demonstrated with large objects and coarse models. The approach may not be suitable for the manipulation of detailed components.

Work has also been done in the sensing and modeling of small, targeted construction components. Kim et al. [8] scanned individual stones with a combination of projected laser beam and charged-coupled device (CCD). However, the highly irregular stones were simply modeled as cuboids of corresponding principle dimension (i.e., tight-fitting bounding boxes). Kahane and Rosenfeld [9] used a similar projected laser and CCD to measure the gap width between adjacent wall tiles to aid in the placement of tiles by an autonomous tiling robot. Although the gaps were targeted and measured accurately, they were only modeled by a single parameter: gap width. Such simple models may not be sufficient for detailed construction manipulation tasks.

Authors like Sicard and Levine [10] and Kim et al. [11] employed a method called polygonal approximation and syntactic analysis to extract 2D models from weld joint data obtained from a projected laser beam and CCD. In this approach, data points were evaluated one by one and combined into linear segments via polygonal approximation. The segments were then merged according to prescribed syntactic rules used for describing weld joints. However, the syntaxes developed in such studies were only capable of handling a handful of simple joint types because the complexity of segmentation and syntactic rules tends to increase with increasing component complexity. Furthermore, such methods are susceptible to failure under conditions of partial object occlusion and incomplete sensor data.

All of these studies suffer from limitations which inhibit their employment in the robotic perception and manipulation of detailed construction components. Such limitations include the need for human intervention, the lack of semantic object recognition, the lack of modeling detail necessary to perform detailed work, the inability to handle a variety of complex components, and the susceptibility to modeling failure under partial object occlusion and incomplete sensor data. The research described herein seeks to address such limitations by enabling a construction robot to autonomously perceive its workpieces through the fitting of geometrically complex models to sensor data with sufficient fidelity to ultimately adapt its plan and perform detailed construction work.

3 Research Contribution

This paper offers three central contributions. First, this paper introduces a modified search algorithm for such purposes as fitting a geometric model to a point cloud, fitting a point cloud to another point cloud, or fitting a point cloud to a map. Specifically, the modified algorithm is called Generalized Resolution Correlative Scan Matching (GRCSM) and is a generalization of Multi-Resolution Correlative Scan Matching (MRCSM) [12]. Second, this paper introduces a construction component model fitting technique, also referred to as GRCSM, in which the GRCSM algorithm is applied in order to fit a model of a construction component to a robot's sensor data. Lastly, this paper provides an initial investigation into the capabilities and limitations of the GRCSM construction component model fitting technique as a model fitting tool for construction robot perception via experimentation.

4 Technical Approach

This work focuses on the detailed modeling of targeted workpieces for robotic manipulation. Specifically, this work employs a model fitting technique whereby complete models of construction components are fit to point clouds so that contextual meaning can be directly applied to the data. Although the technique can be applied to either 2D or 3D models and sensor data, 2D models and sensor data are used here.

Despite the existence of numerous construction tasks to which such modeling techniques could be applied, construction joint filling is used as an example application in this work due to its commonality across a range of construction activities. Activities such as welding, caulking, drywall finishing, tile grouting, spray insulating, and pipe soldering may be classified as joint filling. In this paper, joint filling refers solely to the placement of filler or sealant material into the joint, although the full treatment of an actual construction joint might require additional tasks such as scraping, cleaning, masking, priming, backing, tooling, and cleaning.

4.1 General Setup

Many interdependent technological advancements must come together to support the successful operation of a construction robot on a real-world construction project. Rather than attempting to address all aspects of the problem at once, this research focuses on a portion of the problem, leveraging the assumption that the other supporting components are also in place. The general setup is described as follows.

First, it is assumed that the construction robot has access to a Building Information Model (BIM) containing the designed geometry of the construction project, which is reasonable considering the rapidly expanding use of BIMs in architecture, engineering, and construction [13]. Second, it is assumed that the robot has been placed, tele-operated, or autonomously navigated in such a manner that it has reached the near vicinity of the object of interest. Furthermore, it is assumed that the robot's pose estimation error is small enough that it can aim its sensor in the direction it expects to find the object, and despite pose errors, still detect the actual object within the sensor's operational window. This is a reasonable assumption considering that today's indoor mobile robots are able to localize themselves on the order of several centimeters and a single degree [14]. Lastly, it is assumed that the sensor is capable of adequately sensing the object of interest. In reality, highly reflective or transparent materials tend to degrade the data quality of many sensors, and specialized sensing modalities may be necessary for such cases. In the experiments described here, materials were intentionally chosen based on sensor compatibility.

4.2 Modeling

In order for a robot to identify or manipulate a construction feature, a feature model is first needed. Construction joints are used as an example here to demonstrate feature modeling. For most construction joints, the majority of the feature's descriptive information lies transverse to the joint. Thus, one modeling strategy would be to model the feature in thin 2D slices and assemble the slices to create a 3D model. Such an approach is employed in this work. Given that the square butt joint is arguably the simplest and most common joint type, it is used as the illustrative example.

The techniques presented in this paper tend to be best suited for situations in which modeling accuracy requirements permit the fitting of fixed models to the data. Given that a joint's primary feature of interest is the gap formed by two construction components, a model in which each of the two component models is free to translate and rotate offers considerable descriptive capability for the gap. Since each of the two individual components has three degrees of modeling freedom, and the gap is defined by a combination of those two components, the gap model has six degrees of freedom. The square butt joint model is shown in Figure 1, where it has been decomposed into an individual component model, a combined component model, a separated component model, and a gap model.

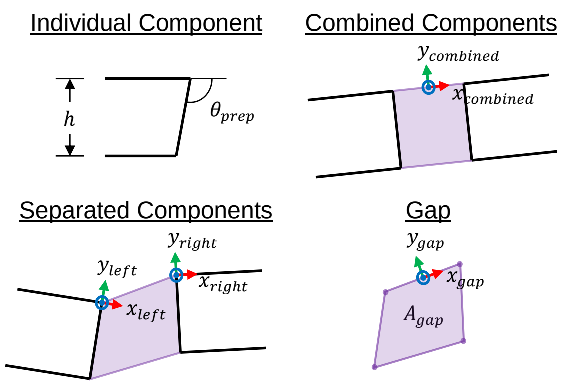

Figure 1. Square butt joint model decomposed into individual component, combined component, separated component, and gap models

4.3 Sensing

A wide range of sensors could be used for the sensing of such construction components. In addition to various modalities (e.g., optical, ultrasonic, laser, etc.), sensors can output data in a range of dimensions (e.g., 2D, 3D, etc.). Since laser data can easily or directly be converted to spatial data, and because the majority of a joint's descriptive information lies in its transverse plane, the authors chose to use a 2D laser rangefinder in this work.

4.4 Model Fitting

In this paper, the authors take the approach of fitting complete models to sensor data so that any contextual meaning associated with the model can be directly related to the data. One of the benefits of this approach is that it does not require sophisticated rules for segmenting data, regardless of the complexity of the model. Another benefit of this approach is its robustness to incomplete sensor data.

The technique presented here for fitting models of construction components to sensor data is referred to as the Generalized Resolution Correlative Scan Matching (GRCSM) construction component model fitting technique. It employs a search method called the Generalized Resolution Correlative Scan Matching (GRCSM) search method, which is a generalization of Olson's Multi-Resolution Correlative Scan Matching (MRCSM) search method [12]. Like MRCSM, GRCSM is a brute force search method that uses multiple resolution levels to quickly narrow a search. However, the two methods differ in that MRCSM performs a search over two resolution levels, while GRCSM searches over any arbitrary number of resolution levels. GRCSM automatically determines and implements the appropriate number of resolution levels based on the specified search window size and desired fit tolerance.

One particular benefit of the GRCSM search method is its immunity to local minima entrapment, which is a well-known issue for search methods like Iterative Closest Point (ICP) [15]. The GRCSM construction component model fitting technique can be generalized to 3D data and 3D models, but is presented here in the context of 2D data and 2D models.

The GRCSM construction component model fitting method is comprised of three primary stages: determining the appropriate number of resolution levels, building a component model lookup table for each resolution level, and fitting the sensor data to the component model by searching for a best fit. The first step in determining the appropriate number of resolution levels is to determine the search-range-to-tolerance ratio r for each degree of freedom (e.g., x, y, and θ), as shown in Eq. (1), where w is the search window size and t is the loosest allowable fit tolerance.

$$r = w/t \tag{1}$$

The number of resolution levels L is then determined as shown in Eq. (2), where s is the search test quantity per level for each degree of freedom and *ceil* is a function that rounds a number up to the nearest integer.

$$L = ceil\left(\frac{\ln(r)}{\ln(s)}\right) \tag{2}$$

The second step in the GRCSM method involves building a component model raster lookup table for each resolution level, starting with the highest resolution table. The table and its entries can be thought of as a uniform grid of cells. The dimensionality of the table corresponds to the dimensionality of the search (e.g., 2D, 3D). The size of the high resolution table is determined along each dimension as shown in Eq. (3), where c is the number of high resolution grid cells. Margins can be added to the high resolution table in integer multiples of s^{L-1}, but c should still refer to the expression shown in Eq. (3).

$$c = s^L \tag{3}$$

The scale q (e.g., $1\ mm/grid$) of a cell along any dimension is given by Eq. (4).

$$q = w/c \tag{4}$$

The component model is then projected onto the high resolution lookup table. If the model already exists as a bitmap representation, or can easily be converted to such form, then it can be directly inserted into the table, provided appropriate scaling. Alternatively, the model's vertices can be projected onto the lookup table and intermediate points can be interpolated between the model's vertices. After a bitmap representation of the model has been established, a probabilistic distribution is applied to the model to reflect the stochastic nature of the sensor, as suggested by Olson [12]. For simplicity, the authors employ a radial Gaussian distribution with standard deviation equivalent to that of the sensor. The bitmap representation and stochastic counterpart for an arbitrarily shaped object profile are shown in Figure 2.

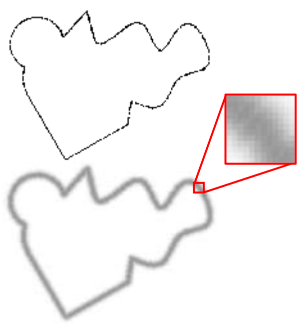

Figure 2. Bitmap (top) and stochastic (bottom) representations of an example arbitrary profile

After the high resolution lookup table is complete, lower resolution lookup tables are produced by iteratively employing Olson's [12] technique for generating a low resolution lookup table. To generate a lower resolution table, the first cell of the lower resolution table is set to the maximum value found in the first $s \times s$ block of cells in its high resolution counterpart. Similarly, the second cell of the lower resolution table is set to the maximum value found in the second $s \times s$ block of the high resolution table, and so on. As such, each new table becomes $1/s$ the size of its higher resolution counterpart. This process continues until L tables, including the high resolution table, are obtained. The lowest resolution table then becomes of size $s \times s$. An example set of lookup tables for an arbitrarily shaped object is shown in Figure 3, where dashed lines have been superimposed on the lowest two resolution levels to help illustrate the process.

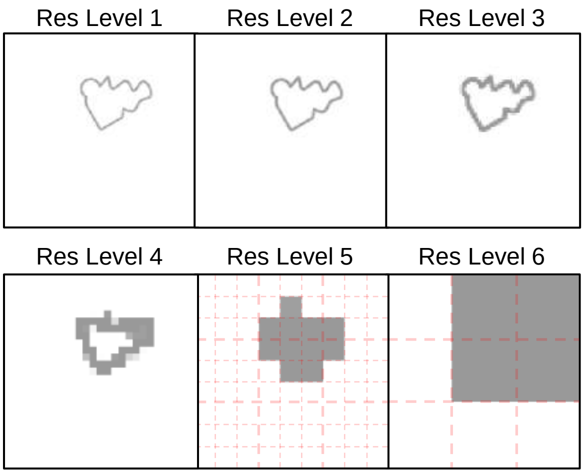

Figure 3. Model lookup tables at various resolution levels for an arbitrarily shaped object

It is expected that such lookup tables may only need to be built once for a construction feature if it possesses a uniformly designed cross section, as is the case for most construction joints.

The third step in the GRCSM method involves fitting of the sensor data to the component model by searching for a best fit between the data and the lookup tables. Using the expected sensor-to-joint pose as a reference, the data points are projected onto the lookup table and the corresponding values are summed to provide a fit score. To start, the data points are transformed and projected onto the lowest resolution table using various pose combinations. For each degree of freedom, the immediate search window i is given by Eq. (5), where v is the current resolution level.

$$i = \frac{qc}{s^{L-v}} \tag{5}$$

The immediate search window is divided into s uniform intervals, such that test points lie at the center of each interval. Similarly, s test points are also created for the other degrees of freedom. The data is then projected onto the table for each of the f^s pose combinations. The table values are summed, and the total fit score is recorded for each combination. The scores are then added to a list, and the pose of highest score is removed from the list and explored at a new resolution level. This process is repeated until the highest scoring pose found on the list coincides with the highest resolution level (Level 1). Such pose is then selected to represent the best fit between the data and the model. An example search process is shown in Figure 4.

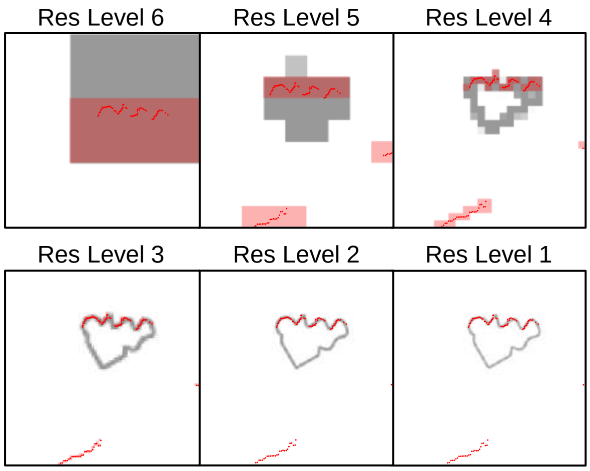

Figure 4. Example GRCSM search process showing the best fit results at each resolution level leading to the final fit result

It should be noted that during the process, it is possible to move bi-directionally along the resolution spectrum and jump more than a single level, given that search transitions are dictated by the highest score found in the score list. Furthermore, it should be noted that the scores in the score list have both an associated pose and resolution level. That is, the same pose can be explored at more than one resolution level.

For the case of a single construction component, the GRCSM model fitting process is straightforward. However, for the case of a construction joint, which is comprised of two components, the process occurs differently. First, a combined model is built from the two component models such that their relative pose matches the BIM. The GRCSM method is applied to the combined model. The pose corresponding to the fit of smallest error is selected as the combined pose estimate. The process is then repeated for each component individually, using the combined pose estimate to initialize the search. Furthermore, the search window for the individual components is limited to a fraction of the designed gap width in order to avoid erroneously fitting a model of one component to the sensor data of other components. The resulting pose estimates are then adopted as the component pose estimates, and the joint gap is modeled directly from the transformed component models.

5 Experiment

An experiment was conducted in a virtual environment to evaluate the ability of the GRCSM model fitting approach to estimate the geometry of a square butt joint that deviates from its expected, i.e., designed, geometry. A randomized square butt joint was generated by specifying information about the gap and the two components that comprise the joint. The transverse parameters of the expected joint are listed below, where a, b, and c are counterclockwise rotations about x, y, and z, respectively.

- Gap width (top corner to top corner): 25 mm
- Workpiece thickness: 25 mm
- Workpiece width: 200 mm
- Expected pose in world frame:
  $\bar{x} = 0\ mm, \bar{z} = 50\ mm, \bar{a} = 0°, \bar{b} = 0°, \bar{c} = 0°$

The joint was extended along a third dimension by uniformly spacing two-dimensional cross sections, or slices, along the world y-axis. The joint was made continuous by interpolating between particular slices designated as transition slices. The joint was generated by randomizing various geometric joint parameters. The joint was comprised of 83 cross-sectional slices and took the form shown in Figure 5. Dashed lines denote the joint's 83 cross-sectional slices, and solid lines denote the joint's 12 transition slices.

A virtual sensor was used to generate virtual sensor data of the joint. The virtual sensor was modeled after a 2D scanning laser rangefinder that outputs range and bearing measurements. Loosely modeled after the Hokuyo URG-04LX-UG01, the sensor was assigned bearing increments of 0.352° (10 $bits$) and a range standard deviation of 3 mm. Uncertainty in the sensor's bearing measurement was neglected. The sensor's scan window was set to $\pm 30°$. The virtual sensor scanned the joint while translating along the world y-axis, 250 mm directly above the expected center of the joint. The virtual sensor data was generated by projecting a beam onto the incident joint face, finding the point of intersection, and adding a normally distributed random range error corresponding to the sensor's standard deviation. The resulting virtual sensor data is shown in Figure 5.

The GRCSM construction component modeling fitting technique was then applied to estimate the poses of the two workpieces at each slice along the length of the joint. For the GRCSM search, the fit tolerances for x, y, and θ were set to $\pm 0.5\ mm$, $\pm 0.5\ mm$, and $\pm 0.3°$, respectively. The test quantity per level was set to three, and the search windows for x, y, and θ were set to $\pm 121.5\ mm$, $\pm 121.5\ mm$, and $\pm 45°$, respectively. All computational processing was performed in MATLAB using an Intel® Core™ i7-4900MQ 2.80 GHz central processing unit.

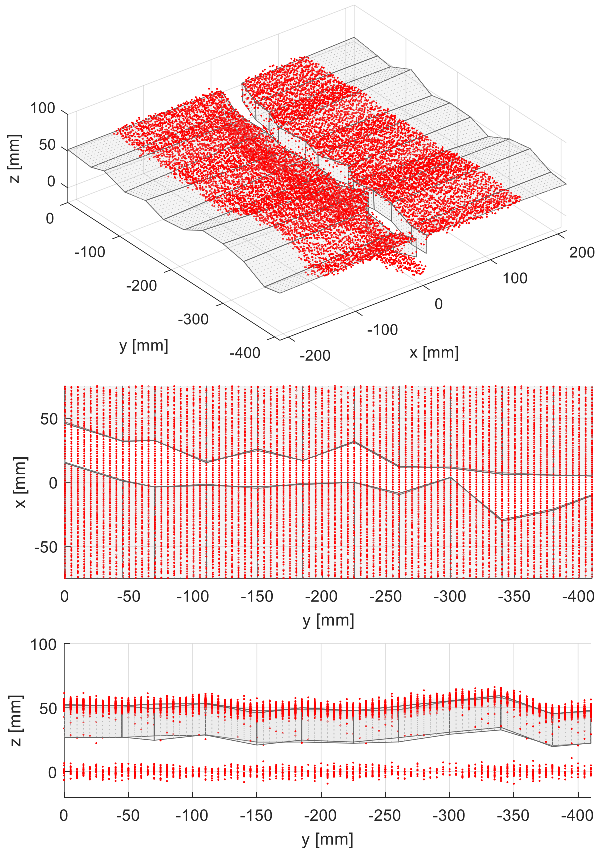

Figure 5. Virtual square butt joint and sensor data

The dataset was processed a second time to provide a comparison between the MRCSM and GRCSM search algorithms. MRCSM was simulated in the experiment by restricting the number of GRCSM resolution levels to two, with an equal number of tests for each resolution level.

Because the gap is defined by the two workpieces, the gap's pose and geometry was extracted directly from the workpiece model results. The 2D gap geometry (e.g., cross-sectional area) was converted to 3D (e.g., differential volume) by projecting the information half the distance between slices in both directions.

6 Results

The gap modeling results for the GRCSM model fitting technique are shown in Figure 6, where the results are represented as a collection of gap pose estimates and differential gap volumes estimates, and the gap origin is defined as the midpoint between upper corners of the workpiece models.

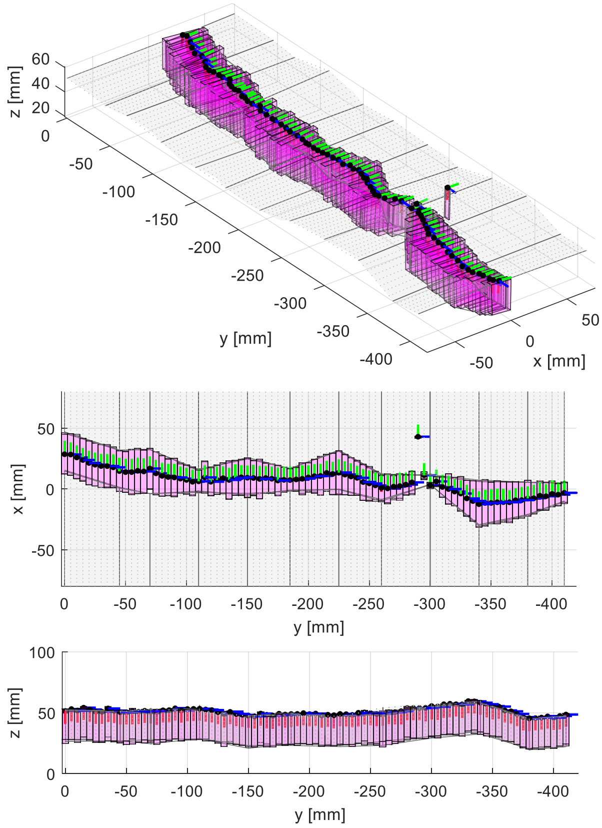

Figure 6. Model fitting results using the GRCSM construction component model fitting technique

The model fitting pose estimation error statistics for the virtual joint are shown in Table 1, and a plot of the estimated poses and differential volumes are shown in Figure 7.

Table 1. Absolute gap pose error statistics

	Min	Max	Mean	Std Dev
$\lvert err_x \rvert\ (mm)$	0.0	37	1.6	4.0
$\lvert err_z \rvert\ (mm)$	0.0	2.2	0.6	0.5
$\lVert err_{pos} \rVert\ (mm)$	0.0	37	1.7	4.0
$\lvert err_\theta \rvert\ (deg)$	0.1	10	2.3	2.0
$\lvert err_V \rvert\ (cm^3)$	0.0	1.3	0.3	0.2

The mean processing time was found to be 0.082 $s/scan$ for the GRCSM component model fitting technique. Additionally, the mean processing time was found to be 630 $s/scan$ when using MRCSM to perform the search, suggesting that the GRCSM search algorithm executed the search an average of 3100 times faster than the MRCSM implementation.

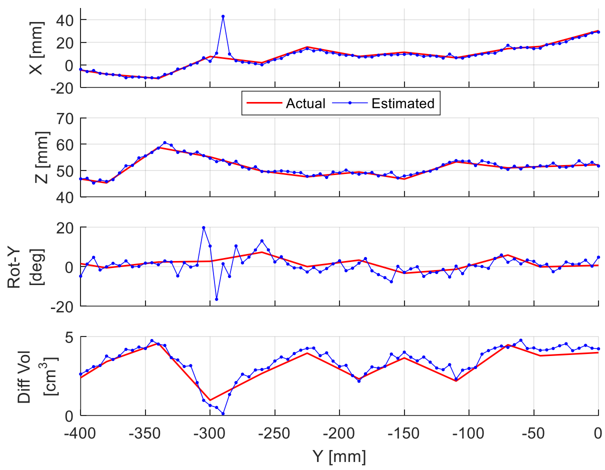

Figure 7. Gap pose estimates using GRCSM

7 Discussion

GRCSM was explored as an alternative model fitting approach to ICP that is free of local minima entrapment. Although ICP is sufficiently robust and accurate for many coarse model fitting applications, the authors anticipate that an entrapment-free approach will be critical for detailed construction tasks, such as welding.

As indicated by the experimental results, the GRCSM model fitting technique appears capable of estimating the geometry of a virtual construction joint. At a rate of 0.082 $s/scan$, the processing time for the entire joint was found to be 6.8 s. This appears reasonable for a real-time scan-and-plan procedure in a real-world construction operation. With further algorithmic and hardware improvements, it is not unreasonable to expect that processing times can continue to be reduced.

This research provides a construction component model fitting technique which enables a construction robot to perceive and model the workpieces in its immediate environment so it can ultimately adapt its plan and autonomously perform construction work. Despite the large uncertainties in robot pose, workpiece pose, and workpiece geometry, this framework enables the robot to perceive the workpiece directly and perform quality work. As opposed to past construction component modeling techniques, this technique eliminates the need for human involvement, provides a level of semantic recognition, offers sufficient modeling detail for detailed construction work, handles a variety of complex component geometries, and offers improved robustness to partial object occlusion and incomplete sensor data. The GRCSM component modeling technique appears to be a promising tool for the geometric estimation of construction components, especially for situations involving full automation, detailed construction work, incomplete sensor data, and complex object geometry.

8 Conclusion and Outlook

The objective of this research was to explore the extent to which a construction robot can perceive and model construction work components, which is a critical step in making adaptive manipulation decisions to accomplish work. This paper began by briefly describing the sources of uncertainty confronting the construction robot and driving the need for component modeling. The Generalized Resolution Correlative Scan Matching (GRCSM) construction component model fitting technique was then introduced to address such a need. An experiment involving the geometric estimation of a virtual construction joint was presented to evaluate the ability of the GRCSM construction component model fitting technique to model construction joints.

It was confirmed that the GRCSM construction component model fitting technique is capable of estimating the pose and geometry of a virtual construction joint. It was also found that the GRCSM search algorithm is significantly faster than MRCSM in executing the model fitting searches described in this paper. However, it was found that GRCSM is susceptible to modeling failure under certain conditions.

Future work is needed to compare the performance of the GRCSM construction component model fitting technique with other model fitting techniques, such as polygonal approximation and syntactic analysis, for construction feature modeling. It may also prove beneficial to explore the use of segmentation in the GRCSM construction component model fitting technique for such purposes as improving robustness to nearby objects. Additional work is also needed to evaluate how the construction component model fitting technique handles cases with multiple similar objects or unexpected objects in the scene. Lastly, additional work is needed to convert a component model into a robot plan and physically execute the plan on a real construction feature.

Abstract –

Tracking design completeness during the early phases of complex construction projects is a vital need for project participants to measure their progress. It is also a challenge, because design completeness depends on both geometric details and engineering information related to the model. Tracking level of development (LOD) of the designed objects is a partial solution that focuses on level of geometric detail of the design elements. However, engineering analysis, documents and process records behind the design are thereby neither assured in terms of completeness nor related to the elements. To address this aspect of the problem, the Construction Industry Institute (CII) published Model Maturity Index (MMI) definitions and the Model Maturity Risk Index (MMRI) Toolkit which aim to help management and engineering teams to provide accurate and timely information about design progress and productivity in building and industrial type construction projects. In this research, new MMI definitions and a related MMRI table is developed for the Track Line discipline in MRT projects by conducting a literature review on track line design and by seeking related experts opinions. Semi-automated assistance for populating the MMRI table using an interface management system integrated with a BIM is also described but is not the main focus of the paper. More accurate engineering progress measurements should be facilitated by the research results.

1 Introduction

Measurement of the design progress is an evolving challenge in today's 3D modeling dominated design environment [1]. Improvements in the software engineering and computer science fields extended traditional 2D and 3D technical design drawings into more intelligent visual modeling processes in construction industry. Today, Building Information Modeling (BIM) philosophy which can be defined as crating a virtual prototype of the system, is getting more and more important in the construction industry [2]. The main idea behind BIM is creating an intelligent model of the project which includes not only graphical details, but also engineering information of the system such as material data, wind force, cost, schedule, and facility management information, etc. [3].

Today, there are several 3D modeling software options on the market that engineering design can be done on the shared design files among the project stakeholders. Although these improvements bring huge flexibility and power to the construction industry such as automatically superimposing different design files and being able to detect clashes, creating walk-through views of the design models, and estimating projects' quantity takeoff automatically, etc., it is hard to measure engineering design progress during the design phase of the projects.

Traditional design progress measurement technique was counting the completed engineering drawings and completed issued-for-construction files. However, it is hard to perform this technique on 3D models, since 3D design is an evolving process on the same design files. Measurement of design process becomes even harder on complex construction projects, since many project participants are involved in the design of the project.

There are different approaches and tools for measuring design progress in both the literature and industry today. One of these approaches is tracking Level of Development (LOD) of design elements in the model. Mainly LOD definitions are focusing on graphical details on the design elements. However design progress is not only related with the graphical details and representation, it is also related with engineering information added to the model, and documents and process records behind the design. Another approach to measuring design progress, which focuses on engineering information added to the model, is tracking Model Maturity Index (MMI) levels of the project disciplines. Both LOD and MMI level approaches are explained in the literature review section of this paper in detail.

Also, there are several Building Information Modeling (BIM) maturity assessment tools available today that help users to measure their project performance on BIM implementation. Arup, which is a global engineering and design firm, developed one of these BIM maturity assessment tools in 2014 [4]. The main purpose behind Arup's BIM Maturity Measurement (BIM MM) tool is to assess the BIM implementation maturity in projects and compare it between different projects. Although BIM MM tool provides a measurement on "maturity", the usage area of this tool is different than measuring design maturity of the project itself. Therefore BIM maturity tools will not be further explained in this paper.

This paper is part of an ongoing research project related with measuring design progress on complex capital projects. The main focus in this conference paper is on explaining currently used methods for tracking design progress, and introducing a conceptual semi-automated framework for tracking design completeness of Track line discipline in Mass Rapid Transit (MRT) projects. The novelty of this research is developing methods to fill the knowledge gap on design progress measurement for a class of projects that doesn't have specific design maturity definitions. Briefly, the validation approaches of this research are: creating functional demonstrations, getting experts' reviews, and compare developed measurement framework quantitatively with existing systems. Presenting quantitative results from the proposed framework at this time is beyond the scope of this conference paper.

2 Literature Review

2.1 Level of Development (LOD)

Generally, 3D models of construction projects range between a conceptual drawing to a fully detailed and coordinated construction model. One way of measuring design completeness in construction projects is tracking Level of Development (LOD) level of the elements on the model. In 2008, the American Institute of Architects (AIA) released a contract document, "AIAE202-2008 BIM Protocol Exhibit," which defines Level of Development (LOD) and LOD levels, which are related primarily to amount of design detail in the model. According to the AIA, LOD 100 represents a conceptual drawing, while LOD 500 is the as-built model; LOD gets higher during the design phase of the project and reaches its highest level during the construction phase [5]. In 2017, The Level of Development (LOD) Specification which follows CSI Uniformat 2010 organization and LOD schema developed by AIA, is released by BIMForum. In this specification, general insight and definitions of LOD levels for the design elements specified in Uniformat 2010 is provided [6].

Mainly LOD level definitions are related with the graphical details on the design elements on the model. In other words, as the accuracy of the design of the elements gets higher, the LOD level of that elements also gets higher in the model. However, there is no such LOD level of the complete design model. LOD levels are defined only for elements on the model. It cannot easily or consistently be aggregated to total LOD level for project [7,8].

LOD can be added as a shared parameter to the models created on Autodesk Revit to track design progress of the project. During the design phase, LOD level of the elements can be arranged manually by the design team according to the LOD definitions that they created for their project' design elements. When each element's LOD level is defined on the model, the project team can track changes on these levels to see progress in their projects.

2.2 Model Maturity Index (MMI)

Most of the engineering progress in the early phases of complex capital projects is not graphical-design related, and such progress must be captured as well in order to have a complete idea about the progress in the project. Examples of such engineering processes are diverse and include geotechnical studies, mechanical and control systems design, and structural systems analysis.

Similar to the AIA, the Construction Industry Institute (CII) published metrics to measure progress in model-based engineering projects in 2017. These metrics are called Model Maturity Index (MMI) and they are focusing on engineering information added to the 3D model, and documents and process records behind the design. Similar to LOD, MMI definitions have levels ranging between MMI 100 which mainly refers to a conceptual design, to MMI 600 which indicates that facility management data is included to that discipline.

Until today twelve sets of MMI definitions which are namely: Piping, Structural, Instrumentation, HVAC, Equipment, Civil, Electrical, Fire Protection, Layout, Foundations, Buildings, and P&IDs, have been established by CII. Each of these definitions is providing a clear set of modeling requirements for each MMI level in that discipline to fulfill. The MMI levels are calculated per discipline per location on the 3D model, and calculations are done by the Model Maturity Risk Index (MMRI) tool developed by CII [9].

While LOD levels are mainly related to the design detail on the model, MMI levels are related to the amount of the information in the model. In other words, both graphical and non-graphical information associated with the project is reflected with MMI levels. Another difference between LOD and MMI levels is, LOD is mainly related with details on the design of the model elements, while MMI levels are prepared for design disciplines in the project.

2.3 Model Maturity Risk Index (MMRI)

The Construction Industry Institute (CII) developed Model Maturity Risk Index (MMRI) tool that includes questionnaires for each discipline that they defined MMI definitions. By filling these tables for a specific location in the project, MMI levels per discipline in that specific location can be calculated. It also provides percentage of remaining work to achieve higher MMI level within the discipline in specific location too.

The questionnaires in the MMRI tool have inter-disciplinary relationships between the disciplines too. Mainly the questions on the tool are based on the information added to the model such as site plan, geotechnical investigation, design parameters, equipment data, clash detections, etc. The user of the tool needs to select appropriate answer from drop down menu which includes answers as Yes, No, Not applicable, Design Specified, Loaded, Confirmed, etc. for each question. Each of these answers would have connections with different MMI levels and also weights on MMI level calculation. As an example Foundation is a discipline which CII provided MMI definitions and MMRI table. The questionnaire for Foundation in the MMRI tool has questions about the size and location of the design components. While the answer of “preliminary design” to these questions has connection with MMI 100, the answer of “design specified” has connection with MMI 300.

The main usage area of the tool is expected to be a guide showing current maturity of the model and required modeling effort of specific disciplines in different locations on the project. The project team can have better communication in model reviewing meetings by filling the questionnaires, and obtaining current MMI levels of the specific modeling disciplines in different locations.

3 Tracking design progress of Track Lines in Mass Rapid Projects

Mass Rapid Transit (MRT) systems such as Light Rail Transit (LRT), Bus Rapid Transit (BRT), Subways, etc. are important for solving the traffic congestions and mobility of the people in the crowded cities. These MRT projects are generally considered as complex projects due to their size, engineering design and construction complexity, financial approach, contract type, and delivery method.

Although these projects can be considered as linear projects where there are many identical units that are repeated, the graphical details and engineering information added to the model would change location to location on the design file. According to the expert’s opinion from railway industry, it is hard to track design progress in MRT projects since design details and engineering information added to the models are not always similar all around the project. In other words, there would be locations such as stations or areas between stations, where the design model is close to the as-built version, while others locations are still in conceptual design phase.

In this research paper, new conceptual MMI definitions and an MMRI table is defined for the Track Line discipline on Mass Rapid Transit (MRT) projects. Although type of track lines is different in heavy rail and light rail systems, a generalized definition that can be applied on different type of track line systems will be created. However, in order to provide specific examples related with the MMI definitions and MMRI table, among different type of MRT projects, the main focus will be on Light Rail Transit (LRT) projects.

LRT projects are a subdivision of mass rapid transit systems and according to the American Public Transportation Association (APTA), the definition of LRT system is “an electric railway system characterized by its ability to operate single or multiple car trains along exclusive rights-of-way at ground level, on aerial structures, in subways or in streets, able to board and discharge passengers at station platforms or at street, track, or car-floor level and normally powered by overhead electrical wires”. According to the report published by International Association of Public Transport (UITP) in 2015, LRT and tramway systems are operated in 388 cities all around the world. Europe is the richest region in terms of the number of the LRT projects. A total of 206 cities in Europe had LRT or Tramway system in-service. Eurasia follows Europe with 93 cities having LRTs [10].

Track lines on LRT projects would be different than on other types of MRT projects’ track lines, since the main difference of the LRT projects is that the light rail vehicle (LRV) would have the ability of operation in mixed traffic on the street when it is necessary [11]. Therefore, track line types used in LRT projects are generally thinner and they can be used in mixed traffic conditions. In LRT projects, different type of tracks such as ballasted track, direct fixation track, embedded track, etc. are used [11]. Although there are many differences on design of these various track lines on MRT projects, generalized definitions for measuring design completeness of the track line discipline in different type of projects will be created.

3.1 Proposed MMI definitions for Track Line Discipline

Light Rail Transit (LRT) projects can be divided into many different disciplines. In this research, a model LRT project is divided into 14 disciplines which are namely Administration, Procurement, Quality Management, Earthwork, Track line, Structural, Operations/ Maintenance, Mechanical, HSE, Signaling, Civil, Electrical, Telecommunication, and Multidiscipline. Among these disciplines, Track Line discipline is selected for this research to establish new MMI definitions.

In order to create MMI definitions for Track Line disciple, currently available MII definitions provided by Construction Industry Institute is studied, literature on Track Line design is researched in detail, and main design components that can be used for tracking design is selected. The created conceptual MMI definitions for Track Line discipline can be seen on Table 1. This could be further disaggregated and used for each track line section.

Table 1 Conceptual Model Maturity Index Level Definition for Track Line Discipline

MMI Level	Definition
100	Generic model of the site plan, route, and topographic maps are created. Existing conditions have been quantified and graphically represented.
200	The preliminary geotechnical investigation report has been received. The engineering team decided type of tracks to be utilized. Track line components graphically modelled with preliminary size and configuration, as follows; - Site plan, topographic maps and surveys - Horizontal and Vertical layout design - The route of the project - Track components - Track ballast/bed design Design performance parameters, as defined by the project, are associated with model design components as graphic or non-graphic information.
300	The geotechnical investigation report has been received and confirmed. Project-specific layout specifications and track line specifications are attached to the related components. Track line components graphically modelled with design-specified size and configuration, as follows; - Site plan, topographic maps and surveys - Horizontal and Vertical layout design - The route of the project - Track components - Track ballast/bed design Project plans and permits have been submitted to AHJ (Authority Having Juristiction). The environmental and remediation requirements have been submitted to AHJ.
350	Track line components graphically modelled with confirmed size and configuration, as follows; - Site plan, topographic maps and geotechnical investigation - Horizontal and Vertical layout design - The route of the project - Track components - Track ballast/bed design Project plans and permits have been confirmed by AHJ The environmental and remediation requirements have been confirmed by AHJ.
400	Track line components graphically modelled with approved size and configuration, as follows; - Site plan, topographic maps and geotechnical investigation - Horizontal and Vertical layout design - The route of the project - Track components - Track ballast/bed design The IFC (Issued for Construction) drawing package and specifications have been submitted. Project plans and permits have been approved by AHJ.

	The environmental and remediation requirements have been approved by the AHJ.
500	As built: as build conditions are graphically represented in the model
600	FM-enabled: as-built models are supplied with Facility Management information as outlined by project scope

3.2 Proposed conceptual MMRI table for Track Line Discipline

Although Track Line related MMI definitions are at the conceptual phase, a conceptual MMRI table for the Track Line discipline is created to explain how design progress will be calculated with this method.

To create the MMRI table for the Track Line discipline, first the CII MMRI tool is reviewed in detail and seven main categories that would be used in Track Line design are selected among the existed tables. The selected categories are namely; Project data, Design components, Track supports, Routing, Specifications, Related Studies and Permits, and Submittals. Then, fourteen criteria according to the defined MMI level definitions are created under selected categories. In order to be consistent with existing MMRI tables, some of the defined criteria is selected from CII' MMRI tables, while some of them are defined after conducting a literature review and by seeking related experts' opinions on track line design. Developed conceptual MMRI table for Track Line discipline is presented on Table 2.

Applicability column will be added to the right end of the developed MMRI table with the options of "Not Applicable, Yes, No, Loaded, Confirmed, Design Specified, Approved, etc. In order to obtain MMI level of Track Line discipline for a specific location on the project, the applicability of each criterion on the Table 2 is required to be filled with these options for that specific location on the project.

In the MMRI tool developed by CII, these tables require manual entry, and each criterion in the table is connected to an MMI level definition. By these connections, after filling these tables for the project, it would show the MMI level result of that discipline in the specified location. In this research, created MMRI tables are filled with semi-automated assistance by using Building Information Modeling and Interface Management systems data per location. This paper is part of an ongoing research related with measuring engineering progress in complex capital projects by integrating Building Information Modeling and Interface Management Systems. According to the CII Interface Management Implementation Guide, an interface management system is defined as "the management of communications, relationships, and deliverables among two or more interface stakeholders" [12]. By integrating these two systems, some automated assistance to fill MMRI tables can be created. However, details of BIM and IM system integration and semi-automated assistance by using these systems will not be described in detail in this paper. As a general example; geotechnical investigation reports can be tracked over the IM system by checking interface agreements, and request for information system data between civil works and infrastructure stakeholders of the LRT project, since they would share that information with each other over these systems. Similarly, track line layout design related criterion or Track ballast/bed design related criterion can be answered by using LOD levels of the related elements on the BIM file.

Table 2 Conceptual MMRI table for Track Line Discipline

Categories	Code	Criteria
Project Data	C1	The geotechnical investigation is ______
	C2	The site plan, topographic maps and surveys are ___
	C3	Existing conditions have been quantified and graphically represented
Design Components	C4	Horizontal layout design is_
	C5	Vertical layout design is___
	C6	Model of track line components is created with approximate size, material, and location
	C7	Design performance parameters, as defined by the project, are associated with model design components as graphic or non-graphic information
Track supports	C8	Track ballast/bed design is_
Routing	C9	The routing of the track lines has achieved a status which is: _
Specifications	C10	Project-specific layout specifications are____ _
	C11	Project-specific track line specifications are
Related Studies and Permits	C12	Permitting requirements are
	C13	Environmental and remediation requirements are
Submittals	C14	The IFC (Issued for Construction) drawing package and specifications have been submitted

Similar with the CII MMRI tool, the proposed table for the Track Line discipline would provide a MMI level result for each specific section on the project after filling the applicability column. As an example; when the criterion "Existing conditions have been quantified and graphically represented" is filled with "Confirmed" while all others are only "Loaded", MMI level would be 100, but even though Project Data and Design Component related criteria are in the status of "Confirmed", while Track Support and Routing related criteria are in the status of "Loaded", MMI level would still be 200 for that area. In that case, when Track Support and Routing related criteria obtain the status of "design confirmed", then the result of the MMRI table for that specific area on the project would change to MMI 300.

An example filled MMRI table for the Track Line discipline in a hypothetical LRT project station area is presented on Table 3.

Table 3 An example filled MMRI table

Location: CNS Station		
Categories	Criteria Code	Applicability*
Project Data	C1	Confirmed
	C2	Confirmed
	C3	Confirmed
Design Components	C4	Design Specified
	C5	Design Specified
	C6	Design Specified
	C7	Design Specified
Track supports	C8	Loaded
Routing	C9	Loaded
Specifications	C10	Loaded
	C11	Loaded
Related Studies and Permits	C12	Loaded
	C13	Loaded
Submittals	C14	No
MMI Level		**200**

4 Conclusion and Future Work

In this paper, a conceptual framework for measuring design progress on Track Line discipline in Mass Rapid Projects is proposed. The proposed framework contains new Model Maturity Index definitions for the Track Line discipline and a related MMRI table to measure design progress. New MMI definitions and an MMRI table is developed by conducting a literature review on track line design and by seeking related experts' opinions.

An example filled MMRI table is also presented after explaining the proposed framework. Semi-automated assistance for populating the MMRI table using an interface management system integrated with a BIM is also described but is not the main focus of this paper. As future work, the calculation method behind the CII MMRI table will be investigated and applied to this research.

Optimisation of mixture properties for 3D printing of geopolymer concrete

A. Kashani[a] and T.D. Ngo[a]

[a]Department of Infrastructure Engineering, The University of Melbourne, Australia
E-mail: kashani.a@unimelb.edu.au, dtngo@unimelb.edu.au

ABSTRACT:

Freedom of design, customisation, automation, waste minimisation, reduced labour and building complex structures with cheaper materials are the main initiatives for developing 3D printed structures. The fresh properties of concrete are the most important aspects of a successful 3D printing. Concrete requires high workability for extrusion, optimum open time and high early strength in order to support the subsequent layers for 3D printing. Therefore, a mixture design that can satisfy these requirements is needed. Geopolymer concrete is a sustainable solution to traditional Portland cement-based concrete that uses waste materials. In addition, the controlled alkali-activation of geopolymer precursors in order to achieve optimum setting and workability compared to Portland cement provides freedom of mixture design for 3D printing. This paper will investigate the fresh properties of geopolymer mixtures in order to find an effective mixture that is compatible with 3D printing technology and can be also strong enough to stand as a structure. Rheology (workability), open time and compressive strength, as well as, printing parameters such as extrusion pressure and printhead speed was studied in order to achieve a successful geopolymer mixture for 3D printing.

3D Printing; Mixture Design; Geopolymer Concrete; Additive Manufacturing;

1 Introduction

Additive manufacturing technology (in particular 3D printing of concrete structures) has been introduced to the construction industry for more than a decade. However, 3D printed structures are still under-developed and there exist only a few successful trials which resulted in full-scale production.

Khoshnevis B. [1] developed the contour crafting (CC) technology for the automated construction of buildings and infrastructure on earth and other planets. CC is a similar technology to inkjet printing. This method uses high pressure in order to extrude the concrete through a large nozzle of the printhead attached to automatic cranes which move in XYZ directions. On the other hand, the D-shape method was developed by Enrico Dini. The D-shape printer consists of a stationary horizontal frame (the base) with four perpendicular beams at each corner. The printhead is attached to the beams and moves upward (vertical direction). The printhead has approximately 300 nozzles (20 mm apart) spanning the entire base and utilises a magnesium-based binder to fuse sand or stone dust particles in a process of additive manufacturing. A limited number of successful full-scale 3D printed structures got publicity worldwide namely, the 3D printed residential house in Amsterdam (2014) by Dus Architects and also the mass production of 3D printed houses in Shanghai by WinSun (2014).

The benefits of additive manufacturing are freedom of design, reduced labour, customisation, automation, waste minimisation, and building complex structures with cheaper materials. Despite these benefits, there exist few drawbacks that would require further research and development in order to adopt this technology to the next generation of the construction industry. Printing of subsequent layers of materials results in void formation between them thereby causing additional porosity during the manufacturing process. The void formation can reduce mechanical performance because of the reduction in adhesion between the printed layers. Anisotropic behaviour is also common in 3D printed structures. As the result, properties of material inside each printed layer is different compared to that of at the boundaries between layers or the mechanical properties in each direction is different (affected by the orientation of the printed layers). The layer-by-layer appearance of the sides of 3D printed concrete (opposite to the flat sides of casted concrete) is another challenge owned by the nature of additive manufacturing. These challenges need to be addressed by new materials and machine design.

The fresh properties of concrete are the most important aspects of successful 3D printing of concrete. The possibility of aforementioned challenges can be reduced by controlling these properties. Not only the printability of the mixture is determined by fresh properties of concrete but it also substantially affects mechanical properties of concrete after setting [2]. Rheology of the mixture determines the workability and extrude-ability of the concrete for smooth printing of layers with good shape-stability, less void formation and reduced chance of blockage of the nozzle. The rheological behaviour of concentrated suspensions (e.g. concrete) changes versus time and is of great importance for a hassle-free printing [3]. Even minor changes in rheological behaviour during the time-span of printing can potentially affect the properties of the 3D printed structure. Another important fresh properties of concrete for 3D printing is open-time. There exist an optimum time for the printed layer to get initial strength in order to hold subsequent layers but still wet so the layers can fuse together before final setting. The open-time is related to the initial setting time of the concrete. A sufficient open time is required to support subsequent layers [4]. A well-designed concrete mixture needs to satisfy the requirement of controlled rheology, optimum open-time and suitable strength for a successful 3D-printed structure.

2 Background

A limited number of studies on the effect of the mixture design on fresh properties of 3D printed concrete has been carried out, which are briefly discussed.

Gosselin C. et al [5] developed a printing process method which controls the rheology of the mortar for a longer time-span without a reduction in early strength. This method pumps the accelerator and the premix mortar from two separate reservoirs via separate tubes and then combines it at the printhead before the extrusion. As the result, rheological behaviour before extrusion slowly changes (because of no accelerating admixtures in the mortar reservoir) but after the addition of the admixture at the tip of the nozzle, the mixture can set quickly and get a higher early strength to hold subsequent layers. The reduced open-time results in faster printing and higher buildability. Paul S.C. et al [2] investigated different concrete mixtures and found that the rheological properties of concrete mixtures, especially thixotropic behaviour (changes in the rheological behaviour versus time), is an influencing factor for pumping and printing.

Zareiyan B. and Khoshnevis B. [6] suggested the smaller maximum aggregate size and higher cement to aggregate content which results in higher strength and better interlayer adhesion. The increased thickness of the layers with more time lapse between subsequent layers increased the adhesion between layers but decreased the compressive strength of the printed structure. A shorter setting time is also shown to increase the possibility of cold joints between layers [6]. Kazemian A. et al [7] showed that the addition of silica fume and nano-clay can remarkably increase the shape-stability (the stability of the printed layers against settlement and deformation caused by printing of the subsequent layers) of 3D printed cement paste.

2.1 3D printing of geopolymer concrete

Geopolymer (or alkali-activated materials) is a concrete-like binder with approximately 80-90% less associated CO_2 emissions and mechanical, durability and thermal properties comparable with or exceeding those of normal concrete made of Portland cement [8, 9]. Geopolymer is made in a process of alkali activation of aluminosilicate-based materials (precursors) such as blast furnace slag, fly ash, silica fume or metakaolin [10]. The fresh properties (as well as mechanical properties) of geopolymer concrete greatly change based on the mixture design selected from a variety of precursors, activators, different ratios between them and water to solids (w/s) ratio [11-13]. The limitless mixture design of geopolymer with vastly different fresh properties compared to that of Portland cement (the common binder of normal concrete) introduces more possibilities to design a suitable mixture for 3D printing.

Xia M. and Sanjayan J. [14] investigated geopolymer 3D printing based on a powder-bed method which consists of ground blast furnace slag, sand and ground anhydrous sodium silicate (alkali activator). The liquid binder in order to fuse the powders based on a 3D pattern was water with a small amount of 2-Pyrrolidone. The printed cubes had a considerably low strength of 0.9 MPa with the dimensional expansion of less than 4%. Post-treatment of the samples at a higher temperature (60^oC) in an alkali solution substantially increased the strength up to 16.5 MPa showing a great extent of unreacted powders after printing and before the heat-treatment.

This study looks into finding a suitable mixture design for 3D printing of geopolymer paste by an inkjet method similar to contour crafting (smaller scale). Fresh properties of the paste i.e. rheology and open-time, as well as strength, are the key experimental factors in order to find an optimum mixture design of the precursors, activators and w/s ratio. Finally, required pumping pressure and printing speed necessary for successful 3D printing was studied.

3 Materials and methods

3.1 Materials and mixture design

A mixture of ground granulated blast furnace slag (hereinafter slag) from Australian Builders, fly ash from Cement Australia and silica fume from Redox was used as geopolymer precursors. The chemical composition of the precursors are displayed in Table 1 (determined by X-ray fluorescence (XRF) analysis and excluding loss on ignition). The ratios of slag: fly ash: silica fume were 3:1:0.5 based on the preliminary results of fresh properties and strength of different mixtures of the geopolymer precursors tested in the laboratory.

Table 1. Chemical composition of the precursors determined by X-ray fluorescence (XRF)

	Fly ash	Slag	Silica fume
Na_2O	0.81	1.51	0.00
MgO	1.27	5.56	0.00
Al_2O_3	25.13	14.01	0.00
SiO_2	42.09	32.83	96.85
P_2O_5	1.10	0.07	0.00
SO_3	0.41	2.28	3.15
K_2O	0.41	0.35	0.00
CaO	13.56	41.90	0.00
TiO_2	1.44	0.53	0.00
MnO	0.18	0.22	0.00
Fe_2O_3	13.16	0.50	0.00
Total	100.00	100.00	100.00

Sodium meta-silicate powder (SiO_2: 50 wt.%, Na_2O: 46 wt.% and water: 4 wt.%) was used as the activator. Sodium silicate is a corrosive material and needs to be used carefully. However, there is no negative impact on the environment by using this activator. Two ratios of 8 and 10 weight % of the activator per total mass of precursors and three water to solids (w/s) ratios i.e. 0.31, 0.33 and 0.35 were used as variables. In total, 6 samples were tested for rheological behaviour, open-time (initial setting time) and compressive strength. The codes of these samples are shown in Table 2. The optimum mixture based on the fresh properties and strength results was used for 3D printing where optimised printing speed and pumping pressure was trialled.

Table 1. Samples codes of the six geopolymer mixtures

Activator per solid wt. %	w/s ratio		
	0.31	0.33	0.35
8%	G8-31	G8-33	G8-35
10%	G10-31	G10-33	G10-35

3.2 Test methods

3.2.1 Rheology

A Haake Rheometer (Viscotester 550) was used to measure the yield stress of the different mixtures. The paste was mixed for 5 minutes using a plenary Hobart mixer and poured into a cylindrical plastic container (d: 50 mm and h: 150 mm). The vane H with four perpendicular blades (width: 5mm and height: 25 mm) was inserted into the paste until the blades were entirely submerged. After 60 seconds resting in order to dissipate any accumulated stress after the insertion of the vane into the paste. The rotation rate of 0.2 rpm was applied until the maximum torque was recorded. The measurement was repeated three times and the paste was hand-mixed (to avoid settlement of particles) and rested before each measurement. The maximum torque was converted to yield stress based on the geometry of the vane H corresponding to the methodology used in previous works [15, 16]. The average of three measurements was reported. Yield stress versus time at an interval of 15 minutes up to 45 minutes was measured for each mixture in order to understand the rheological behaviour of the mixtures as time passes.

3.2.2 Initial setting time

The Vicat needle was used to conduct the initial setting time test of the samples and was related to the open-time. The test was conducted according to ASTM C191-13. The fresh sample was penetrated by the Vicat needle and the penetration depth was recorded versus time. The penetration readings were done at 15 minutes intervals. The approximated initial setting time was recorded when a penetration of less than 25 mm was achieved. The penetration was repeated for each mixture three times (freshly made each time). The average of three measurements was reported.

3.2.3 Compressive Strength

Compressive strength was measured using a Technotest compression testing instrument with a loading rate of 1 N/(mm^2.s). The paste was mixed for 5 minutes using a plenary Hobart mixer and poured into a 50 mm cubic moulds, sealed with a plastic bag, cured at around 25^{o}C for 21 days and then were tested. Two parallel surfaces of the samples were smoothed using a sandpaper before applying the load. The maximum load before failure was divided by the surface area under load in order to calculate the compressive strength. Five samples were tested; the compressive strength results were averaged and reported.

3.2.4 3D printer

A 3D-Bioplotter inkjet printer from envisionTEC was used for printing of the geopolymer paste on a small scale. A nozzle with an internal diameter of 1.65 mm was used. The paste was mixed for 5 minutes using a plenary Hobart mixer and poured into special plastic syringes. A controlled pneumatic pressure at the back of the syringe is used by this printer to extrude the materials from the nozzle. Horizontal speed of the head of the printer is also controllable. A combination of horizontal speed, pressure and nozzle size (in addition to the rheology of the mixture) determine the thickness of the printed layer. A 50×50 mm rectangular hollow column was designed by Solidworks and used as the input CAD file for 3D printing. The thickness of wall was 3.5 mm or approximately twice the diameter of the nozzle (in order to accommodate to layers side-by-side).

Figure 1. The inkjet 3D printer used in this study to print geopolymer

4 Results and discussion

4.1 Rheology of the geopolymer mixtures

Unlike Portland cement, the rheological behaviour of the alkali-activated materials (geopolymer) is less well known. This is due to the complexity of the chemical environment and reactions taking place, in addition to different physical properties of the main precursors. For example, an alkali silicate-activated slag has an extremely complicated solution environment with high ionic strength and alkalinity, which is a very challenging environment in understanding rheological behaviour [11]. On the other hand, rheology modifiers such as common superplasticizers (that improves workability without increasing w/s) in Portland-cement based materials underperform in geopolymers [17]. Despite the recent aims for designing a suitable superplasticizer for geopolymer concrete [18], those superplasticizers having a minor effect on the rheology of geopolymers compared to that of Portland cement-based systems.

Internal forces between particles in a concentrated suspension of geopolymer are, namely, short-range repulsion forces, normal and shear stresses, fluid pressure, electric double layer forces, inertial and hydrodynamic effects and sedimentation [19]. The balance of these forces determines the yield stress (as one of the main rheological parameters of the fluid). The relationship between concrete slump (a common workability test in the construction industry) is complicated but normally higher slump height (higher fluidity) corresponds to lower yield stress [20]. Better pump-ability and easier flow which is essential for extrusion require lower yield stress and viscosity. However, a very low yield stress material does not hold its shape after extrusion which results in collapsing and self-levelling (not desired in 3D printing). Therefore, an optimum yield stress which allows easier flow of geopolymer for extrusion during 3D printing but at the same time avoid self-levelling and collapsing of the printed layer of concrete (which also needs to support successive layers of concrete) is required.

Figure 2 shows yield stress of the six samples of geopolymers for 3D printing. The effects of the w/s ratio and the wt.% of the activator are shown for the mixture of solid precursors used in this study.

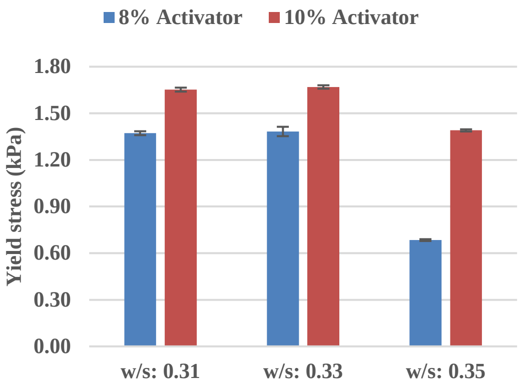

Figure 2. Yield stress of the geopolymer mixtures at different wt.% of activator and w/s ratios

The higher w/s ratio results in an excess water which is no longer used to fill the voids and therefore covers the surface of particles and separates them. The separation of particles by the excess water results in a reduction of bonding forces between particles hence it reduces the yield stress. The substantial reduction as the result of increasing w/s ratio from 0.31 to 0.35 for the sample with 8 wt. % activator is clear in Figure 2. The increase of water from w/s of 0.31 to 0.33 did not change the yield stress. The reason is possibly because of the fact that the amount of excess water for both w/s ratios are negligible in order to facilitate the particle movement and reduce the yield stress. In another word, the sample with w/s of 0.31 is very dry (unsaturated with water) and needs a substantial amount of water before any changes in rheological behaviour takes place.

The addition of alkali activator provides a higher pH and different electrolyte environment in the fresh binder paste (compared to Portland cement-based binders), causing differences in the surface chemistry of particles and their interactions. For instance, the dissolution of slag particles at higher pH (provided by the higher amount of alkali activator) can affect the size of the slag particles and their packing thereby affecting the amount of excess water [11]. Besides the fact that high concentration of ions in the fluid between particles may also cause flocculation of particles thereby increasing the force between particles and yield stress.

In general, an increase in activator dosage results in faster reaction and a higher rate of yield stress increase as previously shown in [11] and also in this study (Table 3). Yield stress can depend on time and shear history which is known as thixotropy. The alkali reaction as time passes affect inter-particle forces via the formation of new chemical or physical bonds between the particles. It also can increase the volume fraction of solids in the fluid as some of the water molecules becomes chemically bound to the solids during the reaction. Therefore, water consumption during the reaction process of geopolymer reduces the amount of excess water which is necessary to disperse slag aggregates. As the results, yield stress increases as time passes.

Table 3. Yield stress (kPa) vs. time of the geopolymer samples (values above 2 kPa shows the sample is semi-hard and yield stress is not measurable)

Sample codes	t=0 min	t=15 min	t=30 min	t=45 min
G8-31	1.37	>2 (hard)	-	-
G8-33	1.38	1.68	1.95	>2 (hard)
G8-35	0.68	1.37	1.76	1.98
G10-31	1.65	>2 (hard)	-	-
G10-33	1.67	2.00	>2 (hard)	-
G10-35	1.39	1.48	1.76	>2 (hard)

The higher amount of water and lower amount activator slows down the yield stress increase by reducing the pH and diluting the system. The only system that can be workable for an extended period of time of 1 hour is the sample with the lowest amount of activator and highest w/s among the samples (G8-35). This sample also has the lowest initial yield stress which was good for extrusion but not suitable for shape-stability after the extrusion. The next options which have prolonged workability (up to 45 minutes) but higher initial yield stress for better shape-stability are G8-33 and G10-35. The required pumping pressure is directly affected by the yield stress of the sample, thereby if the yield stress changes quickly, the pressure also needs to be adapted for homogenous printing. Therefore, minimum changes in yield stress vs. time-span of printing is desired,

4.2 Open-time of the geopolymer mixtures

The suitable time-span to print the subsequent layer of concrete is considered as open-time which is directly affected by the initial setting time of concrete. An optimum open-time is required for the printed layer in order to quickly get a minimum strength to support subsequent layers but long enough so the printed layer is still wet and the subsequent layer can fuse into the previous layer. The printed geopolymer transitions from a fluid material to a semi-solid and then a solid material because of the reaction of the precursors and the activator.

The initial setting time of the geopolymer mixtures with different ratios of water and activator to solid precursors are shown in Figure 3. It can be seen that higher wt.% of the activator (10%) results in considerably lower setting time because of a faster reaction, higher pH and a higher rate of dissolution of particles. Also, a higher w/s ratio causes prolonged setting time by lowering the pH, the rate of dissolution and reaction. The initial setting time can be as low as about 35 minutes for G10-31 up to 230 minutes for G8-35. As mentioned, very short setting time (open-time) although is a sign of getting strength quickly to support the subsequent layers, it can result in less adhesion (fusion) between layers and most importantly the mixture can lose workability for printing very quickly.

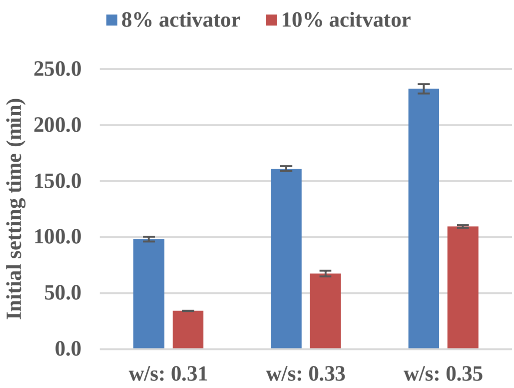

Figure 3. Initial setting time of the mixtures at different wt.% of activator and w/s ratios

The lower setting time can also increase the chance of the blocking the pipes or hardening the sample inside the reservoir. Table 3 shows that G10-31 with an initial setting time of about 35 minutes, is only print-able for less than 15 minutes and after that, yield stress increased and the paste is almost not pump-able (extrude-able). On the other hand, very long setting time (e.g. G8-35) can result in less strength which may not hold the subsequent layers resulting in deformation of bottom layers because of the mass of top layers (inferior shape-stability). It must be noted that sometimes initial yield stress is enough to support a limited number of subsequent layers so then prolonged setting time (slower reaction) would not be problematic (even beneficial for homogeneity of printing) in this case.

It must be noted the reaction also affect the fluidity and extrude-ability of the mixture because the rheological properties are also changing vs. time (Table 3). Reduction in changes of yield stress vs. time is required for homogeneity of printing. However, the samples with lower yield stress changes vs. time showed higher initial setting time (comparing Figure 3 and Table 3). Therefore, a combination of open-time, initial yield stress and changes of rheology vs, time is important to find a suitable geopolymer mixture for 3D printing. And sometimes one property needs to be sacrificed for the other based on prioritising the requirement for printing that can be a better homogeneity, higher number of layers (improved build-ability), easier extortion (better workability) and etc.

4.3 Compressive strength of the geopolymer mixtures

Apart from the fresh properties of the geopolymer mixtures for successful printing, the mechanical properties such as compressive strength must be sufficient enough for a structure. Figure 4 shows the 21-day compressive strength of the geopolymer mixtures with different amount of activator and water to solid ratios.

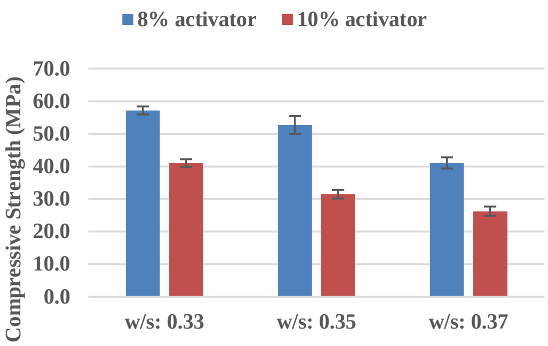

Figure 4. Compressive strength of the geopolymer mixtures at different wt.% of activator and w/s ratios at 21 days

The samples with a lower percentage of the activator (8 wt.%) showed higher strength compared to the samples with 10 wt.% of the activator. Lower alkalinity drive formation of a particular geopolymer gel which increases the mechanical performance [8]. Also, higher w/s normally results in a lower strength of geopolymers as shown in Figure 4.

It must be noted that the samples with 10 wt.% of the activator, despite having faster reaction evidenced by lower initial setting time and faster changes in workability (higher rate of increased yield stress vs. time), showed lower compressive strength. Therefore, 8 wt.% of activator seems a better option for 3D printing considering all these factors.

4.4 3D printing of the geopolymer mixture

Considering, three factors of rheological behaviour, open-time and compressive strength, the samples with 8 wt.% of the activator showed higher strength, increased open-time and reduced change of yield stress vs. time compared to the sample with 10 wt.% of activator. Among the samples with 8wt.% of the activator, G8-3, the yield tress changes increased rapidly (Table 3) and after 15 minutes the workability massively dropped. Therefore, the other two mixtures with higher w/s which are G8-33 and G8-35 are considered for 3D printing.

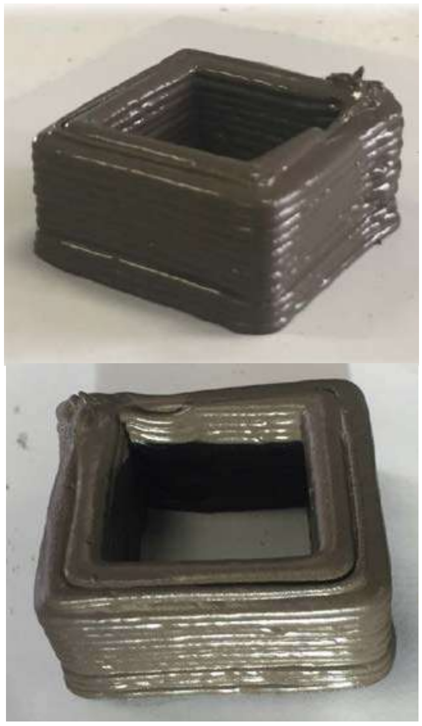

Figure 5. The 3D printed sample of the G8-33 geopolymer mixture (dimensions: 50×50×30 mm)

For G8-35, the printed geopolymer, after extrusion from the nozzle, showed insufficient shape-stability (the printed filaments collapsed and started to spread). This is because of the considerably lower yield stress of this sample as shown in Figure 2. The deformation was significant after printing of the third layer. Therefore, it is concluded that yield stress of around 0.7 kPa for this sample was insufficient for self-supporting of the printed layers. On the other hand, printing of G8-33 was successful as shown in Figure 5 (12 layers and each wall has two filaments printed side-by-side).

Apart from an optimum mixture design, a proper extrusion by the 3D printer is also essential to get the desired quality. Two critical parameters (pumping pressure and printhead speed) considerably affect the printing quality. Pressure is important to ensure an extrusion of a continuous filament from the nozzle. Higher pressure can also push the previously printed layers and affect the shape-stability of the object. The speed of the printhead also determines the time gap between printing of successive layers. Higher speed also may results in discontinuation of the filament (skipping) while printing (which results in air gaps) and it adversely affects shape-stability of concrete (quickly printed layer on top of each other provides a short time span for concrete to set and self-support the structure). Therefore, a combination of speed and pressure in addition of the size of the nozzle determines the thickness of each printed filament; lower speed and higher pressure cause thicker filaments (because the extruded volume of the paste exceeds the volume of material required for a specific length) and vice versa.

The optimum pressure for printing of G8-33 is around 70 to 90 kPa (about 60 times higher than the yield stress of the material) and the optimum speed for this pressure is around 25 mm/s (printing of each layer takes approximately 20 s). The printing of the sample in Figure 5 takes about 4 minutes which is considerably smaller time period compared to the setting time of this mixture. The reservoir capacity of the printer was limited so printing of a larger sample was not possible in one load (reloading takes a considerable amount of time which can affect the quality and homogeneity of the printed object).

The shape-stability of the sample was very good as shown in Figure 6 and except the first layer (because of the uneven substrate), the thickness of other layers are similar with negligible deformation after printing of the successive layers. As the result of the negligible changes in yield stress of the material in the short time period of printing, it can be concluded that the initial yield stress of G8-33 (i.e. ~1.4 kPa) was enough for self-supporting of the number of printed layers. The average thickness of each layer is 2.5±0.2 mm (i.e. approximately 1.5 times larger than the internal nozzle diameter). The thickness of the layer can be controlled by the extrusion pressure and speed of the printhead as well as nozzle diameter. Also, the fusion of the layers seems excellent and no air-gaps between layers is recognizable (Figure 6).

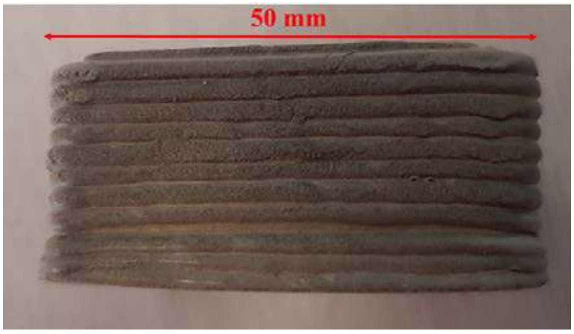

Figure 6. A side view of the 3D printed sample of the G8-33 geopolymer mixture

5 Conclusions

The material properties of a few geopolymer mixtures for 3D printing was studied. Rheology (workability), open-time and compressive strength as well printing parameters such as pumping (extrusion) pressure and printhead speed were studied in order to achieve a successful geopolymer mixture for 3D printing.

In particular, the effect of percentage of the activator and water to solid ratio was studied. The optimised mixture has 8 wt.% of the activator and water to solids ratio of 0.33. Consistent filaments of this mixture were successfully printed through a 1.65 mm diameter nozzle with negligible deformation after printing because of higher initial yield stress and minor changes in yield stress versus time for this mixture. The open-time (setting time) was also high enough to get an excellent fusion (adhesion) between the layers. The compressive strength of the sample was around 50 MPa at 21 days. The optimum extrusion pressure and the printhead speed for the optimised mixture were found to be around 70-90 kPa and 25 mm/s, respectively. However, long-term durability and load-bearing capacity such as the development of internal stresses (which can result in cracking) needs to be investigated in the future studies.

Abstract -
Automation of construction is urgent needs for improving efficiency of works, reducing the number of personnel, and working in extreme environments such as other planet or moon or disaster-stricken area. However, the current situation is still insufficient due to reasons of such complexity of work and high risk especially at building sites. In terms of heavy machinery in building construction, it is indispensable to measure its own position and attitude because their precision directly relates to construction accuracy. If lifting and delivering works can be unmanned or teleoperated, it is expected to drastically reduce the number of personnel and improve efficiency. In this research, we have found that a mating connection mechanism can aid teleoperating construction. This mechanism works without any fastener, that is utilized in the construction of the temporary cover of Fukushima Daiichi nuclear power plant unit 1, with RTK/GNSS (Real Time Kinematic, Global Navigation Satellite System) positioning systems is possible to realize the teleoperating construction. By conducting confirmatory experiment of positioning system using a tower crane, we have confirmed the normal operation of all systems. In terms of position and azimuth angle, the accuracy is sufficient to meet requirements for building construction with the mating connection mechanism. Regarding ICP matching by LIDAR (Laser Imaging Detection and Ranging), it was confirmed to be possible to compute the altitude angle with extremely high accuracy utilizing point cloud information from the LIDAR and CAD data using the ICP (Iterative Closest Point) matching library. Detailed preliminary unmanned building construction concept and some results are shown in this paper.

1 Introduction

In recent years, automation of construction is urgently required with aims of improving efficiency of works, reducing the number of personnel, and working in extreme environments such as other planet/moon[1, 2] (Fig. 1) or disaster-stricken area. However, the current situation has not progressed rapidly due to reasons of such complexity of work and high risk especially in building sites. Automation of construction works by an unmanned system requires precise positioning method of the self and the target, object recognition and shape recognition system, precise and high speed control, etc. Among them, obtaining detailed position information of the moving object is the most important technique. In terms of heavy machinery such as a crane lifter in particular, it is indispensable to measure its own position and attitude, and their precision directly relates to construction accuracy. If lifting and delivering works can be unmanned or teleoperated, it is expected to dramatically reduce the number of personnel, positioning work of structures, changing work of materials, scheduling lifting plan of cranes, etc. Furthermore, smooth collaboration of information with design, construction control and building management will be achieved. A certain degree of positioning error can be tolerated with our mating connection mechanism (Fig.2).

Figure 1. Concept of Lunar Base Construction (Shimizu Corporation)

Several applications of GNSS/RTK in the field of civil engineering have been reported, however, in the building field, there has been little effort so far due to the high accuracies of the position and attitude are required. In this research, we have investigated whether GNSS/RTK receiver can satisfy the requirement by using single frequency receivers, although "fix"(high-accuracy) solution of a single frequency receiver is difficult to always maintain, a problem in which an attitude angle can not be detected, and two or more frequencies receivers are expensive relatively, and so on. At the same time, redundancy performances of IMU and LIDAR have been investigated as alternate methods.

2 Method

2.1 Unmanned Construction in Extreme Environments

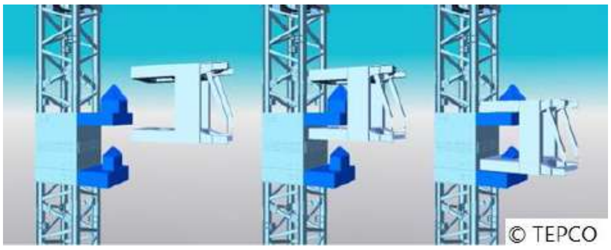

Figure 2. Mating Connection Mechanism

Concerning unmanned construction method, we have experienced and accumulated the engineering techniques in building the temporary cover over the damaged reactor building unit 1 of Fukushima Daiichi nuclear power plant by the teleoperating construction system in high radioactive environment (Fig. 3). All works are conducted with remote control using multiple sensors, cameras, and a crane. It is inevitable that the crane and a lifted object have positional errors, then a tolerate technique is required for safe and reliable jointing. We adopted a mating connection mechanism without any fastener or welding work shown in Fig. 2 that is composed of square holes and quadrangular pyramids. The mechanism is able to tolerate the position and attitude errors of their determination and control by passive adjustment, therefore, fundamentally we adopt the mating connection mechanism positively in this research for building at extreme environments.

Figure 3. Temporary Cover over the Damaged Reactor Building of Unit 1

Concerning the navigation, in these days, low-cost GNSS receiver, single frequency RTK and IMU (Inertial Measurement Unit) are available with ease, and the performance of LIDAR is further improved. Especially global navigation satellites can be seen at least 10 (maximum about 40) in real-time (GPS (United States), GLONASS (Russia), Galileo (Europe), Beidou (China), and QZSS (Japan)). Comparing to other navigation method (single, differential, static, etc.), RTK has advantages of instantaneity and accuracy, although two receivers (base and rover) are required. Thus, lots of GNSS receivers are introduced, distributed, and integrated in our system that can manage highly accurate position and velocity (3-axis) / attitude angle and angular velocity (3-axis) of heavy machinery and lifted objects. Although GNSS is not available on other planets or on the moon, a relative navigation system can be established by another method (e.g. radio navigation, indoor messaging system, pseudolite, total station), and their accuracies are equivalent performances to GNSS. The positioning system is designed as dual-use for uncertain/extreme environments and general building construction site on the earth (Fig. 4) for the reasons stated above, it can also contribute to productivity enhancement.

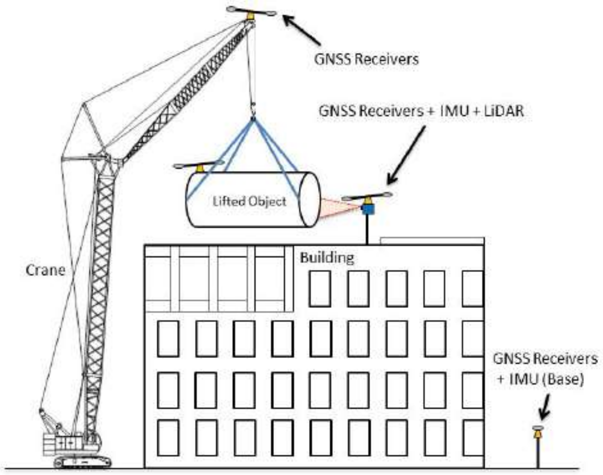

Figure 4. Concept of Unmanned Building Construction

Moreover, we conduct experiments with actual machines with the aim of realizing a production site that can operate construction robots, heavy machinery and general machinery all at once by collaborating with BIM (Building Information Modeling).

2.2 RTK-GNSS Navigation System

2.2.1 Concept

In order to acquire the position and orientation of a crane and a lifted object, the system shown in Fig. 5 was developed. For the purpose of obtaining yaw angle at each position, one pair of GNSS receivers (u-blox NEO-M8T) and antennas (Tallysman TW2710) are located. Since the error of the altitude information is relatively large compared to horizontal position, it also has a barometer (MS5611), which is integrated with a signal from the IMU (AU7554) and transmitted via wired/wireless Ethernet to a microcomputer. Accurate position data is output by analyzing the GNSS signal by the library "RTKLIB" which

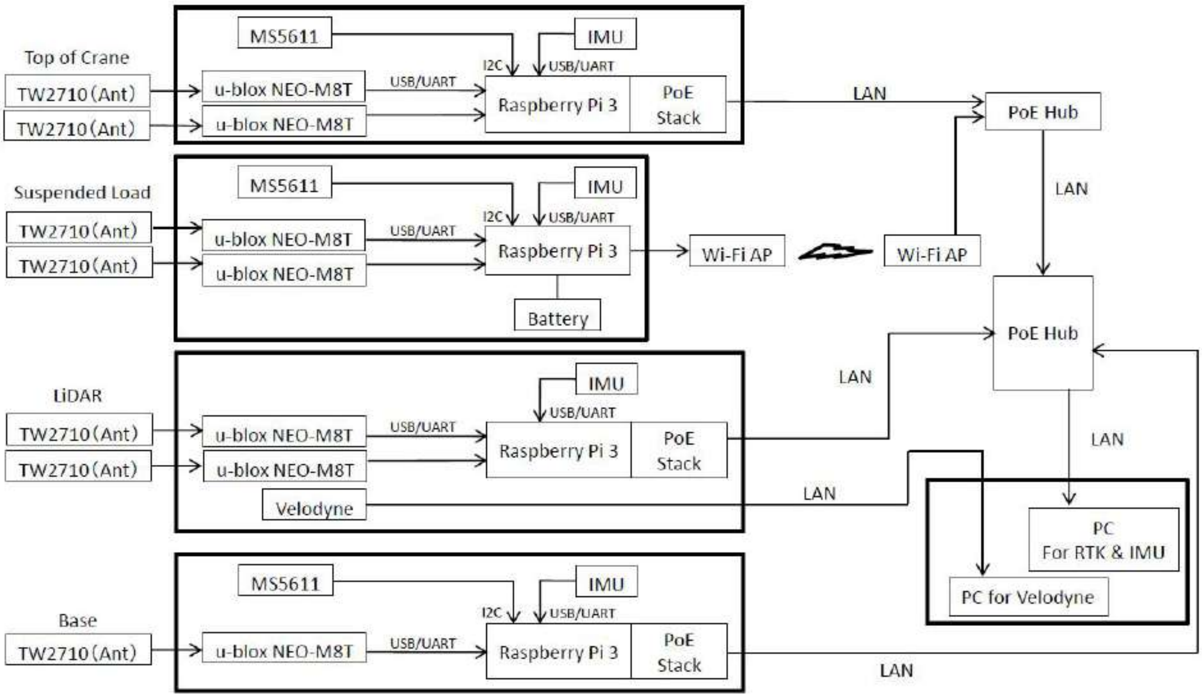

Figure 5. System Diagram

is developed by Takasu[3, 4]. By conducting Loosely-Coupled integration[5, 6, 7] using IMU and barometer signals, appropriate extrapolation is tried to be performed even when RTK solution falls into "float" (low-accuracy solution) using extended Kalman filtering[8, 9, 10] with white noise assumption, or smoothing technique. Internal clocks of microcomputers (Raspberry Pi 3) are synchronized by each time acquired from GNSS, then it can be compensated using the time in integrating multiple sensors.

2.3 System Setup

We developed a measurement system module shown in Fig. 6-7 that is composed of instruments listed up in table 1. PoE (Power on Ethernet) is introduced for power supply of the almost all systems because of the difficulty in accessing the top of the crane for battery charging frequently. However, lifted object is accessible with ease and has the risk of disconnection of wired instrument, batteries and WiFi access point are also attached to it. All electrical systems are in a waterproof-dustproof box, and external antennas are also waterproof. GNSS antennas are attached on wide aluminum plates, and located at 1.5 m height due to prevent the effects of multipath signal on the ground.

In addition, point cloud information from LIDAR is matched by ICP algorithm[11] using the CAD shape data that is stored in the database, thus the attitude angle of the

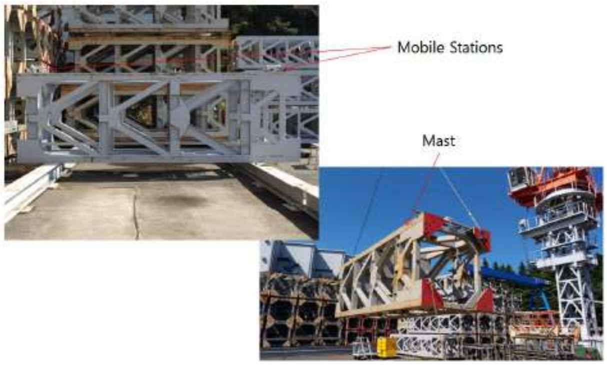

Figure 8. Experimental Site

lifted object is calculated. By adopting the above method, it becomes possible to have redundancy without relying on RTK-only information only.

3 Results

In order to confirm the accuracy of RTK at the building construction site, IMU integration, and the possibility of position and attitude detection by LIDAR, demonstration experiments by lifting was carried out at a facility where a tower crane is permanently installed. The GNSS receiver was installed on several fixed points and lifted object on the ground, and the LIDAR was installed so as to be fixed to the GNSS module and face the direction of the lifted object. Four GNSS antennas are placed at the four corners of lifted object to calculate the azimuth or attitude (Fig. 8). LIDAR is placed in a position where the approach and separation are repeated to see how the difference in point cloud density affects. For the purpose of confirming calculation accuracy of state, a series of operations of lifting the object were repeated 5 round trips by hoisting motion (about 1 m in height), horizontal motion (about 15 m) by slewing, and grounding by hoisting motion. Furthermore, in order to confirm the influence of multipath of RTK/GNSS, it was repeated to move from the place where the stock is accumulated to the open place.

Figure 9 shows the solutions of antenna positions on the lifted object. "1L" or "2R" in the legend means left and right antenna of each measurement system 1 and 2. The average number of satellites used for calculation was about 17. According to preliminary experiments, it is known that the "fix" (high-accuracy solution) rate is highest when 30 deg of masking elevation angle of satellite and 30 dB of masking SN ratio of GNSS signal was applied. In figure 10, the blue line and the green line represent the fix solution and the float solution respectively. Occasionally the position sometimes deviated greatly, then Kalman filter was applied to correct it, however, it did not work well because the slewing speed at the time of the experiment was too slow. Nonetheless, some degree of accuracy is maintained even with a "float" solution, and overall it was within 5.0 cm, which is a general RTK/GNSS error.

Regarding ICP matching by LIDAR, we adopted a method to compare the point cloud obtained by Velocyne LIDAR[12] and the 3D CAD model of the lifted object as shown in figure 11. Although it has symmetry in the rotation in the long axis direction, it seems that there is no problem because the introduced method has high initial value dependency and that the lifted object basically performs only yaw rotation. The CAD model is transformed into point clouds, and the result of executing matching using the ICP library[11] is shown in figure12.

The coordinate system is the LIDAR-referenced, and relative positions and orientations are calculated by fitting a point cloud model in the database to the measured point cloud. Differences of position and attitude estimation by GNSS-RTK were within 0.1 deg and 1.0 cm under optimal condition. However, there were some cases of matching failure, for instance, when the point cloud was not sufficiently obtained. In addition, since one calculation

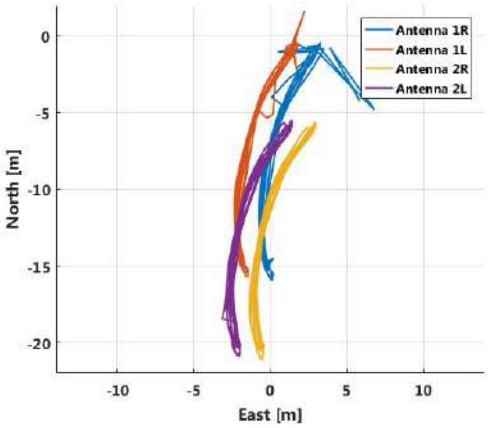

Figure 9. Position Results

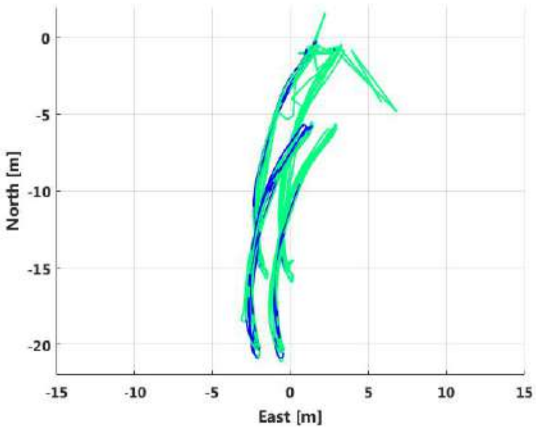

Figure 10. Position Accuracy

time was about 1 second on a typical personal computer, it seems that real-time processing at 1 Hz is also possible. Since there is a problem that LIDAR also detects surrounding objects, recognition and extraction functions will become necessary in the future. Figure 13 shows the distance between the antennas installed on the lifted object calculated from the result of RTK/GNSS position. The correct distance is 1.5 m, and although a slight deviation is observed in "float" solution, the error is kept within 3.0 cm. Based on the above results, we calculated the azimuth angle (Fig. 14). The longer the distance between the antennas, the more stable the azimuth can be calculated. It can be calculated with an accuracy of about 1.0 deg even if the distance is 1.5 m, so it was found that it can be used as an alternative way to a magnetometer.

4 Conclusion

We designed and fabricated a position and attitude determination system for lifted objects for the sake of unmanned construction, and confirmed its usefulness by carrying out the experiments in situations that is similar to

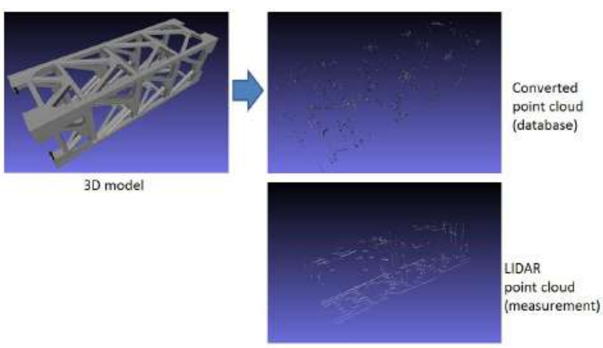

Figure 11. Pointcloud Comparison

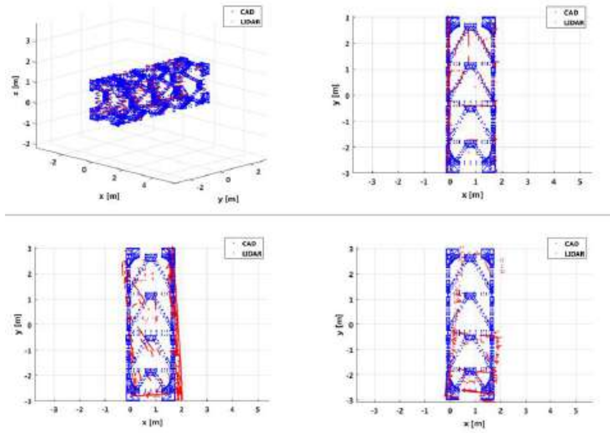

Figure 12. ICP Results

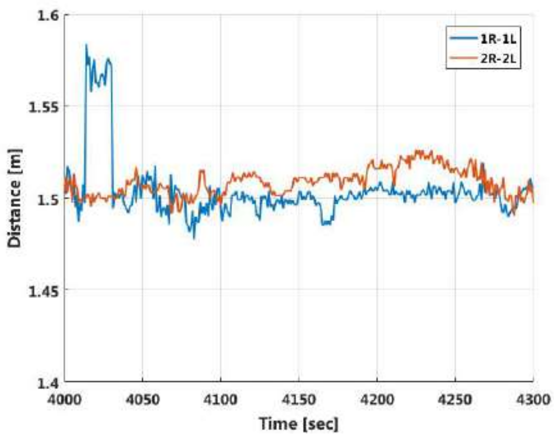

Figure 13. Distance between Antennas

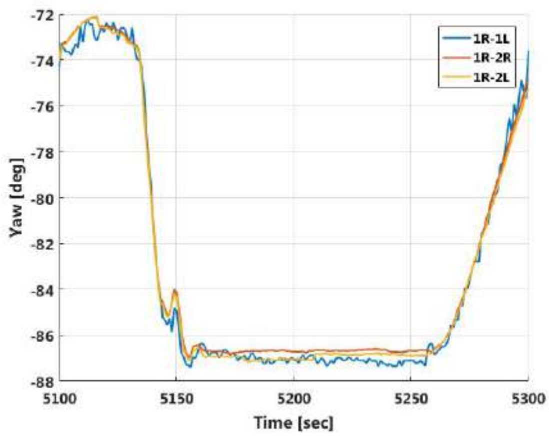

Figure 14. Azimuth Results

actual building construction sites. There was concern that the satellite radio wave environment deteriorated due to surrounding cranes and metal structures, nevertheless the calculation of the position was within the general accuracy of RTK/GNSS without using any optimal filtering. Therefore, it was confirmed that the system would be able to perform remote control using our mating connection mechanism.

ICP matching using point cloud information also succeeded and it was found that there was a possibility that it could be used as a redundant means, however issues such as accurate point cloud extraction of objects remained.

In the future, we plan to develop a system that is able to visualize the position and azimuth of the lifted object in real-time.

Abstract

Temporary work is about 10% of the total construction cost, and affects completeness of a building since it is directly related to the quality of building. However, BIM-based design of temporary work is used as a complement to the 2D design. Furthermore, the inspection and evaluation of temporary facility is carried out only at the self-evaluation of contractor which is so inefficient because the inspectors are spending a lot of time searching for the standards to check and a checklist for the check is also made manually. These are factors that make lower self-evaluation level of the contractor due to missing information or error.

The objective of this research is to develop prototype of temporary work based on BIM for improving the tasks of design and inspection. In this paper, the BIM-based design and inspection work process were defined. Then, the prototype which can design and inspect temporary work was developed based on the BIM library for one of the most typical item. By using the prototype, the BIM library can be used at the design stage to perform the BIM design for the temporary work, so that a high-quality BIM design is possible even if the BIM modeling expert is not present. By automating the generation of checklists, it is possible to prevent human errors that occur due to manual method.

1 Introduction

Installing temporary works in a construction project is about temporarily building and using structures for building the main structure, on the completion of which the temporary works are removed. Even though they are temporary facilities which are used only during the construction period and then removed, installing temporary works takes up about 10% of the total construction cost[1]. And because the task is so important, directly related to construction cost and quality, that its technology decides whether a building project is complete or not, it requires systematic design and inspection. Despite such importance, however, the current BIM-based design of temporary works, which specifically serve to build the main structure, is done exclusively in such a way that after 2D design is completed first, its 3D rendering is used as an accessory tool[2]. Lately, various kinds of research are conducted with a view to applying BIM to the construction industry, but research done on temporary works remains insufficient. For this reason, we are running short of software and professionals specialized in the installation of temporary works, and temporary works design that plays by rule of thumb with 2D drawings causes conflicts among parts, thus leading to the redoing of the work. Therefore, we urgently need to draw up reasonable and scientific temporary work design and management plan[3, 4]. In this light, the ultimate goal of this study is to develop a system that can implement the design and inspection of temporary works and which directly engages in the BIM library-based installation of temporary works. To fulfill the ultimate goal of the study, this paper aims to develop a prototype for the BIM library-based temporary works design and inspection system.

2 Classification of temporary works

Matters related to the technical standard for the temporary works installation in a construction project are specified in the Standard Integrated Construction Codes established by Ministry of Land, Infrastructure & Transport (MOLIT)[5]. The MOLIT Standard Integrated Construction Codes was created in 2016 for efficient management of construction standards. As the past classification standards varied and their details overlapped and clashed for the specifications, the Standard Specification of Building Projects and the Standard Specification of Temporary Works Installation

Table 1. Temporary Works Installation Classification according to Korea Construction Specifications (KCS)

Code Number	Code Name	Code Number	Code Name
21	Temporary works installation	05	Generals on formwork and temporary shoring
10	Generals on Temporary works installation	10	Formwork and temporary shoring for construction of high-rises and high towers
20	Common temporary works installation	15	Formwork and temporary shoring for exposed aggregate concrete
05	On-site temporary works	20	Formwork and temporary shoring for other types of concrete
10	Construction support equipment	60	Scaffold installation
15	Environmental management facilities	05	Generals on scaffold installation
30	Temporary earth retaining work	10	Scaffoldings
40	Cofferdam, construction road, construction access road, temporary stream crossing, bypass	15	Bar grating stair treads and walkway
45	Temporary bridge and road deck panel	70	Safety facilities installation
05	Temporary bridge	05	Generals on safety facilities installation
10	Road deck panel	10	Fall hazard prevention facilities
50	Formwork and temporary shoring	15	Falling objects prevention facilities

were integrated. The Standard Integrated Construction Codes divides into Korean Design Standard (KDS) and Korea Construction Specifications (KCS), each categorizing into Commons, Facilities, and Projects.

The specifications for the temporary works installation are defined in the Facilities of Korea Construction Specifications (KCS) and are managed with Korea Construction Specifications (KCS) as shown in Table 1. KCS is composed of the category of temporary works installation with the code of “21 00 00”, the 8 sub-categories, and 15 sub-sub-categories. The temporary work installation is specified into the different sub-categories of Generals, Materials, and Installation, thus providing installation inspection and measurement information. Therefore, this study taps into the temporary work classification of KCS which quality control construction engineers should use to conduct on-site checks.

3 The BIM-based temporary works design and inspection process

In general, the work system for BIM-based temporary works design is as shown in Figure 1. By acquiring required drawings such as floor plan, elevation drawing, site plan, and section drawing, one figures out what different lines on drawings represent, performs the modeling of parts by eliminating as many unnecessary elements including centerline, dimension line, and text as possible, and arrange on drawings entered attribute data.

The above series of processes can be efficiently handled in a short period of time by BIM design professionals but problematically requires large workforce and much time for SMEs or single-specialty construction companies. By creating and using a BIM library for temporary works and thereby reducing the workforce and time that are put into the BIM modeling, one can lower the barrier to the BIM adoption.

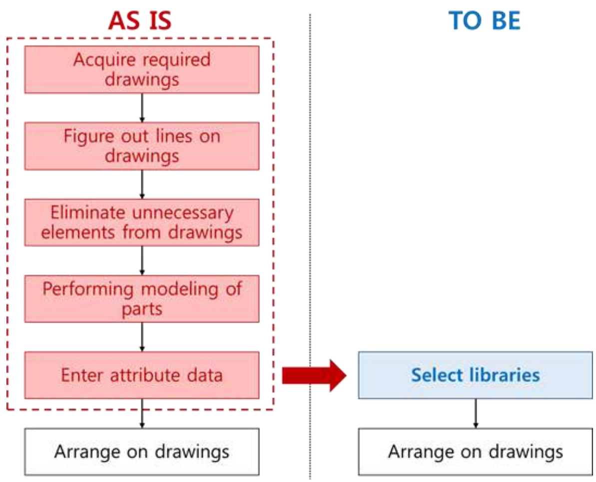

Figure 1. As-Is and To-Be for the work system for BIM-based temporary works design

In general, the builder’s work system for temporary works inspection is divided into the inspection preparation stage and the inspection results processing stage. The work process in the inspection preparation stage involves preparing documents needed for inspection by checking the criteria for the objects of inspection and creating an inspection chart as shown in Figure 2. As it has to extensively search and check various related documents to verify the criteria for the object of inspection, the builder's implementation of the tasks of the inspection preparation stage is inefficient. Furthermore, since the inspection chart for checking its own evaluation is manually prepared, human errors may intervene. This also explains how inefficient work makes the builder work perfunctorily, which downgrades the inspection standards and lowers the quality of facilities. Therefore, to solve the problem, BIM should be used to automatically extract the criteria for temporary works and automatically generate an inspection chart.

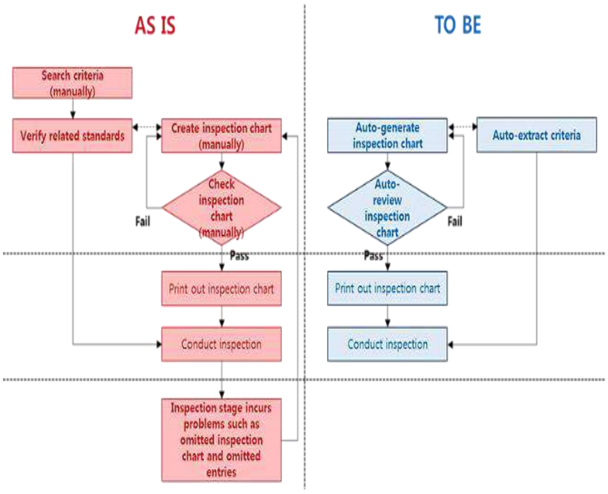

Figure 2. As-Is and To-Be for the Temporary Works Inspection Preparation Stage

Additionally, the work process for the inspection results processing stage involves creating and reviewing the inspection results and therewith creating inspection report, as shown in Figure 3. In processing the inspection results, the builder has to perform all the related tasks manually, which should be automated to minimize data errors and increase work efficiency.

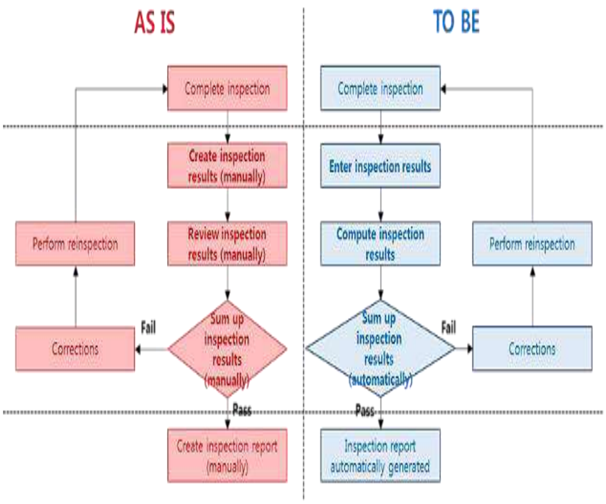

Figure 3. As-Is and To-Be for the Temporary Works Inspection Results Processing Stage

4 A prototype for the BIM-based temporary works design and inspection system

For this paper, I have developed the prototype for the BIM-based temporary works design and inspection system based on Excel by selecting scaffoldings, which are most frequently used and take up the largest cut of the construction budget for the temporary works installation. The algorithm for the BIM library-based temporary work design is as shown in Figure 4.

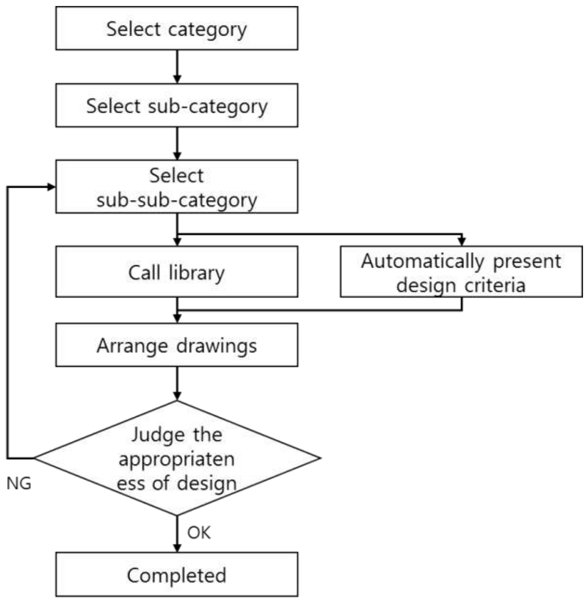

Figure 4. Algorithm for the BIM-Based Temporary Works Design

According to the temporary works classification as described in Table 1, the conditions are selected in categories, sub-categories, and sub-sub-categories to call the library. When the library is called, the criteria that should be applied in designing the current temporary works are automatically presented to minimize design errors and thereby enable the design of the temporary works. Then, the type, structure, and specifications of the designed temporary works are examined to decide if their design is appropriate, and unless something inappropriate is found with them, the design is completed. The prototype for the temporary work design that has been developed based on the algorithm as shown in Figure 4 is as seen in Figure 5.

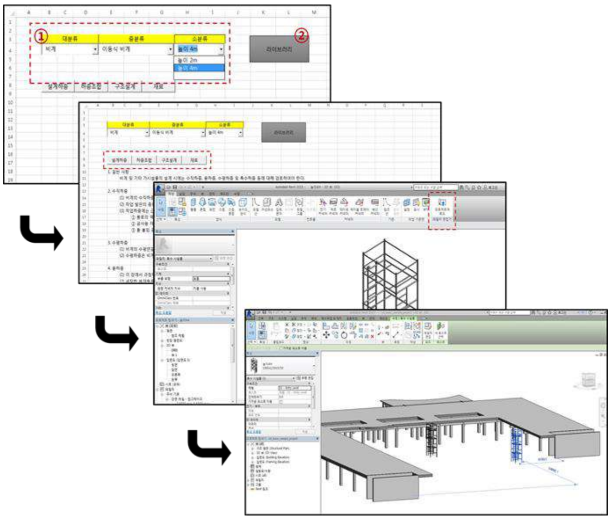

Figure 5. The Prototype for the BIM-Based Temporary Works Design

In this study, the algorithm for the BIM-based temporary works inspection is as shown in Figure 6. The BIM model for the temporary works which is designed based on the BIM library designates and exports attribute data, which is called by the inspection module.

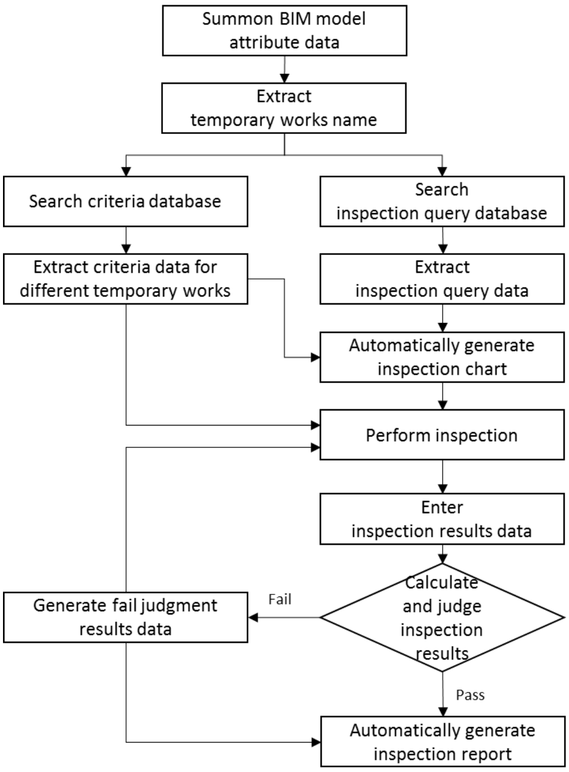

Figure 6. The Algorithm for the BIM-Based Temporary Works Inspection

The criteria database or the inspection query database for generating inspection chart is searched by extracting only the data on the temporary works name from among the summoned attribute data. The criteria shall be extracted for different temporary works through the searched criteria database, while the inspection chart shall be automatically generated by putting into the inspection chart form the temporary work inspection criteria that are extracted from the inspection query database. Also, the results of the inspection for different criteria shall be automatically calculated and judged by putting into the inspection module the inspection results data which are generated after inspection is implemented. By generating the failed criteria with the judgment results, data needed for reinspection is provided, and finally, the inspection report is created.

The prototype for the temporary works inspection system that has been developed based on the algorithm as shown in Figure 6 is as shown in Figure 7.

Figure 7. The Prototype for the BIM-Based Temporary Works Inspection

5 Conclusion

As the tasks of designing and inspecting temporary works are manually implemented in an inefficient manner, there has been concern about human errors and perfunctory operation. Therefore, the study has been conducted for the purpose of increasing the efficiency involved in the construction engineer's design and inspection of the temporary works installation. And looking to improvement, I have presented a prototype for the BIM-based temporary works design and inspection system.

First of all, to accomplish the goal of the study, I have identified the temporary works classification from earlier studies and established the work process for the BIM-based temporary works design and inspection. On this basis, I have developed the algorithm for the BIM-based temporary works design and inspection and the prototype for the system. The BIM-based temporary works design and inspection system as described in this study will greatly reduce the time required for work and automate what is otherwise manual operation, thus preventing human errors and improving the operational convenience.

This study is significant in that as basic research, it has developed a prototype with a view to developing the BIM-based temporary works design and inspection system. However, it has its limitations in that it has failed to complete a system that has perfect functions with regard to its system. Therefore, further research will be carried out to develop a system that can support the design and inspection of the entire temporary works by upgrading and adding functions for a future system

Abstract:

In recent years, considerable concern has arisen over the application of Building Information Modeling (BIM). BIM has been widely utilized for solving the drawbacks of traditional preliminary cost estimation by creating a cost-estimation model. However, since the function of structural analysis and design in BIM is still in its developing stage, the model still lacks precise information of the structural engineering. As a result, the model hypothesizes the structural engineering quantity on the basis of the empirical formula, contributing to a slight inaccuracy in its approximation. Hence, to overcome these shortcomings, this research presents a conceptual cost-estimation model created by linking ETABS (a software used for structural analysis and design of buildings) to the BIM-based model. With the integration of the ETABS and the BIM model, the proposed model can simultaneously consider the two factors (the budget, and the structural analysis) for cost estimation in the early stages of the project: (1) establishing a BIM model on Revit, (2) applying ETABS to conduct structural analysis and design on the BIM model, (3) obtaining quantity takeoffs of the BIM model by Navisworks, (4) retrieving unit price data from PCCES software through results of the quantity takeoffs, and (5) ratifying whether the projected cost meets the owner's budget. The proposed model is tested via a building located on a certain university campus in northern Taiwan. The results show that the proposed conceptual model is significantly superior to the original BIM-based model, and demonstrate that the proposed model can be practically implemented and provide adequate results for the projected cost.

Building Information Model; Cost-Estimation; ETABS; Structural Analysis and Design

1 Introduction

Cost estimation is one of the most critical tasks concerned by all participants in the architecture, engineering, construction, and facilities management (AEC/FM) industry throughout the lifecycle of a building project [1]. In the early stages of conventional construction, there is always enormous and complex information for the cost estimation, causing each cost item can not be calculated and shared accurately in time [2]. Therefore, the management of cost estimation is not only time-consuming but also prone to error. To address the issues, recent years have seen growing importance placed on research in the management of cost estimation.

Building Information Modeling(BIM) as an emerging process and technology has been widely adopted in the building construction industry. BIM is a new approach to design, construction, and facilities management, in which a digital representation of the building process used to facilitate the exchange and interoperability of information in digital format [3]. Through object-oriented concept of BIM, BIM is able to establish the information of each building item and connects it to the cost items to form a BIM-based cost-estimation model. With the increasing usage of BIM, the BIM-based model has been a popular solution for the drawbacks of traditional cost estimation.

However, the BIM-based cost-estimation model still lacks precise information of structural engineering, since functions of structural analysis and design in BIM are still in its developing stage [4]. For example, in the aspect of structural analysis, though it can conduct basic static analysis, and display moment diagrams and structural reactions on the model, advanced analysis is still beyond its ability. As a result, the BIM-based model has trouble with defining the accurate information of structural engineering (beam, column, slab, and wall) crucial to preliminary cost estimation. To overcome the disadvantages, a conceptual model to link ETABS, a professional software used for structural analysis and design of buildings, with BIM is presented in this paper. With the benefits of ETABS, the functions of structural analysis and design of BIM can be enhanced dramatically.

In the paper, we present a conceptual cost-estimation model for linking ETABS and BIM. The paper firstly confers how to integrate the information of ETABS and the BIM software based on the exr. file extension created by Application Programming Interface(API), and discusses the methods of modifying the BIM model when the projected cost doesn't meet the owner's budget. It is hoped that the proposed model will solve the problems about the integration of the accurate information of structural engineering into the BIM-based cost-estimation model, and contribute to a more comprehensive assessment for the civil engineering in the preliminary stages.

2 Review of recent studies

2.1 Structural analysis and design on the basis of BIM

Chang [4] proposed a research that Revit Structure combined ETABS to execute the integration of design. The research firstly established a Revit model subjected to the various external forces. The Revit model with related information was then transferred to ETABS to perform the mechanical analysis and structural design process. Design results were then sent back to BIM platform to renew the members. And since IFC format was not well-developed enough to transfer the structural engineering information between the two software, the research utilized the API as an information transferring interface to renew and create the members. The results found that the data of basic components, such as beams, columns, and plates, could be completely transmitted between the softwares. However, the research was only tested via a simple model, which seems too premature to apply on construction in practical. For example, when the resources in the projects are complicated, whether it will cause other errors related to information delivery between the two softwares, all of which are worthy of being investigated further.

2.2 Applying BIM to estimate construction costs in early stages of projects

Elbeltagi et al. [5] presented a comprehensive cost estimating and monitoring model based on the concept of BIM. With a visualization aid, BIM model could add the color coding help to pinpoint the element clashes, saving considerable time delays and cost wasting. Also, visualization helped construction team to absorb and realize the project information. The results showed that the proposed BIM framework could be considered as an effective tool for the cost estimation in the projects.

Lu et al. [6] thought that traditional method for cost flow analysis were based on the manual integration of time and cost, which was very time-consuming. Therefore, the research presented a BIM-based 5D model of cost estimation on the basis of Navisworks. The research firstly established a BIM model, and took off the properties of items to calculate the quantity of the cost items, which can be stored as a quantity database. The factors of time and cost were subsequently added into the quantity database to create a BIM 5D model. The research utilized this model to analyze the cash flow of the projects. The results found that compared to traditional method, the quantification in Navisworks is simplified and automated, contributing enormous benefits to the cost estimation. What's more, with consideration of time and cost, the whole framework can help contractors analyze the cash flow and make appropriate decisions for different design in construction projects.

Cheung et al. [7] pointed out that current BIM tools were less able to handle concurrency and integration at early design stages, affecting the accuracy of cost estimation; thus, the authors proposed a multi-attribute based tool to address the need to evaluate various aspects of building design, and detailed the cost estimation module that enabled quick and intuitive exploration of early stage design in a 3D environment.

3 Cost estimation of construction practice in the early stages

In the early stages of the projects, a lot of engineering information is still in an uncertain status. Under the condition of limited information, there are, however, some common approaches of preliminary cost estimation in practice, including the cost estimation of Taipei City Government, and the cost estimation of Public Construction Commission of Taiwan. In the end, the chapter will summarize the common parts of these methods to demonstrate the cost-estimation model the research presents is deserving deliberating in depth.

3.1 The cost estimation of Taipei City Government

Taipei City Government divides the cost of the project into direct cost and indirect cost. Direct cost includes structural engineering, decoration engineering, and MEP engineering. The cost of structural engineering (a part of direct cost) is calculated by the total area of the floor multiplied by an empirical value following the rules of Taipei City Government; then, the cost of the other parts of direct cost is calculated by the cost of structural engineering multiplied by an empirical value, and so is indirect cost. In other words, almost all the cost items are presumed by an empirical value (Wang, 2016) [9].

3.2 The cost estimation of Public Construction Commission of Taiwan

Public Construction Commission of Taiwan divides the cost of the project into design cost, indirect cost, price index cost, decoration engineering cost, interest cost, all of which are calculated by direct cost multiplied by an empirical value. And the direct cost is calculated by the area of the floor multiplied by an empirical value. That is to say, like the cost estimation of Taipei City Government, in the preliminary cost estimation, each cost item is involved in a hypothesized calculation (Wang, 2016) [9].

3.3 Summary

From what have been discussed above, we can safely draw a conclusion that due to severe lack of the information of the projects in the early stages, most of cost items' estimation are calculated by an empirical value, especially the cost estimation of Taipei City Government and Public Construction Commission of Taiwan, almost all the cost items are calculated by direct cost multiplied by an empirical value, and the direct cost are calculated on the basis of the cost of the previous projects. Therefore, if the conceptual cost-estimation model the research proposed can be applied into the projects, the problems of scant information in the early stages will be solved by BIM, transmitting the precise information of structural engineering into the preliminary cost estimation.

4 Proposed model

The procedure of the proposed model firstly establishes a BIM model, and then transfers the model to ETABS to conduct structural analysis and design. After analysis and design, the model is then sent back to the BIM software to renew the members, and obtains quantity takeoffs by Navisworks and retrieves unit price data from PCCES software. In the end, the research discusses how to get an alternative cost via the proposed model when the projected cost does not meet the owner's budget. The research selects Revit as the BIM modeling software since it is a commonly-used software in Taiwan. Figure 1 shows the establishment of this proposed model includes five main steps: (1) establishing a BIM model on Revit, (2) applying ETABS to conduct structural analysis and design, (3) obtaining quantity takeoffs by Navisworks, (4) retrieving unit price data from PCCES software, and (5) ratifying whether the projected cost meets the owner's budget.

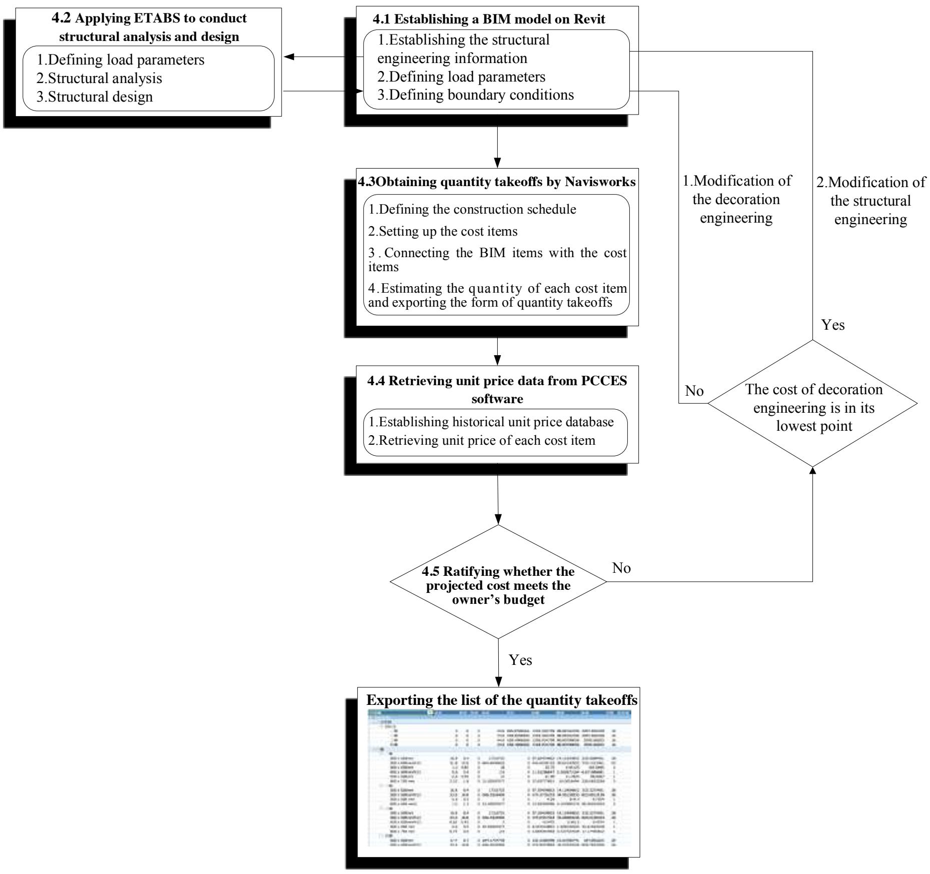

Figure 1. Proposed model

4.1 Establishing a BIM model on Revit

As the BIM handbook [10] noted, when the BIM model needs to conduct structural analysis and design, there are three requirements for the BIM model: 1. establishing the structural engineering information 2. defining load parameters 3. defining boundary conditions.

After establishing the Revit model on the basis of the three requirements, the research utilizes Application Programming Interface (API) as the intermediary of information interoperability between Revit and ETABS instead of Industry Foundation Classes (IFC), since IFC is not functional enough to transfer comprehensive information between ETABS and Revit, causing some elements, such as beams, essential to structural analysis are missed in the transferring process.

On the contrary, the API is capable of exporting the Revit and ETABS model into an exr. file extension to provide a shared format for the two softwares. The API has four functions, "Import to Create New Revit Project from ETABS SAFE or SAP2000 Model", "Import to Update Existing Revit Structure Model from ETABS", "Export to Create New ETABS SAFE or SAP2000 Model", and "Export to Update Existing ETABS Model". Through the functions of the API, the Revit and ETABS models are able to be renewed and established.

The research exports the Revit model into an exr. file extension by the function of the API, "Export to Create New ETABS SAFE or SAP2000 Model", and imports it into ETABS to create a new ETABS model.

There are two categories of the information the exr. file extension is imported into ETABS, the detectable and the undetectable category. The detectable information is the items of structural engineering, including grid, column, beam, wall, slab, boundary condition, and load while the undetectable information is mainly the items of architectural engineering (window, door…etc.) and some structural material properties (density of material and mechanical properties of material), all of which will notify the users in the form of a red signal through the window of the API.

For the undetectable information, the research adds physical properties of the material in the Revit model, or replenishes the structural properties of the undetectable information to transform information from the undetectable into the detectable one.

4.2 Applying ETABS to conduct structural analysis and design

However, to conduct complete structural analysis and design, there is still relatively little information imported from the Revit model; thus, the research needs to define more parameters in ETABS, and requires more professional functions of structural analysis and design from ETABS. The process of structural analysis and design includes three main steps: 1. defining load parameters, 2. structural analysis, 3. structural design.

After structural analysis and design, the information of the ETABS model is imported into the Revit model by the function of API, Import to Update Existing Revit Structure Model from ETABS, renewing the Revit model based on the results of structural analysis and design.

There are two categories of the information the exr. file extension imported into Revit, the detectable and the undetectable category. The detectable information includes grid, column, beam, wall, slab, boundary condition, and load while the undetectable information is nonlinear elements and parts of analysis and design data (rebar area…etc.).

For the undetectable information, the research sorts out the information of the Excel structural analysis and design summary report; then, add it into the Revit model additionally.

After importing ETABS information to Revit, the Revit model is still able to be modified and established, and the information of the Revit model established before being imported to ETABS can be preserved after the structural analysis and design.

4.3 Obtaining quantity takeoffs by Navisworks

To estimate the projected cost after structural analysis and design, the cost estimation is divided into two steps, quantity takeoffs and retrieving unit price data. The research selects Navisworks as the quantity takeoffs BIM software since the system of Navisworks is the same as Revit's, which can reduce the errors of interoperability of information.

To establish a new Navisworks model, the research imports the rvt. file created by Revit into Navisworks by the function of Navisworks, Append, which can record the path of archive and renew the information between the two softwares in time. In doing so, the results of quantity takeoffs can be updated when the Revit model is modified.

After importing the rvt. file into Navisworks, all the information is detectable, such as area and volume. And if the projects need to add additional information into the Navisworks model, the users can utilize the function of Navisworks, "Add New Property".

Through the windows of Navisworks Quantification," Quantification Workbook", "Item Catalog", and "Resource Catalog", the process of quantity takeoffs includes four main steps: 1. defining the construction schedule, 2. setting up the cost items, 3. connecting the BIM items with the cost items, 4. estimating the quantity of each cost item and exporting the form of quantity takeoffs.

After the four steps, Quantification Workbook displays a form of the quantity of each cost item, which can be exported into an Excel form. The Excel form of quantity takeoffs can be divided into different types of forms, including item-pivoted or resource-pivoted forms. For the project, the research selects resource-pivoted forms as the quantity takeoffs form.

4.4 Retrieving unit price data from PCCES software

After sorting out the results of the quantity takeoffs, the quantity takeoffs retrieves unit price from PCCES software to estimate the projected cost. The research selects PCCES as the software of unit price database. And, the process of retrieving unit price from includes two main steps: 1. establishing historical unit price database, 2. retrieving unit price of each cost item.

4.5 Ratifying whether the projected cost meets the owner's budget.

To measure up the requirements of the construction in practical, the research ratifies whether the projected cost meets the owner's budget. In this section, the research hypothesizes the projected cost does not meet the owner's budget, and modifies the model to adjust the cost. The research proposes a scheme to reintegrate the building information for an alternated projected cost on the basis of the proposed model.

Base on the condition of the construction in practice, the modification of the model can be divided into two parts, "decoration engineering" and" structural engineering", and the sequence of the two modifications is first decoration engineering and then structural engineering in the order of complication. Firstly, the modification of decoration engineering includes paint, tile…etc. Since decoration engineering is not in the consideration of structural analysis and design and interior design, the modification of decoration can skip the process of structural analysis and design. When the cost of the decoration engineering has already been decreased to its lowest point, the modification of structural engineering is the next option; the modification of structural engineering includes beam, column, slab, and wall. It requires to not only reanalyze and redesign the structure but also inspect if the interior design corresponds to the laws of the government and the request of the owner. Therefore, the research utilizes the function of API, "Export to Update Existing ETABS Model", to provide an update regarding to the modification of structural engineering to the ETABS model. In doing so, the preprocess of structural analysis and design (defining load parameters) can be skipped.

5 Case study

The proposed model is tested via a building located on a certain university campus in northern Taiwan, as presented in Figure 2 The building was finished in 1982, main building material is reinforced concrete, four floors with no basements, and total area of the floor is 5814.83 ㎡.

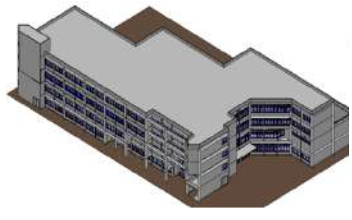

Figure 2. The tested Revit model

5.1 Establishing a BIM model on Revit

The research creates a new project on the construction template in Revit, and builds columns, beams, slabs, and walls respectively; dead load is the weight of the building, which is 0.5KN/m^2, and live load is 2.5KN/m^2, following the rules of the government, and then, assign the loads to the slabs in an uniform distribution; the research sets the boundary conditions as the fixed one at the junctions of columns and ground.

After establishment of the Revit model, the research utilizes the function of API, "Export to Create New ETABS Model", to export grid, column, beam, wall, slab, boundary condition, and load of the Revit model to create a new ETABS model. The results show the items of the Revit model are successfully detected in ETABS, and the ETABS model is able to be modified.

5.2 Applying ETABS to conduct structural analysis and design

The process of ETABS structural analysis and design includes three main steps: 1. defining load parameters, 2. structural analysis, 3. structural design.

After structural analysis and design, the research utilizes the function of API, "Import to Update Existing Revit Structure Model from ETABS", to import information of the ETABS model to update the Revit model, and export the results into an Excel summary report.

To perform the cost estimation, the research establishes the other engineering items, such as ceiling, tile, excavation, skirting, slope protection, and flooring, and then exports the Revit model into a rvt. file.

5.3 Obtaining quantity takeoffs by Navisworks

The research imports the rvt. file into Navisworks by the function of "Append". The items for quantity takeoffs includes geotechnical engineering (excavation and slope protection), structural engineering (concrete, rebar, and formwork), and decoration engineering (ceiling, skirting, flooring, paint, and tile). Furthermore, to retrieve unit price of each cost item, the quantity takeoffs unit of each cost item is the area or volume of the material.

The process of Navisworks quantity takeoffs includes four main steps: 1. defining the construction schedule, 2. setting up the cost items, 3. connecting the BIM items with the cost items, 4. estimating the quantity of each cost item and exporting the form of quantity takeoffs. After the quantity takeoffs, the results are sorted out in Table 2.

5.4 Retrieving unit price data from PCCES software

The quantity takeoffs retrieve unit price from PCCES software to estimate the projected cost. The process of retrieving unit price from includes two main steps: 1. establishing historical unit price database, 2. retrieving unit price of each cost item. Table 2 is the detail of the projected cost; the total projected cost is 38,266,229 NTD.

Table 1 The list of the projected cost

Engineering items	Quantity	Unit	Price (NTD)	Cost (NTD)
reinforced concrete 280kgf/cm^2	3,974	M^3	2,115	8,405,010
rebar SD280	395	T	15,673	6,190,835
rebar SD420	104	T	16,432	1,708,928
formwork	19,817	M^2	332	6,579,244
excavation	4,382	M^3	166	727,412
light-gauge steel frame	5,930	M^2	873	5,176,890
red paint	161	M^3	710	114,310
granitic tile	1,902	M^2	4,000	7,608,000
flooring	5,852	M^2	300	1,755,600
			Total	38,266,229

5.5 Ratifying whether the projected cost meets the owner's budget

The projected cost presented above is about thirty-eight million and three hundred thousand NTD; in contrast, the research hypothesizes the owner's budget is thirty-six million NTD, the difference is about two million and three hundred thousand NTD. Therefore, the research provides an alternated project to meet the owner's budget, which includes two modifications: 1. the modification of the decoration engineering 2. the modification of the structural engineering.

1. The modification of the decoration engineering

To decrease the projected cost, the research changes the granitic tile into cheaper tiles, grey-faced tile, and also modifies the red paint and the light-gauge steel frame of the floors into the cheaper materials.

Since the Navisworks model was established by the function, "Append", the modification can be updated to the Navisworks model by the function, "Refresh". In this way, the cost items do not have to reconnect with the BIM items; then, the results of the quantity takeoffs can be renewed.

On the condition of the lowest cost of the decoration engineering, Table 2 shows that the original projected cost decreases about sixty hundred thousand NTD, which is still a gap of one million seven hundred thousand NTD between the alternated projected cost and the owner's budget. Hence, the research modifies the structural engineering items.

Table 2 The list of the projected cost after the modification of the decoration engineering

Engineering items	Quantity	Unit	Price (NTD)	Cost (NTD)
reinforced concrete 280kgf/cm^2	3,974	M^3	2,115	8,405,010
rebar SD280	395	T	13,412	6,190,835
rebar SD420	104	T	15,000	1,708,928
formwork	19,817	M^2	332	6,579,244
excavation	4,382	M^3	166	727,412
light-gauge steel frame	5,930	M^2	873	5,176,890
red paint	161	M^3	650	104,650

granitic tile	1,902	M^2	3,700	7,037,400
flooring	5,852	M^2	300	1,755,600
			Total	37,685,969

2. The modification of the structural engineering

To decrease another one million seven hundred thousand dollars, the research deletes the partial area of the third and fourth floor, decreasing the number of columns, beams, slabs, walls and rebar, as presented in Figure 3.

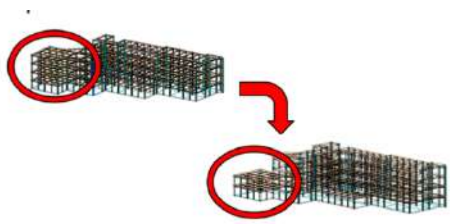

Figure 3. The modification of the structural engineering

The research updates the ETABS model by the function of API, "Export to Update Existing ETABS Model", and then conducts the structural analysis and design again.

After analysis and design, if there are deleted items in the Revit model, the steps of the quantity takeoffs are the same as the modification of the decoration engineering, which do not need to reconnect the cost items and the BIM items; however, if there are added items in the Revit model, it is necessary to reconnect the cost items and the BIM items in Navisworks.

The results show that after the structural engineering modification, the alternated projected cost decreases another two million NTD. In summary, these two modifications decrease two million and six hundred thousand NTD, which meets the budget of the owner, as presented in Table 3.

Table 3 The list of the projected cost after the modification of the decoration engineering and structural engineering

Engineering items	Quantity	Unit	Price (NTD)	Cost (NTD)
reinforced concrete 280kgf/cm^2	3,654	M^3	2,115	7,728,210
rebar SD280	379	T	15,673	5,940,067
rebar SD420	92	T	16,432	1,511,744
formwork	19,017	M^2	332	6,313,644
excavation	4,382	M^3	166	727,412
light-gauge steel frame	5,560	M^2	873	4,853,880
red paint	154	M^3	650	100,100
granitic tile	1,820	M^2	3,700	6,734,000
flooring	5,427	M^2	300	1,641,600
			Total	35,550,657

Through the hypothesis, it's proved that the proposed model is capable of developing an alternated projected cost on the basis of interoperability of information; hence, if the proposed model can be applied on the projects in practice, the projects will have the ability to adjust the cost to meet the owner's cost precisely and smoothly, and also through the comparison between the original projected cost and the alternated projected cost, the owner will have a more comprehensive understanding of the current condition of the projects, achieving the goal of the projected construction cost in the early stages.

6 Discussion of the results

The research compares the proposed model with the model of the preliminary cost estimation Wang et al. [11] proposed. In the two models, the common part is the application of BIM on the quantity takeoffs; in addition, the cost items, the unit price of the cost items, and the tested building are identical while the main difference is the consideration of structural analysis and design, which contributes to different quantity of structural engineering. Therefore, the research discusses the margin of the two projected cost to prove the proposed model has the beneficial effect on the cost estimation in the early stages.

The projected cost of Wang et al. [11] is 42,190,382 NTD, which is a 10% difference between the two projected cost. That is to say, the difference between the projected cost of structural and non-structural analysis and design can be up to 10%, which is unacceptable to the preliminary cost estimation. The difference will not only produce the difficulties on the management of the projects in the late stages, but also influence the progress of the construction. In conclusion, the preliminary cost estimation of the projects should put the structural analysis and design into consideration.

7 Conclusions and suggestions

In civil engineering, a recent surge of research on BIM has given us new opportunities and solutions for the issues of the cost estimation in the early stages. However, since the structural analysis and design of BIM is still in its infancy, there is still a strong assumption of the quantity of the structural engineering. Hence, the purpose of the research is to present a conceptual cost estimation model to better control the details of the projected cost in the early stages.

After the test, through the BIM-based conceptual cost-estimation model considering structural analysis and design, the research successfully estimates a projected preliminary cost, and is also able to alter the cost within the owner's budget. In addition, the research compares the proposed model with the preliminary cost-estimation model Wang et al. [11] proposed. The result of the comparison concludes with certainty the proposed model is feasible. In the end, the research hopes the proposed model should be of importance in the applications of constructions and provide a more comprehensive functions to the lifecycle of the projects.

Three of the suggestions are worth summarizing:(1) The interoperability of information between ETABS and Revit is still defective. For example, the damper cannot be identified in the exr. file extension. Therefore, the research suggests that an area of future research that should be considered is how to enhance the accuracy of the interoperability of information between ETABS and Revit. (2) There are a variety of BIM softwares, and so as the softwares of structural analysis and design. Perhaps future research could examine the interoperability of information between different BIM softwares and structural analysis and design softwares to refine the functions of BIM structural analysis and design. (3) In this research, the model is tested via a RC building and Taiwan architectural laws and guidelines. In the future, the research suggests the other researchers can adopt this conceptual model in different scenarios, such steel building or other countries' laws and guidelines, and accumulate all these implements to form a dynamic database. According to different scenarios, the dynamic database will enhance the ability of the proposed model by providing a wider range of applicability.

Acknowledgments

The authors would like to highlight Autodesk's contribution in their support to the BIM building softwares. And The authors thank the Ministry of Science and Technology of Taiwan for financially supporting this research under Contract No: MOST 106-2813-C-009 -024 -E. We also thank National Chiao Tung University for their technical assistance regarding the use of Autodesk softwares. Additionally, we are indebted to the CEO of the BIM center of NTU, Rong-Chin Guo, for providing valuable information and practical experience.

Abstract –

This research aims to develop a knowledge base for a disaster management question-answering dialogue system. The rapid growth of the amount of data has led to the variance of data in terms of their formats, sources, and attributes. Hence, the difficulties of decision makers to accomplish their missions accurately and efficiently have increased. To solve this problem, we developed a question-answering dialogue system for disaster management.

In our previous research, we found that the information most likely retrieved in response to a user's request can be determined by calculating the similarity between the keywords and the user's input in a handcrafted keyword–information mapping table. However, we also noticed that managing the mapping table was a tedious task. Moreover, for the inputs that had more than one keyword, the system was unable to provide integrated information. Therefore, we constructed a knowledge base to optimize the performance and maintainability of the system.

To build the knowledge base for disaster management, we designed the domain model by performing an abstraction on the knowledge of professional information providers and the required data on disaster management, while considering their source, certainty, and spatiotemporal features.

The query of requested information from the knowledge base is composed of mentioned entities in the user's input. For the dialogue system to recognize the entities, we applied entity recognition. The subtasks include segmentation, tagging, similarity calculation with the names of the entities in the knowledge base, and intent detection to determine the desired knowledge of the user.

Keywords –

Knowledge base; Disaster management; Entity Recognition

1 Introduction

With the advance of information technology, the capabilities of massive data storage and data productivity have triggered an evolution in the usage of information, especially in the area of disaster management. Decision making in disaster management relies on the gathered information and the knowledge of decision makers. Due to the rapid growth of the amount of data, more data and information are being consumed now than in the past. This has led to the variance of data in terms of their format, source, and attributes, which has in turn increased the difficulties of the decision makers to accomplish their mission accurately and efficiently.

To assist the decision makers in efficiently and accurately utilizing, selecting, and processing information, we developed a dialogue system for disaster management. The dialogue system is based on text input by the decision makers using their devices, such as smartphones or tablets. It provides the data, information, and corpora for the topic of interest by treating the user's inputs as queries.

In our previous research, for providing information and data to the user, we developed a handcrafted keyword–information mapping table and used a fuzzy search algorithm. By searching keywords in the user's input, the system provides the most suitable information from the table to the user. During the implementation, we noticed that it was tedious to manage the keywords and information in the mapping table. In addition, a user experience test revealed that for the inputs that had more than one keyword, instead of providing integrated information, the system could only retrieve the part that mapped to one of the keywords. Therefore, we constructed a knowledge base to optimize the performance and maintainability of the system.

To build the knowledge base for disaster management, we designed a domain model to describe the knowledge base. The domain model is often used in software engineering and ontology engineering. We performed an abstraction on the knowledge of professional information providers and the required data on disaster management, while considering their source, certainty, and spatiotemporal features. A diagram composed of the models, the slots of the models, and the relations between the models was developed. The entities of the knowledge base are later used to recognize entities in the user's inputs. By entity recognition, the intent of the user and the proper response to the user's query can be determined.

2 Previous Research

We developed a dialogue system to provide data to the decision makers of the Water Resources Agency in Taiwan. The language of the dialogue system is Chinese, and the system is implemented as a chatter bot via LINE, a commonly used messaging application in Taiwan.

2.1 Algorithm

To determine the proper responses to a user's request, we developed a handcrafted keyword–information mapping table on the basis of experiments and the needs of the staff and decision makers of the agency. By searching listed keywords in the user's input, the system provides the most suitable information from the table to the user.

The matching of keywords from the user inputs and mapping table are sorted by the similarity of strings. Unlike in English, there is no space in a sentence to segment words in Chinese; therefore, we simply regarded each character as a single token, instead of using a single word as a token.

The similarity is calculated by comparing the number of same characters in the input text and each keyword in the mapping table, using Equation (1).

$$sim(d_j, q) = \frac{\sum_{i=1}^{t} f_{i,j}}{t} \tag{1}$$

- d_j is the j-th text from the corpus of the system.
- q is the user's input.
- t is the number of tokens in the user's input. The tokens are the characters of the text in this case.
- $f_{i,j}$ is the count of appearance of the i-th token in the user's input in the j-th text from the corpus of the system.

For the keyword(s) with a similarity score of 1.0, the system returns the information related to the keyword(s) to the user. If none of the keywords has a similarity score of 1.0, the system returns a list of keywords with a similarity score that is higher than 0.5 to the user so that the user can improve the inputs.

2.2 User Test

The system was tested by the staff of the Water Resources Agency. The users pointed out the following flaws in the system performance:

- Lack of reaction to stickers.
- Requirement of adjusting the views of data presented by tables. Tables are often too small when displayed on smart phones.
- Poor performance in case of long inputs.
- Poor performance in realizing natural language.

In addition, during the user test, in some given tasks for testing that required integrating different types of data, the time taken for accomplishing those tasks was higher than for easier tasks. Instead of retrieving all of the requested information simultaneously, the users had to split the input into fundamental queries to retrieve one part of the information at one time.

2.3 System Management and Maintenance

The keyword–information mapping table was directly handcrafted in the system codes. Hence, it was tedious and difficult to manage the keywords and information in the mapping table. Moreover, it resulted in a lack of flexibility in extending the mapping table, making the task of improving the system performance challenging.

3 Objective

The objective of this research is to develop a knowledge base for improving the ability of the dialogue system to perform the following:

1. Recognize the intent and provide the information requested through user inputs.
2. Respond with proper information depending on the user's request.
3. Provide a better solution for managing data.

To meet these objectives, we developed a knowledge base for disaster management, a system for processing the user input to retrieve the information sought, and a user-friendly console for the system.

4 Methodology

The methodology includes two parts: knowledge base and named entity recognition. The knowledge base stores and provides information, data, and knowledge. Named entity recognition completes the task of recognizing the intent and given information in the user's input.

4.1 Knowledge Base

4.1.1 Overview

A knowledge base is a manually compiled knowledge collection [1]. Knowledge is extracted into entities, relations, and attributes in a knowledge base. A knowledge base can be used to enable intelligent applications such as question answering [2]. The successful integration of a question-answering system prompted us to develop a knowledge base of the required information for management decision making in water-resource-related disasters.

Information extraction techniques are used in the construction and update of knowledge bases. Two types of information extraction methods exist: rule-based and statistical methods. Specifically, rule-based methods are more useful in closed domains where human involvement is both essential and available [3]; hence, we chose a rule-base method for information extraction in our study.

4.1.2 Domain Model

We performed an abstraction on information and data by discussing with the experts from the staff and information providers of the Water Resources Agency. By considering the source, certainty, and spatiotemporal features of the required data on disaster management, we designed a domain model as the model of the knowledge base. The domain model describes the structure of the knowledge base. Models of the domain model are the abstraction of knowledge, data, and information. The entity-relationship model (ER model) diagram is applied as a visualization tool for the system engineer and the disaster management experts to discuss and verify the domain model. The model, slot of attributes, and relation between entities can thus be defined.

The entity in the knowledge base is the instance of the model in the domain model. The attribute of entities is the slot of models filled with values. The relation between entities in the knowledge base is the relation in the domain model. The roles of the from-end and to-end models/entities are defined in association with the relation in the domain model.

4.1.3 Challenges

One of the main challenges in the construction is that the requested information during disaster management may be in the form of streaming data [4]. Therefore, the knowledge base should be capable of updating data in a timely manner. Data can be categorized into two types:

- Static data: data that seldom change, such as the name and location of facilities.
- Streaming data: temporally updating or increasing data, such as observations of precipitation and water levels, logs of transportation resources, meetings, and operations during disaster events.

In the implementation, streaming data are collected from the application programming interface (API) of the information system of the Water Resources Agency. When the data are updated, we archive them into the database of our system in the originally provided format, and extract them using the related model of the domain model into the knowledge base.

The other challenge is that the source of different data and information varies. The requested data of the Water Resources Agency may be provided by other government institutions such as the Central Weather Bureau. In our research, we focus on the data provided by the Water Resources Agency alone.

4.2 Named Entity Recognition

4.2.1 Overview

Named entity recognition (NER) is one of the tasks in information extraction and its purpose is to recognize the entities mentioned in documents. In our research, NER is applied to recognize entities in the user's input in order to query requested information from the knowledge base.

4.2.2 Segmentation and Tagging

The input text is segmented for retrieving a list of words. In addition, position-of-speech (POS) tagging is used to determine the type of each word. Nouns are regarded as candidate entities for later comparisons with the entities in the knowledge base.

In addition, words or phrases tagged as time are extracted and transformed into date/time objects in the system using handcrafted rules. For example, if "yesterday" appears in the input text, it will be transformed into the absolute date of the previous day.

4.2.3 Similarity Calculation

After retrieving a list of nouns, by searching the names of entities and models, the system can recognize the entities or mentioned models in the input and retrieve the requested information from the knowledge base. The type (e.g., location, person, and not-categorized) and content (i.e., the exact text of the word) of the nouns will be compared with the following:

- Names of entities in the knowledge base.
- Names of slots for attributes of the entities.
- Data types of attributes of the entities.
- Values of attributes of the entities.
- Names of models in the domain model.
- Names of slots of the models.
- Data types of slots of the models.
- Names of relations in the knowledge base and the domain model.
- Names of roles of two related entities or models.

The texts mentioned above compose a corpus of the system. The similarity of words in the user's input and the texts from the corpus are calculated using the cosine similarity by treating the texts as vectors in a vector space.

Each character plays the role of a unit vector on different dimensions of the vector space. The vector representing each word is composed of unit vectors, and the weights of unit vectors are determined by text model term frequency–inverse document frequency (tf–idf). The similarity of a word in the user's input and the text from the corpus of the system is calculated using Equations (2), (3), and (4).

$$sim(d_j, q) = \frac{\sum_{i=1}^{t} w_{i,j} \times w_{i,q}}{\sqrt{\sum_{i=1}^{t} w_{i,j}^2} \times \sqrt{\sum_{i=1}^{t} w_{i,q}^2}} \quad (2)$$

$$w_{i,q} = (1 + \log f_{i,q}) \times \log \frac{N}{n_i} \quad (3)$$

$$w_{i,j} = (1 + \log f_{i,j}) \times \log \frac{N}{n_i} \quad (4)$$

- d_j is the j-th text from the corpus of the system.
- q is the user's input.
- t is the number of tokens in the user's input. The tokens are the characters of the text in this case.
- $w_{i,j}$ is the weight of the i-th token in the user's input in the j-th text from the corpus of the system.
- $w_{i,q}$ is the weight of the i-th token in the user's input in the input itself.
- $f_{i,j}$ is the count of appearance of the i-th token in the user's input in the j-th text from the corpus of the system.
- $f_{i,q}$ is the count of appearance of the i-th token in the user's input in the input itself.
- N is the number of the texts in the corpus of the system.
- n_i is the number that contains the i-th token of the user's input.

The nouns from the user's input will be regarded as the entities or models whose related text has a higher similarity score than the given threshold.

4.2.4 Intent Detection

If the name of any model in the domain model is recognized in the user's input, the model(s) will be treated as the intent of the user's request. The desired instances of the intent model(s) will be retrieved from the knowledge base by filtering by other recognized entities and date/time objects extracted from the user's request.

On the other hand, if only entities are recognized, the system will return the entities and links to related entities to the user for further usage.

5 Implementation

5.1 Domain Model

There are, in total, 43 models, 214 attributes, and 126 relations in the domain model. The relations can be categorized into 53 types.

Table 1. Information of models in the domain model. Type 1 refers to static data while type 2 refers to streaming data.

Model name	Type	# of slots
Institution	1	2
WRA Affiliation	1	3

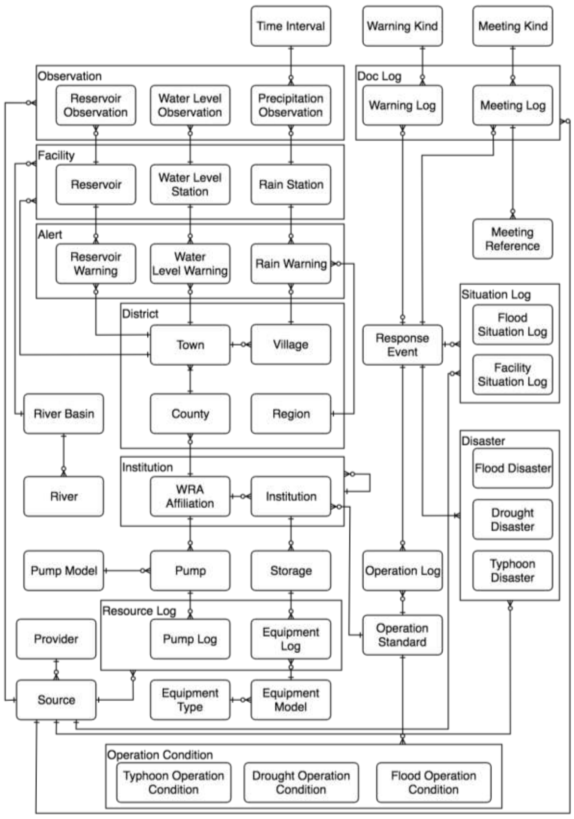

Figure 1. ER model diagram of the domain model.

5.2 System

Python is used in the development. Each part of the system is constructed using the various Python libraries or modules:

1. Jieba [5]: Chinese text segmentation module, used for the segmentation and POS tagging of the user's input. The algorithm of Jieba is based on a prefix dictionary structure to achieve efficient word graph scanning. The dictionary of Jieba can be extended.
2. Django [6]: The web framework consists of an object-relational mapper (ORM), which mediates between models of data and relational databases, used for implementing the domain model and the knowledge base. The domain model is implemented by the ORM, and the data of entities are stored in the database. By mediations using the ORM, the data can be transformed back to entities. It also provides an automatically generated graphical user interface (GUI) console for managing the data in the system.

In development, SQLite3 is chosen as the database for testing and validation.

First, static data and information are added directly to the knowledge base using the domain model. Second, the API listener of the system checks up the APIs of streaming data. If an update is detected, the system archives the newest data in original formats, transforms the data into entities using the models, and adds them to the knowledge base.

After the construction of the knowledge base, the Jieba dictionary is extended by adding texts from the corpus of the system, which is mentioned in 4.2.3. To increase the capability of referring the different names of the same entities, models, slots, and relations, aliases are attached to them, which are also added to the Jieba dictionary.

The transformation of words or phrases tagged as time is done by rules written in regular expressions and compiled in Python. They are transformed into native Python date/time objects and can be used as the attributes of entities or the slot values of models directly.

The data can be managed on the automatically generated console. Adding, modifying, and deleting data on the new system is much easier than on the original one.

The entire system runs as a web application. It receives the messages from LINE, following which the proper information is processed and returned to LINE.

6 Results and Discussion

In the current progress, we focus on recognizing and retrieving requested information by direct relation to other mentioned entities, such as facilities with their locations, in the user's input. By adjusting the threshold of similarity to 0.9 and adding handcrafted rules to improve the accuracy of recognition, the system can currently retrieve requested information from the knowledge base.

For example, when the system receives the text, "Tell me the Rain stations in Taipei City (告訴我臺北市雨量站)," by entity and model recognition, the system determines that the intent is to retrieve rain stations in Taipei City; therefore, it shows the list of rain stations in Taipei City. On the other hand, when the system receives the text, "Rain stations in the Da-an District of Taipei City (臺北市大安區雨量站)," it recognizes Taipei City and Da-an District as a county-level district and a town-level district, respectively, and then determines that the intent is to retrieve rain stations situated in only the Da-an District of Taipei City instead of the other district in Taichung City, which is also called Da-an; therefore, it shows the list of rain stations in the Da-an District of Taipei City.

However, the system can still not retrieve information that is not directly related to other entities provided in the user's input. In addition, setting the threshold of similarity to 0.9 might lead to missing relevant information. Setting the threshold too low, however, may reduce the retrieval speed, lower the accuracy of recognition, and cost more time and computation resources.

7 Conclusions

In this research, to improve the performance of the dialogue system for disaster management, we developed a knowledge base and designed a recognition process; we implemented the system to recognize the intent and provide the information mentioned in the user's input by replying with accurate information depending on the user's query.

By designing a domain model of the knowledge base through discussions with experts, we developed a system to provide and manage the information requested in disaster management. The knowledge base and the domain model increase the capability of the system in recognizing the user's intent and query.

In future work, to improve the accuracy of intent and entity recognition, the similarity between the keywords and the user's input by considering the slot and relation structure of models will be discussed. In addition, the feature of retrieving the requested data and information that do not directly relate to the mentioned entities in the user's input will be developed.

Abstract –

The marking robot has been developed for the purpose of streamlining marking operations at power plant construction sites and accelerating equipment installation work. This robot can draw line segments with accuracy of 1 mm or less on floors and walls of the construction site in cooperation with a three-dimensional measuring instrument. In addition, it is possible to write arbitrary characters such as position information of drawn line segments.

The marking robot is mainly composed of a marking mechanism and a wall traveling mechanism. The marking mechanism for drawing line segments and characters has been realized by a combination of a XY plotter and an ink jet printer. The small printer head is attached to the XY plotter instead of a pen. And a prism target for a total station is located just above the nozzle of the printer head. By moving the plotter to the four corners of its movable range and measuring its position, the command value of the cooperative operation of two axes of the plotter necessary for drawing an arbitrary line segment and characters is calculated.

On the other hand, by combining a vacuum suction device and a four wheel drive mechanism, the wall traveling mechanism which makes the marking robot of about 50 kg run on a concrete wall has developed.

In this report, we will report on structure of the marking robot, cooperation method of the robot and three-dimensional measuring instrument, and application case of the robot to construction site.

Marking robot; Three-dimensional measuring; Total station; XY plotter; Ink jet printer; Wall traveling mechanism

1 Introduction

In order to achieve requests for shortening construction period from customers and ensure construction quality in construction and remodelling work of thermal power plants and the like we the construction company actively introduces rationalization using the latest technologies such as IoT. This report relates to rationalization of marking work at the time of installation of equipment.

When installing equipment at construction sites we draw many lines on floors or walls of the sites as marks which indicate installation positions of equipment, for example positions of anchor bolts, by using surveying instruments such as automatic levels, transits, and tape measures. Normally, this marking work is carried out prior to the installation of each equipment, but as the construction progresses, the already installed equipment becomes interfering matter, which leads to decrease in efficiency of marking work and increase in the cause of mistake.

Therefore, we are planning to introduce a construction method to draw all the markings before the installation work starts. But in the construction work of a large-scale thermal power plant of 1,000 MW class, the number of the marking is more than thousands. Thus, efficient carry out of the marking work is needed for introducing the method. This is reason why we have developed a support system for marking work using a robot.

Here, some examples of previous studies on the marking devices for construction are shown below. First, Ohmoto et al. developed a marking system which consisted of a self-propelled marking robot that had a cross shape stamp, a laser range finder that guided the robot to the marking position, and a total station for accurately positioning of the stamp. By using this, they semi-automated the work to mark the cross lines with 2 mm accuracy on the floors of building construction sites. On the other hand, Yokoyama et al. developed a marking system to mark the positions of anchor bolts for ventilation jet fans mounted on the tunnel ceiling of highways. Their system consisted of a motor driven total station and a marking device. And the marking device had a cross line stamp on XY positioning mechanism at the tip of a cylinder mechanism extending to the ceiling. By using this, they realized high-place work of marking without scaffolding.

As described above, there are already some kinds of the marking system that use the total station to position the cross stamp at marking points. However, what can be obtained by the stamping method is information of "points". On the other hand, in some cases, information of "lines" indicating the installation orientation of the equipment etc. is also important. Furthermore, if the coordinate values of the marked points and lines, and the name of the equipment to be installed, etc. are not clearly indicated in the vicinity of the markings, there is a possibility of incorrect installation work. Therefore, in this research, we decided to develop marking system which can draw arbitrary line segments and characters on floors and walls of plant construction sites by linking with the motor driven total station.

2 Development of Marking System

2.1 Concept of Marking System

The basic requirement specifications considered in developing this system are shown below.

1. To draw arbitrary line segments and characters on indoor and outdoor concrete floors and walls.
2. To draw line segments with position accuracy of 1 mm or less.
3. Work efficiency equivalent to the conventional one.
4. Easy operation of the system.
5. Marking on walls without scaffolding

The basic concept of the system determined based on the above required specification is shown in Figure 1. The system consists mainly of the following three elements.

1. XY plotter type marking robot
2. Motor driven total station
3. Wireless controller of the system

First, the marking robot needs to draw arbitrary characters besides line segments, so we decided to adopt a relatively simple XY plotter system. In addition, to move on the floor and climb the wall the robot is needed a moving mechanism such as motorized wheels and a wall sticking mechanism using vacuum fan. Using the moving mechanism, we aimed to realize marking work on walls without scaffolding. In addition, we considered that the autonomous movement of the robot to marking points stated in the previous studies mentioned in section 1 was a future development item. Therefore, as our first step of the development, an operator of the system moves the robot to marking points with operation of a remote controller.

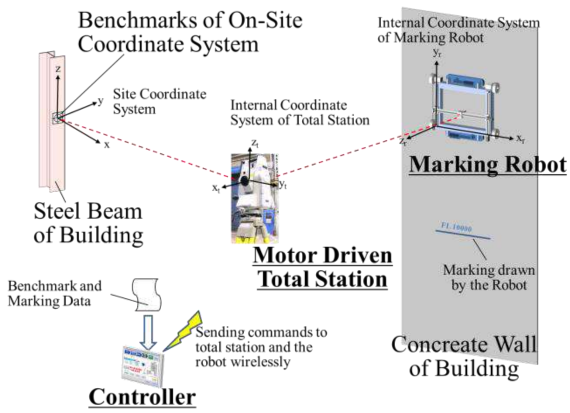

Figure 1. Schematic diagram showing the basic concept of the marking system

The total station is needed as a three-dimensional measuring instrument for grasping positions and orientations of the robot in on-site coordinate system. And the instrument is needed to have measurement accuracy higher than the marking target accuracy of 1 mm. Furthermore, a motor driven one is useful because that can collimate and track prism targets automatically. That can be adopted to automatic measurement of positions and orientations of the robot etc.

The wireless controller of the system is a general tablet PC on which software dedicated to this system was installed. From the controller, various commands to total stations and the robot are given wirelessly. The system operator inputs information such as coordinate values of benchmarks and line segments to be drawn to the controller in advance of the marking work. Based on the inputted information and measurement results of the benchmarks and the robot, the system gives the robot the motion command of the XY plotter necessary for marking.

2.2 Development of Marking Robot

The appearance of the marking robot developed based on the concept mentioned above is shown in Figure 2. And representative specifications such as external dimensions are shown in Table 1. On the other hand, the appearance of the total station adopted to the system is shown in Figure 3. And representative specifications such as measurement accuracy are shown in Table 2.

The robot consists mainly of a marking mechanism, a wall traveling mechanism, and a control unit of those two mechanisms. The following sections explain the concrete contents of each mechanism.

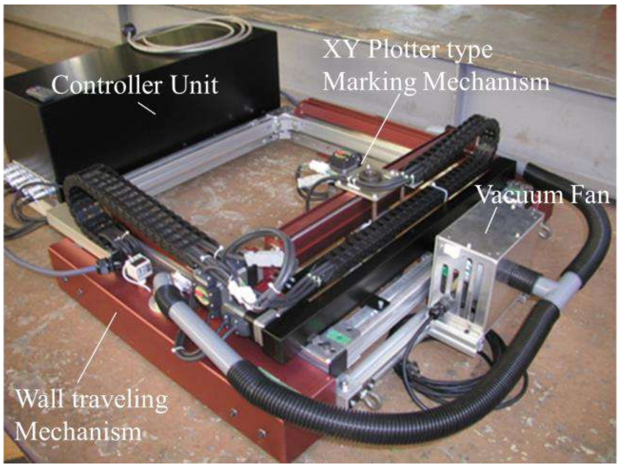

Figure 2. Appearance of the marking robot

Table 1. Specification of the marking robot

Item	Specification
Dimension (mm)	L:1,500 x D:1,000 x H:400
Weight (kg)	56
Main material	Aluminum
Power supply	A/C 100V

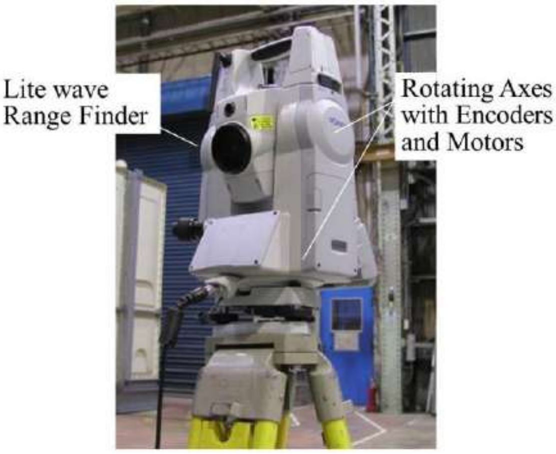

Figure 3. Motor driven total station used for the marking system

Table 2. Specification of the total station

Item	Specification
Manufacture / Model	SOKKIA / NET05
Accuracy of angle measurement	0.5”
Accuracy of distance measurement with using a prism	0.8mm+10^{-3}mm/m

2.2.1 Marking Mechanism

The appearance picture of the marking mechanism separated from the robot is shown in Figure 4. As shown (a), the overview of the mechanism is a two-axis linear motion device imitating an XY plotter of about 700 mm square. Here, the linear motion device is driven by stepping motors. However, as shown in (b), an inkjet printer was adopted instead of a drawing pen of XY plotter.

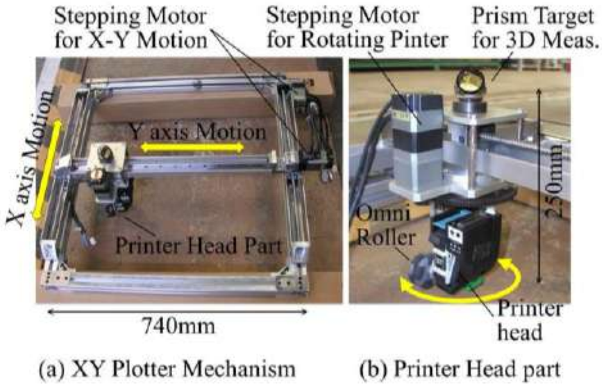

Figure 4. XY plotter type marking mechanism using the inkjet printer

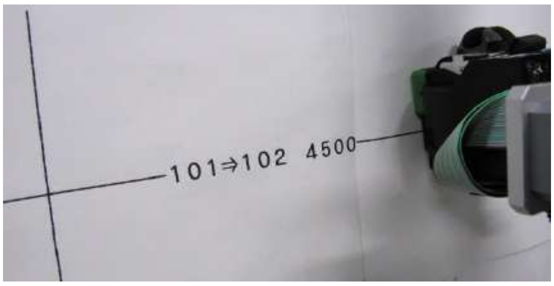

Figure 5. Example of line segments and characters printed by the inkjet printer

This special printer was developed for applications such as printing bar codes and letters on a cardboard box flowing through a production line. Using this, by simply running the XY plotter linearly, it is possible to print an arbitrary character string on the trajectory of the plotter. Incidentally, the height of the drawn characters is about 13 mm at maximum. Therefore, the efficiency of drawing characters is better than the original XY plotter, which needs to move the pen for the number of stroke counts of all the characters. In addition, control of the linear motion can be done simply by specifying only the coordinates of the start and end points and moving speed.

However, for proper printing without distortion, it is necessary to arrange the nozzles of the printer in parallel with the moving orientation of the XY plotter.

Therefore, as shown in (b), a stepping motor for turning the printer head was provided. Further, the printer head can move up and down so as to be able to absorb irregularities on the printed surface. In addition, a spring force acts on the print head in a orientation to press the head against the print surface. Depending on this spring force and an omni roller, the distance between the printing surface and the nozzle can always be kept at a distance suitable for printing. An example of line segments and characters drawn by the printer is shown in Figure 5.

On the other hand, a prism target for measuring the position and orientation of the robot by the total station was provided just above the nozzle of the printer head. This will be described in detail in the next section.

2.2.2 Marking Procedure in Cooperation with Total Station

The flow of the marking operation by the system is shown in Figure 6.

First, it is necessary to measure the benchmark which is the known point of coordinates in the on-site coordinate system by the total station and to obtain the transformation matrix between the internal coordinate system of the total station and the on-site coordinate system.

When after obtained this matrix, the controller of the system can command the motor driven total station to illuminate the work place where marking is drawn next with a built-in laser pointer. After that, a system operator moves the robot to the work place with the pointer as a guide.

Next, in order to draw line segments, it is necessary to obtain the transformation matrix of the internal coordinate system of the robot and the on-site coordinate system. Therefore, the system sequentially moves the XY plotter of the robot to the four corners of its operating range, and in each corner, makes the total station to measure the prism target described in the previous section. As a result, the position and orientation of the robot in the on-site coordinate system can be grasped, and a desired transformation matrix can be obtained.

By following the above procedure, the marking work can be executed by converting the start and end points of the line segments inputted as the coordinates of the on-site coordinate system into the local coordinate system of the robot as shown Equation (1).

$$(\boldsymbol{p}_{start} \quad \boldsymbol{p}_{End}) = f \cdot g \cdot (\boldsymbol{P}_{start} \quad \boldsymbol{P}_{End}) \qquad (1)$$

Here, $\boldsymbol{P}$ represents the coordinate values of the start and end points of the line segments described in the on-site coordinate system. And $\boldsymbol{p}$ represents those of the line segments expressed in the internal coordinate system of the robot. Also, f represents a coordinate transformation matrix between the total station and the robot, and g represents a coordinate transformation matrix between the on-site coordinate system and the total station.

Meanwhile, when marking on slopes, it is necessary to correct the start and end point coordinates of the line segments due to the influence of the height from the print surface to the prism target of the robot. The reason why the correction of the printing position on the slopes is necessary and the idea of the correction amount are shown as schematic diagram in Figure 7.

(1) Operator measures the benchmarks by using total station according to demand from the system

(2) Operator choses the marking data to execute

(3) The system indicates the point selected in (2) by using the laser pointer of the total station

(4) Operator moves the robot to the marking point according to the laser pointer

(5) Operator gives execution command of marking to the system

(6) The System measures position and direction of the robot by the total station

(7) The system executes marking work

Figure 6. Marking work flow by the system

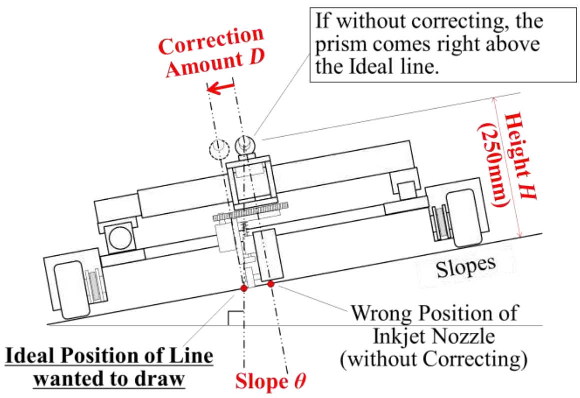

Figure 7. Schematic diagram showing the correction amount of the printing position required when marking on slopes

The prism target of the robot is located at the height H from the printed surface. Therefore, when drawing line segments on slopes, if the XY plotter is controlled so that the prism target passes right above target coordinates of the start and end points of the line segments, as shown in the figure, the lines wanted to draw and ones actually drawn have deviation.

Therefore, when measuring the robot position and orientation, the gradient θ of the slop is obtained, and the print position correction amount D shown in the expression (2) is calculated.

$$D = H \tan\theta \tag{2}$$

The results of the accuracy verification test of the marking mechanism are shown in Section 3.

2.2.3 Wall Traveling Mechanism

A picture of the bottom of the marking robot is shown in Figure 8. Both sides of the marking mechanism is the wall traveling mechanism. The inside of the left and right aluminum boxes is evacuated by a vacuum fan and the boxes are sticked to wall surface. And the mechanism travel the wall by motor driven wheels provided inside the boxes. By adopting four-wheel drive system that connects front and rear wheels with roller chain, not only going up and down but also turning by in-situ is possible.

Storing the wheels in the boxes makes it simple in structure, and since the reaction force from the wall surface by the suction is transmitted to all the wheels, a high payload can be obtained.

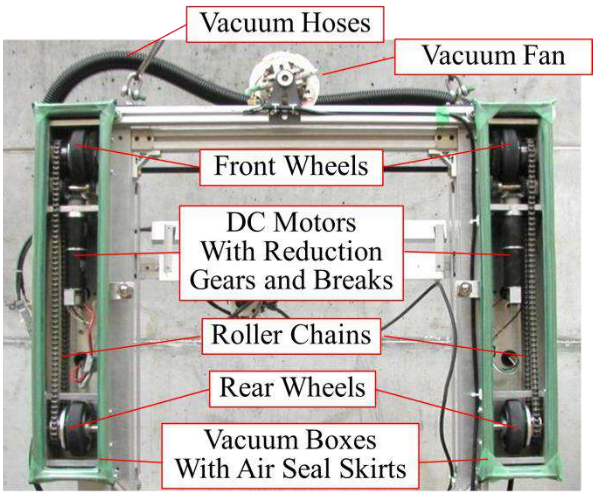

Figure 8. Bottom view of the marking robot

As shown in Figure 9, "skirt" which is the part that makes contact with the wall is made of rubber and sponge material and closely sticked to the wall without gaps. Furthermore, in order to reduce the friction between the skirt and the wall surface during running, a tape is affixed on the skirt.

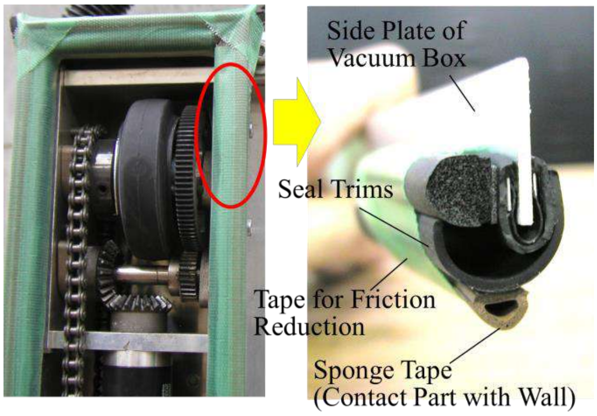

Figure 9. Cross-section shape of the air seal skirt

Table 3. Specification of the wall traveling mechanism

Item	Specification
Dimension of vacuum box (mm)	L:645 x D:100 x H:100 (Sticking Area: 0.065m^2)
Maximum pressure of Vacuum Fan (kPa)	-18
Output of motor for driving wheels (W)	150

Here, as shown in Figure 10, the force F required for the wall traveling mechanism to climb the wall at a constant speed while carrying the payload M (the mass of the robot) is obtained by equation (3).

$$\begin{aligned} F &= (m + M) + f_1 + f_2 = m + M + f \\ &= m + M + N\mu \end{aligned} \tag{3}$$

F: Driving force required to climb wall (N)
m: Mass of the wall traveling mechanism (N)
M: Payload (N)
f_1: Rolling resistance of the wheels (N)
f_2: Friction resistance between skirts and wall (N)
f: Wall climbing resistance (Summation of f_1 and f_2)
N: Wall sticking force (N)
u: Total coefficient value of rolling friction of wheel and static friction of skirt (-)

In addition, at this time, since the wheels must not slip, the driving force F must be equal to or less than the product of the static friction coefficient u_0 of the wheels at the time of rotation is restrained and the sticking force N, as shown in equation (4).

$$F \leq N\mu_0 \tag{4}$$

Here,
u_0: static friction coefficient of the wheels at the time of rotation is restrained (-)

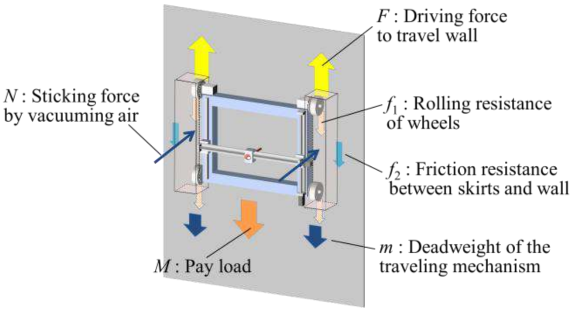

Figure 10. Schematic diagram showing the forces acting on the robot when climbing the wall with constant speed

Based on the relationship shown above, the maximum value of the payload that can be loaded on the wall traveling mechanism is represented by a linear function of the wall sticking force N as shown in Expression (5).

$$M_{mac} = N(\mu_0 - \mu) - m \tag{5}$$

3 Performance Verification of Marking System

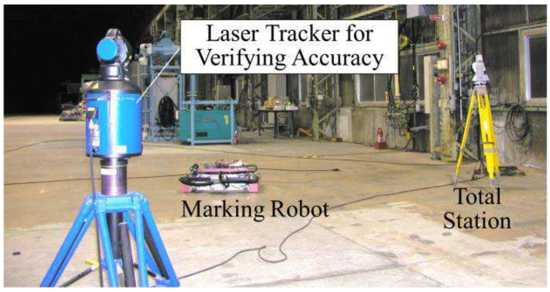
3.1 Verification Method

3.1.1 Verification Method of Marking Mechanism

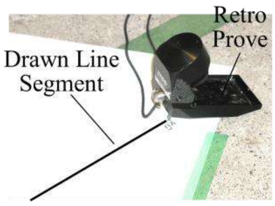
Items to be verified for accuracy of the marking mechanism are shown below.

1. Repeatability of drawing: To confirm whether there is any deviation between line segments drawn when the orientation of the robot are changed.
2. Correction of drawing position at sloops: To confirm whether accurate line segments are drawn on sloops according to equation (2).
3. Position accuracy of line segments drawn: To confirm whether accuracy of drawing position of line segments satisfies development objective.

In order to confirm the three items mentioned above, we did marking work on the floor of an area assumed a construction site, and measured the position of line segments drawn by using a high-precision three-dimensional measuring instrument "laser tracker". Figure 11 shows pictures of the verification test. Here, the main specifications of the laser tracker are shown in Table 4.



(a)Overall view of the test



(b)Drawing of line segments by the robot on white paper put on floor

(c)3D measurement of end point of drawn line by using "Retro prove" which is one of tools for laser tracker

Figure 11. View of verification test on marking accuracy

Table 4. Specification of a laser tracker using the test

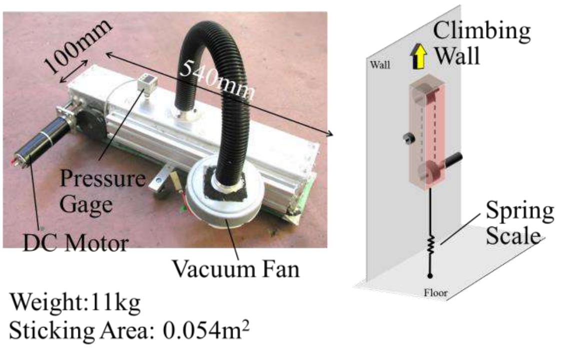
Item	Specification
Manufacture / Model	FARO / Xi
Accuracy of angle measurement	18um+3um/m
Accuracy of distance measurement by ADM	20um+1.1um/m

3.1.2 Verification Method of Pay Load of Wall Traveling Mechanism

In order to establish the design guidelines of the wall traveling mechanism to be mounted on the marking robot, we verified the payload of the mechanism by using a small test model.

(a) of Figure 12 shows the test model used the test. Area of the vacuum box and mounting position of the DC motor of the test model are different from ones of the marking robot shown in Figure 8. But the performance of the motor and the vacuum fan and the structure of the skirt are same of the robot.

As shown in (b) of Figure 12, we measured the reading of a spring scale which was connected between floor and rearward of the test model when the test model stopped to climb the wall because the driving force of the test model and the force of the spring scale was balanced. The test was repeated with changing the sticking force to wall by controlling output of the vacuum fan.



(a) View of the Test Model (b) Measurement Way of Payload

Figure 12. View of a test model of wall traveling mechanism and schematic diagram showing the way of measuring pay load

3.2 Result of Verification Test

3.2.1 Verification Result of Marking Mechanism

- Repeatability of drawing

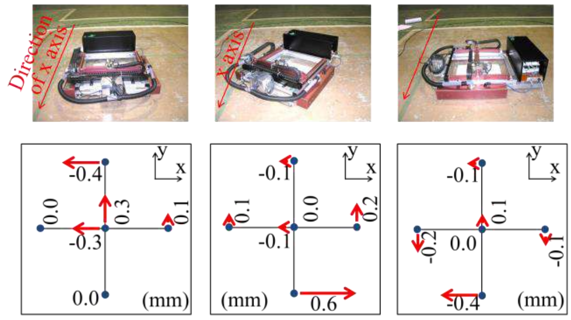
Figure 13 shows the result of the verification test. A cross shape line was drawn three times changing the orientation of the robot by about 45 degrees as shown in the upper photographs of Figure 13. After the drawing operation, positions of five points including the end points of each line segment and the intersections of the cross line were measured by the laser tracker. Here, length of each line segment is about 400mm.

Horizontal and vertical lines in the lower diagrams of Figure 13 show cross lines drawn. And numerals in the diagrams show the deviations between the target values and the measured values. In a similar way, arrows in the diagrams show the orientation of the deviations.

Among the three cross lines, 0.6 mm shown in (b) was the largest deviation. From this result, it can be said that the three cross lines were drawn in exactly the same place.

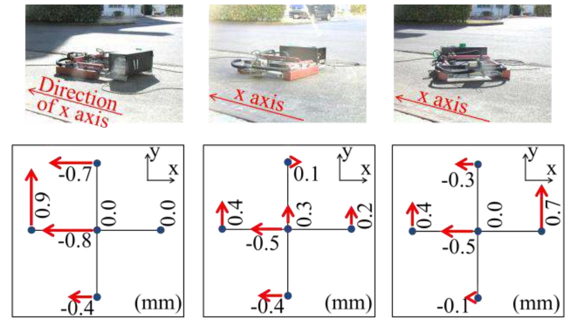
- Correction of drawing position at sloops

Figure 14 shows the result of the verification. As in the test mentioned above, a cross shape line was drawn three times on a sloop changing the orientation of the robot. Here, the angle of the sloop we used for the test was about 3 degrees. Thus, if correction is not done, 13mm of deviation between target values and measured values occurs according to equation (2). On the other hand, the deviation was 0.9 mm at the maximum as shown in (a). Thus, it was confirmed that the correction was performed correctly.



(a)Parallel with x axis (b)-45deg. rotation (c)-90deg. rotation

Figure 13. Confirmation results of repetitive positioning accuracy



(a)Parallel with x axis (b)90deg. rotation (c)135deg. rotation

Figure 14. Confirmation results of repetitive positioning accuracy on a slope

- Position accuracy of line segments drawn

Table 5 shows the evaluation results of the deviations between target values and measured values of coordinates of the intersection point of nine cross lines drawn on the horizontal floor. The maximum deviation from the target value was 0.7 mm, the average was 0.4 mm, and the standard deviation was 0.15 mm. Based on the above results, we judged that the development objective of the drawing accuracy 1 mm or less was achieved.

Table 5. Distance between the intersection of the nine crosshairs drawn by the robot and the true value

Maximum (㎜)	Average (㎜)	Standard Deviation (㎜)
0.7	0.4	0.15

3.2.2 Verification Results of Pay Load of Wall Traveling Mechanism

Figure 15 shows the result of pay load verification of the test model. This figure is a scatter diagram showing the relationship between wall sticking force and payload of the test model. The abscissa of the graph is wall sticking force, which is calculated by the product of the design value of sticking area of the test model and the measured value of the vacuum pressure, and the ordinate axis is the reading of the spring scale. In this case, the reading of the spring scale can be paraphrased as a payload of the test model.

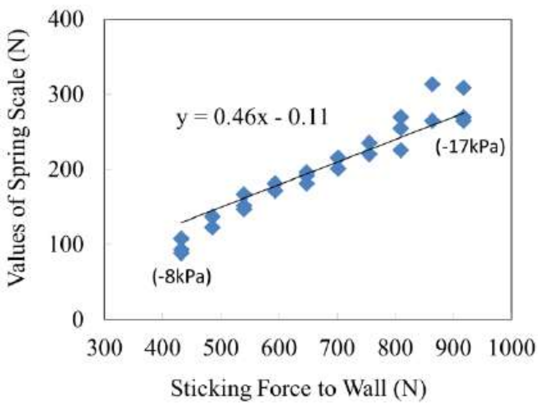


Figure 15. Verification result of pay load of the test-model wall traveling mechanism

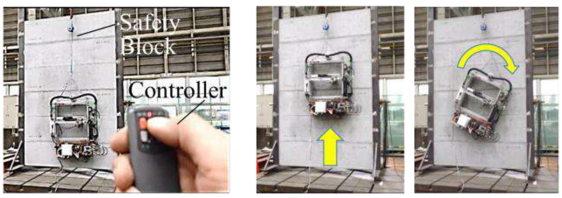
As shown in the graph, the sticking force and the payload are almost linear relations. At vacuum pressure of -17 kPa, which is almost the maximum capacity of a vacuum fan, the sticking force was about 900 N and the payload was about 300 N. Since this result is the data of one traveling mechanism, about 600 N of payload will be obtain when two traveling mechanism are used.

A line segment in the figure is linear approximation result of the data. Here, with reference to Equation (5), the intercept of the linear equation was assumed to be 0.11 N of the weight of the test model. As a result, the term (u_0 - u) of the friction coefficient shown in the formula (5) was experimentally found to be 0.46.

With reference to the above results, in the design of the final version, the sticking area of the vacuum box was set to 1.2 times of the test model, taking into consideration the safety factor and the dimension of the marking mechanism. Pictures the marking robot climbing the wall is shown in Figure 16.



(a)The Robot Travels Wall by Wireless Control (b) Climbing Motion (c) Turning Motion

Figure 16. Traveling and marking on concrete wall with using the developed marking robot

4 Conclusion

In order to rationalize the marking work for equipment installation at plant construction sites, we have developed the marking system and got the following conclusions.

1. We developed the XY plotter type marking mechanism using an inkjet printer and made it possible to draw arbitrary line segments and characters by linearly moving the XY plotter.
2. As a result of the verification test of the marking accuracy, it was confirmed that the robot can draw line segments with an accuracy of 1 mm or less. Therefore, the development objective accuracy was achieved.
3. We confirmed that the wall traveling mechanism which sticks to walls by using vacuum fan and moves on wall with a four wheel drive mechanism realized the wall traveling of the marking robot with its own weight of 56 kg.

5 Future Prospects

We have already applied this system at two of our plant construction sites and drawing accuracy have been achieved. However, there are issues such as counter measures to cool the control unit of the robot in outdoor work and weight saving of the robot.

From now on, we are planning to apply the robot to construction sites in earnest and calculate concrete effect, while working on countermeasures for the above problem. Furthermore, we will also work on improving performance such as addition of autonomous running function of robot to marking position.

Abstract –
Off-site construction has undergone a rapid development driven by their favorable characteristics, such as fast construction, waste reduction and clean on-site environment. Nevertheless, frequent engineering changes often create unpredictable challenges for precast production planning, resulting in production delay or additional storage costs. In order to achieve the target of just-in-time production and lean construction, it is vital to harmonize the supply chain communication amongst different phases of component production, transportation and on-site assembly. The automatic exchanges and conveyance of the process information amongst different phases are nearly impossible due to the mismatching definitions of semantics and syntax used in different planning software that are adopted in different construction phases, e.g. assembly design, component production, and on-site assembly. To address this problem, the Process Specification Language (PSL) is explored in this paper to unify the process information from multiple planning software applications. A translation framework of process information communications in the off-site construction supply chain has been developed based on the functional analysis. Semantic mapping and extensions of PSL are proposed, given the specific requirements of off-site construction scheduling management. Finally, the superiority of this method is demonstrated using two case studies to confirm the scheduling and sequencing information interaction amongst the phases of assembly design, component production, and on-site construction can be enhanced by the present method.

Process Specification Language; PSL; Supply Chain; Off-Site Construction; Process Ontology

1 Introduction

Compared to the traditional cast-in-situ construction methods, the successful management for off-site construction relies much more on the efficient precast supply chain management [1]. However, the supply chain management of off-site construction still faces many challenges, and the failure of just-in-time delivery of precast components is one of the most vital reasons for the delay on the construction site [2]. If the precast components arrive too early on the construction site, it will result in an increase in cost and on-site storage[3]. The off-site construction supply chain phases consist of planning, design, fabrication, delivery and on-site assembly. Frequent engineering alternations in the fabrication and construction phases, and the lack of or less effective coordination and communication, have made such problems more prominent. Improving the coordination and interoperability for various phases and parties, is considered to be the key to solve such issues in the off-site construction supply chain management [4].

The lack of ICT interoperability is primarily owing to the incompatibility amongst the syntaxes of the languages and the semantics of the terms [5] adopted in different phrases. To overcome this issue, one approach is to develop and update the different direct translators or core database adopted in different phases for each application, which lacks the required accuracy. The alternative approach is to develop a common data standard, e.g. IFC and EXPRESS. The NBIMS (National Building Information Modeling Standard) released the 'Information Delivery Manual for Precast Concrete' to further improve its support for data exchange during the life cycle of off-site construction projects [6]. At present, IFC standards can be used to communicate the product data and primary process data, but the necessary concepts and definitions to support more complex processes, e.g. the complicated scheduling and sequencing information are missing [7].

Construction supply chain management includes a set of process-driven activities. Precast fabricators usually apply ERP (Enterprise Resources Planning) system with MES (Manufacturing Execution System) and APS (Advanced Planning and Scheduling), to deal with the tasks of production scheduling, delivery planning and factory site storage. Contractors use the project management software to develop and control the assembly schedule on the project sites. The communication and coordination between the precast fabricators and contractors is based on delivery order, which is closely related to the progress of fabrication and construction. Thus, it brings up the question on how to achieve the information compatibility and interchangeability amongst the different software packages is of great practical relevance.

PSL ontology is considered as the process information interaction tool applied to the construction and supply chain management [8]. This paper incorporate the process information from different construction planning software and then apply the PSL ontology to strengthen the supply chain communications for off-site construction.

2 Literature Review

2.1 PSL Ontology

The concept of Ontology originated from the field of philosophy. Gruber defined it as 'an explicit specification of a conceptualization' [9]. To date, the research on ontology mostly focused on exploring how to describe a wide range of knowledge-sharing behaviors [10]. Ontology has a unified standard in the interpretation of knowledge items, suitable for data interoperability, information search and retrieval, automated inference and natural language processing in computer. Edward et al.[11] described a system to support multidisciplinary analyses of complex engineering problems by using pre-project planning ontology. Sheryl et al.[12] developed a feature ontology to support construction cost estimation by transforming the designer-focused product models into the estimator-focused product models.

Process Specification Language (PSL) is a set of logic terms to describe process which is applicable to manufacturing, engineering and business processes including production scheduling, process planning and management, business processes reengineering, simulation, realization, modeling and project management. ISO 18629provides the theoretical framework and application guides fpr PSL [13]. PSL contains 38 modules with more than 300 concepts in total. The core theory of the PSL ontology is illustrated in Figure 1 [14].

Cutting-Decelle et al. [15] illustrated the basic theorem of PSL and pointed out that PSL could be used for the representation and exchange of process information in Architectural Engineering and Construction (AEC) industry. PSL was proven to offer the interoperability improvement in the multiple process-related applications due to the function of formal semantic definitions and complete automization [16]. An ontology-based framework based on PSL was established, and the semantic presentation of design using PSL as well as the application in two case studies using CAD/CAM software were illustrated [17]. PSL was used to support the process information communication between multiple software including AutoCAD, Construction Computer Software and Microsoft project [18]. The main-stream methods and techniques to building supply chain communications were presented, including a new semantic-based approach [19]. PSL was used for information exchanges in a cross-disciplinary supply chain environment to describe the business process network and the information exchange of supply chain nodes amongst fabricators, suppliers and contractors [20].

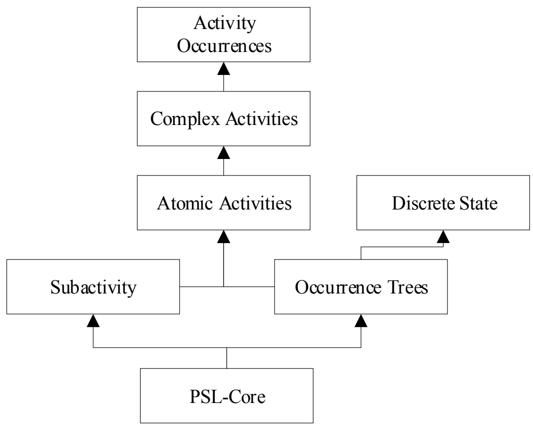

Figure 1. Core theory of the PSL ontology[12]

Cheng at al.[21] developed ontology mapping and information exchange amongst PSL, ifcXML and aecXML which can be applied in the project scheduling in the construction industries as the ontology standards. More studies have shown the ability of PSL in the information exchange of project scheduling among different software applications, e.g. Primavera P3, 4D Viewer Microsoft Project and Microsoft Excel [22]. Another study investigated how the PSL was used to indicate potential conflicts and to perform consistency checking on project scheduling information [23]. On this basis, a prototype framework enabling the remote collaboration of heterogeneous systems was proposed and a standard for data exchange based on PSL ontology was established [24]. A simulation access language (SimAL) based on PSL ontology was described to access and develop software applications for internet purposes[25]. A case study communicated online weather forecasting information with project scheduling and management application was illustrated to describe the use of the SimAL.

In summary, limited research has focused on the application of PSL ontology in AEC industry, which mainly targeted traditional on-site construction management. The instant interaction of process information is essential due to the tight connection of off-site production and on-site construction. Therefore, PSL ontology needs more research focused on its application, as it has the potential to bridge the gaps on the integration of off-site construction.

2.2 Knowledge Interchange Format (KIF)

KIF is a formal language designed to exchange knowledge among disparate computer systems, which is the grammar of PSL [26]. KIF was proposed and developed by the Logic Group of Stanford University and is a proposed draft American National Standard (pdANS).

KIF is based on the first-order logic and its language description includes syntactic and semantic standards. KIF supports declarative semantics, and the language is logically comprehensible [27]. KIF has two variants, i.e. the linear and structured KIFs. All expressions for linear KIF are ASC II strings, and the structured KIF includes characters, language elements, expressions and comments.

3 Process Information Communication in Supply Chain for Off-site Construction

3.1 Information Flow between Engineer, Precast Fabricator and Contractor

The supply chain of off-site construction contains a large array of parties including clients, architects/engineers, contractors, suppliers (precast fabricators) and consultants linked with comprehensive information flows [28]. In general, clients mainly take part in the planning and operation phases, and the consultants may not participate in the actual construction activities. The dynamic and constant communication of information amongst engineers, precast fabricators and contractors is vital for supply chain management during the whole construction processes. The information flowchart is presented in Figure 2.

Architects will pass the design model to engineers in the early stages based on the commencing order instructed by clients. The precast assembly drawings (PAD) made by engineers are then sent to precast fabricators and contractors simultaneously. On this basis, contractors can draw up the construction scheduling (CS), which will be subsequently sent to the precast fabricator. The precast fabricator can work out the production scheduling to meet the requirements of PAD and CS. The precast components will be produced in batches according to their specified delivery dates, and the contractor will use them for the construction assembly at sites.

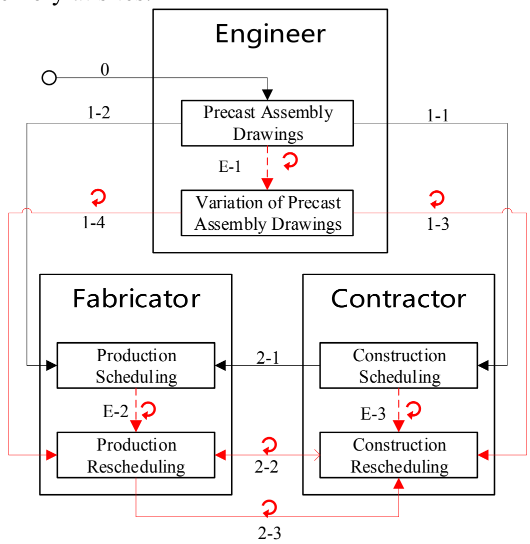

Figure 2. Typical information flow in supply chain

Table 1 Information Exchange and Type

Number	Information Exchange	Type
0	Start Order	Process
1-1	Building Information	Object
	Assembly Sequencing	Process
1-2	Component Design	Object
	Resource Require	O&P
	Assembly Sequencing	Process
2-1	Construction Scheduling	Process
1-3	Building Information Change	Object
	Assembly Sequencing Change	Process
1-4	Component Information Change	Object
	Resource Require Change	O&P
	Assembly Sequencing Change	Process
2-2	Construction Rescheduling	Process
2-3	Production Rescheduling	Process

A large number of engineering changes caused by unexpected situations occur frequently during the construction processes. The variation of PADs is required re-drawn by engineers when the architect modifies the design or the original design error is found and rectified (E-1). After the variation notification of precast design is sent to precast fabricators and contractors, the Production Rescheduling (PR) and Construction Rescheduling (CR) should be formulated accordingly. In addition, the production may also be triggered by the equipment failure or raw material supply delay (E-2). On the contractor side, some uncontrolled factors, such as weather conditions, construction machinery failure, may also lead to the necessity of PR (E-3). As a result, the precast fabricator may also develop PR based on the updated CR. Although these engineering changes occur on a random basis, it tends to occur frequently throughout the entire construction duration owing to the complexity of the construction environment. In summary, the type of the complicated information communication is listed in Table 1.

3.2 Applications by Software

The process information of supply chain can be divided into two types, i.e. business and construction information. Many different software packages can facilitate the construction management. For example, BIM-based software, such as Autodesk Revit, Tekla Structures, Nemetschek Allplan, Structure Works and IDAT CCAD, can support engineers to prepare precast assembly drawings. Precast fabricators use ERP (Enterprise Resource Planning) packages to manage the planning and scheduling of production, e.g. SAP ERP, IDAT ERP, Asprova APS and Nemetschek TIM. MES (Manufacturing Execution System) applications such as RIB SAA may also be adopted by precast fabricators to control machines for automatic production. Contractors often use Project management tools for on-site construction management, and the Microsoft Project, Oracle P6 and Autodesk Navisworks are widely adopted for such purpose. The typical software types used in different phases are shown in Figure 3.

Figure 3. Typical software used in different phases

3.3 Process Information Communication Using PSL Ontology

The process information communicate amongst different applications through syntactic and semantic translation. Figure 4 illustrates an example of data transferring between precast fabricator and contractor. The original files from IDAT ERP or MS Project can be transformed into their KIF syntax. And then they can be transformed into PSL ontology (KIF syntax and PSL terminology), where they can have some exchange. This process is reversible, through which the new data can be send back to their original applications in an opposite direction.

Although the ontology of the original application is usually hidden, users can create their own ontology based on the output from the application. The semantic translator unifies the terminology of each application with PSL definitions.

.

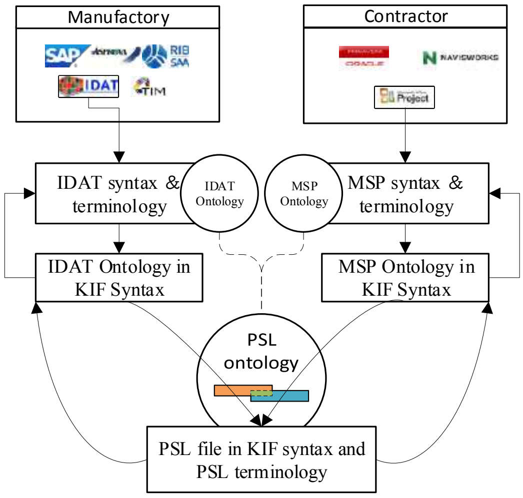

Figure 4. Process information exchange via PSL

4 Process Information Communication for Scheduling

The production scheduling of components needs to be synchronized with the on-site construction scheduling. However, the production and construction planning may be easily affected by the unpredictable factors on each side. In the current practice, the precast fabricator monitors the production anomalies and communicates with contractors on a weekly basis. The negative consequence as a result of this type of communication practice includes the sub-optimal decision-making, inadequate utilization of production capacity, and lagged feedback of information, which will lead to the failure of just-in-time delivery and lean construction. This will cause the delay in the overall project progress and the cost increase for both fabrication and construction. PSL ontology can be utilized to tackle this problem, namely, unify the production and construction scheduling via instant data transfer and synchronized communication. In doing so, the entire process information can be integrated into a single system and the scheduling can be automatically updated should any change in one of the process take place.

4.1 PSL Ontology Mapping for Construction Scheduling

MS Project and Oracle P6 are frequently used to perform construction scheduling in Construction management. Other software with the 4D management capabilities such as Naviswork also share the same principles and basic concepts as MS Project for scheduling management. Multiple concepts including tasks, duration, constraints, ordering relationship, order and resource requirement can be described with these applications. The logic of duration and ordering relationships can be expressed with Gantt chart, using different dependences relationships. The dependence elements include predecessors, successors, basic types and absolute/relative leading or lagging times, as shown in Figure 5, in which the relation between multiple process is also illustrated both in their full and abbreviated terms, e.g. Finish-to-Start and FS.

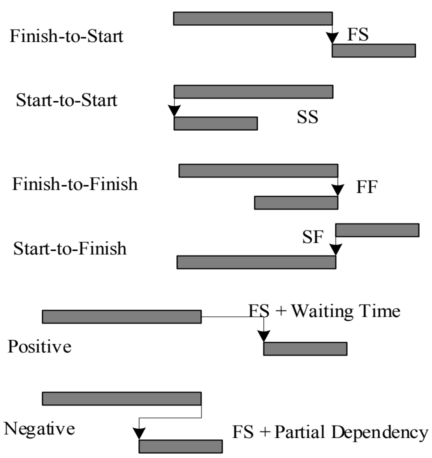

Figure 5. Construction Dependencies in Gantt Chart

Table 2 Semantic mapping of dependences relationship

Concepts in Project Management Apps	PSL terms
Predecessor/Successor	before-start, before-end, after-start, after-end
Finish-to-Start	meets, end-equal-start
Start-to-Start	starts, start-equal-start
Finish-to-Finish	finishes, end-equal-end
Start-to-Finish	start-equal-end
Positive Lag	before-start-delay, before-end-delay
Negative Lag	after-start-delay, after-end-delay

PSL ontology provides enough terms to represent the dependence relationship with the ordering relation extension and temporal ordering relations extension . A semantic mapping between dependences relationship and PSL ontology is listed in Table 2.

4.2 PSL Ontology Mapping For Production Scheduling

Two kinds of casting beds and casting flows exist in precast concrete plants, e.g. the mobile and fixed casting. The mobile casting method is more widely adopted owing to the higher level of mechanical automation and the efficiency in the space use. Hence, the mobile production mode is analyzed in this case study. The production scheduling can be shown by Production Gantt Chart as Figure 6 [29].

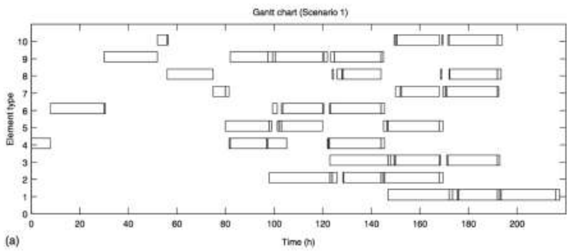

Figure 6. Production scheduling for Mobile Precast Concrete Casting [29]

In the streamline production mode, the semi-finished products may directly be sent into the back-end production line. The ordering relationships are more complicated than these in construction scheduling. Additional dependences relationships of SSFF, FSF and FFS are shown in Figure 7. For instance, SSFF means the start of the first production triggers, the start of the second and both lines will finish at the same time; FFS means that the second line will commence after a period of time following the first line, its predecessor, commences; FSF means that apart from the first round where the finishing of the first line triggers the starting of the second one, the remaining start of the first line will all depend on the finishing of the second line.

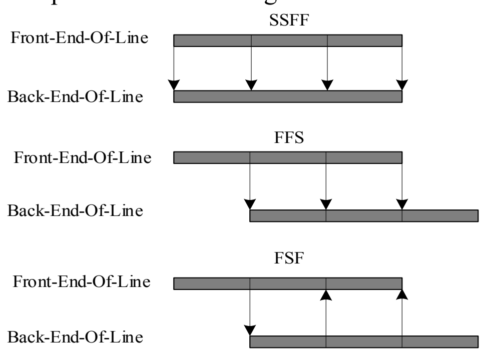

Figure 7. Production Dependencies in Gantt Chart

The relationship of SSFF, FSF and FFS can be described by PSL ontology as in Table 3.

Table 3 PSL term extensions for complex concepts

Concepts	PSL terms extensions
SSFF	*(defrelation SSFF (?a ?b) := (exists (?a1 ?a2 ?a3 ?a ?b1 ?b2 ?b3 ?b) (and (subactivity ?a1 ?a2 ?a3 ?a) (subactivity ?b1 ?b2 ?b3 ?b) (mutually-occurring ?a1 ?a2 ?a3 ?a) (starts ?a1 ?b1) (starts ?a2 ?b2) (starts ?a3 ?b3) (finishes ?a3 ?b3))))*
FFS	*(defrelation FFS (?a ?b) := (exists (?a1 ?a2 ?a3 ?a ?b1 ?b2 ?b3 ?b) (and (subactivity ?a1 ?a2 ?a3 ?a) (subactivity ?b1 ?b2 ?b3 ?b) (mutually-occurring ?a1 ?a2 ?a3 ?a) (meets ?a1 ?b1) (meets ?a2 ?b2) (meets ?a3 ?b3))))*
FSF	*(defrelation FSF (?a ?b) := (exists (?a1 ?a2 ?a3 ?a ?b1 ?b2 ?b3 ?b) (and (subactivity ?a1 ?a2 ?a3 ?a) (subactivity ?b1 ?b2 ?b3 ?b) (mutually-occurring ?b1 ?b2 ?b3 ?b) (meets ?a1 ?b1) (meets ?b1 ?a2) (meets ?b2 ?a3))))*

4.3 Example of Scheduling Communication using PSL Ontology

The information communication contains syntactic and semantic translation into the PSL ontology. The semantic translation is separately presented by PSL ontology mapping for construction scheduling and production scheduling. An example of information communication between MS Project and IDAT ERP software is introduced below.

It is a four-step work. Firstly, the MS Project data file is represented with PSL syntax and MS Project terminology, and then further written as a complete PSL representation. Next, these PSL representations are further transformed into PSL syntax and IDAT ERP terminology. Finally, the PSL syntax and IDAT ERP terminology is written as input file for IDAT ERP. The first two steps are shown below as an example， and the next two steps are the mirror work to the first two. This study takes an example to describe scheduling with multi dependences relationship in Figure 8.

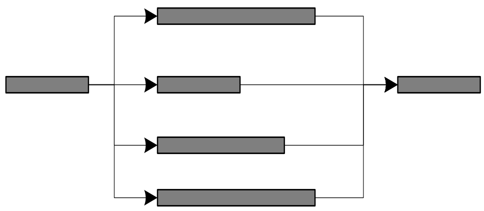

Figure 8. The example of multiple predecessors

The scheduling data written in MS Project using the VBA (Visual Basic for Applications) language, and the coding format and terminologies defined in VBA. The scheduling data file in MS project's representations is as below.

```
{Project        multiple Predecessors –opening (x)}
{Task           predecessor activity,
                intermediate activity group,
                successor activity}
{Dependence     order relationship as scheduling (x)}
{Period         duration as scheduling (x)}
```

For the translation process, a syntactic translator needs to be developed to read the scheduling file from MS Project. The syntactic translator then translates the original data to a presentation with PSL syntax and MS Project terminology as below.

```
(forall (?x)
(=>(multiple_predecessors-opening ?x)
    (task ?a ?b ?c)))
(forall (?b)
    (=>(and(activity_group ?b1 ?b2 ?b3 ?b)
    (StartToStart ?b1 ?b2 ?b3)
    (Period ?t1 ?t2 ?t3 ?b1 ?b2 ?b3))))
(forall (?occ)
(=>(and (ActualStartDriver ?a ?b ?c)
    (FinishToStart ?a ?b ?c)
    (Period ?t4 ?t5 ?t6 ?a ?b ?c)))
```

The PSL syntax can be mapped to PSL definitions. The presentation of the scheduling file adopts PSL ontology, which contains PSL terminology and PSL syntax as below.

```
(forall (?x)
(=>(multiple_predecessors-opening ?x)
    (activity ?a ?b ?c)
(forall(?b)
    (=>(and (subactivity ?b1 ?b2 ?b3 ?b)
        (starts ?b1 ?b2 ?b3)
        (=>(duration ?b1 ?t1))
        (=>(duration ?b2 ?t2))
        (=>(duration ?b3 ?t3)))))
(forall (?occ)
    (=>(and (occurrence_of ?a ?b ?c)
        (meets ?a ?b ?c)
        (=>(duration ?a ?t4))
        (=>(duration ?b ?t5))
        (=>(duration ?c ?t6)))))
```

5 Process Information Communication for Assembly Sequencing

BIM is usually adopted for virtual assembly analysis in addition to the complicated Precast Assembly Drawings. The assembly sequencing from virtual assembly analysis will be sent to precast fabricators and contractors. Process information of assembly sequencing is paramount between the communication of contractor and precast fabrication. The wrong assembly sequencing will result in project delays and additional costs for contractors. To the precast fabricators, the assembly sequencing will determine the stacking sequencing in transport vehicle and on-site yard. The correct stacking sequencing enables the crane to hoist the components directly one by one in order to save construction time and the storage space.

5.1 Example for Assembly Sequencing Process

The example project is a residential based on shear wall structure. The main structure consists of the precast shear walls, precast columns, laminated slabs and laminated beams. The BIM model build by Allplan is shown in Figure 9.

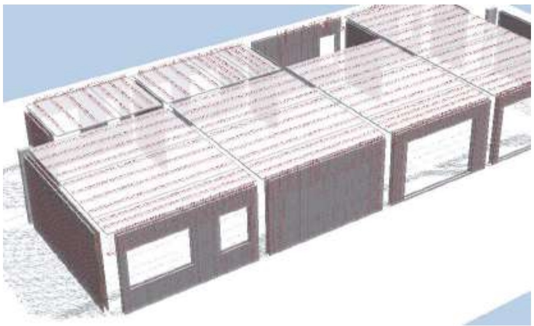

Figure 9. BIM model of the example project

Figure 10 illustrates the positions of precast components in the room at the corner, and the numbers have been assigned for each component. The entire assembly sequencing process of this room is described by IDEF3, as shown in Figure 11 and Figure 12. Figure 11 shows the main activities of the whole assembly process. The precast shear wall and the precast column must first be assembled before the laminated beam is assembled. Figure 12 illustrates the sub-activities of shear wall assembly. The inner wall (S3) and the wall on the other side from crane (S1&S2) will be first assembled. The outer wall and the wall near the crane will be finally assembled to insure the hoisting space.

5.2 Assembly Sequencing Process by PSL Ontology

In order to describe the assembly sequencing process, the PSL ontology is used to translate the activities as indicated in Figure 11.

```
(subactivity assemble-shear-wall)
(subactivity assemble-column)
(subactivity assemble-beam)
(forall (?occ))
    (<=>(occurrence_of ?occ assemble-room1)
    (exsits (?occ1 ?occ2 ?occ3)
    (and (occurrence_of ?occ1 assemble-shear-wall)
    (occurrence_of ?occ2 aseemble-column)
    (occurrence_of occ3 assemble-beam)
    (subactivity_occurrence ?occ1 ?occ)
    (subactivity_occurrence ?occ2 ?occ)
    (subactivity_occurrence ?occ3 ?occ)
    (soo-precedes (soomap ?occ1)(soomap ?occ 3) assemble-room1)
    (soo-precedes (soomap ?occ2)(soomap ?occ3) assemble-room1)
    (strong_parallel ?occ1 ?occ2 assemble-room1))))))
```

6 Conclusion and Future Work

This paper presented the novel method of PSL ontology to improve the supply chain communications for off-site construction. PSL ontology has rich definitions to describe process activities in scheduling and sequencing. It can be used to provide a common framework to exchange data originated from different application packages used in various construction phases. While IFC provides the fundamental data structure of BIM applications, PSL has the potential to be incorporated with IFC so that the supply chain communication for off-site construction can be integrated into both domains of the building information and construction activities.

Abstract –

More and more high-rise buildings are being erected in extensively populated countries such as China nowadays with the requirement of higher living standards. However, on the one hand, with the development of aging society, the labor shortage has become a remarkable problem; on the other hand, the danger and difficulties in construction increase significantly with the height of the buildings. Thus, the application of automation and robotics technology is expected to ease such problems and concerns. Up to now, various methods and systems using automation and robotics technology have been proposed to be used in high-rise building construction. This paper summarizes the major advance on the application of automation and robotics technology in high-rise building construction through a literature survey and suggests directions of further research in this field. First of all, the research scope, the method and the results of the literature survey are presented. Then, based on the survey results, the relevant applications are summarized regarding the three parts of high-rise buildings, i.e., earth and foundation work, superstructure erection and façade installation. Finally, the future directions and opportunities mentioned in existing research are summarized and discussed. This paper provides a valuable aid in future research and application of automation and robotics technology for high-rise buildings.

Keywords –

Automation and robotics; High-rise building; Earth and foundation work; Superstructure erection; Façade installation

1 Introduction

Due to the demographic and economic developments, the number of the world's high-rise buildings is growing rapidly. The emergence of high-rise buildings mitigates the pressure of the growing population, but also requires a large quantity of labor force during the construction. Meanwhile, the number of young workers is decreasing at the construction site, due to the aging population in many countries in the world. What is more, the safety problems and the workers' psychological fear of the height are also remarkable challenges at the construction site of high-rise buildings. Obviously, both the predictable labor shortage and the life safety of the workers call for leveraging machines and robots to replace human labor in high-rise building construction.

The application of automation and robotics technology in the construction industry have been reviewed in several papers. Bock [1] suggested that conventional construction methodology had reached its limits, and outlined five aspects of future opportunities for construction automation: robot-oriented design, robotic industrialization, construction robots, site automation, and ambient robotics. Son et al. [2] analyzed the topics and contents of 1671 papers in International Symposium on Automation and Robotics in Construction (ISARC) proceedings from 1990 to 2008, to identify trends and future directions of automation and robotics technology in construction. Vähä et al. [3] surveyed on sensor technology and its potential use for construction automation and reviewed robotic applications in the main construction procedures. Taylor et al. [4] summarized the existing automated machinery and construction robots in Japan, and suggested that construction environments should be more structured and controlled to apply construction robots. Maas and van Gassel [5] discussed the development of automation and robotics technology and its influence on performance management, construction engineering, and construction management.

These papers have presented the application of automation and robotics technology in the construction industry as a whole, pointed out the key research areas and analyzed the current and ongoing research and development trends. However, there is a lack of a systematic review of the application of automation and robotics technology in high-rise building construction.

This paper summarizes the major advance on the application of automation and robotics technology in high-rise building construction through a literature survey and suggests directions of further research in this field. To this end, considering the characteristics, the paper focuses on three sub-phases of high-rise building construction: earth and foundation work, superstructure erection and façade construction. In Section 2, the research scope, the method and the results of the literature survey are presented. Then, by analyzing the survey results, Sections 3, 4 and 5 respectively present the application of automation and robotics technology in the construction of foundation, superstructure and façade, and Section 6 summarizes the future directions of automation and robotics technology for high-rise buildings. Finally, the paper is concluded in Section 7.

2 Research Scope and Literature Retrieval

The definition of the term "high-rise building" varies in different countries. For example, according to Chinese standards, a high-rise building refers to a residential buildings over ten stories or 28 m, or a nonresidential buildings over 24 m; in Japan, a high-rise building is over eight stories or 31 m; and in the U.S., it is over 24.6 m or seven stories. Besides, the high-rise buildings taller than 100 m are called "skyscrapers". In this paper, the high-rise building is not strictly defined, and it covers the definitions in different countries and includes the skyscrapers.

To implement a systematic literature review, a comprehensive search was conducted in the major databases, including Engineering Village, Scopus, ASCE, and Web of Science. The search keywords included "high-rise", "robot", "automation", "construction", "assembly", "installation", "machine", "equipment", etc. However, the publications in the form of editorials, books, discussions, or published before 2000 were excluded because they are considered to be of little value for the review. By reading the titles, abstracts and conclusions, we filtered out unrelated papers and finally obtained 50 papers. Particularly, we found the review on application of automation and robotics technology in the sub-phase of earth and foundation work is already comprehensive (which is further explained in Section 3), so we only included three latest review papers of earth and foundation work in this study. The distribution of the retrieved papers related to superstructure and façade (47 papers) is shown in Figure 1.

3 Application in Earth and Foundation Work

The earth and foundation work is an essential sub-phase for the construction of each type of buildings. It contains many repetitive operations and is also among the most dangerous work in building construction. Therefore, the research on the application of automation and robotics technology in earth and foundation work is one of the pioneers in the construction industry, and numerous papers have been published on this topic. Several reviews have been conducted in recent years to summarize the major studies comprehensively. To avoid repetitive work, this study only presents three latest reviews published in 2016 and 2017.

Naskoudakis et al. [6] reviewed 73 papers published from 2006 to 2015 about earthmoving equipment and divided them into seven main research themes, one of which is robotics and automation. Two sub-themes were then identified, i.e., unmanned construction, and real-time monitoring and detection. Azar and Kamat [7] provided a comprehensive review of the technical advances in earthmoving automation in both industry and academic community and discussed the limitations and future directions. They classified the studies of earthmoving equipment automation into four categories: equipment tracking and fleet management, safety management, equipment pose estimation and machine control, remote control and autonomous operation, among which the last one was identified as the most immature fields. Dadhich et al. [8] provided the background of the autonomous earthmoving, and presented a survey covering the key research topics and identified the knowledge gaps of automation of earthmoving machines, especially the operation of wheel loaders in a short loading cycle. In this review paper, the main knowledge gaps were identified as fragmented rock excavation, communication for remote operation, and operator experience during remote operation.

The major specific technologies included in automation and robotics technology and their applications mentioned in the above studies are identified and summarized in Table 1.

4 Application in Superstructure Erection

For the sub-phase of superstructure erection of high-rise buildings, the construction difficulty increases significantly as the building height grows, which mainly appears in three aspects, the low productivity and safety concerns due to the manual work in hazardous working environment, the vertical transportation of workers, materials and equipment, and assembly of heavy objects, especially for steel structures. Thus, the related studies are classified into three sub-themes corresponding to the three aspects: automated construction systems, automated lifting systems, and robot-based steel assembly systems. The following sub-sections will describe them respectively.

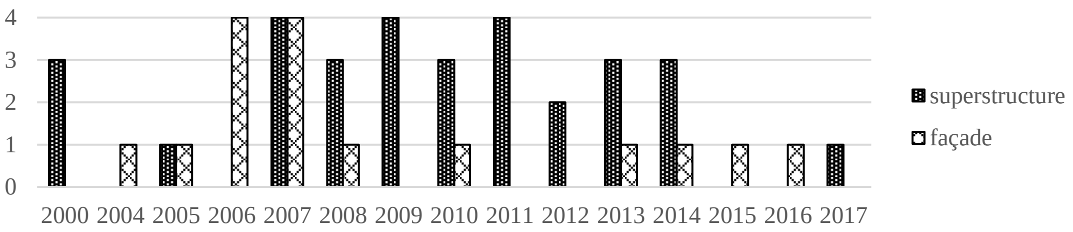

Figure 1. Distribution of the related papers of superstructure and façade

Table 1. Summary of the major specific technologies and their applications in the above studies

4.1 Automated Construction Systems

Automated construction systems are designed to stabilize the construction process and improve the productivity of high-rise building construction by establishing a comfortable working environment which is suitable to employ the automated equipment and robots. In this study, seven related papers were identified.

Miyakawa et al. [9] proposed an automated building construction system (ABCS) for high-rise steel structures, which integrates three parts: 1) a synchronously climbing structure that encloses an all-weather working space, called "Super Construction Factory (SCF)"; 2) a parallel delivery system for material lifting; and 3) centralized management systems, for production management, equipment operation management and machine control. Based on ABCS, another system called "Big Canopy" was developed for prefabricated high-rise reinforced concrete buildings [10, 11], which adapts to the characteristics of reinforced concrete construction.

Compared with the conventional method, ABCS and Big Canopy successfully improved the working conditions and construction productivity. However, the equipment configuration of the SCF limits the versatility of automated construction systems. Moreover, the costs and weights are extremely high because of the combination of the robots, massive cranes and lifting systems [12, 13]. Therefore, Kang et al. [12] developed a robotic-crane based automatic construction system (RCA system) for steel structures of high-rise buildings, which comprises a construction factory (CF), a steel assembly system and a monitoring and control system. In RCA system, the tower crane was installed at the core of building so that the heavy lifting and robot systems are independent of the CF, which decreased the weight of the system and reduced the construction cost as well as provided a convenient working space. Kim et al. [13] developed several conceptual CF alternatives to improve the working environment, and evaluated them with the Computational Fluid Dynamics method. The evaluation procedure and results provided an economical approach to select the CF in high-rise building construction.

With the development of the automated construction system, assessment methods were proposed to measure the economic and construction efficiency. Kim et al. [14] developed a benefit/cost analysis process for the application of robot-based construction automation systems, which can measure the economic viability of the automated systems. Van Gassel [15] conducted a simulation of the construction process of a Dutch high-rise building, involving the use of an automated construction system. By comparing the simulation results and the real construction data, the paper verified the economic benefits of automated construction systems, and promoted the application of automated construction systems in the Netherlands.

4.2 Automated Lifting Systems

For high-rise buildings, the vertical transportation of workers, materials and equipment significantly influences the construction efficiency. Therefore, several studies have been conducted to improve the automation level of the vertical transportation equipment. Eight related papers are identified.

Kim et al. [16] proposed a table formwork lifting system integrated with construction hoists, which improves the productivity, cuts down the high initial cost and overcomes extra work for assembly and operation. Cho et al. [17] developed a hoist-mountable intelligent toolkit for the lift car. With this toolkit installed, an existing lift car can be converted to an intelligent one, which can utilize remote sensing and communication technologies to capture the information of material movement and manage it intelligently. Based on this toolkit, a concept of a smart robotic lift [18] is proposed, with functionalities of automatic loading/unloading operation and wireless communication.

Operation planning and optimization are major factors to determine the productivity of the automated lifting process. Sin et al. [19, 20] proposed an unmanned smart lifting system and devised an optimized operation algorithm for twin or multi-cage lifts, which can reduce work hours and traffic queues. Cho et al. [21] provided a simulation method of construction hoists to calculate the lifting cycle time according to lifting heights and loads, and to generate an optimal hoist operating plan. They also developed an optimal algorithm [22] for path planning of the multi-lifting operation in super-tall buildings. These algorithms and methods optimized the automatic control of the lifting system, and thus enhances the work efficiency of vertical delivery.

Operation monitoring is another important aspect, especially for the smart tower cranes. Lee et al. [23] proposed an automated lifting-path tracking system for a robotic tower crane, which used laser devices to measure the linear distance, and an encoder and an accelerometer to measure the horizontal and vertical angles. The system monitors the operation actions of the tower crane and is helpful in safety management and lifting path planning.

4.3 Robot-based Steel Assembly Systems

The robot-based steel assembly task in high-rise buildings can be divided into three aspects: alignment of the steel components and the bolting holes, transportation of the bolting robot, and bolting operation. Fourteen related papers are identified.

A research team from Korea University continuously studied on robot-based steel construction and proposed a robotic beam assembly system (RBA system) [24-26], which comprises three sub-systems: a robotic bolting device, a control system, and a robotic transport mechanism. The bolting device [27] consists of an end-effector for bolting operation, a robotic manipulator that places the end-effector in the bolting position, and a cabin as the control station. The robotic transport system [28] consists of a cross-wired lift and a rail sliding mechanism, respectively in charge of the vertical and horizontal transfer of the RBA system. Lee et al. [29] also proposed a robot-based steel beam assembly system with sub-systems of transportation and positioning. The transportation system combines a rail with a boom, and the positioning system comprises four wires-suspended motion control devices which can be teleoperated.

The steel components to be assembled are usually suspended from the tower cranes and have the problem of swinging, which affects the alignment operation. For easier and more precise alignment of the pendulum-like heavy objects, Jung et al. [30, 31] developed a robotic manipulator control algorithm to grip the steel components stably and efficiently. Bae et al. [32] designed an end-effector to fix the relative motion of the steel components and the end-effector itself. Mo et al. [33] developed a bolt-hole detection system with a 3D camera, which can estimate the location of a bolt-hole precisely and is robust in different illumination conditions.

To provide a safer and more convenient working environment for the human operators, Jung et al. [34] proposed a teleoperation system based on the RBA system. A control station is built outside the cabin, which comprises two joysticks, monitoring systems, and a controller for teleoperation. Liang et al. [35] developed a robotic assembly system for steel beam erection and assembly, which consists of four methods: rotation, alignment, bolting, and unloading. The system works autonomously without an operator in high places.

5 Application in Façade Installation

Façade installation is a common operation in high-rise building construction, which deals with heavy glass ceiling panels and exterior wall panels made of various materials. The operation locations are hazardous for workers to access and there is a high risk of injury and damaging the expensive panels in manual operations. In addition, the requirements of high-precision panel positioning and suitable weather condition further increase the difficulty. With these problems, façade installation robots and systems have been a hot research topic. A total of 16 related papers are identified.

The macro/micro motion-based robot is widely adopted in the proposed systems for both wall panel and glass ceiling installation. As shown in Figure 2, these robotic systems are usually combined with two relatively independent systems, respectively for macro and micro motion. The macro motion manipulator is usually a commercially available mini-excavator [36-40] or an aerial lift [36, 41, 42] to lift and move the panels, and the micro motion manipulator is usually a multi DOF robotic end-effector for precise handling of the panels. The installation is based on human-robot cooperative manipulation, which requires an intelligent manual robot controller to feedback the reaction forces from the environment. Compared with the manual operation, the robotic systems can improve the productivity and lower the safety risks at the construction site. Particularly, Cinkelj et al. [37] developed a closed-loop control system for the semi-automated façade assembly system by upgrading a commercial hydraulic telescopic handler. The closed-loop computer control significantly improves motion performance to meet the precision of façade installation and assures straight line motion of the end-effector.

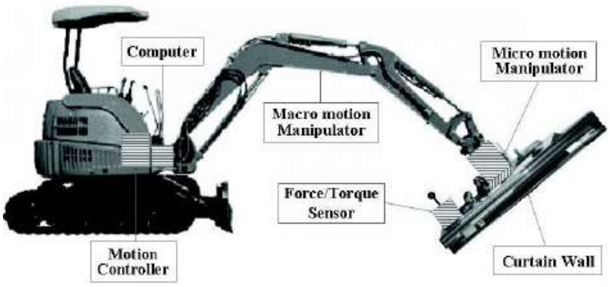

Figure 2. A typical macro/micro motion-based façade installation system [36]

Pan et al. [43] improved the conventional tower crane-based installation method and proposed a concept of a precast concrete panel installation system for high-rise buildings, which provides an integrated approach for panel loading, transportation, assembly and management. Van Gassel et al. [44] proposed a concept of a self-supporting robotic curtain wall system that integrates the assembly, disassembly and user functions of the curtain wall. Furtherly, they designed the mechanics and workflow of a self-assembling curtain wall system [45]. The stand of the system remains as part of the façade after installation, with the potential to serve in the following robot applications for disassembly or other user functions.

6 Discussion and Future Directions

As shown in Table 2 to Table 4, we summarized the major future directions and opportunities mentioned in the above-reviewed papers.

In the sub-phase of earth and foundation work, the current research is at the stage of semi-autonomous and tele-remote operation while the future work is towards fully autonomous operation. Therefore, the real-time communication, the situation awareness of the operator, the characterization of the geometry, and autonomous operation algorithms appear to be major problems. In addition, the technologies of Artificial Intelligence (AI) and machine learning are prospective to be adopted to deal with the various machines and materials and improve the automation level.

The automation and robotics technology application in the sub-phase of superstructure erection is divided into three sub-themes. First, the automated construction system was a versatile construction system when firstly proposed, while it has converted to several light-weight and independent systems, and the previous concept has evolved into "construction factory", which develops at the aim of providing a more desirable working environment for both workers and robots. Second, the automated lifting system should be combined with a ground-delivery system and a smart central control system to optimise the communication and operation planning. The radio-based technologies such as RFID are helpful in the lifting management. Finally, the robot-based steel assembly system is developing in the direction of teleoperation and autonomous operation, and the method of precise alignment of the wire-suspended swinging objects remains to be improved.

Table 2. Summary of the future directions (Sub-phase of earth and foundation work)

Future directions	Reference
Implementation of unmanned construction equipment and aircraft	[6-8]
Adoption of vision-based technology for monitoring	[7, 8]
Improvement of the situation awareness and reaction of the operator	[7]
Improvement of the real-time communication for remote operations and among the machines	[7, 8]
Adoption of AI and machine learning technology to support variations in machine and material	[7, 8]
Improvement of automatic pile shape and geometry classification with the technology of Simultaneous Localization and Mapping (SLAM)	[7, 8]
Development of autonomous loading algorithms and the method of fragmented rock loading	[7, 8]

Table 3. Summary of the future directions (Sub-phase of superstructure erection)

Future directions	Reference
1. Sub-theme: Automated construction system	
Simplification of the construction and dismantling of the temporary structure	[10, 11]
Improvement of the delivery efficiency	[10, 11]
Extension of the functions to be applicable for special-shaped building construction beside rectangular ones	[12]
Development of a light-weight system	[13]
Improvement of the simulation method	[13]
2. Sub-theme: Automated lifting system	
Implementation of RFID and USN technologies to improve the management	[17]
Optimization of the communication among the lifts, workers and the control system	[19, 20]
Improvement of the operation planning to adapt to various condition changes and lift unit changes	[22]
3. Sub-theme: Robot-based steel assembly system	
Extension of the functions to be applicable for special-shaped building construction beside rectangular ones	[24]
Development of complete robotic automation steel assembly system	[26]
Estimation and minimization of the shock of wire-suspended objects and development of robots that can absorb tremendous shock from heavy swinging objects	[30]
Improvement of the actuator for the alignment end-effector	[32]
Development of intuitionally joystick to improve operational performance	[34]
Adoption of AR and haptic technology to improve the working environment	[34]

The research on the sub-phase of automated façade installation is also on the way to teleoperation and autonomous operation to avoid human operators working in high places. Besides the remote operation techniques for human-robot cooperative manipulation, the development of algorithms and control strategies, and the implementation of related sensors will also improve the motion precision and installation performance. In addition, the façade installation robot can be adapted to other tasks involving lifting and carrying.

Although various technologies have been adopted in the application of automation and robotics technology in each construction sub-phase to deal with different problems, there are some basic equipment and operations.

Table 4. Summary of the future directions (Sub-phase of façade installation)

Future directions	Reference
Improvement of human-robot cooperative manipulation	[36]
Teleoperation based on force feedback	[36]
Development of software for integration of the handler into semi-automated façade assembly system	[37]
Implementation of inclinometers and ultrasonic sensors for automated leveling and distance measurement	[37]
Development for more application in other tasks involving lifting and carrying	[37]
Development of a mobile platform to replace the excavator for macro motion	[38]
Development of the control strategy and algorithms for human-robot cooperation	[36, 41]

Moreover, the steps of the automation process are also similar. For example, the five steps towards the autonomous operation of earthmoving machines [12], i.e., manual, in-sight teleoperation, tele-remote operation, assisted tele-remote operation, and fully autonomous, are also suitable in the development process of automation and robotics technology in other construction sub-phases. Therefore, the specific-task robots and automated systems are expected to learn from each other and may develop to handle more versatile tasks.

7 Conclusions

This paper summarized the application of automation and robotics technology in high-rise building construction from 50 papers published from 2000 to 2017 to provide a systematic review of the recent research and developments in this field from the perspective of three major construction sub-phases: earth and foundation work, superstructure erection, and façade installation. The paper also discussed future directions in each sub-phase in construction based on the literature.

This paper is expected to contribute to the knowledge body in that provides a valuable aid in future research and application of automation and robotics technology for high-rise buildings.

Abstract –

Retrofits of existing buildings have great potential to reduce global energy consumption and greenhouse gas emissions. Energy modeling of existing buildings, which is commonly conducted to prioritize retrofit strategies, relies on as-is building energy models (BEMs) that represent actual conditions of buildings. Recent efforts have focused on leveraging sensing technologies such as laser scanning and photogrammetry to capture as-is conditions of buildings and developing automatic methods for creating BEMs using the captured data. However, the majority of these efforts are limited to reconstructing 3D facade geometries with poor semantic information for rough BEM use. To this end, this paper presents a framework for an image-based approach to construct complete and semantic as-is BEM geometry models for existing buildings. The framework consists of four modules: 1) the data capture module that collects digital images of building facades and interior spaces and relevant "placement" information for geometry definition; 2) the building surface geometry reconstruction module that recognizes main building components required by BEM and reconstructs their 3D surface geometries from captured images; 3) the semantic enrichment module that adds the required geometry-related semantic relationships among the reconstructed building elements and interior spaces; and 4) the BEM creation module that stores the semantic geometry model in IDF data model. This framework is expected to extend existing research by creating complete (i.e. include not only building facades but also interior spaces) and semantic-rich as-is BEM geometry models.

Building energy model (BEM); building surface geometry; image-based 3D reconstruction; semantic enrichment; existing buildings; IDF

1 Introduction

The building sector accounts for almost 35%-40% of the total energy end-use worldwide [1, 2]. In this sector, most energy consumption is contributed by the operation of existing buildings [3]. Retrofits of existing buildings towards energy efficiency improvement have been well recognized as an important role in reducing global energy consumption and greenhouse gas emissions. Building energy simulation is a powerful and computerized approach for assessing building energy performance [4]. In building retrofit decision-making processes, this approach is commonly used to prioritize various retrofit strategies by quantifying their potential energy performance improvements and associated cost savings. To implement such simulations reliably, as-is building energy models (BEMs), which represent the actual conditions of existing buildings, need to be created first.

The creation of a BEM for an existing building requires large amounts of inputs, which typically include building geometry, constructions, HVAC systems, space loads, local weather data, operating schedules and other relevant parameters [5]. In the current practice, these inputs are primarily manually prepared by energy modelers using design documents (e.g., 2D CAD drawings and specifications) and/or actual photos [4]. This manual process is usually labor-intensive, costly, and error-prone, and inevitably arbitrary due to the human interpretation of the design documents [6]. Furthermore, the resulting BEMs may only exhibit the as-design rather than the as-is conditions of buildings [7]. This is because buildings tend to be deteriorated in performance and usually undergo various renovations over their service lives. In addition, design documents for many old buildings are even not available.

To address these issues, some recent efforts have focused on leveraging sensing technologies such as laser scanning and photogrammetry to capture as-is conditions of buildings and developing approaches that can use the captured data to automatically create as-is BEMs or as-is

BIMs for energy analysis purposes [8, 9, 10, 11]. According to the type of input data, these approaches can be roughly categorized into two groups: point cloud-based approaches and image-based approaches.

Point cloud-based approaches extract 3D semantic models from the point clouds of buildings that are usually collected from a laser scanner. Wang et al. [9] developed a methodology for automatically reconstructing 3D surface geometries of building envelopes using point cloud data. In their method, five types of building components required by BEM (i.e., walls, doors, windows, floors and roofs) can be recognized and reconstructed. Dı´az-Vilarin˜o et al. [8] developed a 3D as-built modelling methodology for solar shading analysis of existing buildings. In this method, three types of building envelop components (i.e., external walls, floors and roofs) and surrounding shades are considered. As both works only focus on the reconstruction of building facades, their outputs only support some rough and preliminary energy analysis (e.g., envelope choices, building orientation and shading analysis). They cannot be used for more complex energy analysis like whole-building energy simulation which requires the geometric description of entire buildings including building interiors (i.e. internal thermal spaces).

Semantic as-is modelling of building interiors using point cloud data has also been explored by some researchers, but they do not have a specific consideration for BEM use. In other words, the resulting models usually do not carry all semantic information (see details in Section 2) required by BEM. For example, Xiong et al. [12] proposed a context-based approach to semantically reconstruct building interiors. However, in the resulting models, the semantic information included mainly refers to the component type (i.e., walls, floors, ceilings windows, and doorways) that each 3D surface belongs to. Other required semantic information for a surface are not included, such as the geometric/topologic relationships between this surface and other surfaces and outside conditions (facing to outdoor environment, an indoor space or another surface).

Image-based approaches in 3D as-is condition modelling have received increasing attention in recent years. On one hand, as-is condition capture using digital cameras is more convenient and economic than using a laser scanner [13]. On the other hand, the accuracy loss of point cloud-based approaches due to noisy and missing data could be effectively addressed by image-based approaches [13,14,15]. In the context of as-is BEM creation, a recent work was conducted by Cao et al. [11] who developed an approach to reconstruct building facades from low-resolution aerial images. Building facade components including walls, doors and windows can be recognized. Again, this approach does not handle building interiors so that it cannot produce detailed geometry models required by complex building energy simulation. Another significant limitation of this approach is that it cannot automatically merge building facades reconstructed from different images into a single model. This approach requires additionally manual efforts to combine surface models generated from different images.

To address the limitations in existing efforts, this paper aims to develop a framework for an image-based approach to automatically construct complete and semantic as-is BEM models for existing buildings. This paper specifically focuses on detailed building geometry model creation for accurate whole building energy simulation purpose. The particularities of the proposed framework are threefold: (1) it enables the recognition of building components and the extraction of their surface geometries from images of both building facades and interiors; (2) it provides the mechanism to automatically merge the surface models generated from individual images into one single and uniform model; and (3) it computes all geometry related semantic information required by BEM.

The rest of the paper is structured as follows: Section 2 explains the features of BEM geometry models and the relevant semantic information requirement; Section 3 details the main modules of the proposed framework; and Section 4 concludes this paper and outlines future work.

2 BEM Geometry Model Description

A BEM geometry model mainly consists of three types of information: building geometry, coordinate systems, and geometry related semantic information. Building geometry is composed of basic building elements (e.g., walls, floors, windows, doors, and roofs, etc.) and shading devices, which are usually defined as a collection of planar surfaces [16]. Geometrically, the surfaces of building elements are 3D polygons with a normal pointing to the outside of the zones that they bound [16]. The geometry of each surface is depicted in a given coordinate system, which can be global or local. These coordinate systems enable the integration of these surfaces to form a complete building model. The geometry related semantic information mainly include the building object type that each surface represents and the geometric/topological relationships between those surfaces (i.e. building elements). These kinds of semantic information are detailed later in a specific case.

The organization of these information varies in different BEM tools as they usually have their own internal data models. In this paper, EnergyPlus is selected as the target tool due to its prevalence and wide utilization. Input Data File (IDF) is the native input format of EnergyPlus. In IDF, the building geometry can be described by six classes in an up-bottom approach [17], as shown in Figure 1. The roles of these classes are described as follows [17]:

- *Site:Location*: to define the location of a building.
- *Building and Zone*: to define the hierarchical coordinate systems for the building geometry description.
- *BuildingSurface:Detailed*: to define building components including walls, floors, ceilings and roofs.
- *FenestrationSurface:Detailed*: to define opening elements including windows and doors.
- *Shading:Zone:Detailed*: to define attached shading elements of a building.

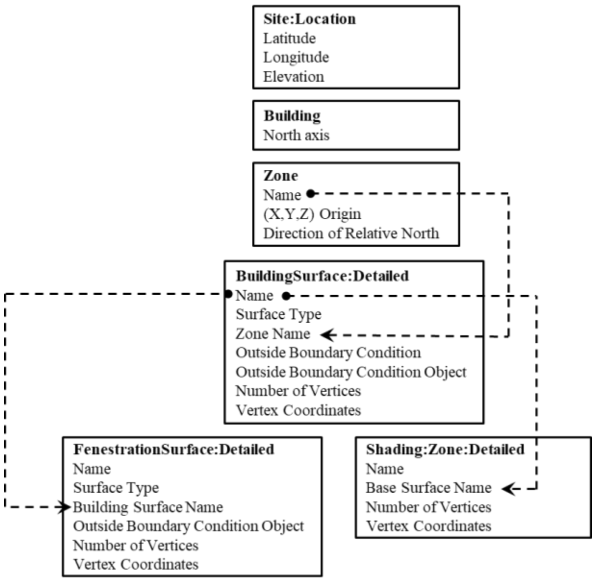

Figure 1. IDF classes for building geometry description. Note: classes providing general surface definition methods are selected; for each class, only geometry definition related attributes are listed; and only attached shading devices are considered.

Essentially, the latter three classes with various attributes provide means of defining building geometry with semantic information. In these classes, common attributes including *"Number of Vertices"* and *"Vertex Coordinates"* are used to define the exact surface geometries of building elements. Other attributes specify the required semantic information, which are summarized as follows [17]:

(1) *"Surface Type"*: to specify the building element type that the surface represents.

(2) *"Zone Name"*: to specify the zone that the surface bounds. This attribute builds the geometrical/topological relationship between building elements and relevant zones.

(3) *"Building Surface Name"*: to specify the parent surface (i.e. a building component) that this surface (i.e. an opening element) is attached to. This attribute builds the geometrical/topological relationship between openings and the building components that host them.

(4) *"Base Surface Name"*: to specify the surface (usually a wall) that this surface (i.e. a shading element) is attached to. This attribute builds the geometrical/topological relationship between shading elements and their influenced walls.

(5) *"Outside Boundary Condition"*: to specify the condition of the other side of this surface. The condition can be outdoors, ground, a surface that bounds another zone, or adiabatic.

(6) *"Outside Boundary Condition Object"*: to specify the surface that is located on the other side of this surface. This attribute together with attribute (5) build the geometrical/topological relationship among non-shading element.

Most efforts on automatic as-is modelling of existing buildings for energy analysis are limited to reconstructing surface geometries of specific building elements (e.g. facades and shading elements) with poor semantic information (usually only includes (1) and (3)). The framework proposed in this paper aims to achieve an automatic creation of complete building geometry with all semantic information required by whole building energy simulation.

3 Framework for Constructing As-is BEM Geometry Model Using Digital Images

The proposed framework consists of four modules (see Figure 2): image and placement data collection, building surface geometry reconstruction, semantic enrichment, and BEM geometry model creation.

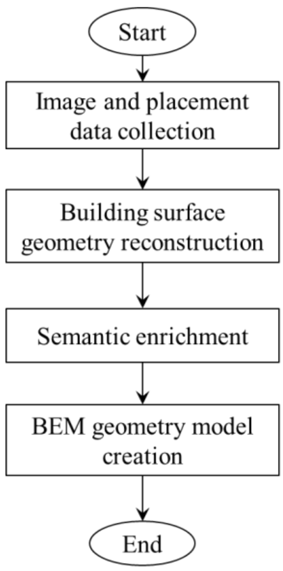

Figure 2. Proposed as-is BEM creation framework

3.1 Module 1: Image and placement data collection

The digital images of building facades and interiors as well as relevant placement data need to be collected for the 3D reconstruction of the entire building. Image data can be conveniently collected by some commonly used and economic devices with the image taking function. In this paper, a drone with an amounted camera is used to capture images of building envelops and a smartphone is used to capture images of building interiors. The placement data refers to a set of measurable parameters that can be used to determine the relative spatial relationships among the building elements in different images. The need of the placement data is because building elements reconstructed from an individual image can only be defined in an assumed coordinate system but the relationships between the assumed coordinates of building elements in different images are unknown. The placement data helps to geometrically link the building elements extracted from different images. Using one-storey building as an example, Figure 3 illustrates the parameters that need to be measured and the principle how these parameters are used to determine the relative spatial relationships between building elements in different images.

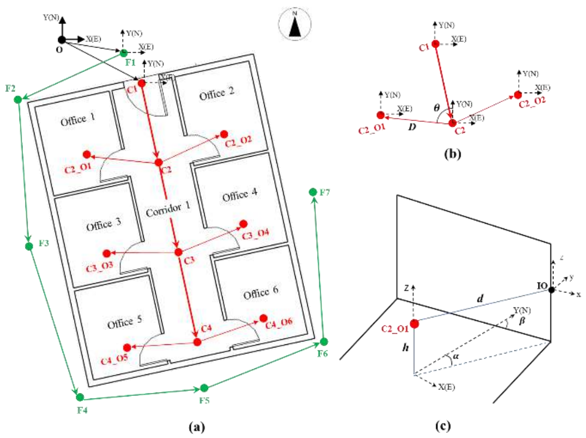

Figure 3. Data collection: (a) reference points setting; (b) parameters required for computing TR_CC; and (3) parameters required for computing TR_IC

In Figure 3(a), two sets of reference points are set up for building facades and building interiors respectively. These reference points work as a medium for geometrically connecting the building elements that can be viewed from these points. The point **O** refers to the root point used for combining the two sets of reference points. Two requirements should be satisfied for setting these points: (1) the range of vision from these points together can cover entire building facades and interiors; and (2) two adjacent points should be able to see each other. The method to obtain the required placement information is detailed as follows.

First, set up two types of 3D coordinate systems:

- Local coordinate system for reference points (see Figure 3(b)): origin (0,0,0) is set at a constant height from a floor (for interior points) or from the ground (for exterior points), axis X refers to East, axis Y refers to North, and axis Z is decided based on X and Y using the right-hand rule.
- Local coordinate system for each image (see Figure 3(c)), more specifically for describing vertical elements in each image: origin (0,0,0) is located on the right edge of the wall surface (when facing the surface at relevant reference point) and at the height same to relevant reference point, axis Z is identical to that of relevant reference point, axis Y is perpendicular to the surface of the vertical element and points to the outside of the space (or outdoors) that the surface bounds, and axis X is decided based on Z and Y using the right-hand rule.

Second, establish the transformation relationships (denoted as TR_IC) between the coordinate system of images and their corresponding reference points. Through TR_IC, a building element surface can be transformed from its own local coordinate system (LCS) to the LCS of the reference point. This means that the geometries of building elements sharing a common reference point can be linked together in the LCS of the reference point. Figure 3(c) illustrates three parameters (i.e., α, β and d) that need to be measured for computing TR_IC.

Third, establish the transformation relationships (denoted as TR_CC) between the coordinate systems of two adjacent reference points. Through TR_CC, a building element surface defined in the LCS of a reference point can be transformed into the LCS of any other reference point. In other words, building elements reconstructed from individual images can be combined as an integrated building model. Figure 3(b) illustrates two parameters (i.e. θ and D) that need to be measured for computing TR_CC.

Among the five parameters, all angular parameters are measured using a smartphone with the embedded compass, and all distance related parameters are measure using a portable and cheap laser rangefinder.

3.2 Module 2: Building surface geometry reconstruction

Based on the images and placement data collected from Module 1, this module reconstructs building surface geometry in two steps: vertical building element reconstruction and horizontal building element reconstruction.

3.2.1 Vertical building element reconstruction

Vertical building elements including walls, windows, doors, and columns are reconstructed from relevant images. First, a neuro-fuzzy system (NFS) based algorithm, as shown in Figure 4, will be established for the automatic recognition of building elements contained in an image. In order to take into account the possibilities of information shortage and inaccuracy in collected images, the fuzzy logic algorithms are investigated, which can reason with imprecise information. Fuzzy logic systems can make decisions even with incomplete or uncertain information. However, individual fuzzy logic algorithms cannot automatically acquire the rules used to make those decisions and have its own limitations. To overcome these limitations, this paper adopts an intelligent hybrid system (i.e., a neuro-fuzzy system), which combines fuzzy algorithms with neuro-computing systems. Interpretability and accuracy, which are main strengths of the neuro-fuzzy method, are the key criteria for choosing algorithms in this module.

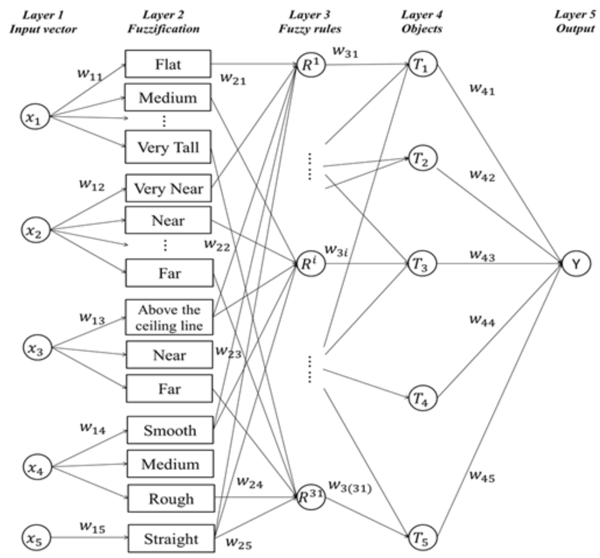

Figure 4. Architecture of proposed NFS for Module 2

Second, an image-driven feature extraction system will be developed to obtain the geometric dimension of these recognized building elements. A ruler will be set in the target scene (i.e. the scene that is to be pictured) for the reference of measuring dimension. Real distances for boundary edges of each recognized element are calculated based on the pixel distance (d_p), which is defined by the Euclidean distance ($d_{Euclidean}$) for a binary image $B[i, j]$:

$$d_p = d_{Euclidean}([i_{1p}, j_{1p}], [i_{2p}, j_{2p}]) = \sqrt{(i_{1p} - i_{2p})^2 + (j_{1p} - j_{2p})^2}, p \in \{l, r\} \quad (1)$$

where $[i_{1p}, j_{1p}]$ and $[i_{2p}, j_{2p}]$ represent the locations of different pixels in the binary image; l is the length of lines (e.g., line 1 and line 2) defined by the pixel distance for each selected component; and r is the length of the reference ruler measured by the pixel distance.

Images of horizontal shading devices like overhangs are processed additionally based on the adjustment on the neuro-fuzzy system and the image-driven feature extraction system.

Finally, each extracted surface is output as a polygon with a list of ordered 3D vertices in its own LCS. The "ordered" for an interior surface means that the resulting polygon is defined with a normal pointing to the outside of the space that the surface bounds, while for an external surface its normal points to the outdoor environment.

3.2.2 Horizontal building element reconstruction

Horizontal building elements including floors, ceilings and roofs are inferred based on the reconstructed vertical building elements. More specifically, the slab and the ceiling of an interior space are extracted from the vertices (with smallest z value and largest z value respectively) of vertical walls and columns that enclose the same space. Specifically, these wall and column surfaces need to be transformed first into LCS of the space (i.e. the LCS of a reference point in the space). Therefore, the resulting slab and ceiling surfaces are defined in the LCS of the space. Similarly, the geometry of a roof is inferred from the vertices (with largest z values) of all external wall surfaces that have been transformed into a same coordinate system.

The expected output of this module is a complete building surface model including building facades and interiors (see the example shown in Figure 5). In the output, all the surfaces are defined in the LCS of corresponding reference points, and the transformation relationships between the LCS of reference points are also stored.

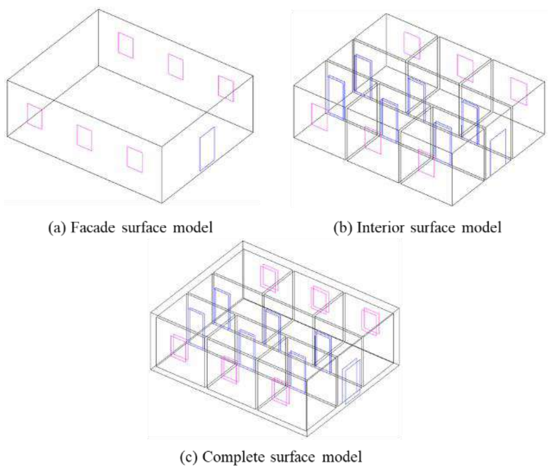

Figure 5. Visualization of the resulting building surface geometry model

3.3 Module 3: Semantic enrichment

So far, for a surface, its geometry defined in the coordinate system of a reference point, and some semantic information (i.e. the space that the surface bounds and the building element type that the surface represents) have been obtained. This module further adds the remaining semantic information required by BEM for each surface. The whole process is implemented in four steps which are detailed as follows.

3.3.1 Building surface geometry transformation

In this step, all surface geometries are transformed from their own coordinate systems to the root coordinate system based on the transformation matrices between control points. In the case of Figure 3(a), the root coordinate system refers to the coordinate system set on the control point **O**. Surfaces defined in the coordinate system on a control point like **C2_O1** can be transformed into **O** by tracing the established image collection route **C2_O1** -> **C2** -> **C1** -> **O**. By this transformation, all surfaces are described in a uniform coordinate system, which enables the geometry operations involved in the following steps.

3.3.2 Semantic enrichment for surfaces of walls, floors, ceilings, columns and roofs

As introduced in Section 2, the IDF class BuildingSurface:Detailed is used for defining surfaces of walls, floors, ceilings and roofs. Columns considered in this paper are treated as walls so that they can be accepted by the IDF data model. For these surfaces, two types of semantic information, i.e. Outside Boundary Condition and Outside Boundary Condition Object, need to be added (see Figure 1). In IDF, the outside condition of a surface can only be one of the situations: Surface (i.e. these is another space on the other side), Adiabatic (i.e. these is a building element on the other side), Outdoors, and Ground, etc. [15]. This means the surfaces reconstructed from Module 2 may need to be spilt by taking the outside conditions into account. A typical example is illustrated in Figure 6(a): the wall surface colored with red has two different outside situations, i.e. space (i.e. Room 2 and Room 3) and building element, while the wall surface colored with green has one outside condition. Therefore, the red wall surface needs to be geometrically spilt into three pieces and the green wall surface does not need (see Figure 6(b)). Only if the outside condition of a surface is Surface, the Outside Boundary Condition Object will be specified (see Figure 6(b)). A specific algorithm to achieve this semantic enrichment process is developed and Figure 7 shows its pseudocode. Figure 8 shows the processing result of the building surface geometry model by this step.

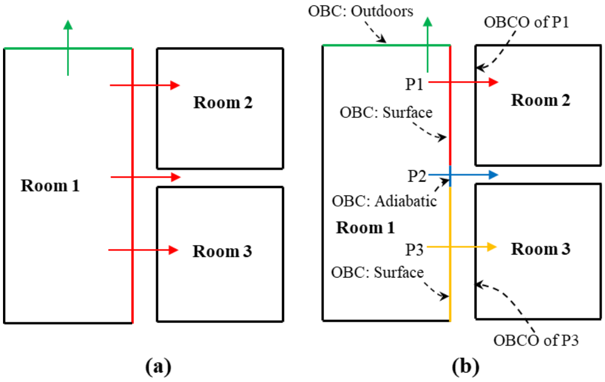

Figure 6. Illustration of the outside conditions of a wall surface. Note: Outside Boundary Condition = OBC; Outside Boundary Condition Object = OBCO.

```
Input: Reconstructed building surfaces S
1:  Extract surfaces of walls, floors, ceilings and roofs from S and
    store as S_walls, S_floors, S_ceilings, S_roofs respectively
2:  foreach  s ∈ S_walls do
3:      find all surfaces s_all that represent the same wall to s
4:      foreach t ∈ s_all  do
5:          project t onto (s_all - t) (all other surfaces in s_all) along the
            normal direction of t
6:          spilt t into two parts: Part 1: t ∩ (s_all − t);
            Part 2: t − (t ∩ (s_all − t))
7:          if  Part 1 are internal and not empty  then
8:              set the outside condition of Part 1 as Surface
9:              set the outside condition object of Part 1 as t ∩ (s_all − t)
10:         else if  Part 1 are empty  then
11:             set the outside condition of Part 1 as Adiabatic
12:         else if  Part 1 are external to outdoor environment  then
13:             set the outside condition of Part 1 as Outdoors
14:         else if Part 1 are external to ground  then
15:             set the outside condition of Part 1 as Ground
16:             set the outside condition object of Part 1 as t ∩(s_all − t )
17:         end if
18:         if  Part 2 are not empty  then
19:             set the outside condition of Part 1 as Adiabatic
20:         end if
21:     end foreach
22:     S_walls ← S_walls - s_all
23: end foreach
24: repeat process from Line 2 to Line 21 for S_floors, S_ceilings,
    S_roofs  respectively
```

Figure 7. Semantic enrichment algorithm for the surfaces of walls, floors, ceilings, and roofs

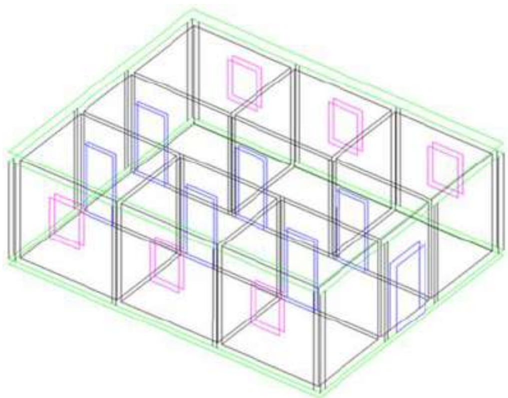

Figure 8. Visualization of the processed building geometry model

3.3.3 Semantic enrichment for surfaces of windows and doors

Surfaces of opening elements (i.e. windows and doors) are defined with *FenestrationSurface:Detailed* in IDF. For these surfaces, two types of semantic information, i.e. "*Building Surface Name"* and "*Outside Boundary Condition Object"*, need to be computed. The first type specifies a parent surface (usually a wall surface) that holds the opening surface. Such parent surface can be computationally detected by finding a surface, the polygon of which geometrically contains all the vertices of the opening polygon.

An opening element (except external openings) is usually defined as a pair of opening surfaces in BEM. For an opening surface, the *"Outside Boundary Condition Object"* specifies another corresponding opening surface, which can be detected by the following procedure: first, identify all other opening surfaces that are parallel to this surface; second, compute the distances between all the identified surfaces and this surface. The surface nearest to the opening surface is thus recognized as the target.

3.3.4 Semantic enrichment for surfaces of attached shading devices

For a shading device surface, the base surface (usually an external wall surface) that it is attached to needs to be specified. The base surface can be easily detected by finding a building facade surface, which geometrically contains one edge of the shading device surface.

3.4 Module 4: BEM geometry model creation

After the semantic enrichment of all building surfaces are finished, an IDF-based BEM geometry model is generated in this module by wrapping these objectified surfaces with corresponding IDF classes following the syntax of IDF schema. Surfaces of walls (columns), floors, ceilings and roofs are defined with the IDF class *BuildingSurface:Detailed* and its attributes; surfaces of windows and doors are defined with *FenestrationSurface:Detailed* and its attributes; and surfaces of shading devices are defined with *Shading:Zone:Detailed* and its attributes. All surface geometries have been transformed into a common coordinate system which takes North as Y axis and East as X axis. This coordinate system is actually identical to the global coordinate system used in IDF [15]. Therefore, a global coordinate system rather than a set of local coordinate systems is used in the resulting IDF geometry model. This means that the values of the attribute *"North Axis"* of *Building* and the attribute *"Direction of Relative North"* of *Zone*, which are used to define hierarchically local coordinate systems for IDF geometry models, can be ignored (i.e. no need to calculate). The geographical location of a building defined by *Site:Location* is usually directly obtained from a weather data file.

Once these geometries, coordinate systems and the semantic information for an existing building are integrated and well organized into IDF format, a corresponding semantic IDF geometry model for this building is achieved. It can be used together with other input data such as local weather data and construction materials to conduct energy performance analysis for the building for various purposes (e.g. assessment of retrofit strategies and optimization of operating schedules).

4 Conclusions and Future Work

In this paper, we present a framework for an image-based approach to automatically construct complete and semantic BEM geometry models for existing buildings. The framework consists of four modules. In the first module, we develop a specific data capture approach which can obtain the "placement" information in the process of collecting images of building facades and interiors. The "placement" information helps to Module 2 to combine surface geometries of building elements extracted from individual images into a uniform building model. Specifically, a neuro-fuzzy system and an image-driven system are presented for recognizing vertical building elements (i.e. walls, windows, doors and columns) from images and reconstructing their surface geometries respectively. The approaches for reconstructing horizontal building elements (i.e. floors, ceilings and roofs) are also introduced. In Module 3, computational approaches for enriching geometry related semantic information required by BEM are proposed. The generation of IDF-based geometry models is explained in Module 4.

This framework is expected to extend existing research by: (1) enabling the reconstruction of building elements from images of building facades and interiors; (2) providing the mechanism to automatically combine the reconstructed elements from individual images into one uniform model; and (3) allowing the addition of all geometry related semantic information required by BEM. The resulting BEM geometry models can be used for accurate and detailed energy simulation purpose.

For future work, all the approaches and algorithms involved in the proposed framework will be compactly implemented and examined. Several multi-storey office buildings with regular shapes and less furniture in building interiors will be selected to verify the proposed framework in terms of the feasibility and the accuracy.

Abstract

Apartment housebuilding takes too long time and optimal solutions are seldom found. In housebuilding projects, there is an increased popularity of using virtual models for analyses of structural integrity and floor layout. However, these analyses are seldom coordinated since the models rarely are linked and the designers are not working close enough. As such, optimal designs are hard to find and time flies since even small changes turn into many iterations between design and structural analysis. General building information modeling and virtual design and construction methodologies suggest the use of interoperability and automation to bridge these gaps. There are examples of design tools that link different models using off-the-shelf tools or programming. However, most of the housebuilding companies seldom have these advanced tools or have the competence to do advanced programming. In this paper, we suggest an approach of using visual programming in a common BIM-software to explore the linking of different models. As an example, we study design of roof trusses since for many different roof shapes the same rules usually apply to the design of the truss. This project connects a BIM-software and a FEM-program with a master model. The model automatically generates a roof with the designed truss, draws the representation in a BIM-software and analyze it in a FEM-program. The early evaluations of this visual programming based approach are promising as there are possibilities to connect other domain models and create an even richer evaluation bases for early apartment housebuilding design.

Keywords –

Roof trusses; Design automation; Finite element model

1 Introduction

The housebuilding industry strives to cut lead times, increase quality and reduce cost. In early design, many important decisions are taken which will impact the rest of the building life cycle, why the use of virtual models are increasing in popularity to predict life cycle effects, e.g. structural integrity, energy consumption, constructability changes due to design changes. Although more and more models are being used during design there is still a challenge to coordinate design and analysis in a way that promotes evaluation of more design alternatives than just a few, why solutions tend to be good enough instead of optimal. Making changes in models tend to take time since not all models are linked with each other and not always have parametric capabilities. Building information modelling (BIM) sets the framework for how to create parametric and information rich models [1], and virtual design and construction (VDC) likewise sets the framework for visualization, interoperability and automation [2]. Thus, BIM and VDC targets this challenge on an overarching level.

Looking in to more specific applications several researchers exemplify applications of how to link models, e.g. [3], or automating design tasks, e.g. [9], using off-the-shelf tools or text-based programming, such as C++ or Python. These types of applications are suitable for larger housebuilding companies or very specialized consultant companies with competences and resources to handle such advanced technology. But, many small and medium sized construction companies do not have these opportunities.

Therefore, the aim of the paper is to suggest an approach that creates a master model using visual programming languages (VPL), since VPL with its graphical interface enables a lower threshold to climb than most text-based programming languages.

There are examples of architects using VPL to automated generation of more shape-based buildings or artefacts [4]. Other examples of VPL use includes leveraging it to enable BIM-based assessment of environmental performance [5]. The use of VPL for model coordination within construction design and analysis is yet to be detailed by the research community. The approach suggested in this paper is exemplified with a design tool for roof trusses.

2 Background

This paper deals with virtual construction and particularly how to use models to enable flexible and efficient design and analysis during early design of buildings. As mentioned above the fields of BIM and VDC are framing the theory for this paper and below we introduce the areas of design automation and master models which are key topics for the presented approach. Research regarding roof truss design tools are also described.

2.1 Design automation

Design automation stems from the area of parametric mechanical CAD (computer aided design) and can, according to Cederfeldt and Elgh [6] within the manufacturing industry, be a way of developing tools that enable re-use of engineering solutions. According to Sandberg et al. [7] design automation in construction relates to several different techniques of which we here briefly introduce knowledge-based engineering, configuration and modularization.

Knowledge-based engineering (KBE) is essentially rule-based CAD where rules are implemented using for example object oriented programming. These rules are used to generate geometry models, finite element models, reports, bill-of-materials etc. [8]. The term knowledge-based comes from the act of acquiring knowledge from engineers to allow for automating some of their routine tasks to free time for more challenging engineering tasks. This act of automating engineering tasks has been used by experienced engineers since the dawn of the computer, as one of the important roles of the computer is to automate tasks.

Configuration is usually enabled by developing a product platform which consists of a limited number of modules that can be combined into many products and can be used during detailed design [9]. So, compared to KBE, configuration usually is connected to modular product architectures while KBE also is used for more integral product architectures. KBE can be used for both early, system and detailed design while configuration is more common to apply in detail design. Of course, there is overlap here and one could say that a KBE tool is used to configure a product. A difference is that KBE tools also can include generation of analysis models. In short configuration can be seen as a subset of KBE.

Some architects do design automation by building up parametric models using VPL such as Grasshopper, Dynamo, GenerativeComponents etc., [4]. This is a more shape-based type of parameterization that uses more advanced mathematical expressions, compared to KBE and configuration, and is suitable for calculating the form of more advanced shaped architectures. In a more similar fashion to KBE, the use of VPL has been seen in the realm of environmental concern. For example, Asl et al. [5] presented a framework for BIM-based performance optimization where VPL was used to generate design options, assess environmental performance, and search for the optimal design solutions. Other applications of VPL include Khaja et al. [10] that investigated using VPL to automatically populate non-geometric data into BIM models for operations.

2.2 Master models

The idea with master models is to reduce the need for manual updates of virtual models and instead create a governing product definition that is linked to other domain models of interest, e.g. finite element models, energy calculations, micro climate estimations. So, when the product definition is changed in the master model, this change automatically propagates to all other linked models. This idea has featured some modelling computer systems since the 1970s, [11].

The main idea of having information stored in one place connects to the idea of the BIM-hub [1] and some off-the-shelf CAD and BIM software also feature master model capabilities. Some examples are the connection between the BIM-tool Revit and Vico Office for model-based cost estimation and planning, or Revit and Robot for structural integrity evaluation, although these links require many manual interventions as well.

Negendahl [4] describe three ways of coupling tool models: 1) *combined model method*, where the design and analysis functionalities essentially are integrated but the user is restricted to the options and features offered by a particular software, 2) *central model method*, which is close to BIM where the data is centralized in a shared data schema usually using IFC (industry foundation classes) or other neutral formats such as gbXML (Green Building Extensible Markup Language) and is argued to be time consuming to use in team based design exploration, and 3) *distributed model method*, is compared to the central model method not hierarchal, instead the connections are more distributed into a more flat model organization.

The field of multidisciplinary design optimization (MDO) also connects to the master model idea by embracing the importance of linking models to each other allowing for automated design and analysis loops. According to Díaz et al. there is still research work to do to overcome parametrical issues and challenges to create interoperability between models, [3].

2.3 Roof truss design tools

Shea et al. [12] present a performance-driven generative design tool for cantilever roof truss design. GenerativeComponents (Microstation) is used together with an optimization process called structural topology and shape annealing within the generative structural design system called eifForm. By applying XML models, it is possible to link these softwares together.

Flager et al. [13] present a method for fully constrained design applying gradient-based optimization that also is exemplified for steel roof trusses for a sports arena. The process integration and design optimization software ModelCenter was used together with the Digital Project CAD software and a finite element analysis software. The implementation was evaluated with conventional design and the results showed that the implementation took 30 man-hours longer but evaluated almost 500 times more solutions.

Villar et al. [14] describe how to use genetic algorithms to optimize the design of heavy timber trusses. This research is centered around an analysis model where the design optimization is done. It was found that genetic algorithms are effective for optimization of glulam roof truss structures.

2.4 Research motivation

Since off-the-shelf MDO tools as well as automating BIM activities usually involves advanced programming in this paper explores how the possibility of using VPL to mitigate the parametrical and interoperability issues by creating a master model. Also, automatic design tools connecting design and analysis models seem to focus steel structures why it is a need to investigate automatic design tools for timber roof trusses.

3 Research process

This research was conducted by studying earlier research to motivate the research gap and serve as input to the development of the proposed approach. Developing the master modelling approach was an iteration between studying literature, generating ideas and developing the example tool.

Discussion were held with designers from a company that was interested in the field of making design and analysis more efficient using virtual models. The company conducts design and production of prefabricated modular multi-family timber buildings. Roof truss design was identified as an interesting topic, since they are featured in all projects, and an implemented design tool has the possibility to be used continuously in future projects. The company supplied drawings from a recent building project as input to the tool development. The drawings showed a surprising number of different configurations and the possibility to standardize the design of roof trusses was identified as an opportunity for saving design costs. As a way of limiting the design space the company articulated that it is most economic to use trusses with same length for the top beam.

The development of the example tool was done mainly by the first author and discussed among the authors. First, a simple version was developed to investigate if Revit, Dynamo and Robot worked as expected. Then the tool was further refined to incorporate more details and parametric capabilities. When the second version was developed the tool was evaluated against relevant literature.

4 Results

4.1 Proposed approach

The proposed master modelling (MM) approach is shown in Figure 1. A design and analysis loop can be conducted and contains 1) giving product definition input to the master model, 2) generating analysis models, 3) evaluating objective function (design goals) and 4) if not satisfied repeat.

The MM contains the logic done in VPL that represents the building geometry and its properties as well as other parameters needed for linking to the other domain models. If the VPL part is not enough in terms of built-in functionality to automate the generation of the domain models, scripts and software-specific macros might be needed. A database with additional information regarding e.g. materials, environmental product declarations can be either part of the MM or provided as a linked resource. If a fully automatic design and analysis loop is reached, then optimization is possible to conduct. This could be done either through the VPL part or by a separate managing unit using e.g. MATLAB or text-based programming.

Using the MM starts with giving input. If it is a fully automated MM then the input concerns the optimization, e.g. objective function, possible parameter values, maximum number of iterations. Then the MM is executed and models are generated and evaluated until the optimization unit is satisfied or maximum number of iterations are done. If the MM is used in a semi-automatic fashion, then the input is values for the design parameters and then the model generation is executed. When the models have produced their results, the user or users within the design team must evaluate the results and decide if another design and analysis loop should be initiated.

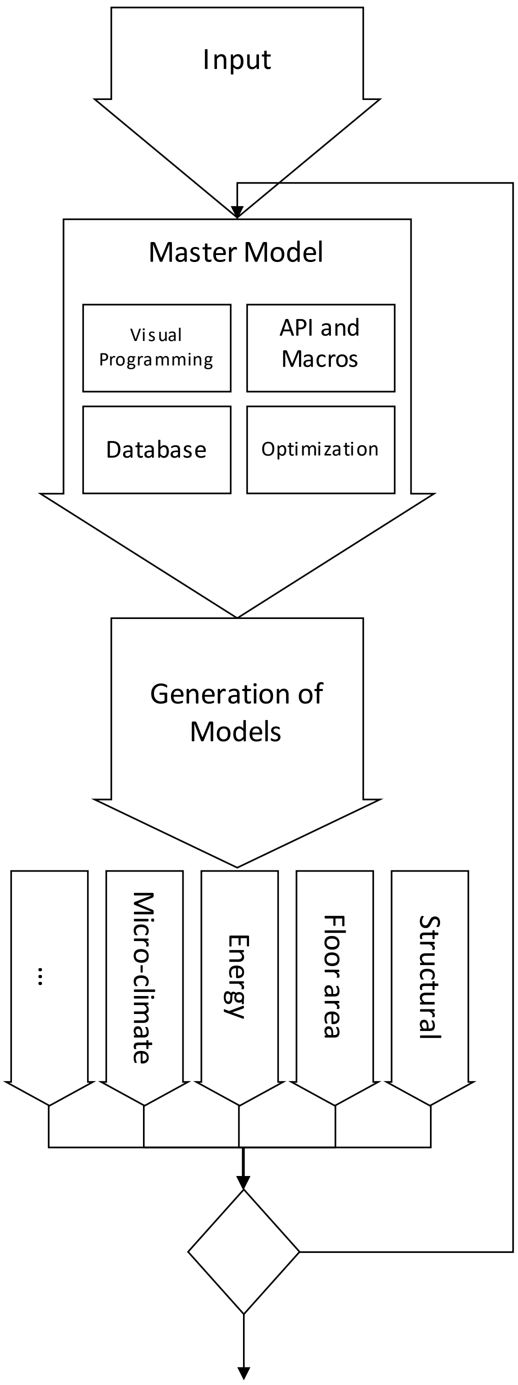

Figure 1. The proposed master modelling approach.

4.2 Example

Here, the inner workings of a MM approach for a framework of a double pitched roof is explained. Dynamo is used as the VPL of choice as it provides links to both a BIM tool, namely Revit, and a tool for structural analysis, Robot. A two-stage approach is adopted. First the whole geometry for the framework is created in Dynamo using points and lines. Then, depending on the situation, the geometry is either used to generate the BIM representation within Revit, or sent for structural analysis in Robot.

4.2.1 Dynamo model

The framework of a roof contains several trusses that are set in given spacing. To generate the framework, Dynamo uses points that in pairs create lines. Only the coordinates of the three corners of each truss are necessary to specify in an Excel sheet, see Figure 2. Each point contains x-, y-, and z-coordinates in the Cartesian coordinate system to describe it and users must type in the coordinates in a specific order. It should be noted, that the x-coordinates must be typed in column A, y-coordinates in column B and z-coordinates in column C.

	A	B	C
1	0	0	0
2	8	0	0
3	4	0	3
4	0	1,2	0
5	8	1,2	0
6	4	1,2	3

Figure 2. Input coordinates in Excel.

Each row describes one point and every three rows describe one triangle. The first point of each triangle is the bottom left corner, the second point the bottom right corner and the last point is the top point. With that method, it is possible to create as many triangles as needed for the framework. The Excel sheet is linked in the Dynamo model so that Dynamo can read the data and generate the specified points. Then, Dynamo generates lines between each of the three points and the lines of these triangles will later be defined as top or bottom chords.

The second input is for the “box”, a room to fit within the framework, which can be used as e.g. a utilities room. These input parameters, for the box, control the length, width, and height and its bottom left position. Dynamo creates a box from the bottom left point to the upper right point of the box. In the next step, lines (diagonals) between the chords are generated to support the triangles. There are two different ways how they are built that depend on if the box intersects a roof truss or if it does not.

1) The box does not intersect a roof truss: All triangles that does not intersect the box are generated like a W-beam. At first an uneven number of sections must be selected. It is possible to choose between 3 up to 9 sections. More than 9 sections are not necessary for a roof truss. The sections are the subdivision of the bottom

chords. The top and bottom chords are subdivided in equal lengths with points. Lines connect the points to build diagonals.

2) The box intersects a roof truss: First the framework for the box is built. Dynamo generates vertical lines on each side of the box. They reach from the bottom chords to the top chords. A horizontal line between the vertical lines is generated to mark the height of the box. Diagonals are created to support the top chords next to the box. Two separate cases of the intersection between the box and roof truss are managed:

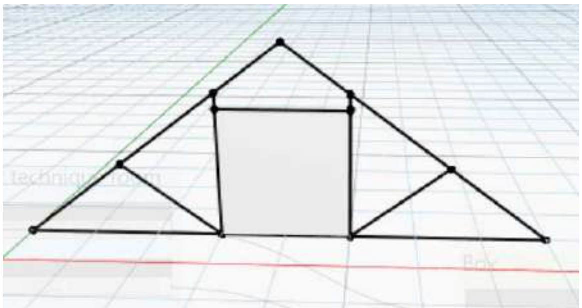

Figure 3. Case a) Box in the middle.

Case a) the box is placed in the middle under the left and the right top chords, see Figure 3. In this case Dynamo generates a diagonal line on the left side and a diagonal line on the right side of the box. Each line starts on the bottom side of the box and ends at a specific point of the top chords. That point is in the middle of the distance between the start of the top chords and the end of the vertical line of each side.

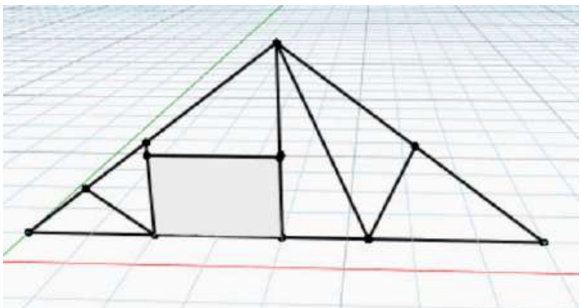

Figure 4. Case b) Box is on one side.

Case b) describes a position of the box, where it is on one side of a truss, see Figure 4. Two diagonal lines will be generated at the side without box. They start at the half distance between the one side of the box and the corner of a truss. The top point of a truss is an endpoint and the middle of the top chords is the other endpoint. The program generates a diagonal line like in case a) at the side with the box. The program generates four lines that are used for wind bracings. They start at each bottom corner of the framework. The endpoint is at the top of the second truss or rather the next before the last truss. All lines are joined in a list at the end of the Dynamo model. The list will be used for the Revit model and the Robot model.

4.2.2 Revit model

The Revit model uses a node within Dynamo that contains a collection of all the lines generated for the trusses. It distinguishes the lines in the different structural elements of the framework, e.g. top chords, and assigns the appropriate structural framing type to them. This information is then relayed to Revit where a representation of the truss is generated. Through the change of parameter values, different aspects of the elements in the trusses can be altered, e.g. rotation and dimensions.

4.2.3 Robot model

The Robot model uses the same collection of lines as the Revit model. However, due to differences in object types, Dynamo does not send the lines automatically to Robot. As such, they must first be changed into analytical bars before they can be transferred. See Figure 5 for an excerpt of how coding in Dynamo looked.

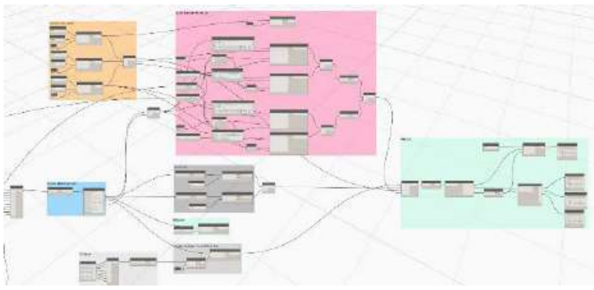

Figure 5. Code in Dynamo for generation of the Robot model.

For the whole and larger programming layout see the Appendix on the last page of this paper.

5 Discussions and conclusion

A master modelling (MM) approach based on visual programming languages (VPL) has been presented and exemplified with a roof truss design tool. MMs could increase the chance of finding optimal solutions instead of just good enough solutions since the design and analysis loop enables multiple solutions to be evaluated. Compared to configuration, [9], MMs could be used for developing building systems since the optimized solution could be reused and therefore could become a member of a company’s product platforms. Compared to the tool model coupling methods that Negendahl [4] presents the

MM, and especially the presented example, is closer to the distributed model since the models are created in a process flow, i.e. first the Dynamo geometry model is created, then the Revit model is created and lastly the Robot model is created. Also, Asl et al. [5], with their case study showed an application of VPL in closer resemblance to configuration where parametric changes are made to existing objects. Although, the authors also acknowledge that their framework could be used in a far broader extent than exemplified.

VPL is more graphical and possibly more intuitive compared to text-based programming languages. VPLs makes it possible to link models and the master model in our example is a Dynamo model that is linked to Revit and Robot. The example show that several roof truss solutions can be found faster than manually generating the different geometrical representations in Revit and Robot.

The design teams that could use a tool like this should preferable have members from each of the included domain models, in our example architect and structural engineer. With the design team having basic programming skills it would be possible for them to develop tools like this and keep them maintained with latest data.

As Negendahl [4] argues, the presence of VPL does not solve all interoperability issues why the inclusion of scripting (potentially using text-based programming) and macros in the MM is important to increase the possibilities for full automation capabilities. For fully automated master models, the early design stages are suitable since then the building design is still overarching and therefore less effort is needed for automation.

Compared to other truss design tools, e.g. [12] and [13], the presented tool was developed within a BIM environment which is important to increase the possibilities for model coupling between architects and structural engineers. Also, the presented tool is for timber truss design and analysis where earlier similar tools have a majority within steel trusses. There are examples of timber truss design tools, e.g. [14], but most of them are design tools for structural engineers and not for both architects and structural engineers.

Future work involves connecting more models and implantation of full automation to enable more efficient optimization. Conducting design studies is also of interest.

Abstract –

On-site data collection during construction activities help in evaluating productivity rates and preparing more accurate schedules. One of the challenges here is in collecting data automatically such that activity start times and durations can be computed reliably. This paper proposes a methodology to infer construction activities that are being performed on site using the structural responses collected from construction equipments. This methodology is applied to the case of a launching girder, an equipment used in the construction of viaducts in metro rail projects. There are four stages involved in the construction of a viaduct; Auto launching, Segment lifting, Post tensioning and Span lowering. Strain values from the launching girder are used to predict the stages of construction using machine learning techniques. Support Vector Machines are used to classify the strain data into one of the four classes corresponding the stage of construction. Data from a typical construction cycle is used for training. Using the model generated by the training data, subsequent activities can be inferred.

Keywords –

Support Vector Machines, Machine Learning, Automated Data Collection, Construction Progress Monitoring

1 Introduction and Background

Construction activities are inherently complex with the large extend of uncertainties involved in site conditions. Well prepared construction schedule is essential for successful implementation of any construction project. Problems caused by an optimistically biased baseline schedule of a construction project can be rectified by real time accurate construction monitoring. Most of the time, precise monitoring of construction activities are highly challenging. Control of project performance based on manually collected data is a strenuous task. Depending upon the level and accuracy of data required, the cost and effort associated with manual data collection and interpretation of the same for useful information are high [1]. Automated data collection techniques such as barcode [2], Radio Frequency Identification [3], Ultra wide band [4], Global Positioning System [5], imaging [6], LIDAR [7] etc. provide reliable data about on site construction progress. Automated data collection methods generate more accurate and integrated control information less expensively. However, the effectiveness of each mode of automated data collection is highly dependent on the type of construction activities involved. Lack of mobility is one of the major drawbacks of currently existing automated data collection techniques. Major project control decisions are usually delayed due to lack of real time progress monitoring or lag in reporting and interpretation of existing progress data. These problems are addressed by integrating the progress monitoring system with main equipment involved in the construction activity.

Sacks et al. proposed a system which use automatically collected data from a central construction equipment for real time progress monitoring which help in better project performance control [8]. The monitoring system consists of a decision rule processor which uses a knowledge base, as well as data from the Building Project Model and a monitoring 'black box' installed on the equipment. The construction equipment selected by Sacks et al. is a tower crane which is used for lifting majority of materials used in construction. Navon and Shpatnitsky monitored an earth moving equipment for automated progress monitoring of road construction [9]. They developed a monitoring and control model which uses location of the equipment and time of measurement collected, using GPS technology as input data.

Depending upon the type of construction, the central equipment to be selected for automated progress monitoring varies. Soman et al. measured structural responses from a launching girder (LG), an equipment used for construction of viaducts to monitor progress of construction [10,11]. Auto launching, Segment lifting, Post tensioning and Span lowering are the four stages involved in the segmental construction of a metro rail viaduct. Structural response data from the equipment is acquired through a strain based wireless sensing system. Model based system identification methodologies were then used to find out the state of the construction process to monitor the progress [11]. Three different algorithms were evaluated in this work. The first algorithm used a conventional system identification methodology based on a population of models that represents various possible states of the structure. This approach could not accurately identify the stages of construction. A modified system identification methodology which uses domain specific knowledge in the form of possible sequences of construction activities provided the best results. While this approach has been proved to be successful, there is high computational and cognitive complexity involved. Thousands of models need to be created and simulated using finite element analysis software. Model free approaches using machine learning techniques do not have this drawback. These methods do not require models of physical behaviour and are entirely data driven.

Machine learning techniques use data to enhance the performance of software [12]. Some of the major applications of machine learning include device control, recognising biometric parameters, robotics etc. With recent advances, machine learning has entered into almost all industry including construction. Tixier et al used machine learning models Stochastic Gradient Tree Boosting (SGTB) and Random Forest (RF) to predict injuries in construction industry [13]. This study has given dependable probabilistic forecasts of likely outcomes of occurrence of an accident. Akhavian and Amir used machine leaning methodologies to identify and classify activities of construction workers from the data collected using sensors embedded in smart phones [14]. Machine learning techniques are extensively used in structural health monitoring [15] as well as durability and service life assessment of structures [16].

A support vector machine (SVM) is a machine learning technique that has been found to be successful in solving pattern recognition problems [17]. SVM can be used for supervised learning tasks like regression and classification [12]. It has found wide applications in various fields of construction industry. Complex problems such as contractor prequalification can be successfully solved with decision support framework based on SVM [18]. Wauters and Vanhoucke showed that SVM regression model delivers better project control forecasting results than the presently available Earned Value and Earned Schedule methods [19]. Evolutionary Support Vector Machine Inference Model (ESIM) is developed by combining SVM and fast messy genetic algorithm (fmGA). ESIM is capable of determining Estimate at Completion (EAC) of a project [20], identifies the critical parameters that influence the success of a project [21] and acts as a intelligent decision support system for effective construction project management [22]. SVM techniques are extensively used in areas which demand attention to details and patterns, handling of huge amount of data, precise analysis and prediction of future demands. Some of those applications include selection of materials [23], prediction of demand of equipments [24] and working posture analysis of labours [25]. However, inferring construction activities for progress monitoring using predictive analysis by support vector machines classification has not been explored yet.

This paper aims to infer the construction activities of the metro rail viaduct from the structural responses collected from the launching girder using SVM classification.

2 Support Vector Classification

In a simple binary classification problem, the data points are categorised into two classes labelled as positive or negative. The user supplies the training data consisting of values of attributes and label of each of the data point. The learning task is to determine the function that separates the data points into classes. Figure 1 shows a binary classification in which data points consisting of two variables are separated by a straight line. Here, the decision boundary (also known as the classifier or the discriminant) is linear. Decision boundary will be a hyperplane when a linear function divides the classes in multiple dimensions as shown in Figure 2. Equation of a hyperplane is given below [12].

$$f(x) = w_1x_1 + w_2x_2 + w_3x_3 + \cdots + b = 0 \qquad (1)$$

where w_1, w_2, w_3... represent weight factors, x_1, x_2, x_3... stand for input variables and b represents the bias. All the points belonging to one class lie above the hyperplane and those belonging to the other class lie below the hyperplane. The learning algorithm finds the best hyperplane by adjusting the weight factors appropriately. The value of the function f(x) for the first class will be greater than zero and for the second class will be less than or equal to zero.

SVM outputs an optimal hyperplane known as the maximal margin classifier, for a given labelled training data. A good separation is achieved by this hyperplane that has the largest distance to the nearest training data points of any class [12]. Figure 2 shows a maximal margin hyperplane. From the decision boundary, nearest negative data points and positive data points are equally distributed.

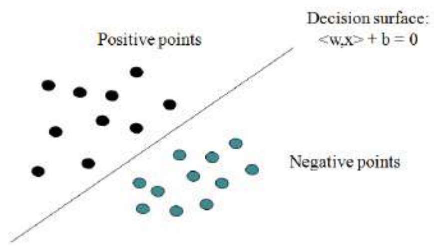

Figure 1. Binary Classification of data points with straight line as decision boundary

When we label the training data as $\{x_i,y_i\}$, i = 1, ... , l, $y_i \in \{-1,1\}$, $x_i \in R^d$, the equation of the hyperplane can be written as given in (2). The solution is obtained by Kuhn - Tucker conditions as given in (3). $\alpha_i, i = 1, \ldots, l$, stand for positive Lagrange multipliers introduced.

$$f(x) = sgn((w.x) + b) \tag{2}$$

$$w = \sum_{i=1}^{l} \alpha_i y_i x_i \tag{3}$$

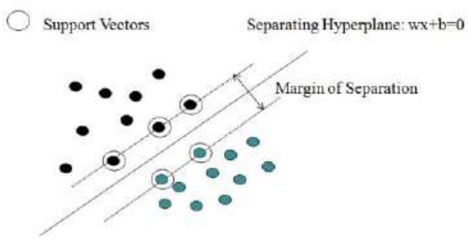

Figure 2. Classification of data points with linear separating hyperplane

We will not get a feasible solution, when we apply the above mathematical model to non-separable data. Therefore, positive slack variables are introduced in the constraints with an additional cost. Larger the value of the newly introduced parameter C in the constraint, higher the penalty to errors [17].

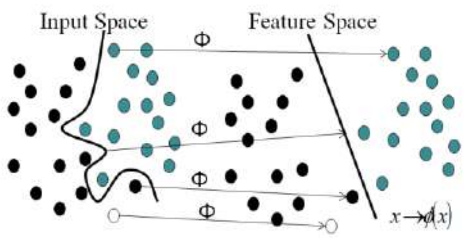

Figure 3. Nonlinear classification of data points with radial basis function

The decision function (2) can also be written as (4). In nonlinear classification, first we embed the data into a high dimensional feature space by a map ϕ and then separate the classes using a maximum margin hyperplane as shown in Figure 3. By suitably introducing a kernel function, K as in (5), the decision function will take the form (6). All concepts of linear classification cases are applicable to nonlinear classification cases. By using kernel function as in (7) the support vector algorithm develops radial basis function (RBF) classifier [26]. Here, σ is the width of the Gaussian kernel.

$$f(x) = sgn\left(\sum_{i=1}^{l} y_i \alpha_i.(x.x_i) + b\right) \tag{4}$$

$$K(x, x_i) = (\phi(x).\phi(x_i)) \tag{5}$$

$$f(x) = sgn\left(\sum_{i=1}^{l} y_i \alpha_i.K(x, x_i) + b\right) \tag{6}$$

$$K(x, x_i) = e^{\left(\frac{-\|x-x_i\|^2}{2\sigma^2}\right)} \tag{7}$$

3 Methodology

Strain readings collected from 14 different locations on the launching girder (LG) in the previous study [11] are used in this research. The objective of this research is to determine whether patterns in strain data could be used to infer construction activities using support vector classification.

11,130 strain gauge readings were used, each from 14 locations of the launching girder during the erection of the viaduct which consisted of 26 cycles. One set of strain data was collected every minute during this measurement sequence. The construction activity corresponding to each data point was obtained from the log book. Strain data for one cycle consists of strain values for the operations, auto launching, segment lifting, post tensioning and span lowering. Data for one cycle is used for training the algorithm and the strain data for other 25 cycles were used for prediction. The aim is to test whether the activities are correctly predicted when compared to the entries in the log book. Prediction is done by linear as well as nonlinear SVM classification. RBF is used for nonlinear classification. The error penalty, C is varied from a range of 10 to 50 and width of the Gaussian kernel, σ is varied from 0.1 to 0.5. It is examined whether these parameters affect the accuracy of prediction as explained below:

In each cycle, data for one operation (such as auto-launching) is taken as the set of positive examples and data for all the remaining operations are taken as negative examples. The SVM is trained using this data for one cycle and remaining data is used for prediction. If the recorded data in the log book matches the identified class, it is considered as correct prediction. The percentage of correct predictions is computed. The results of analysis is discussed in next section.

4 Results and Discussion

Prediction results for each operation involved in a cycle using linear SVM classification and nonlinear SVM classification with RBF are given. Percentage of correct values in prediction (P) is plotted against operations that are treated as the positive class during training (Figures 4-8).

Table 1. Effect of C and σ on Percentage of correct predictions (P) of LG operations

Operations	Linear SVM classification	Nonlinear SVM classification with RBF
Auto launching	P increases as C increases.	P decreases as σ increases; remains same for σ = 0.3 and 0.2, then decreases. Change in C value is not having much impact on result.
Segment lifting	P increases as C increases till C= 20, then decreases.	P increases as σ increases. Change in C value is not having much impact on result.
Post tensioning	P increases as C increases till C= 20, then decreases for C= 30, again increases with C. C= 20 gives better results than other higher values.	P increases as σ increases. Initially P increases with C, then decreases. Value of C corresponding to peak P values, changes with σ value.
Span lowering	P increases as C increases till C= 30, then decreases.	P increases as σ increases. P increases as C increases till 20, then decreases.

Auto launching is having highest percentage of correct predictions. Predictions using RBF gives better results in all the cases, meaning that the decision boundary is non-linear. Prediction of auto launching using RBF gives zero misclassifications in all combinations of C and σ except for C = 20 and σ = 0.2. For that combination of parameters 2 misclassifications were obtained with 98.77% of correct values in prediction. Post tensioning is the operation which shows lowest percentage of accuracy in prediction. Figure 9 shows instantaneous variation of strain at sensor location near middle span of the launching girder during each operation in a cycle. From Figure 9, we can observe that pattern of instantaneous variation of strain during post tensioning is similar to that of span lowering. This makes the prediction process difficult. Initial strain variation pattern of auto launching and segment lifting are similar. This might be the case for all the adjacent operations. But segment lifting operation gives much better results compared to post tensioning. This might be due to large number of training data points involved as well as significant difference in pattern of strain variations.

The percentage of correct predictions (P) varies differently with different combinations of C and σ. Effect of each parameter on each of operations in linear SVM classification and nonlinear SVM classification with RBF are summarised in Table 1.

Soman et al used three system identification methodologies for predicting the construction activities from structural responses [10]. Out of that, a modified system identification methodology using domain specific heuristics is found to be most effective. Table 2 compares the prediction results of linear and nonlinear SVM classification with the modified system identification methodology based on heuristics (MSI). SVM classifications give better predictions compared to MSI in terms of percentage of correct values when you compare the best predictions. As discussed earlier, the best prediction results are from nonlinear SVM classification with RBF and for auto launching operation. In medium level prediction results, only nonlinear SVM classification performs better than MSI. But the identified operation is post tensioning instead of segment lifting as in other methods. As you compare the worst prediction results, MSI gives the most accurate results. Here we can observe the influence of the type of operation identified and values of C and σ. In order for the SVM classifications to give best results we need to carefully choose the tuning parameters.

5 Conclusions

The feasibility of using structural responses from an equipment to infer construction activities is studied in this paper. SVM classification using linear and nonlinear kernels are used to classify the strain data collected from site. Error penalty, C and width of the Gaussian kernel, σ are used as tuning parameters for the study.

It is observed that certain operations such as auto launching and segment lifting can be identified accurately with both classification methods. Computer based pattern recognition is found to be essential in clearly identifying these operations which involve minute changes in strain data, which cannot be accurately detected by humans. Certain other operations such as post tensioning cannot be identified with either of the methods.

Table 2. Comparison of prediction results of linear and nonlinear SVM classification with modified system identification method based on heuristics [10]

Method of Prediction	Prediction Results					
	Worst Prediction		Medium Prediction		Best Prediction	
	Predicted operation and details of prediction method	Percentage of correct values	Predicted operation and details of prediction method	Percentage of correct values	Predicted operation and details of prediction method	Percentage of correct values
Modified system identification method based on heuristics	Span lowering, with modeling error	79	Segment lifting, without modeling error	81	Auto launching, without modeling error	95
Linear SVM classification	Post tensioning, C = 10	37.39	Segment lifting, C = 40	74.89	Auto launching, C = 50	99.23
Nonlinear SVM classification with RBF	Span lowering, C = 10, σ = 0.5	44.24	Post tensioning, C = 50, σ = 0.2	87.09	Auto launching, C = 20, σ = 0.5	99.23

Strain data alone is not enough in such cases. We might have to include additional sensors like accelerometers to obtain more details about the operations. Strain data from one location is not sufficient to identify operations. Some locations give better strain variations compared to others. Therefore location of sensors should be carefully chosen.

In linear classification, error penalty C is having significant influence. However, accuracy of prediction increases with increase in C only up to certain extend in each operations. There is an optimal value of C for each operations which comes in the range of 20-30.

Nonlinear SVM classification with RBF is mostly governed by width of the Gaussian kernel, σ. Except in auto launching operation, increase in σ value gives better results. Changes in C value for constant value of σ have not much effects on certain operations such as auto launching and segment lifting. Interestingly, both of these operations follow similar strain variation pattern in the initial stage. Post tensioning and span lowering have optimal values of C for a constant σ value. With careful selection of the values of the parameters, SVM classifications can produce better results compared to modified system identification method based on heuristics.

Inferring construction activities from structural responses using support vector machines is possible with optimal values of C and σ determined for each operation. With the help of heuristics and additional types of sensors at best locations, prediction results can be improved.

Acknowledgements

Authors wish to extend their sincere gratitude to Mr. Ranjith K Soman who collected the structural response data for his post graduate project. Authors also wish to thank the help and support extended by Larsen and Toubro Construction and Hyderabad Metro Rail Limited in enabling field collection of data. The doctoral research of the first author is supported by the scholarship from the Ministry of Human Resource Development (MHRD), Government of India.

Abstract –

Adding manually thermal insulation onto an existing building is an inefficient and labor-intensive process. To avoid such manned labor on site, recent approaches have been developed for installing prefabricated modules onto existing buildings´ envelopes. However, the monitoring and the analysis of these approaches expose that these procedures are still time-consuming and inaccurate. In mass manufacturing industries, robots facilitate time reduction while ensuring accuracy. Nevertheless, the main challenge for adopting robotized manufacturing and installation processes in building renovation relies on the constant customization of the prefabricated modules, both off-site in the factory and on-site in construction. In pursuance of improving such situation, the authors conceived a novel process that automates the customization, the manufacturing and the installation processes of the modules. The solution integrates and links systems such as accurate coordinate acquisition, parametric design, digital manufacturing of elements and robotic assembly and installation of the modules. The main body of this paper describes the structure of this novel conceptual process. This process has been initially proofed, addressing mainly the feasibility and the correct sequence of each of the steps. The results show that this novel process, after further development, can be a solution for gaining efficiency on the building renovation processes.

Keywords –

Renovation, robotic, parametric, prefabrication

1 Introduction

Achieving a zero-energy consumer building stock is a goal of the European Union [1]. Currently, the most used and “traditional” method comprises the addition of an insulating layer on the exterior wall or facade of the building. After that, the operators spread mortar or place a waterproof material to protect this insulating layer. This procedure is time consuming and requires scaffold installation in front of the building´s façades [2]. In order to gain efficiency of the process, the European Union prepared a research call [3] defining the next main requirements for the applicant proposals:

- Use prefabricated modules with integrated energy efficiency devices and renewable energy sources.
- Use advanced computer based tools for integrating the value chain over the life cycle of the project.
- Move from individual manufacturing to mass-customization.
- Reduce the installation time by at least 30%, compared to a typical renovation process for the building type. For that purpose, high accuracy is needed

The BERTIM project (2015-2019) [4] was selected within this call. The main challenge relies on using timber-based prefabricated modules to cover existing buildings´ envelopes. The results of a preliminary demonstrator [5] of this research project showed that improvements in manufacturing and installation were still required in order to obtain a more efficient process.

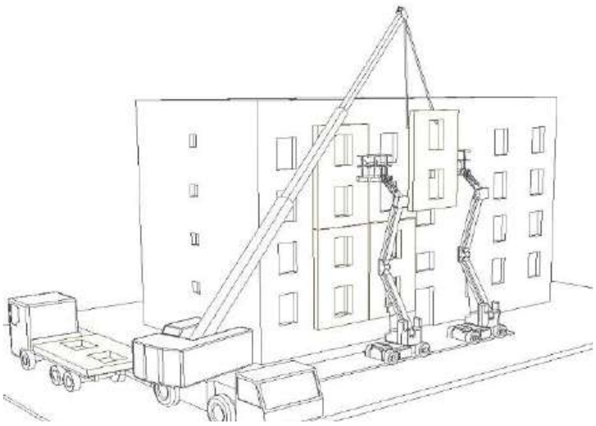

Figure 1. View of current installation process techniques of prefabricated modules for building refurbishment with mobile cranes.

The remainder of this paper is to explain and verify an integrated process that ameliorates the procedures of the demonstrator of the project [5]. For that purpose, some points have been outlined. First, the main challenges of the research are presented in chapter 2. After that, a solution that spans the research gap is defined in chapter 3. The verification process is described in chapter 4. Finally, in the last chapters, the future necessary works are outlined.

2 Multi-Aspect research gap

According to previous studies [5], the procedures used for adding a 2D module onto existing buildings are still excessively time-consuming. Time consumption affects different aspects: the design or layout-planning period, and the manufacturing and installation processes. This yields an increase of cost and therefore prefabricated solutions lose competitiveness in comparison to manual procedures [2]. As outlined in previous papers [5], it affects especially to the on-site installation phase. In other industries, a solution to these problems is the use of robotic and automated technology in order to improve the performance. There have been advances in product flexibility and flexible automation [6]. But normally, robotic manufacturing requires a standardized product. Moreover, building renovation requires fully bespoke products, adjusted to the existing geometry and function. The product´s size shape changes constantly. Therefore, a flexible robotic manufacturing process is needed for a customization. There are already some experiences where the linkage between a parametric design and a robotic control was developed [7],[8],[9]. These studies are focused on complex geometries more than the assembly of fully prefabricate units.

Besides, preliminary research [5] determine that the existing manufacturing processes produce 2D timber modules with excessive tolerances, with around 10+/- mm of deviations. For a highly prefabricated module in the rest of the construction industry, i.e. curtain wall modules, the tolerances cannot exceed 1 +/- mm. In previous studies, it was determined that the accuracy of the modules and the placement of the connector was crucial for a proper fasten. Furthermore, in the BERTIM project, it has been concluded that the insertion of services, and therefore, pipes and ducts must fit. This requires high accuracy.

Between the 2D module and the existing building, there is a connector that consists in two parts. This was further explained in previous publications [10]. One part, (Part 1) is fixed onto the existing building and the other part (Part 2) is fixed onto the 2D module. This way, the 2D module is supported on the connector, which in turn is supported on the existing building. With current techniques, accurately locating Part 1 of the connector is time consuming. Prior to this research, an interfacing Matching-Kit [1] has been defined and proved, which corrects the possible deviations of Part 1. The problem arises with the placement of Part 2 onto the 2D module; the location differs from case to case.

2.1 Information workflow, data acquisition and layout-planning,

In current processes, there is a lack of a continuous information workflow. This situation leads to errors and misunderstandings. The potential benefits of an integrated process were highlighted before [11] and considered BIM as a starting point for integrating the whole process. But in this case, the link between the robotic tasks and BIM needed further development.

Normally the process of building renovation with prefabricated modules starts with the existing building´s data acquisition. Progress has been made to implement 3D laser scanning for acquiring the data of spatial environment [12]. The question arises, if this technique is accurate enough for manufacturing and installing parts onto a previously built environment with high enough accuracy. Besides, the point cloud management might gather too much information to handle, at least for the façade renovation. Moreover, a faster and more efficient procedure for building renovation is to prioritize key points. This is based on the selection of only necessary information and the discrimination of the unnecessary geometrical information. This technique is already developed [13]**.** At this point, the problem relies on the location of the connector; it is also necessary to determine the location of the connector, which might be placed in a non-expected or undesired location. If the location of this connector is not measured accurately, or it is not placed accurately, the 2D module does not fit [10].

Finally, the re-design or layout-planning of the 2D modules needs to be used by a dedicated parametric software. Software such as Dietrich´s and RenoBIM [4] are developed (or are being developed) for a fast adaptation of the modules´ geometries. Recent studies suggest that the software information can be integrated [14] in the manufacturing and the installation processes. Addressing this, it is necessary to define a specific programming system that integrates the process.

2.2 Off-site manufacturing phase

The manufacturing accuracy of single elements can be gathered currently with CNC machines and even with robots. However, the automation level is limited on the following assembling phases. Currently, the assembly process is a purely manual procedure. Besides, there is a growing complexity of the 2D modules. This

[1] Publication under review process

means that more and more components and elements are included during the assembly process. This negatively affects the sought automation of the manufacturing system.

2.3 On-site installation phase

With current techniques, excessive re-work is necessary after the modules are placed and fixed onto the existing building´s façade [5]. The prefabrication degree of the 2D modules is, depending on the case, around 50% - 70%. This means that the rest of the tasks need to be finished on-site.

In any manner, there is no dedicated machinery for installation processes. Currently, the cranes and scaffolding systems are not suitable to this specific purpose. In previous research [15][16] there has been a study of different options for a robotic installation of modules. It must be mentioned that experiences such as the Hephaestus project [17] are relevant to carry out the installation process of the 2D modules efficiently.

2.4 Objective

For reducing the overall time, the main objective consists on integrating all phases, from existing building´s data acquisition to robotic 2D module installation. It is necessary that, from the acquisition of the key point coordinates of the existing building, the information for manufacturing and installing processes is linked. The solution should enable high prefabrication degree and accurate production and installation of modules. For that purpose, robotizing the off-site assembly and the on-site installation process of the 2D modules is desirable.

Since the 2D modules are customized products, in principle, the robot path and grasping for the assembly process should be programmed specifically for each 2D module. Importantly, there is one point to take into account. The 2D modules follow a pattern, they have many common characteristics and their layout changes according to some parameters. Therefore, the robotic programming could respond also to that parametric characteristic, and subsequently, if the controlling algorithms were arranged adequately, it would not need to be adjusted specifically for each 2D module.

3 Integrated process

In order to address the gap stated before, a solution was drafted. The proposed solution relies on a parametric software based on a visual programming language (VPL). This VPL functions as an integrator of several main points: the data acquisition of the existing building, the 2D module design/layout planning, the robotic manufacturing, and the robotic installation phases.

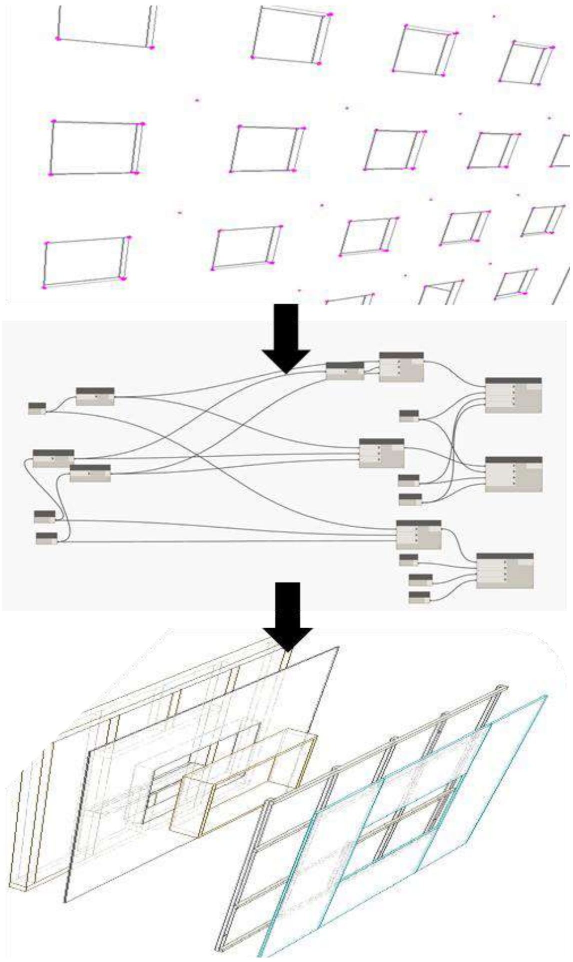

Figure 2. Necessary points´ coordinates in a façade for being inserted in the VPL and definition of every element of the 2D module by using the VPL.

As a primary input of the solution, only the twelve key points of the existing building would be necessary for defining each of the 2D modules. Four points would refer to the perimeter corners of the 2D module, and the other eight would be correlate to the window and its sill. In the case of a regular façade, that would mean that a grid similar to Figure 2. For now, the scope of the solution considers only very simple facades without terraces and balconies. As an output, the VPL would produce the necessary scripts for guiding the path and grasp-planning of the robots. The robotic environment used in this novel integrated process relies on Robotic Operating System (ROS) [17] and implies both off-site manufacturing processes and on-site installation processes.

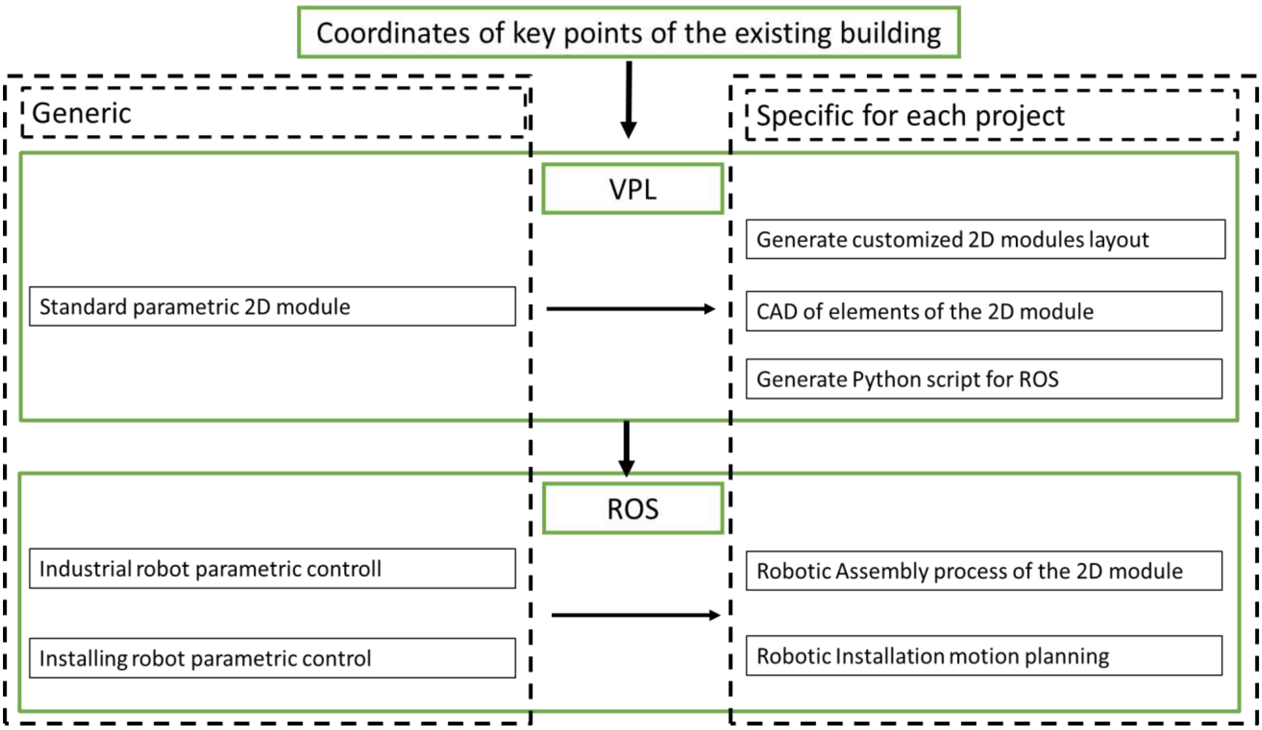

Figure 3. Scheme for the integration of the process.

3.1 Setting out of the standard 2D module

The term “standard” means that there is a library of solutions for the 2D module, with parametric variables regarding the size, shape and outer finishing material. In the case explained in this paper, the 2D module was defined to cover only flat facades, with no terraces or balconies, only with flat windows. The design of the 2D module was based on different layers. The inner layer of the wall was a flexible insulating material that adapts to the irregularities of the existing wall. Then it was followed by a flexible moisture barrier layer. This was to prevent the humidity of the interior of the building from damaging the 2D module itself. The main part of the 2D module was a timber frame, which was filled with insulation. After that a board was placed for rigidizing the timber frame. Following the criteria of previous research, the services were allocated into this timber frame, with extra insulation on the outer surface of the timber frame. For protecting the module from outdoor weather, a waterproof layer fully covered the outer surface. With current techniques, the overlapping of this layers is achieved manually on the site and after that, a finishing layer is placed and windows are inserted in the voids of the timber frame. But the layout and design of this research defined a prefabrication degree of 100%, including the services for RES. The studs and the battens have a maximum separation of 600 mm.

3.2 Setting out of the robots motion and grasp planning

In this integrated process, two types of robotic systems were conceived. On the one hand, there were the already commercialized industrial robots for the assembly of the 2D modules on the factory. On the other hand, there were the installation robots on the construction site.

In the off-site structured environment in the factory, the robot and the automated manufacturing machines and the 2D module´s elements are in recognizable positions. Therefore, an open-loop control system without sensory feedback is foreseen. The visual programming node generates a sequence of the assembly process for each of the elements and the 2D modules. For the assembly process off-site, as defined already before [11], the VPL generates also different types of files such as CAD or STL for the CNC machines and robots.

Besides, on the site, the situation is different. This is an unstructured environment, where the robot needs a calibration and guidance. In first considerations, the closed-loop control system was chosen as the best situation, since it is presumed the robotic system will need a feedback of its location. For that purpose, the selected key points of the building (the points that were acquired during the data acquisition) can be used as a reference for calibrating the robot. There are currently no marketed robots for the full installation of 2D modules. Several options have been envisaged [15],[16],[17]. As a first approach in this research, a stacker crane or Cartesian robot was defined. This Cartesian robot would host a Modular End-Effector similar to the one defined by the authors [19]. This system resembles the already commercialized systems for Automated Storage and retrieval Systems [20].

3.3 Proposed sequence

A building renovation project with prefabricated products requires parallel processes. On-site and off-site tasks need to be synchronized. The integrated on-site process sequence is defined with the next points:

1. The process starts with preliminary data collection of the wall-façade. Basically, it consists of the measurement of the façade´s key points by a digital total station. If the façade is planar, without balconies, the task can be achieved from the ground of the building. The key points are located in the window sill and perimeter of the façade.
2. These coordinates are listed and inserted in the VPL to recreate the façade and the layout of the modules. This step is not attached to the site nor the off-site factory, so it can be carried out in any location.
3. The installation of the robot body. For this research, the robot would be based on a vertical stacker crane. This robot must be calibrated properly according to the 0,0,0 or origin point selected within the building.
4. At this point [2], the onboard tools place the connector´s Part 1 with an accuracyof 20 +/-mm.
5. The onboard measuring device detects the location of Part 1.
6. The Matching-Kit (MK) is fixed by the robot and a planar, known situation is generated.
7. The 2D module is fixed onto Part 1 and the MK.

In parallel, the 2D modules are manufactured using the generated information by the VPL.

a) The data is introduced into the variables of the VPL. Automatically, the layouts of the 2D modules are generated.
b) The CAD and/or STL files are exported by the VPL for manufacturing the parts of the 2D modules. The generation of a CAD file out of parameters is not a novelty; it is used by other processes [11].
c) Every single part is machined and routed in a CNC machine. This way it can be guaranteed that the parts are contoured and milled accurately.
d) The Matching-Kits are produced as an interface. This MK can be produced on-site or off-site.
e) Finally, the assembly of the parts of the 2D modules is performed by the robotic tools. The scripts from the VPL defines the trajectory planning of the desired task, as well as the manipulator control system.

As stated before (ISARC 2016), the process sequence is modifiable depending on some concepts. The arrangement of the on-site sequence (1, 2, 3, 4…) and the off-site sequence (a, b, c, d…) steps presented in this chapter are variable. For instance, if the placement of Part 1 is performed accurately (step 4), the MKs (step c) would not be needed.

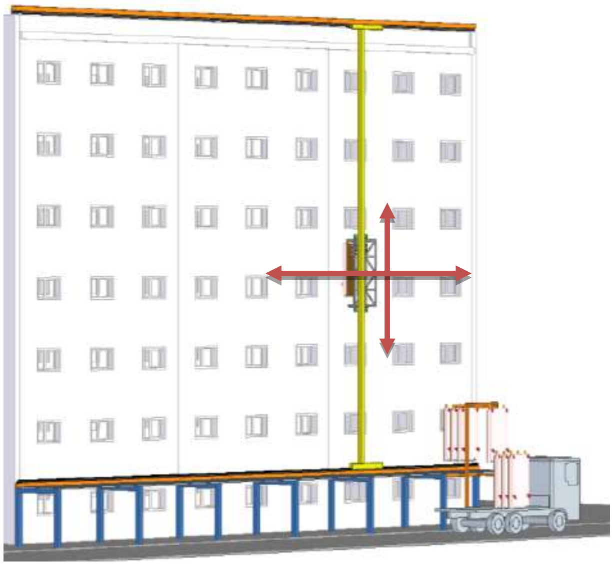

Figure 4. Installation process by a stacker crane (also known as vertical bridge crane).

4 Verification of the integrated process

For the verification of the process, some tests were achieved. The tests consisted of a laboratory experiment and a virtual simulation. The main objective of the tests was to verify the correct sequence of the process.. The verification was achieved in two main scenarios: (1) the robotic assembly of the 2D modules off site with a real robot, and (2) the installation phase on site, virtually. The VPL, Dynamo© [21], was used as an integrator. Dynamo© is a Visual Programming system developed by Autodesk used mainly for Design of parametric objects.

For this test, a sample of a 2D module was used. This sample was a scaled and simplified mock-up of a 2D module, based on timber frame. The 2D module was defined in Dynamo© environment and was parameterized depending of the 4 points of the perimeter of the 2D module. The module was based on eight different timber elements and four different

[2] Points 4, 5 and 6 are described more extensively in another publication under review process.

connectors. For the test, the 2D modules did not have any window, and therefore the eight points referred to in the previous chapter were not necessary. In a previous publication[3], it is explained how the key points of the location of Part 1 were measured.

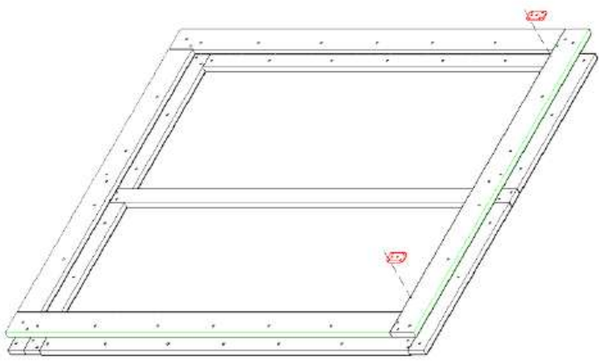

Figure 5. Definition of the 2D module for the Test.

The module was dependent to the existing wall´s key points. During the customization stage in Dynamo©, the data from the coordinates were listed in data sheet file. From here, the sorting node of Dynamo© first generated a solid that defined the façade or the wall, in the case of the test. The STL files generated by Dynamo© were used by a 3D printer for generating the the Matching-Kit interfaces. Finally the CAD model-.dwg file of the timber-frame element are used for routing and milling each of the elements.

Once the elements were accurately produced, the assembly process started. For the controlling system of the robots, ROS [17] was used. ROS comprehends and integrates a set of robot software frameworks. In the case of this research, ROS was used for the industrial robots in the laboratory, in addition to the installation robots in a virtual simulation.

4.1 Off-site robotic assembly of the 2D modules

For this test, the lightweight Jaco© robot by Kinova was used. The Jaco© robot can be installed in ROS environment. Prior to the performance of the robot, the robotic workstation was structured according to the base 0,0,0 origin coordinate. The parts of the modules were also placed in a known location according to this point. The task consisted on moving these elements to a pose goal within the 2D module, according to the 2D layout. The Python script generated in Dynamo© was taken by the Gazebo-Moveit application within ROS environment. The script sequenced the assembly of each of the elements, from the first element to the eighth element. An advantage was that the operator did not need to check the location of the elements, since the task was given directly by the robot.

Figure 6. The Jaco© robot operating with MoveIt ROS.

On this test, only the pick and place task of a relatively small and lightweight element was achieved. For this test, the screwing process was carried out manually. To achieve this robotically, another robot with higher payload and torque capacities would be necessary.

4.2 On-site robotic installation of the 2D modules

This first verification of the installation phase has been achieved virtually, since the robotic stacker crane is not operative for buildings and outdoor conditions. An URDF file that replicates the stacker crane was generated. This URDF was introduced to the ROS-Gazebo environment. Then, the stacker crane robot performed a task that simulated a simple drilling operation according to the given poses by the script.

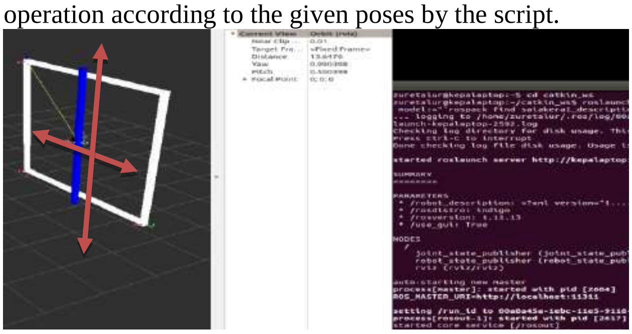

Figure 7. The stacker crane or Cartesian robot in Gazebo ROS.

For now, only the task of the drilling process has been tested and the results are satisfactory, but this process needs to be further developed.

3 Publication under review process

5 Future work

The results of the laboratory verification suggest future work considerations. For the assembly process, the some issues have been foreseen. For instance, the robotic assembly would require sequencing coordinately with the on-site works. The start of 2D module manufacturing depends on the size of the building, the bigger the building is, the earlier the manufacturing process needs to start. Related to that, the authors have envisaged two sequences within the manufacturing process of highly accurate 2D modules. The first is based on the prior routing of every single part of the module and the assembly of them. This is the process that has been explained in the paper. On the contrary, the process can be inverse, by assembling the elements first and then complete final routing of the entire 2D module. In other words, the 2D module can be produced with high tolerances, and then inserted and routed in a CNC machine to get the required contour with precision. Besides, regarding the assembly process, The center of gravity of each of the 2D module´s element should be calculated and taken into consideration before inserting the data on Moveit and Graspeit applications. This way, it should be possible for the robot to grasp the elements in the right position, close to the respective center of gravity. In this research collision detection hasn´t been approached and definitely it is an aspect to take into consideration. The unstructured workplace in the industrial settings must be considered, so the assembled elements are disposed in an aleatory manner.

For the installation process, some other issues must be taken into account. If the stacker crane (or Cartesian robot) system is used, it will depend on the accuracy of the carrier and the linear and rotary encoders. If these devices are not precise enough, another device or sensor would be necessary for positioning. Based on the previous point, a repeatability of the pose will need to be tested. The stacker crane can be up to 30 meters high. At this height, the carrier suffers some balancing and therefore, counter measures will be necessary, such as suction cups for holding the end-effectors.

Finally, this very first approach is limited to simple facades, thus it does not include facades with balconies or terraces. In the future, standard libraries for covering such building parts will be necessary. Depending on the complexity and the size of the building to be renovated, the robots´ controlling system might not be able to handle the data, therefore, splitting the renovation project might be necessary.

6 Conclusions

The existing techniques for manufacturing and installing prefabricated modules for upgrading building facades needs to be raised to a more efficient and automated method. The integrated process presented in this paper offers possibilities for reducing inefficiencies and increasing accuracy on the building renovation process. The proposed process or sequence, based on VPL and robotic assembly and installation, has been verified in a laboratory environment with satisfactory results.

The 2D modules are in general very similar, but they have many particularities; size and location of elements. These peculiarities are demanded by the geometry of the existing building. This means that the robots, both in the industrial settings and on the construction site, need to perform similar operations, but depend on specific parameters each time.

During the verification, with only the given input of the existing building´s coordinates, the VPL processed the data for the assembly robot that performed the assembly of the 2D module. Furthermore, in a simulation achieved in ROS environment, it has been tested that 2D module installation robots have a big potential. Both assembly and installation robotics still need more improvement. In the future, each step of the proposed sequence can be further developed and tested separately.

Acknowledgments

Abstract –

While on the one hand the BIM methodology is an essential reference for the construction of new buildings, on the other hand it is receiving particular attention and interest also from owners of large building stocks who want to take advantage of the benefits of Building Information Modelling so as to have a coordinated system for the sharing of information and data.

This, especially in a process that concerns the management and maintenance of a large building stocks, involves the processing of uncertain information in BIM, particularly when dealing with existing buildings, due to the lack of and/or incomplete documentation, entailing a significant investment in terms of time and additional costs.

Therefore, to represent the reliability of existing building data, we suggest introducing a tool based on Bayesian Network that offers a valid decision support under conditions of uncertainty and is used to evaluate the compliance with the latest standard.

This paper presents a process to provide an integrated database defined by a minimum information level that can be used both to extrapolate and query specific information from a digital building model and populate the decision model in order to evaluate the performance parameters of existing buildings which is based on a Multicriteria decision making approach (AHP).

Keywords –

Building Information Modelling; building stock; data management; Bayesian networks; Multicriteria decision making

1 Introduction

In this work, attention has been given to the role played by public administrations in the management of large building stocks, focusing specifically on school buildings, the majority of which is outdated and lacks of compliance with current legislation.

The purpose of this paper is to propose a decision support model that can be used by public administrations, such as provinces and municipalities, which need to define the priorities of refurbishment actions among the school buildings they own.

This Decision Support System (DSS) concerns multiple regulatory areas in which evaluation is performed, namely Accessibility, Energy Efficiency and Acoustics. In addition, the DSS makes it possible to manage the uncertainties deriving from the scarce availability of necessary data on existing stock. The DSS was conceived so as to be able to obtain the necessary information directly from the Building Information Modelling (BIM) database. In addition, the decision support model includes a multi-criteria evaluation of performance indicators, each related to a determined regulatory area, with the aim of defining a final ranking of the schools assessed, in which the one with the lowest score shows the highest priority of intervention.

In conclusion, the aim of this paper is to develop a BIM-based Decision Support System for the assessment of building stocks which is able to perform the evaluation even in the case it has to manage uncertain or incomplete information. Our tool integrates networks that help evaluate the performance parameters of existing buildings, whose inputs can be retrieved from BIM models, and prioritise refurbishment actions through a multi-criteria assessment approach of some selected performance indicators.

2 Literature review

In many practical cases it is hardly possible to retrieve all the information about existing buildings through the query of the most relevant characteristics contained in a model in a reliable way. Even in the case of existing buildings for which extensive construction and operational documentation is available, some parameters might be uncertain or unknown.

Several research studies have been carried out to develop decision making systems to deal with the extensive and uncertain information characterising the existing stock. DSSs have been developed for a wide variety of engineering-related issues in the construction industry. For example, in [1] since the selection of curtain wall systems involves numerous technical, environmental and economic factors and impacts on all project stages from concept design and manufacture to installation and operation, a decision support system is proposed as a potential solution.

In [2] the authors presented the result of a research carried out with the purpose of establishing a multicriteria method for the assessment of architectural heritage to identify buildings with higher refurbishment priority. The author in [3] created and tested a multicriteria risk-based decision support model for investments in energy efficiency projects under uncertainty of building energy retrofits. In [4], a study was developed to provide systematic means for priority setting of maintenance activities in various hospital buildings as well as a Key Performance Indicator for building performance. Other researches focused on the choice of what information is needed to make models significant to maintenance and on handling uncertainty due to incomplete building documentation [5].

The above listed results are remarkable but do not deal with the compatibility between DSS and BIM models of existing buildings. Indeed, the modelling and conversion of captured data into semantic BIM objects, the updating of information in BIM and the handling of uncertain data, objects and relations in BIM, which are typical challenges in existing buildings [6], must be analysed.

Hence, this paper deals with the development of a BIM based decision support tool based on the use of Bayesian Networks (BNs) for the evaluation of building stock compliance with technical requirements and its ranking according to selected performance indicators.

BNs are an effective representation of knowledge uncertainty, because they provide the possibility of constructing an estimated probabilistic model, since not all information can be accessed. In addition, they make it possible to update the network inputs when new evidence is collected and updates results accordingly. BNs are composed of elementary parts (separate fragments) and recall their outputs in a larger network. They make it possible to reverse reasoning and can manage variables of different types (e.g. Boolean, numerical, interval or label nodes). BNs work with as many data as are available to give accurate results. Moreover, within each iteration, they learn more and refine their model to give updated results.

A great advantage of BNs is that they allow us to combine prior knowledge with new data even if they come from different sources. Once the model is compiled, we can get very quick results by using the already established conditional probability distribution tables.

Many organisations, especially in the public sector, own a large variety of buildings and other types of constructed facilities. These buildings need regular maintenance, as well as occasional renovation, rehabilitation or, perhaps, complete reconstruction [7]. Multicriteria decision making analysis arose to model complex problems like these [8]. Multiple criteria decision making (MCDM) is a generic term for all those methods that exist to help people make decisions according to their preferences in cases where there is more than one conflicting criterion to be taken into account [9]. Following a research throughout scientific literature, it was found that the majority of the methods used are based on AHP, ELECTRE and PROMOTHEE approach [10]. As outlined in [10], AHP can provide decision makers with a robust solution. The most important part of this method is that it puts decision makers' preference first and helps elect a method for their decision making in maintenance management without considering uncertainty rate and problem complexity.

For these reasons, the AHP methodology was applied according to what suggested by Saaty [11].

3 Modelling of school building stock

Although a detailed set of information about existing buildings would be necessary to carry out a reliable assessment of real estates, most of the buildings were built in the pre-digital age [12].

Some public administrations are developing preliminary BIM models of their stock, but they are willing to limit the complexity of these models within the lowest amount of information needed for management and maintenance purposes, in order to make that process affordable. For the reasons stated above, we selected two case studies of school buildings which are particularly complex. In the selected scenarios, there is a clear need to adapt the existing buildings to current legislation in terms of different aspects such as accessibility, energy performance, acoustic etc.

3.1 The case studies

In this paper two school buildings located in Melzo (Milan, Italy) were studied. The first one is the "Ungaretti" primary school, whose surface area measures 4528 m^2 and is arranged on four levels, one of which is the basement and the remaining three floors are above ground. The gymnasium is accommodated in a separate building, which communicates with the main one through two horizontal connections in the basement and one placed on the ground floor. The basement houses the canteen, the kitchen, laboratories, archives, refreshment areas and infirmary. On the ground floor there are classrooms and offices, while on the first floor there are just classrooms and on the second floor classrooms and auditoriums. The restrooms are distributed throughout the building and the gym.

The second case study is the “Mascagni” secondary school located in Melzo (Milan, Italy), which is as large as 5736 m^2 and is composed of three functional blocks. One block holds the classrooms and laboratories located over two floors above ground, the other two blocks hold the cafeteria/auditorium and the gymnasium.

3.2 BIM models

Developing BIM models of existing buildings implies, first of all, a thorough study of available documentation and then an accurate analysis of the real state of the buildings.

The next step involves the construction of three-dimensional BIM models of the buildings (developed through the Autodesk Revit™ platform) containing all the technical elements identified and the organisation of collected information. The models become the materialisation of the technical information related to the element or system they refer to. Each element of the models is “informed” of all parameters, specifications and characteristics of the real elements [13].

Nowadays, buildings information is often incomplete or obsolete, hence, during operation “an inordinate amount of time is spent locating and verifying specific facility and project information”. This is the case of the two BIM models of the two schools selected as case studies: the Ungaretti primary school (Fig. 1-a) and the Mascagni secondary school (Fig. 1-b).

Sometimes not all the information needed to perform a complete assessment is available in the BIM models.

a.

b.

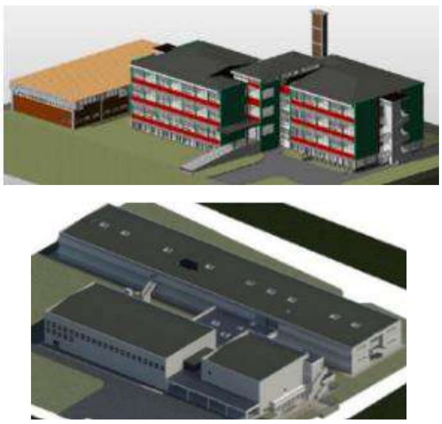

Figure 1. BIM models of the case studies a) Ungaretti school b) Mascagni school.

4 Methodology

Owners of any large building stock, such as public administrations, usually have to manage a huge variety of buildings with a limited budget. For this reason, targeted refurbishing actions are needed to ensure that those buildings comply with the latest standards and public administrators have to make important decisions regarding what part of their stock should be refurbished first.

Hence, the work developed in this paper is made up of several parts (Fig.2):

- A BIM database of the building stock;
- A set of Bayesian Networks for the evaluation of stock compliance with technical requirements and its ranking according to performance indicators;
- An interface between the BIM database and the Bayesian Networks, which automatically picks out relevant inputs from BIM models and transfers them to BN;
- A multi-criteria decision system, which ranks buildings according to the BN outputs;
- A further set of BN that estimates the budget needed to improve the status of any building.

DSS tool based on BN will be shown with the aim of assessing what buildings must be refurbished first.

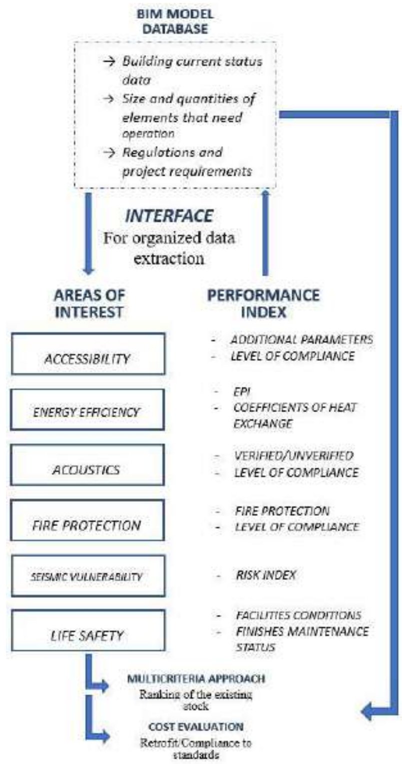

Figure 2. Schematic diagram of the structure of the decision support system.

4.1 Decision support system based on Bayesian Networks

A BN is a directed graph whose nodes are the uncertainty variables and whose edges are the casual or influential links between the variables. Associated with each node there is a set of conditional probability functions that model the uncertain relationship between the node and its parents [14]. Each variable may take two or more possible states of numerical (i.e. discrete), interval (i.e. subdivision into ranges), label or Boolean types. An arc from any set of n variables, called a_i, to another variable b denotes that the set a_i causes b and a_i are said to be the parents of b (b is evidently their child). The strength of those relationships is quantified by conditional probability tables (CPTs), where the probability of observing any state of the child variable is given with respect to all the combinations of its parents' states. In our example this probability is labelled $P(b|a_1, a_2, \dots, a_n)$, where any variable a_i is conditionally independent of any variable of the domain that is not its parent. Thus, we can obtain a conditional probability distribution over every domain, where the state of each variable can be determined by the knowledge of the state of only its parents, and the joint probability of a set of variables E can be computed by applying the "chain rule" [15]:

$$P(E) = P(E_1, E_2, \dots, E_n) = P(E_n|parents(E_n) \qquad (1)$$

That is: the joint probability of a set E_n of variables is equal to the conditional probability of the variable, given only its parents. Other relevant benefits are: the DAG provides a clear understanding of the qualitative relationships among variables; every node can be conditioned by new information (e.g. evidence about the features of a building in our case study); the same belief that updating is supported from consequences to causes, also known as diagnostic reasoning, and can be applied when the budget for renovation is limited and inference must be conducted from child nodes (e.g. cost of renovation) back to parent nodes (e.g. status of a building sub-system); finally, CPTs can describe the relationships among variables of different types (e.g. Boolean nodes, interval node, etc.), even within the same network.

Presently, every local administration performs separate evaluations of existing stock to decide where to focus the intervention first and there is no coordinated assessment at the national level on a proportional distribution of efforts. To that purpose, informed planning according to real priorities is needed, which means detecting any lack of compliance with respect to current legislation, in terms of comfort, energy performances, accessibility, seismic vulnerability, etc.

4.2 Multicriteria ranking

The methodologies for Multi-Criteria Analysis can be divided into two main groups: (i) Multi-Criteria Objectives Analysis (MCOA) and (ii) Multi-Criteria Attributes Analysis (MCAA). In the case of MCOA, the decisional process consists in the selection of the best solution within a group of infinite alternatives, implicitly defined by the problem boundaries. On the contrary, Multi-Criteria Attributes Analysis (MCAA) is a multidimensional evaluation method subset, whose final purpose is to locate the best strategy among a restricted number of alternatives, which are ranked according to their preferences [16]. MCAA can act as a support in the decision-making process [17], which leads through a systematic analysis of the solutions.

As a first step, the hierarchy is defined as follows: the top level is "stock value", the second is composed of all the areas of interest such as accessibility, energy efficiency, acoustics and others; instead, the third level is made up of the outputs from the BN "Level of Compliance" (LoC) node for Accessibility, "EPI" and "Heat Transfer Coefficient" nodes for Energy Efficiency and "Level of Compliance" (LoC) and "Compliance of acoustic requirements", as reported in Section 5. The second step consists in the pairwise comparison between the different areas of interest. As a result, the final ranking is inferred as a combination between the values obtained from the BN and the weights determined by means of the pairwise comparison [18].

4.3 Analysis of the minimum Information level

The next sub-sections show the necessary information to evaluate the level of compliance for the different regulatory areas, particularly the Accessibility Bayesian Network, the Energy Efficiency BN and the Acoustics BN.

4.3.1 Accessibility Bayesian Network

Italian legislation (D.M. 236/89) defines all the requirements and the related technical standards that are shown in the Accessibility Bayesian Network.

The output node 'Level of Compliance' is a child node of several parent nodes, each concerning a specific sub-area [19]-[20]:

- "Accesses": e.g. width, handle height, maximum opening force;
- "Doors": e.g. width, handle height, maximum opening force, maneuvering clearance;
- "Parking spaces": e.g. parking space width;
- "Lift": e.g. car elevator dimensions, car control keypad height;
- "Floors": e.g. floor frictional coefficient, floor joint

width, floor ridges, changes in level;
- "Stairways and Ramps": e.g. handrails, tread and riser size, stair width, maximum slope;
- "Toilets": e.g. water closet position, grab bar location and size, lavatory position;
- "Routes": e.g. clear width of an accessible route, passing space interval;
- "Windows and balconies": e.g. railings, maneuvering clearance, window opening force, handle height;
- "Facilities outlets": e.g. facilities outlet height.

The ratio of verified technical prescriptions (e.g. at the building component level) was evaluated in order to fill in the conditional probability tables of all the ten aforementioned Boolean-type intermediate nodes (admitting "true" and "false" states only).

4.3.2 Energy Efficiency Bayesian Network

The whole Energy Efficiency Bayesian Network was derived from previous research on reduced-order models for thermal simulations of buildings [21]-[22].

With the purpose of learning the CPTs of the BN from data, the reduced-order model was repeatedly run to generate a database containing more than 100 records which was used as a dataset to estimate the CPTs, while casual dependencies were quantified by means of the EM-learning tool implemented in the Hugin™ software program [23].

This network estimates two performance indicators:

- Heat Transfer Coefficient (HTC);
- Seasonal Energy Performance (SEPi).

In this case, the nodes represent the variables of the reduced-order model, while arcs were determined according to the casual relationship between the variables of the same reduced-order model.

4.3.3 Acoustic Bayesian Network

New and existing buildings must be characterised by specific noise insulation performance. The legislation (DPCM – 5 December 1997 "Determination of passive acoustic requirements of buildings") defines all the requirements and concerns:

- Insulation from airborne noises between different real estate units;
- Insulation from external noise (façade insulation);
- Insulation from trampling noise;
- Insulation from the noise of systems;
- Reverberation time of classrooms and gyms.

For each type of noise, the DPCM indicates:

- The indicators to use;
- The threshold values to be met depending on the intended use of the building.

Acoustic BN is divided into two sub-networks, the first of an analytical nature, as it reflects the Sabine equation for the calculation of the reverberation time, the second for the control of the remaining parameters.

4.3.4 BIM semantic enrichment

BIM models must comply with a minimum information level to be able to automatically retrieve information from them and transfer it as inputs in the BN. The management of this information is an extremely important issue from two points of view:

- The kind of information to be entered and how/where to enter it;
- How to extract information from the model in order to be able to carry out successive processing.

After reading the legislation, the verification network was created by taking into account all the aspects that can be evaluated through available information from BIM models. Tools such as SQL and Dynamo, were used to manage data transfer in order to automate the minimum level of information transfer between the BIM models and the networks system.

For both schools, the necessary data were extracted from the respective BIM models related to each requirement of the Accessibility BN, Energy Efficiency BN and Acoustics BN. If the data are not present in the model, they must first be added, if known, and then extrapolated. In the absence of applications that automatically extrapolate information from the BIM model, information must be extrapolated manually.

Table 1 reports the necessary information (available in the model, not available but derived from the models and after post-processing information) for the Accessibility network, Energy Efficiency network and Acoustics network:

Table 1. Necessary information for the networks

Available	Not available	After post processing
Access door width, internal door width, door handle height, ramp width, stairs railing height, stair flight width, hand rail height, tread depth, window parapet height,	Opening doors force, path width and length, door space check, Internal setpoint T, number of floors, lift car depth and width, door clear span, lift platform length	Average transmittance of the opaque and transparent elements, useful floor area, S/V ratio, air-conditioned gross volume, average global irradiation, average external

balcony parapet height, thickness and material of the various constituent layers, intended use, wall type, wall thickness, floor type, layers, floor thickness, internal wall type, window thickness	and width, sink height, toilet lateral wall distance, wc hand rail height, wc nominal height, slope, opening window force, window handle height, balcony operating space, friction coefficient, threshold height	temperature, Ce, Cm, Rm, Rea, Rie, Cih, Irradiation, conduction, gains, Q_op, envelope, power, efficiency, gains_tot, infiltration, forced_ventil, Qh, Epi/EPe, reverberation time, Las_{max}, La_{eq}

5 Results and discussion

These networks were implemented on two schools case studies (Fig.3). For both schools, the necessary data were extracted from the respective BIM models.

a.

b.

c.

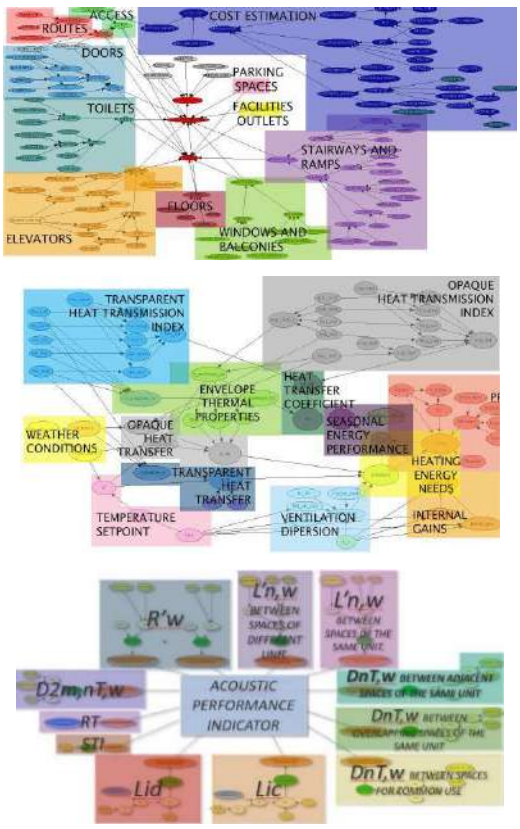

Figure 3. Accessibility Bayesian Network (a), Energy Efficiency BN (b) and Acoustic BN (c).

The Accessibility BN requires 62 inputs, the Energy Efficiency BN requires 32 inputs, while the Acoustics BN requires 30 inputs. Out of the 124 required inputs, 8 and 20 (respectively accessibility and acoustics) were directly available from the BIM model and 39 (regarding accessibility) were available because the BIM designer performed a customised modelling procedure. The remaining data were obtained through combined analyses of several parameters. As for acoustics, the compliance was checked room by room obtaining as output an acoustic performance index for each of them, an arithmetic average between the KPI obtained for each school was calculated.

In Table 2 the values of the BN output nodes are listed. The output “Level of Compliance” (in the second column) represents the ‘true’ percentage value of the node according to the information entered in the network. The other two columns represent the outputs of the Energy Efficiency BN. The rightmost column shows the percentage of ‘true’ of the “Level of Compliance” node of the Acoustics BN.

Table 2. BN outputs for the two cases studies

Case Study	Accessibility	Energy Efficiency		Acoustics
Output	LoC	HTC	EPi	LoC
Units	%	W/m^2K	KWh/m^3y	%
Ungaretti	54,9	2,39	47,04	49,44
Mascagni	55,73	2,55	45,87	55,41

After having obtained the values of the BN outputs nodes, a multi-criteria analysis was applied using the AHP approach for the classification of the two schools to evaluate them in the three regulatory areas.

As a first step, the hierarchy was structured where the first level (goal) is “Intervention Priority”; Accessibility, Energy Efficiency and Acoustics are on the second level (criteria); the third level (sub-criteria) includes the outputs of the nodes “Level of Compliance” for accessibility, “Level of Compliance” for acoustics and “SEPi” and “HTC” for energy efficiency; the fourth level (alternatives) includes the Ungaretti primary school and the Mascagni secondary school.

The second step consisted in the pairwise comparison between the different areas of interest and the different indicators within the same area (e.g. energy efficiency). As a result, the final ranking was inferred as a combination between the values obtained from BN and the weights (Table 3) determined by means of the pairwise comparison, as follows:

$$R = W_A * A + W_{EE} * EE + W_{KPI} * KPI \tag{2}$$

Where A is the "Level of Compliance" for the accessibility and KPI is the "Level of Compliance" for the acoustics reported in Table 2; W_A, W_{EE} and W_{KPI} are the weights (Table 3) and EE is computed as follows:

$$EE = W_1 * HTC + W_2 * SEPi \tag{3}$$

Table 3. Weight values

	W_A	W_{EE}	W_{KPI}	W_1	W_2
Weight values	0.63	0.26	0.11	0.17	0.83

As a result, Ungaretti was assigned {HTC, SEPi}={1, 0.975} and Mascagni was assigned {HTC, SEPi}={0.937, 1}. The application of Equations (2) and (3) to the cases of the two schools gave the following ranking results: R is equal to 0.66 in the case of "Ungaretti" school and 0.67 in the case of "Mascagni" school. Hence, Mascagni is ranked higher, the refurbishment should be prioritised for the Ungaretti school.

More remarkably, the use of Bayesian Networks allows us to draw attention to input nodes even in the case of uncertainty about the selected parameter in the BIM model, or in the case it is completely missing. For example, considering the Accessibility BN, when some information is not available, all the states of a node can be set at the same probability value (e.g. 50% false and 50% true in the case of a Boolean node). A hypothesis was made to show how the outputs can change (Fig.4) depending on the level of uncertainty of the inputs (e.g. door width and handle height) in the BN of the two school case studies, as Table 4 shows:

a.

b.

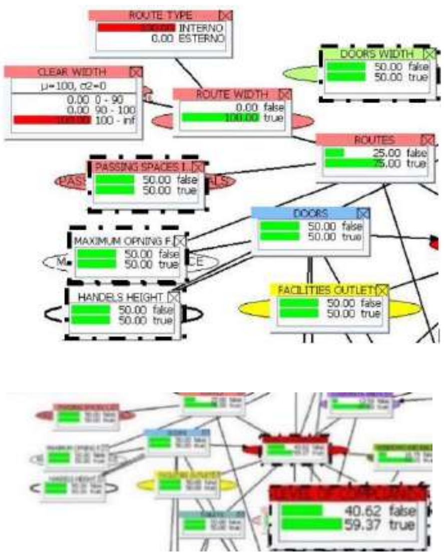

Figure 4. Accessibility Bayesian Network with a level of uncertainty (a) and related results (b).

Table 4. BN outputs of the two case studies with new inputs for Accessibility

Case Study	Accessibility	Energy Efficiency		Acoustics
Output	LoC	HTC	EPi	LoC
Units	%	$W/m^2 K$	KWh/m^3y	%
Ungaretti	59,37	2,39	47,04	49,44
Mascagni	60,21	2,55	45,87	55,41

Table 4 shows the new values of Level of Compliance of Accessibility. The application of Equations (2) and (3) to the cases of the two schools gave the following new ranking results: R is equal to 0.65 in the case of "Ungaretti school and 0.69 in the case of "Mascagni" school. Despite the changes made, the overall assessment remains always coherent, showing that the Ungaretti school is still the school that gets the minor score, so the first to require intervention.

6 Conclusion

To validate the Decision Support System proposed, an actual case project involving two existing schools in Melzo (Milan) was used. The system proposed incorporates 3D BIM models and Bayesian Networks that are capable of semi-automatically evaluating the level of compliance of existing buildings. BNs are a useful means to handle uncertainty due to the lack of some information about existing buildings, because they are capable of dealing with several types of variables and because inference propagation can be inverted. BNs can also consider multiple aspects linked to different regulatory areas simultaneously.

The whole decision support system includes a multi-criteria assessment of some performance indicators, each of them relative to a specific area of interest. The ranking of buildings was performed by means of the AHP approach. Considering the limited budget available to Public Administration, this makes it possible to carry out the evaluations of existing buildings with reduced time and costs.

This paper reported the application in terms of "Accessibility", "Energy Efficiency" and "Acoustics" networks, which were shown to give back reliable results, once interfaced with the BIM models of the case studies. In addition, the development of the BN and the detection of the necessary inputs through the interpretation of regulations give back the amount of information that must be provided by BIM models to perform those analyses.

The methodology detailed in this article can be extended to other regulatory areas such as seismic risk, safety and fire safety.

E-mail: jungsikchoi@gmail.com, stays1006@gmail.com, ihkim@khu.ac.kr

Abstract

This paper describes the development of an automated stand-alone application for generating 2D drawings using information from an IFC file, independent of existing BIM authoring tools. Using the application described in this paper, plan, section and elevation drawings can be extracted with no additional effort. The approach described in this paper, which is based on openBIM technology, will have a strong impact on the construction process especially from the perspective of enhancing productivity by providing a trade-off between conventional and new approaches.

Keywords –

Building Information Modeling (BIM); Industry Foundation Classes (IFC); 2D Drawings Generation

1 Introduction

With the increasing popularity of smart devices and the application of artificial intelligence and other automation technologies, technical applications for business innovations are being implemented in a wide variety of industries. In an attempt to improve productivity and quality in the construction field, openBIM was introduced for business innovation. openBIM can improve efficiency through construction cost reduction and work automation. Therefore, stockholders in the construction industry expect positive effects from the use of this technology. However, the high cost of facility investment and the re-education of users are hindering the introduction of BIM-related technology. In addition, compared with the expected effect, technology based on openBIM is still in the preliminary stages. In order to use BIM technology effectively throughout the construction process, the technology must be more advanced than its current state. Despite the high degree of interest and expectations for openBIM, there is a wide variety of BIM technology deployed in the construction industry because different groups introduced BIM at different periods and the use of BIM is still in the preliminary stage. In the actual business environment, the construction process is changing from the use of 2D drawings to 3D BIM, but the BIM model and 2D drawings are expected to be submitted at the same time during the permit process. In countries where BIM is mandatory, the BIM model is submitted as an IFC file. The generation of drawings that do not rely on commercial software and that follow international standards (IFC) is very important.

Therefore, there is a need for openBIM-based automatic 2D drawing generation technology to avoid duplicating the work of creating both the BIM model and 2D drawings as well as to overcome limitations due to technical gaps, which are the current economic and technical difficulties hindering the adoption of BIM. However, the drawing generation module included in existing BIM authoring tools can only be used with specific tools. This makes it difficult to use BIM in the current environment, and leads to difficulties in BIM facility investment as well as technical gaps between users.

The purpose of this study is to analyze the architectural elements required to generate 2D drawings with the aim of developing an openBIM application capable of generating 2D drawings automatically. The goal is to maximize the effect of BIM to enable individuals undertaking the permit process in a design office to create IFC-based drawings for permit submission after completing the model. Permit officers can also generate the drawings they need and work efficiency can be improved by reducing duplication during the transition period of BIM introduction.

2 Literature review

2.1 openBIM

BIM is based on the concept of using electronic information to generate and express building information. BIM refers to the process and technology of acquiring and managing information electronically, which is important throughout the life cycle of building planning, design, engineering, construction, maintenance, management and demolition [1]. Through BIM, information related to a building can be managed and used electronically, enabling application of the many advantages of computers, such as accuracy and storability. However, the construction industry is huge and complex and a wide variety of software is used by different groups in the industry to handle computerized information. The omission of information and errors in transmission can occur in the process of information exchange between these different programs [2]. To address this issue, buildingSMART proposed the concept of 'openBIM'.

openBIM is a concept focused on independence from specific software or product groups and ensuring interchangeability and interoperability of information between different kinds of software. For this purpose, the IFC format was developed as an international standard data format in buildingSMART and is actively being developed. In 2013, IFC was adopted and published as an ISO16739 standard [3]. IFC is an international standard neutral file format for BIM data exchange and information exchange between the BIM software used in many fields in the construction industry. In the IFC data structure, information about the building is expressed based on the relationship of the objects and the relationship of attributes owned by the objects.

2.2 Necessity of automatic generation of 2D drawings

Unlike the predicted disappearance of 2D drawings with the introduction of BIM, the requirements for 2D drawings have remained consistent. The results of a survey on BIM introduction status in Korea showed that "duplicate work due to creating BIM model and drawings separately" was the primary factor impeding BIM adoption, with 80% of users selecting this response. When introducing BIM to non-users, the ease of generating different sections, facades, and perspectives should be taken into consideration, as this factor has the highest influence on adoption with 62% of responses [4]. In the early stages of BIM introduction, though the duplicate work of generating 2D drawings simultaneously is necessary, it presents an obstacle to BIM adoption. The primary reason for the duplicate work is the difference in the technical levels of the participants in the construction process. Many participants are involved in different stages of construction, from design, permission, and construction to maintenance. However, when BIM is implemented from the design stage, all participants must use this method to complete the project.

Consequently, even if the BIM contract is expanded and the design work is performed using a BIM model, the current contract situation requires 2D drawings and duplicate work remains a necessity. An application capable of generating 2D drawings automatically is needed to solve this problem. Such an application can eliminate the negative elements of BIM introduction by reducing the workload of users, improving productivity and reducing the technical gap.

2.3 2D drawing automatic generation application and research status

There are various methods for generating 2D drawings from BIM models. Drawings can be generated in combination with a 2D drawing generation module in commercial authoring tools. Choi et al. pointed out the limitations of having to use a 2D drawing module in BIM authoring tool to generate drawings. The problem lies in creating an execution design drawing at the same level as CAD, an inability to match the details with the construction level, and lack of a modeling function that can add detailed content [5]. Chae et al. noted that problems will occur in the process of generating 2D drawings using BIM authoring tools, so this method should be applied in parallel with the existing method of creating 2D drawings [6]. Lee et al. stated that drawings generated with a BIM model cannot meet the standards for construction sites. He proposed developing a module to create steel reinforcement construction drawings and process the schedule accurately according to the relevant criteria by using a 3D structure model and taking the architectural structure as the object [7].

The results of previous research on automatic 2D drawing generation using a BIM model show that most of the previous research stays on the stay at those stages, such as instructions to generate 2D drawings using BIM authoring tools, changes in the design process using templates and a module for automatic generation of drawings for use at construction sites. However, methods for generating 2D drawings using a standard such as the IFC optimization criteria or generating a BIM design document are nonexistent. There is also a lack of practical research on solving the problems of 2D drawing generation.

2.4 Summary

BIM can improve business efficiency by embodying real buildings in virtual space. In the initial phase of BIM introduction, both the 2D and 3D processes coexist, resulting in practitioners performing the duplicate work of creating both a BIM model and 2D drawings [8]. Although the practitioners are burdened by the additional work, existing methods for generating 2D drawings from BIM models are incapable of producing detailed technical drawings. The drawings generated currently cannot be used because they do not meet the standard. In addition, there is no complete study evaluating the use of optimization criteria to improve productivity or a standard format to create drawings. In this study, the structure of the standard IFC format was evaluated to develop an application for automatic generation of 2D drawings based on openBIM that can be used for viewing the BIM model regardless of the type of authoring tool used. The goal is to enable users to generate drawings of required parts from the IFC model without inconveniences resulting from the level of BIM introduction and technical gaps.

3 Implementation of 2D drawing automatic generation application

3.1 Overview

3.1.1 Process for 2D drawing generation based on IFC

The process for 2D drawing generation based on IFC is shown in Figure 1. First, in order to visualize the IFC file, the IFC information must be parsed to distinguish the information for model shape expression and the object attribute information. After separation, the information is stored in memory. Solid shape information is generated using the shape expression information, then converted to mesh for 3D shape expression using the Open Cascade library. To visualize the transformed mesh information in 3D, the Direct X library is employed. For the generation of plan and section drawings, visual images for 2D drawings are generated using a mesh cutting algorithm. The remaining lines on the opposite side of the section generated by mesh cutting are unnecessary and are deleted by a removal algorithm before vector information is generated for output. To create annotated elements (such as dimension, grid, level, etc.) in the generated drawings, the information is first extracted from the IFC model and visualized in the generated drawings.

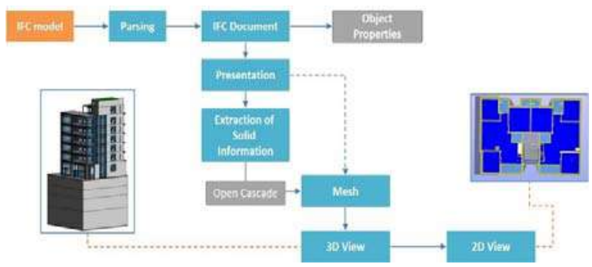

Figure 1. Process diagram

3.1.2 Structure of the application

The information generated from the IFC model is visualized according to the following structure. The structure refers to the classification of the basic structure for IFC. The application was developed in C#, an object-oriented C language, and encapsulation was implemented to use information effectively. During classification, the part needed by Solid calculation calculated through the modular solid calculation is operated as data for visualization. Through the visualization module, the information can be visualized on a computer screen.

To generate a plan drawing, elevation drawing and section drawing with the 3D model, the appropriate data structure for the model should be accurately defined. Section cutting must be applied effectively on the structure based on the cutting plane, and the section cutting results should be expressed accurately without errors. To express the 3D shape information, the structure of the object is mainly used in the triangulation mesh. In this study, we performed section cutting and the generation of section lines in the corresponding plane. However, a relatively complicated computation is required when using a triangular mesh and unnecessary lines may be generated in addition to the section lines. In this study, we mostly needed to generate the section shape. Consequently, we created the object structure as shown below, so that the related work can be completely effectively.

The basic structure of the object was defined as a polyline-made polygon with a hole. The example below shows the shape of one hole in the quadrilateral, but the method presented in this study involves several holes in the polygon. This method can be used to generate a mesh by using a triangulation network after cutting based on the cutting plane.

3.2 Automatic generation of 2D drawing

3.2.1 Generation of elevation drawing

The elevation indicates the elevation shape on four sides (left, right, front, and back). The lines expressed in the elevation can be divided into two types. In the first type, the intersections of the object surfaces form the lines. In the second situation, the intersections of the surfaces form no lines, but the boundaries of a prominent position become the outline. For example, in a curved surface, although there is no line formed by the intersection of surfaces, a section will be presented along the direction of the elevation as a contour line.

When elevation is displayed on the interface of the application, it turns the direction of the camera to the X (Left), -X (Right), Y (Front) and -Y (Back) axes and selects the projection mode as a right-angle mode to display on the interface. In the visualization of the IFC model, when the elevation is displayed, the objects behind the objects shown in the related elevation drawing are presented in an invisible form. In order to represent the elevation drawing on a computer screen, the triangular faces of the obstructed objects are drawn using the background color. On the elevation drawing, the lines that are intended to be hidden should be drawn using the background color, which will make them appear invisible. Therefore, it is not necessary to use the delete calculus separately for obstructed objects. In addition, the elevation drawing can be displayed quickly and effectively.

3.2.2 Generation of section drawing

Generation of a section drawing is based on the plane of the user's desired section, created by cutting off the BIM model and creating an isometric projection in the vertical direction of the section. The section is made up of lines cut from the datum as well as uncut evaluation lines. The method of cutting the building by using the inference plane is as follows. This method is based on the coordinates of the cut-off reference plane, fixing the location of the camera, and truncating all the objects crossing the cross-section and perpendicular planes. The boundary lines of the cutting plane are marked as boundary lines on the screen. This is the same process used in generating the elevation drawing, in order to express section drawings quickly. When displaying a section drawing on the screen, a structure is needed to hide the objects behind the cross-section when the cross-section is displayed.

As shown in Figure 2, the cross-section provides an interface that allows users to set the reference line of the section drawing in the plan drawing for generating section drawings. Currently, the section line can only be created as a straight line.

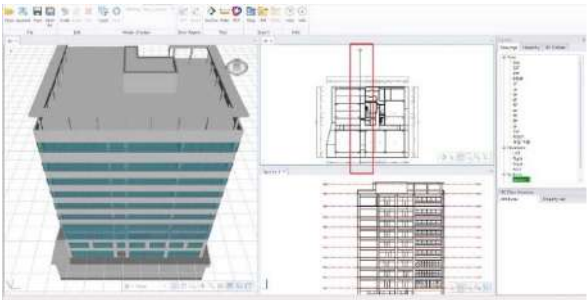

Figure 2. Selecting a section profile to generate any given section drawings of interest

3.2.3 Generation of plan drawing

The generation of plan drawing is a special method for generating the section drawing. It cuts off at the position based on the reference line which is 1.2 m in the upper direction from the surface of each layer, and uses the vertical downward projection method. In order to shorten the computation time for generating plan drawings, unlike the arithmetic method for generating section drawings, information about the object is used, such as the appearance lines on the bottom face.

There is some information in the plan drawing that cannot be expressed by a 3D shape alone. For example, in a swinging door, the direction of the door opening and the door trajectory should be represented. Information regarding the entrance and exit for the opening direction of the door can be generated in IfcDoor. However, IfcDoor only contains information about the location and the direction of the opening. To see the shape and type of the door in detail, the Profile representation in the IfcDoorStyle parameters should be used. In addition, the representation identifier can be used to generate the shape of the 2D accurately. IfcDoor has a separate attribute called Footprint. Although this attribute cannot be expressed in a 3D form, it contains information about the opening and closing of the door, which can be displayed in 2D drawings.

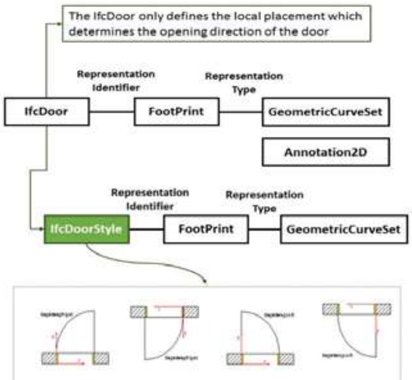

Figure 3. Derivation process to use IfcDoor data

The developed application makes use of related attribute information for creating the plan drawing for the door object. Details of the plan drawing generated in this manner are shown in Figure 4. It is not a 2D scene but rather a 3D Scene, which is created using the Direct X 3D library to express and display the information on the screen quickly. There are many limitations to the rich expression of 2D information, but significant improvements are anticipated in the future.

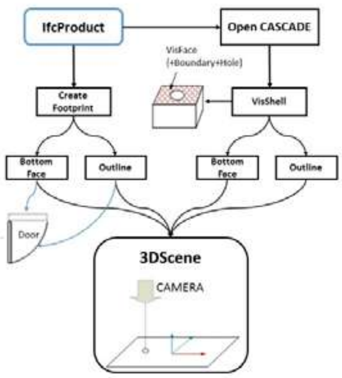

Figure 4. Fundamental algorithm to generate the plan drawing

4 Utilization of 2D drawing automatic generation application

4.1 IFC viewer and the confirmation of information specification

The application developed in this study aims to improve productivity by generating 2D drawings of required parts according to the needs of users after creating a BIM model. The goal is to reduce the duplication of design work and generate accurate drawings according to requirements to improve the efficiency of the work. The application in this study uses the international IFC standard format. The BIM model is based on LOD 300 for permits. The application can generate drawings of any position required by users without the need to consider whether specific authoring tools are available or not. Even if there are differences in the technical level of the users in different stages of the construction process, the IFC file can be used to generate the drawings of the desired parts.

Information in the IFC file can be confirmed using the IFC viewer. The performance of this study based on IFC can inform the users about the location and specification of the information for confirming the accuracy of the IFC files produced in the authoring tools. Therefore, errors in information transmission can be reduced by using the standard format. This is not only to meet the requirements for the permit and construction stages as well as to resolve difficulties because of technical differences, it can also be used to check the accuracy of information when using different kinds of BIM inspection tools to check design proposals at different phases of the design process.

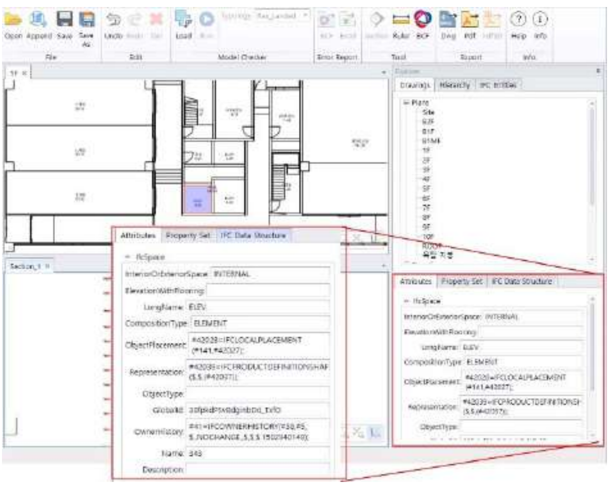

Figure 5. Fundamental algorithm to generate the plan drawing

4.2 Reflecting the optimization criteria of BIM design document generation

In this study, an application for generating 2D drawings based on openBIM was designed according to optimization criteria for BIM design document generation [9]. This means that the documents required in the future building permission process can be incorporated into IFC files using the application developed in this study. This application can generate 2D drawings automatically for submission according to optimization criteria. Therefore, users can utilize the application to generate the drawings necessary for the permit process without knowledge of the optimization criteria for BIM design document generation. This will reduce the amount of the work required by eliminating the duplicate work of creating a BIM model alongside 2D drawings for the permit. It can also reduce the time required to correct errors by generating accurate permission drawings automatically to shorten the time required to obtain permits.

5 Conclusion

In this study, an application for generating 2D drawings from a BIM model by analyzing IFC files was developed. The application can be applied not only in the design stage but also throughout the construction project. As the BIM technology matured, various authoring tools were developed. However, the data specification for each authoring tool is different, which reduced the efficiency of BIM [10]. To ensure that data from various BIM tools are compatible, a standard format must be used [11]. In countries where BIM is mandatory, the BIM model is submitted as an IFC file. The generation of drawings that do not rely on commercial software and that follow international standards (IFC) is very important.

In this paper, the authors use the concept of openBIM unrelated to specific authoring tools. In order to improve the usability, an automatic generation method for submission drawings was developed using optimization criteria for BIM design document generation. In this paper, the description was focused on generation of plan, section and elevation drawings from an existing 3D model. The generation of 2D drawings programmatically is achieved by using the background color for the part behind the cutting plane selected by the user to achieve a hidden effect. However, in order to extract the generated drawings in DWG or PDF format, the drawing lines corresponding to the cutting plane must be generated and an algorithm must be used to remove hidden lines to extract the drawings. In addition, for the presentation of the door object mentioned above, a cross-section of the 3D shape may not contain all the information provided by a 2D drawing (such as the grid, dimension line, expression of void, space information, etc.). Therefore, research on the generation of separate information in the IFC should be continued.

If the developed application can be used in the BIM environment throughout the process of design-permission-construction-maintenance to expand the application scope of BIM, the effect of BIM can be maximized. The application eliminates the need for duplicate or repeat work resulting from the type of authoring tools used or differences in BIM technical level. Unlike the previous process of using specific authoring tools or creating 2D drawings and BIM models separately, the developed application can improve the efficiency of the entire construction process under the BIM environment by generating 2D drawings using openBIM. Therefore, the application is expected to provide support for construction participants, facilitating efficient BIM usage.

Abstract

The public housing construction industry in Hong Kong faces conspicuous challenges of high demands, safety, an ageing workforce, inconsistent quality and stagnant productivity. Compared to the manufacturing industry, the degree of automation in the construction sector lags behind. Based on the on-going consultancy project commissioned by the Construction Industry Council (CIC) in Hong Kong, the aim of this paper is to evaluate the current on-site construction operation and to identify the existing bottlenecks that can be enhanced by implementing robotics and automation. In the current housing construction field, the systematic and scientific method to approach this type of undertaking, especially when closely associated with the industry and authorities, has not been comprehensively discussed. Therefore, this paper highlights the activities that signify these objectives, which include five key activities: literature review, industry survey, on-site case study, co-creation workshops and potential pilot project. The key activities forming the backbone of the project and the outcomes will be illustrated. As a result, a range of proposed robotic applications that are tailor-made for Hong Kong public housing industry are recommended and hierarchically categorised. The results will epitomise the applicable methods that are required when executing the similar type of consultation project. In addition, the findings will inspire the construction industry to initiate and explore innovative, compatible as well as feasible solutions to the implementation of the robotic application in the future.

Construction robotics and automation; Methodology; Public housing construction; Hong Kong

1 Introduction

The Hong Kong Public Housing Construction (PHC) sector experiences three major challenges: first, to satisfy the increasing demand; second, to achieve affordable price, and third, to address demographic changes. In recent years, the manufacturing sector has adopted robotic and automation technology. This paradigm has achieved obvious implications in regard to increased productivity, affordability, constant quality, and improved safety.

In general, compared to the manufacturing industry, the degree of automation lags behind in the construction industry, and the implementation of construction robotics and automation may hold the key to solve the aforementioned challenges [1]. Therefore, the Construction Industry Council Hong Kong (CIC) commissioned the Chair of Building Realization and Robotics (br^2) at Technical University of Munich (TUM) to research and develop construction robots and automation strategies that are tailor-made for the PHC in Hong Kong. This paper documents the on-going project that demonstrates the research objectives, methods and evaluates the outcomes of the current project phase, as well as defines the remaining tasks.

2 Public housing construction (PHC) in Hong Kong

To gain a basic understanding of the Hong Kong PHC sector is decisively important when proposing tailor-made methods in developing construction robots and automation strategy for Hong Kong. Hong Kong is situated at the southern tip of the mainland China, which consists of three main islands, Kowloon, Hong Kong, and New Territories. The development of construction is always challenged by the hilly terrain and high population density [2].

Public housing in Hong Kong, which can date back 50 years ago, has a long history of overcrowding and growing demand. Over 48.8 percent of the population in Hong Kong live in public housing estates today [3]. According to the government census, the average living space per person is 13.2 m^2. Demographically, increasing numbers of retirees will impose more pressure on public housing demand. The government estimates that the housing supply target for the year 2017-2018 is 460,000 units. To make things worse, the housing prices have skyrocketed in recent years, and young people find it extremely difficult to climb up the property ladder. Therefore, the government needs to progressively response by closely working with the PHC sector to solve the aforementioned issues [4].

2.1 Challenges and hypothesis

To be able to catch up with the increasing housing demand, the PHC sector must improve its productivity and speed up the construction lead-time. As a result of the high housing price and construction cost, the quality and standard of the final finishing has to be high to avoid any criticism or even rejection from the Housing Department (HD) or the tenants. As a result of population ageing, skilled workers are scarce in the construction market. The construction industry has to transform its traditional public image from a dirty, dangerous and demeaning industry to a safe, attractive and prosperous one. Subsequently, implementing construction robotics and automation technology will potentially increase productivity, enhance construction quality, and improve on-site operational safety. In addition, it has the potential to transform the status of blue-collar construction workforce to the technology-focused and highly skilled workforce. With this paradigm shift the construction industry might has the potential to attract younger workers to engage in the construction trade [5].

2.2 Research objective and gaps

In general, construction processes are complicated, including many parallels, and sequential tasks are carried out seamlessly. Many stakeholders are involved in each critical phase to ensure that the project is on time and on a budget as well as satisfies key stakeholders' requirements. Despite what have been mentioned, many other factors could also influence the construction process, such as the technological, social, economic factors, and political measures. The main objectives of this project are: first to evaluate current status of the PHC sector by investigate existing construction operation, labour market, regulations and government legislation, then to identify the challenges, key stakeholder's requirements, and to validate key construction processes that can be improved by implementing on-site construction robotics and automation. Finally, a range of robotic applications will be tailor-made and proposed for the PHC sector, bearing wider audiences once the industry sector is reformed. For example, the future construction sector will expose a cross-disciplinary characteristic where many industries coexist and collaborate. In this sense, upgrading the performance of the construction industry not only has positive impact on one industry but also will grant much greater contribution to the prosperity of Hong Kong.

Research has been done on the development of construction robots. However, it has not been studied sufficiently in-depth, and often times only the design concept, hardware and software applications are demonstrated. Thus, limited research topics were particularly conducted related to the PHC in Hong Kong. Existing research does not emphasise issues related to the early stage of the construction robotics development. Therefore, the consultancy project fills the void and demonstrates a comprehensive method that emphasises research methodology in regards to the early stage of the construction robotics development. For example, how to structure an applicable approach that encourages the collaboration between the key stakeholders. It also explores how to interpret the accumulated data into universal requirements that can be further implemented as practical designs. Furthermore, the project explores to develop a practical design concept that reflects the research objectives and suits the practical market demands.

3 Methods

In order to systematically execute the consultancy project, the project has been divided into five phases (Figure 1).

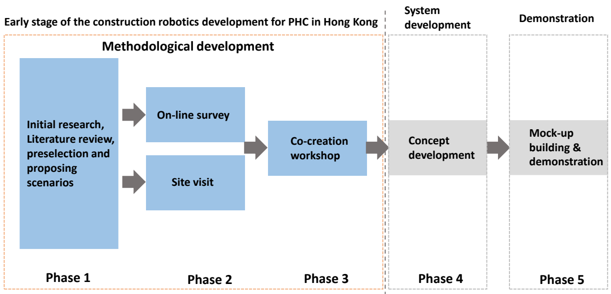

Figure 1. Project phases

The first phase includes initial research, literature review, preselection of the proposed robotics and automation strategies, and proposing use case scenarios. The second phase includes online surveys and site visits. The third phase is co-creation workshops. The fourth phase works on the concept development, detailing and finalisation of the selected system. The fifth phase includes a final demonstration of the system, construction of the demonstration mock-up, validation of the design concept, and planning for future work as well as recommendation for future development. This paper will methodically illustrate from phase 1 to phase 3 of the ongoing project and explore how to use applied research strategies in an early stage decision-making procedure when conducting this type of industry-related and technology-focused consultancy project [6]. The paper also presents current research findings and raises questions in regard to how to address the identified challenges with proposed feasible solutions.

3.1 Background development

During the 1980's, the Japanese construction sector put huge investments into R&D for developing construction robots and automated construction sites. At the time, a shortage of skilled labour, as a result of ageing society, has been a major concern in the Japanese construction industry [7]. Single-Task Construction Robot (STCR) have been developed to address this issue and to attract young workers to get involved in the industry. In general, STCR is designed to focus on executing one or several specific construction tasks in a dedicated working area. Due to the complexity of the construction project, STCR is very different from the robots in manufacturing in terms of the composition, kinematics, navigation, and function. STCR is normally tailor-made to suite all stakeholders' requirements rather than simply integrated into the construction project.

To be able to successfully adopt STCR, it is crucial to follow the notion of Robot-oriented Design (ROD) [8]. The ROD concept was first conceptualised in 1988 by Thomas Bock and later served as the principle for automated construction and robot-based construction sites around the world. This concept emphasizes the idea that during final on-site construction processes, all design parameters should have been considered at the earlier design and production stages. The building components will be designed to be easily handled by robots during the assembly phase. When developing robotic technology for the construction sector, it is far more diverse and complicated than the operation in manufacturing plants [9].

Nowadays, Hong Kong experiences a similar circumstance such as labour shortage, demographic changes, and the urge of increasing construction efficiency. By implementing robotics and automation technologies might be able to tackle some of the aforementioned issues. However, modern buildings consist of many complex structures, layouts, and subsystems. Also, the construction industry can be influenced by other attributes, for example, economy and policies, so that imposing huge constraints when applying robotic technologies in construction. Hence, in the early development phase, it is vital to be aware of key stakeholder's requirements, understand the existing construction operation, and analytically evaluate the construction process. This method helps the project team to enumerate the current demand, and distinguish the optimum strategy.

In principle, there are several hurdles or levels to achieve construction automation, which includes standardisation, semi-automation, and full automation. Standardisation can be achieved through prefabrication, and the prefabrication rates in Hong Kong is relatively high [10]. Prefabrication was introduced to the PHC projects in the mid-1980s in Hong Kong. Then the Hong Kong Housing Authority (HKHA) has promoted extensively the usage of prefabricated elements and standard reusable formwork in the public sector [11]. The most of the contractors are able to achieve 6-day-per-floor working cycle, thanks to the standardisation in design. Optimistically, due to a high degree of standardisation in the PHC sector, so Hong Kong has the potential and willingness to upgrade to the next level.

During the first phase of the research, the background study was conducted, which includes the typology of the building systems, and the labour market shortage analysis in Hong Kong. CIC has provided exclusive statistical information focused on the public rental housing development contracted by Hip Hing Engineering Co., Ltd at Ex-Kwai Chung Police Married Quarters building. The statistics indicate that the following professions will experience the most skilled worker shortage from 2017 to 2025, including carpenter for wooden formwork and joiner, plasterer, terrazzo and granolithic worker, interior/exterior finishing, stonemason, refrigeration, ventilation mechanic for assembly, inspection, and maintenance tasks. The background study provides an essential understanding of the current Hong Kong PHC sector as a whole, evaluates the weaknesses and strength, prioritises research objectives, and formulates feasible strategies.

An introduction booklet is produced during the first phase of research, and it was distributed among the selected stakeholders. The booklet serves as an eye opener for the construction industry due to the unfamiliarity of robotic technologies. It also assists the stakeholders in understanding the project objectives, and to demonstrate potential application which can be applied in the Hong Kong PHC sector. Based on the findings from the background studies and internal discussions between TUM, CIC and key stakeholders, there were 22 robotic and automation systems were proposed.

The 22 selected systems were also systematically distributed into three use case scenarios [12]. The scenarios were contemplated based on the evolution of degree of automation, and their ability to be integrated into industry during the course of the proposed development roadmap. The first scenario aims to demonstrate the potential of single task construction robots (STCR) to assist profession-specific, physically demanding and repetitive tasks on-site. Under this scenario, there are limited alterations which the existing building has to adopt. There is modest impact on the conventional construction industry and the structural performance of the building. It also serves as the backbone for the future development. The second scenario integrates automatic and semiautomatic construction systems. In this scenario, some of the proposed solutions may require alteration of the existing building design. For instance, a higher degree of prefabrication rate is recommended. The building method may need to adopt the use of robotics and automation. The third scenario illustrates the potential of applying fully automated construction system in Hong Kong. In this scenario, the proposed solution can be applied only if the building is designed in consideration of ROD. This scenario describes the ultimate goal that can be achieved when applying feasible automation and robotics technologies in the construction industry in Hong Kong. The scenarios also functioned as project use cases that allow the stakeholder analysis to be conducted [13].

A value matrix is dedicated to the proposed systems under each scenario to classify the functional, and non-functional requirements. For example, in this case, the functional requirements specify the technical specification of the system, the compatibility, the productivity, and the Technology Readiness Level (TRL). The non-functional requirements express the non-measurable function or quality of the system, the governmental policies and regulations, the legal matter, feasibility, and sustainability. The value matrix of the proposed 22 systems was distributed out to the selected stakeholders and scored with a value that measures those requirements fulfilling the stakeholders expectations. It also provides the background information for the online survey in the later stage of the project.

3.2 Online survey

In the first phase of this consultancy study, TUM has identified a series of automation and robotics technologies which has been proposed to PHC. In order to examine the feasibility of these automation and robotics technologies, as well as their potentials to improve productivity, safety, and quality of the industry, an online survey (powered by Google Forms) is conducted, and its methodology and results are described as follows.

3.2.1 The survey methodology

The aforementioned 22 robotic systems in three scenarios are listed in the questionnaire and these systems' technical details are described in the questionnaire. They include: T1 reinforcing bar fabrication positioning; T2 automatic climbing formwork; T3 concrete distribution; T4 concrete levelling and finishing; T5 logistics supply; T6 hoist and positioning; T7 installation and material handling; T8 façade cleaning and exterior finishing; T9 interior painting; T10 interior wall plastering; T11 automated bricklaying; T12 automated interior tiling; T13 robotic marking; T14 exoskeleton; T15 mobile on-site factory; T16 vertical delivery system; T17 building components positioning and handling; T18 façade element installation; T19 prefabrication in HVAC system; T20 sky factory; T21 ground on-site factory; and T22 integrated on-site assembling system.

The survey follows a two-round selection method (adapted from Nanyam, et al., 2015, see Figure 2) [14]. The first round is to examine these proposed systems' feasibility for the PHC in Hong Kong (the primary attribute). Once accepted, all attributes (e.g., feasibility, improvement of productivity, safety, and quality) of these systems are further evaluated. Each question is based on the Likert Scale [15]. In addition, survey participants can leave comments to each technology.

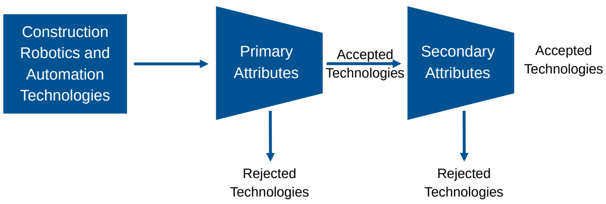

Figure 2. Survey selection method

Equation followed for calculating the TPS of the attributes of each technology:

$$\text{TPS} = \sum_{i=1}^{5} Pi \times Wi \qquad (1)$$

- TPS = Technology Preference Score
- P = Percentage of Preference
- W = Weighted Value (strongly agree=100; agree=75; neutral=50; disagree =25; strongly disagree=0)
- i = Likert Scale

3.2.2 The survey results

The online survey was sent out to more than 200 professionals/stakeholders from Hong Kong construction industry, and 36 effective survey responses have been received. Professionals are from various backgrounds: 36% of the participants are contractors, 28% are consultants, 14% are clients, 14% are policymakers, 5% are academics, and 3% are NGO members. 82.4% participants have more than 10 years of experience in the construction industry.

After calculating the survey data according to the aforementioned method, the survey results are listed as below. Technologies with a score above 70 are strongly/highly recommended; between 50 and 70 are recommended; below 50 are poorly or not recommended. Logistics supply and ground on-site factory are ruled out in the first-round feasibility examination according to the criteria (their feasibility scores are under 50) (Figure 3 & Figure 4).

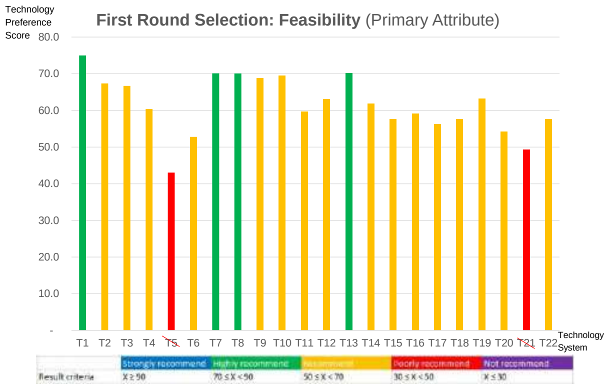

Figure 3. Survey scores of the first round selection

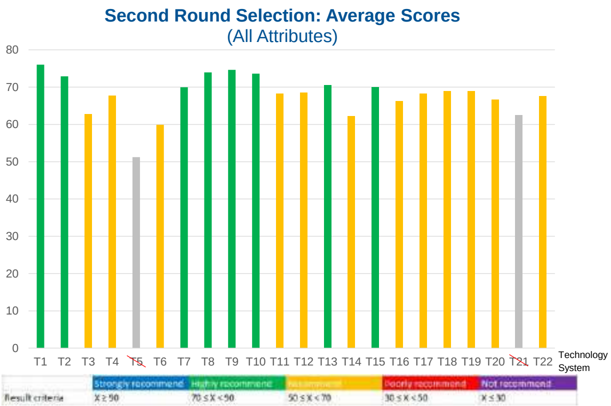

Figure 4. Survey scores of the second round selection

The result of the two-round selection summarised in Table **1** shows that in Hong Kong, the construction robotics and automation technologies are overall approved by the local professionals and stakeholders. The highly recommended technologies are of high priority and thus can be implemented in the near future. The recommended technologies are also demanded, but there is a long way to go before they can be fully implemented. However, due to the actual situation in Hong Kong, some technologies are not practical at the moment, such as T5 logistic supply and T21 ground on-site factory.

Table 1. Final survey results

Highly Recommended Technologies	T1 (Reinforcing Bar Fabrication/ Positioning) T2 (Automatic Climbing Formwork) T7 (Installation and Material Handling) T8 (Façade Coating, Painting, Cleaning and Exterior Finishing) T9 (Interior Painting Application) T10 (Interior Plastering Application) T13 (Robotic Marking) T15 (Mobile On-site Factory)
Recommended Technologies	T3 (Concrete Distribution) T4 (Concrete Leveling and Finishing) T6 (Hoist and Positioning) T11 (Automated Bricklaying) T12 (Automated Interior Tiling) T14 (Exoskeleton) T16 (Vertical Delivery System) T17 (Floor Slab, Beam, Column Positioning and Handling System) T18 (Facade Element Installation) T19 (Prefabrication in HVAC System) T20 (Sky Factory) T22 (Integrated & Automated On-site Assembly System)
Rejected Technologies	T5 (Logistics Supply) T21 (Ground On-site Factory)

3.3 Site visit

Shortly after the online survey, the TUM project team travelled to Hong Kong to conduct a comprehensive on-site case study, which was organised by CIC and Hip Hing Engineering Co., Ltd. The site is located at Ngan Kwong Wan Road in Mui Wo, Hong Kong, and it consists of two residential building blocks (one is 14-storey and the other is 16-storey) (Figure **5**).

Figure 5. Site visit at Ngan Kwong Wan Road

Both buildings are designed as Home Ownership Scheme project. The main objectives of the on-site study are summarised:

- To understand current workflow, techniques, regulations, and tenders process of the PHC.
- To identify the Key Performance Indicator (KPI) that measures construction success of the project.
- To discuss and exchange ideas with the site manager, skilled labour, and contractors in regards to the implementation of construction robotics in Hong Kong.
- To determine which working process is worth automating.
- To map out feasible concepts and roadmaps for the future development.

The site visit focused on the following key areas:

- Reinforcing bar fabrication/ positioning
- Self-climbing formwork or conventional formwork

erection process
- On-site logistics and material handling strategies
- Shear wall component hoist, positioning, and installation process
- Prefabricated bathroom component hoist, positioning, and installation process
- Interior finishing process
- Façade coating, sealing, painting, cleaning, and inspection.

Since the case study building was close to the completion stage, limited site activities could be observed. The construction diary and imagery collected throughout the construction process became a valuable resource to analyse the intended key areas. Detailed interviews were conducted with the site manager, engineers, and skilled labour. Interview questions and answers were documented in the site visit report. Potential areas that can be optimised by implementing construction robotics and automation were identified, which include reinforcing bar fabrication, positioning, formwork erection, prefabricated wall assembly, drywall assembly, façade painting, and interior finishing. One interesting finding is that before the site visits the project team considered on-site logistics and material handling as an integral part of the whole construction process, which has huge potential to be automated. However, during the site visit, the project team realised that the construction site is orderly organised yet extremely congested due to the limited on-site space. Therefore, it is challenging to implement robotic delivery systems, such as automated guided vehicle, allocated docking station, and dedicated loading bays on-site. The project manager also mentioned that it is crucial to test and refine the proposed robotic application in a pilot project, in which the biggest challenge is to introduce construction robots into an on-going project without causing any delays.

3.4 Co-creation workshop

After the online survey and on-site visit, a number of workshops were organised. These series of workshops were a key milestone of the consultancy study. The workshops aimed to seek practical input from industry experts to 1) evaluate the technical feasibility of adopting construction robotics/automation technologies in actual construction sites, and 2) map out pragmatic action plans for the Hong Kong building industry. Consequently, two Technical (T) Sessions and two Policy (P) Sessions were organised. The workshop participants comprised of a broad range of stakeholders including governmental representatives, developers, contractors, consultants, and industry experts. In total, more than 40 participants joined the two-day workshops. The outputs from the workshops were summarised and presented to the CIC Committee on Productivity. The data were used to form a roadmap on adopting advanced construction technologies in Hong Kong.

The main objectives of the T session were to identify the specific tasks and constraints within the on-site PHC that have the potential and are necessary to be upgraded by construction robotics and automation, then to determine the key organisational, technical, functional requirements when implementing construction robotics and automation in the selected on-site tasks. The priority tasks identified from the T sessions include façade/exterior work, interior plastering/painting, automatic formwork, hoist/positioning system, and welding. Detailed sequences of the sub-tasks were identified based on the existing operation of the tasks. For example, the sub-tasks of façade/exterior work include the installation of gondolas, cleaning and preparing the external wall, skim coating, exterior painting, installing the exterior piping, inspecting façade paint quality, and dismantling of the gondolas. Understanding the detailed work sequence will help the project team to identify the general requirements for the specific tasks, which are:

- The proposed system needs to be flexible and easy to install in the confined space on-site.
- The proposed system needs to be compact, lightweight, and easy to manoeuvre.
- The proposed system needs to be easy to adapt to the different designs of the building.
- The proposed system should avoid using temporary fixtures that will increase installation time.
- The proposed system should consider human-robot interaction. The robotic system hardly completely replaces on-site labour but can work together with labour to enhance overall productivity.

Based on the outcomes from the T session, the P session aimed to formulate strategies and action plans on how to implement appropriate technologies for the selected on-site tasks, in which socio-technical issues, work organisation, safety concerns, financial implications, skills requirements, and regulation-related topics were discussed. In conjunction with the potential concerns and opportunities during the implementation of the proposed systems were examined. Subsequently, guidance and potential approaches were forthrightly discussed in terms of how to address economic, managerial, social and political issues when introducing automation and robotics to PHC sector. As a result, industry policies encouraging the adoption of automation and robotics are necessary, which means the government and CIC should consider creating incentive programs for the contractors to adopt robotics and automation in their projects. It is crucial to establish a construction robots supply infrastructure including manufacturers, distributors, training facilities, and maintenance services.

Moreover, the degree of complexity and automation of the robotic system has to be considered during the early design phase. In addition, feasible business models have to be developed based on the scopes of the key stakeholders.

At the end of the co-creation workshops, a number of key performance indicators were identified, which include safety, labour shortage, improve quality, adoptable, compact and flexible design, acceptance, and improve productivity. A key performance study of the selected system was conducted by TUM project team with a spider chart (Figure **6**). The spider chart is used as a metrics to demonstrate a dynamic trend of the influential key performance, and each one is rated by lower to higher variables. For example, in this case, 5 point indicates a better performance score than 4 point. There were 5 finalists chosen for the evaluation, which include façade work and exterior work system, interior painting, plastering system, hoist and positioning system, automatic formwork, and automated welding system.

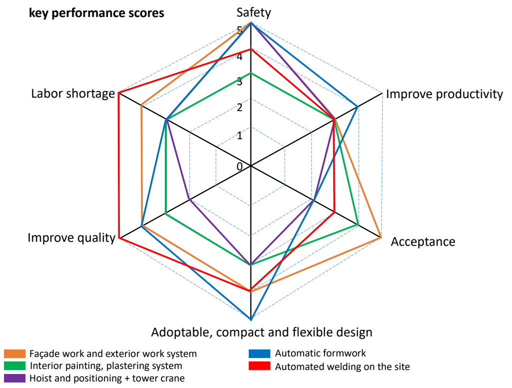

Figure 6. Key performance scores spider chart

The detailed description of the key performance indicators are as follows:

- Safety has been identified as one of the most important criteria for façade and exterior work system, automatic formwork and hoist system, positioning, and tower crane operation.
- The adaptable, compact and flexible design has been identified as the second most dominant measure. It is also pointed out by the participants during the workshops that the proposed system has to be adaptable to the changes in the on-site environment, building layouts, and design features.
- The proposed system needs to address the increasing trend of labour shortage and to improve the finishing quality as well as productivity.
- In general, the acceptance scores indicate that the construction industry is open to the implementation of automation and robotics.
- To convince the stakeholders to adopt automation and robotics on-site, the project team has to carry out a compelling pilot project with attractive incentives with the help of the government.

After discussion with the stakeholders, the project team decided to conduct the next phase of research based on the façade and exterior work system, because 1) it addresses the identified challenges, 2) it achieved balanced key performance scores based on the spider chat, 3) it can be constructed as a scale model in an early development stage with given budget, and 4) it can be implemented in a real construction site with minimum disturbance, hence suitable for future pilot project.

4 Results

During the project, the initial research identified the main requirements of the stakeholders, as well as the proposed strategies and scenarios for implementing construction robotics and automation in Hong Kong. The initial research forms the academic foundation for later phases. The online survey determined the potential systems that can be developed. However, the result is less conclusive, due to stakeholders' experiences and expertise. Nevertheless, the result has paved the way for the on-site visit. The on-site visit validated the requirements of the frontline workers. The feedback from the on-site visit was consecutive, pertinent and knowledgeable. Thus, the accumulated information helped the project team to build up a convincing argument, and draft research evidence and directions during the co-creation workshop sessions, which systematically formulated technical and practical strategies for further developing the project.

As a result, the façade and exterior finishing robot were chosen to be developed as a stimulator to the PHC industry. The proposed system will be a revelation that demonstrates how to adopt robotics and automation in the conventional construction process. In general, the robot will be highly modularised, which can form various configurations based on the design of the target building. Three application modes were proposed based on a ring concept (Figure **7**).

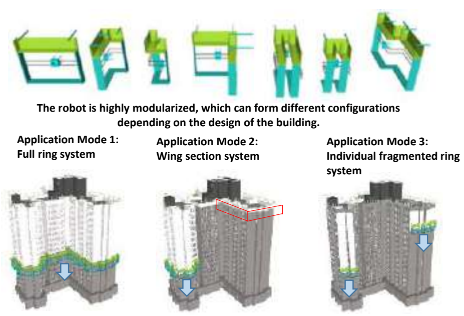

Figure 7. Proposed concept

The first mode is the full ring mode in which the system can be operated as a whole/partial ring up and down along the building surface according to the project schedule. The second one is the wing section mode in which the system can be operated to cover one wing of the building and then be reassembled to the other wings according to the scheduled work plan. The third one is the individual fragmented ring mode in which the system is only designed to paint a specific surface type. For example, the system only paints flat surfaces without any window openings, indentations or protrusions. Currently, the project team is working on the detailed design of the systems where the degree of automation, kinematics, and end-effectors will be finalised. However, due to intellectual property protection issues, the detailed design cannot be revealed at the moment.

5 Conclusion

The consultation project offered an opportunity to perform the systematic study in regard to how to implement robotics and automation technologies in PHC sector from the ground up. Through the initial research, online survey, site visits, and co-creation workshops, the project team have successfully identified the industry demands, stakeholder requirements, yet, narrowed down the research scope and now focuses on the system development as well as real-world implementation. The research findings indicate that the PHC sector in Hong Kong has the potential and willingness to implement construction robotics and automation technology. However, there are also challenges imposed by the existing industry. Many issues and questions cannot be verified at this moment in time, such as the construction industry's reluctance to change, limited understanding of automation and robotics, and lack of robotic infrastructures. How to generate more research incentives, make changes in the government policies, and initiate appropriate business models also need to be taken into consideration. The next phase of the project will be focused on detailing system design, constructing scaled functional mock-up, and disseminating the mock-up to the industry as well as to the public. The research methodology can serve as a guideline when the construction industry executes the similar type of project. In addition, the research will be able to inspire the construction industry to initiate and explore innovative, compatible as well as feasible solutions to the implementation of the robotic application in the future.

Acknowledgements

The authors would like to sincerely thank the Construction Industry Council Hong Kong (CIC) for initiating and funding this research.

Abstract – Industrialized house-builders are moving towards an enhanced production where management of information along the value chain is critical in order to deliver housing projects on time and with the desired quality. Today digital tools and systems are used in both design and production to produce, deliver and instruct actors throughout the phases of a project. However, the information usually exists in different islands and manual transfers are required to keep the flow of information between IT-systems and individuals continuous. A key to improving the ability for the members in different stages of a project to work with the same information is to facilitate different views. One of the building blocks for creating bridges between the islands of information is to introduce bills of materials which can be used to organize information for different purposes. Uniting the use of building information modeling (BIM) with bills of materials (BOM) is therefore our focus in this paper. This is done in the context of industrialized house-building and the facets which it brings to the subject. The aim of this paper is to present an early endeavor into a BOM based approach for structuring information from BIM models. A demonstration tool was developed, and together with application in a case project from an industrialized house-builder, the generation of BOMs from BIM data is illustrated and discussed. The findings illustrates that we can apply different structures to the information located in our BIM models and that we can produce a BOM perspective on our products. Also, it is highlighted that we still need further studies to better understand how application of BOMs in the context of industrialized house-building is realized.

Keywords –

Bill of Materials; BIM; Industrialized; House-Building

1 Introduction

Within the realm of industrialized house-building the use of information and communications technology (ICT) is a facilitator providing conditions for an efficient production with accurate and reliable information [1]. Using ICT to share and provide up-to-date information along the value chain becomes an essential part in effective housing production processes. However, as a house-building project progresses, information is at risk to become fragmented into islands. Use of different tools by actors coupled with requirements on diverse views on information lead to implications where manual transfers between these islands becomes common in order to retain the flow of information. Solutions to this fragmentation has been discussed from angles including using a central repository to achieve greater integration [2] and using the common format of IFC to facilitate information exchange [3]. Within these, Building Information Modeling (BIM) is used as the overarching method and has been highlighted as an assistant in in solving these issues [4]. Furthermore, matters regarding integration, collaboration and information sharing in the context of BIM has also received increased attention in recent research [5].

It could be argued that as industrialized house-building companies retain more control of the value chain, leading to less fragmentation, there are greater chances of success when integrating ICT [6,7]. Despite this, issues exists including the overall management of information [8]. With characteristics from both the construction and manufacturing industry, adopting established practices from the latter has been of interest. As such, attention has been placed on adopting tools and methods, such as Enterprise Resource Planning (ERP) [7] and Product Lifecycle Management (PLM) [9]. However, ICT-tools adopted from other contexts have been targeted as one of the hindrances as these may not be optimal for their new context [6,8,9]. Issues that are present include divergent data structures that interfere with bridging of systems [6,8], and a dissimilarity in the view on projects [9] and construction objects [7]. For accommodating different views on information and to provide product structures through the lifecycle of a product, bill of materials (BOM) is described as a key facilitator [10]. The BOM carries product data between actors and systems, and is an essential part in the ICT toolkit. Previous research on information management within industrialized house-building has however paid little attention to the use of bills of materials as an approach to structuring information. Difficulties in managing information through the value chain, and requiring diverse views on information are however persistent issues. Better maintaining a continuous flow of information, providing accurate and reliable information between actors and tools, are aspects to strive for and to further explore. Therefore, the aim of this paper is to present an early endeavour of uniting the concepts of BIM and BOM in the context of industrialized house-building, suggesting a BOM based approach for structuring information. This approach is exemplified through a case study with a demonstration tool that extends a BIM capable platform to provide a BOM perspective on BIM data. The contribution of this study aim to start setting the groundwork for further studies regarding using BOM as a means to structure information in the context of industrialized house-building.

2 Background

2.1 Industrialized House-Building and ICT

The Swedish housing sector has been subject to an expansive development of industrialized methods. A strive towards shorter lead times, quality of deliveries, and customized buildings are driving forces for house builders to systemize work in their supply chains. Here, industrialized house-building is used to describe methods and principles of a process- and product-oriented alternative to traditional project-oriented house-building [11]. Constructs that constitute industrialized house-building includes management of components, processes and relations in the standardization of house-building platforms, as well as development of ICT for integration. Thus, the ability to provide up-to-date information [7], which is accurate and reliable [1] are key contributions from ICT to an efficient production. With characteristics from both the construction and the manufacturing industry, efforts to adopt patterns from the latter has been previously studied. Ekholm and Molnár [12] highlighted that information systems known from the manufacturing industry have been integrated in the industrialization of the building sector in order to reap from the benefits it has shown. Babič et al [7] investigated creating a link between an Enterprise Resource Planning (ERP) system and BIM. Holzer [13] investigated approaches to create links between Product Lifecycle Management (PLM) systems, together with BIM, to provide information to ERP-systems.

Through a perspective of BIM being used throughout a building's lifecycle, with the resulting information rich model, it becomes a facilitator for information management. With this, a growing interest has been shown areas of collaboration, information sharing, and integration [5]. Through this continuing expansion of BIM as an ICT platform, some research has surfaced investigating the relation between the areas of industrialized house-building and BIM. Lu and Korman [14] discussed benefits and challenges of BIM for modular construction from a perspective of pre-project planning and coordination. Moghadam et al [15] proposed a model for modular construction manufacturing that links BIM and lean. Lu et al [16] presented a BIM-based trade-off platform for industrialized housing. Nawari [17] proposed an information delivery manual for off-site construction. Ezcan et al [18] showed interest in BIM and off-site manufacturing and indicated that it would contribute in areas of IT integration, providing extensive information and improving lead times to mention a few.

2.2 Bills of Materials

At the heart of information systems within the manufacturing industry is the bill of materials (BOM) [19]. This includes systems like MRP (Material Resource Planning), ERP (Enterprise Resource Planning) and PDM (Product Data Management) [10,20]. Throughout the lifecycle of a product, it is used to accommodate different views on information and to provide data structures [10]. There are more than one way to define BOM and three different distinctions are described here: 1) as an organized collection of quantities, 2) as a means to structure information in systems, and 3) as a data repository.

When viewed in its simplest form the BOM provides a collection of the materials and components that comprise a product, together with the required quantities [21]. In a similar vein, and more commonly discussed in the construction industry, is quantity takeoff that offers the amount of materials and components which can be organized into a bill of quantities [21]. Further developments of the BOM exist where it is seen as a product specification, describing the composition of a product and how it is realized from its immediate components [19]. In these extended perspectives, more emphasis is put on the relationships between components (children) and their parents. As such, it becomes decoupled from being the sibling of quantity takeoff, and is instead transformed into a description of how a product is configured. Another take on the BOM exists where it is not only viewed as the underlying structure, but also as an information repository. Some authors describe the BOM as a "product structure data file" [23] or a "database" [24]. The scope of the BOM is thus extended to contain a wide variety of information, e.g. product specifications, part drawings, parts routing, manufacturing processes etc. [24].

A key part in the use of BOMs throughout multiple phases of a product's lifecycle is the different views that can be applied dependent on the use case and activities associated. The Engineering BOM (E-BOM) and the Manufacturing BOM (M-BOM) are two commonly discussed [20,21,24]. The E-BOM is used by designers [21], representing a product from an engineering viewpoint of how the product is functionally formed, however lacking sufficient information regarding manufacturing [25]. This is mitigated by the M-BOM which is a representation of a product based on how it is manufactured [25]. In a more practical sense, the E-BOM is usually managed through a CAD system, where support is provided for the designers to represent their product structure according to their desires. Furthermore, the M-BOM is the result of a transformation of the E-BOM where additional aspects are included such as manufacturing sequence [25], and adding interim assemblies to better depict the manufacturing process. As such, despite describing the same product, these different BOMs manifest themselves with different structures (see Figure 1), providing each phase of a product with the necessary information.

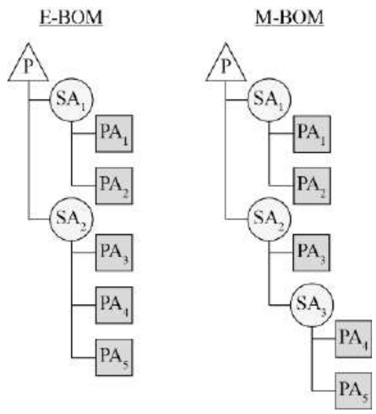

Figure 1. Example structure of an E-BOM and M-BOM, where P is the product, SA is a subassembly and PA is a part (adapted from [20])

Some authors (e.g. [20,26]) have also chosen to differentiate between the usage of BOMs, and the structural representation of BOMs. In these cases, the usage includes for example the E-BOM and the M-BOM. The structural representation includes for example the Traditional BOM, the Modular BOM [27], and the Generic BOM [19]. These different structures exists as Traditional BOM structures might bring issues to companies with large product offerings. As such, application of different structural representations is done to better support different production strategies, such as having high variety offerings or modular product compositions.

3 Generating BOMs from BIM data

3.1 Research approach

In this research, a review of earlier research was used to motivate the gap and to serve as input for the proposed approach. Following, a demonstration tool was developed in order to exemplify the restructuring of BIM data from a BOM perspective. In order to provide an illustration of the approach in a real-world setting, a case project was then used where an application of the demonstration tool is provided. The case project was chosen from an industrialized house-builder in Sweden, who focuses on production of residential housing. The company applies modular construction using lightweight timber frames, complemented with insulation materials and covered with sheathing. Each building is broken down into individual modules which are produced to an almost finished state off-site in a factory, to later be assembled and finished on-site. The case project in question is comprised of 156 modules, and the building ranges from 5 to 10 stories.

As a foundation, and for providing a BIM capable platform which provides a source for the necessary BIM data, Autodesk Revit was used. In order to enable representation of timber framed structures in Autodesk Revit, the add-in MWF Pro Wood [28] was used which in this instance provided design automation capabilities for framing timber walls. The demonstration tool was developed as an add-in to Autodesk Revit written in C#, utilizing access to Autodesk Revit's API to grant access to the data stored within the BIM model. The demonstration tool is composed of three main parts: configuration, generation, and delivery.

The perspective on BOM that is adopted in this paper is targeted towards providing a product specification, with focus on promoting the product composition [19] using product, subassemblies and parts as seen in Figure 1. Among the different views each BOM can encompass, this paper will concentrate on providing an engineering perspective, also denoted as the E-BOM [21]. This is done through using information found in a BIM model which is used as input to the demonstration tool. The underlying structure that is generated in the E-BOM is based on a Traditional BOM structure.

3.2 Demonstration of BOM generation

3.2.1 BIM model

With the demonstration tool in need for input data, A BIM model was created for the case project using Autodesk Revit (see Figure 2) based on 2D drawings provided by the case company. Using commonly available tools in Autodesk Revit, walls, floors, ceilings, doors, and windows were modeled. In addition, using the

MWF Pro Wood add-in, the specified technical solutions for each of the wall types was configured. Through that, studs and sheathings for the exterior and interior walls were automatically generated. As the case project in question is constructed using a modular production strategy, measures were taken in order to represent these modules in the BIM model. To achieve this representation spaces were used as objects to define and provide the boundaries of each module. Except for providing a possibility to include the modules in the BOM, these spaces are also later used in cases where relationships between elements and modules needs to be derived. The floors and ceilings did not receive joists and sheathing but were modeled using their corresponding element types in Autodesk Revit. Furthermore, elements not included in the BIM model was the roof (including trusses), the concrete foundation, and MEP.

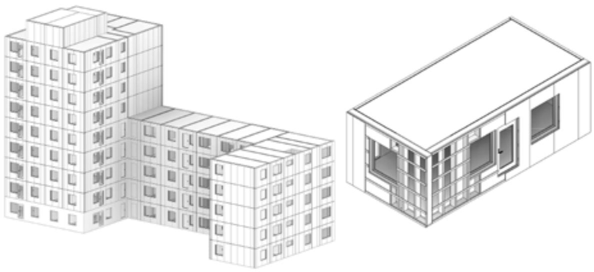

Figure 2. 3D-view of the created BIM-model for the case project with a close up of an individual module showing parts of the studs and sheathing.

3.2.2 Configuration

The first part of the demonstration tool is the configuration stage. Here, a number of options are made available regarding the composition of the BOM, and these choices will act as a basis for the generation of the BOM. The ability is provided to choose what categories will be included, which is this demonstration is bound to project, levels, modules, walls, floors, ceilings, windows, doors, studs, and sheathing. These categories correspond to some of the different categories provided when modeling in Autodesk Revit, and in extension also when using MWF Pro Wood. They also correspond to categories commonly used in timber frame modular construction. Besides selecting the categories of interest, a hierarchical structure can be decided upon by dragging and dropping objects in the tree view. This hierarchical structure determines the parent-child relationship between the categories which will be present in the BOM and describes the product, the subassemblies and the parts. As a category is placed as a child to another, the succeeding generation step will attempt to solve this relationship for each individual instance of that category.

Besides choosing objects and hierarchy, a selection of what attributes from each category should represent the tags is provided. These include using the instance name or family type that is automatically attached to each element in Autodesk Revit, or using the user-defined instance attribute Mark. These tags are later used as labels for each entry in the generated BOM. The purpose of them is to provide a human-readable designation, rather than just using the unique id of each element. It can also be decided if entries in the BOM should be grouped together. It might not always be necessary to include each instance of all categories, so grouping based on type or category is provided as an option. As such, it could be decided that e.g. instead of including each stud as separate entries, they are grouped together based on their type.

For the case project all available elements were selected and organized in a hierarchy as seen in Figure 3. Each category was given an appropriate tag, in this case mainly the type name. Furthermore, options for the groupings were configured such that the major categories are to be kept as instances whereas the individual components (such as studs) are grouped by their type. This configuration was selected with a modular design in mind. As such, with each module, and each wall, being produced individually, this configuration enables the tracing of the constituent elements.

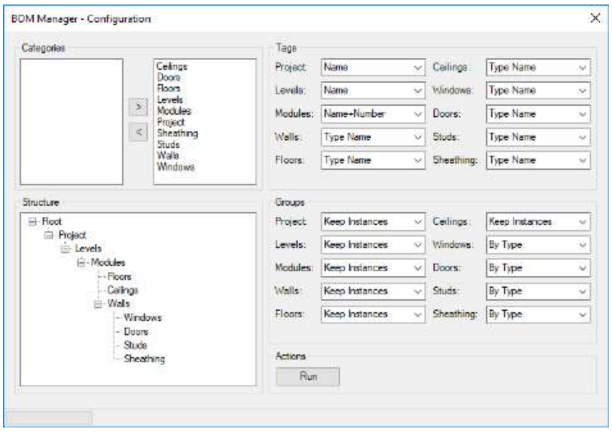

Figure 3. Configuration of the case study project within the demonstration tool.

3.2.3 Generation

With the configuration done, the BOM can be generated based on the input and BIM data available. At the start of the generation all elements are collected from the different categories that was selected. This entails using calls to Autodesk Revit's API in order to fetch each element instance of all selected categories. After the objects have been gathered, further calls to Autodesk Revit's API are made in order to extract the attribute values that correspond to the tags that were chosen for each category respectively, e.g. using the type name.

With the elements collected, it now needs to generate the hierarchy decided in the configuration stage. Depending on the specific relationship situation, this is done either geometrically or through attributes. Autodesk Revit already stores some of these relationships in attributes, for example what level a floor belongs to, or what wall a window is hosted by. The developed demonstration tool is however extending this to enable parent-child relationships between modules and elements, as well as between walls and studs or sheathing. As such, in the cases where there are no attributes to rely upon, a geometrical search is conducted. This is executed by taking an elements bounding box center point and iterating through the chosen parent category, searching for a match where that point is found within the boundaries of another element. If it is determined that a point falls within the boundaries of another element, it is established that a parent-child relationship has been found.

When all the relationships are found the elements are still represented as instances. The last step, if a configuration was chosen where certain categories are to be grouped based on their type or category, is therefore to process the groups. This is done by iterating through all levels of the hierarchy, gathering all siblings on each level and matching them by type or category. Here, it removes all entries of individual instances and replaces them with a group entry, representing a collection of instances.

3.2.4 Delivery

As the generation of the BOM is done, the last stage is to deliver it. A rudimentary viewer was therefore incorporated into the demonstration tool. In this viewer, the hierarchical structure is provided with a listing of the entries in the current BIM model. When an entry in the hierarchy is selected, the basic attributes of that entry is presented. This is done by accessing the attributes that was gathered during the generation of the BOM, but also by directly accessing attributes for the selected element in the BIM model. These attributes include the id, tag, and category of element together with a selection of category based attributes (e.g. dimensions of an element). Alongside this presentation of the BOM, an option is also provided to either export the entire BOM to an Excel-document, or a selection of it. The latter of these exports only the selected entries and its children, excluding the rest.

For the case project a representation of the BOM in the viewer can be seen in Figure 4. Here, the hierarchical functionality is displayed where the constituent elements in individual modules, and individual walls, can be examined. Each entry is also labeled according to their name or type name. Also, a display of attributes which are gathered from the BIM model is shown. The corresponding structure can be seen in the exported Excel document containing the entire BOM hierarchy (see Figure 5).

4 Discussion and conclusion

Issues of managing information and enabling diverse views on information are present within industrialized house-building. Using bills of materials (BOM) as an underlying structure for managing information during a products lifecycle has previously been seen in the manufacturing industry, where it is often built into CAD tools, and supported by PLM and ERP systems. With industrialized house-builders sharing some of the characteristics of the more product-oriented manufacturing industry, approaching information management from a BOM oriented perspective was of interest in this study. As such, this insight was adopted in an effort to generate a BOM based on BIM data. In a demonstration tool, using BIM data as the input, a parent-child hierarchy with links to attributes was generated based on a chosen configuration. This output resulted in providing an engineering view on the BOM, referred to as an E-BOM. This has also been presented when applied on a case of a multi-family residential housing project from an industrialized house-builder. The results shows how the BOM provides a view of a building based on its composition, and in the case study shows how individual modules and walls are composed.

Compared to approaching information management from a central repository [2] or IFC [3] perspective, the use of BOM is in this instance not seen as an overarching solution. It is rather seen from the viewpoint of being a method which can be applied to create an underlying structure to describe a product [19]. The question as such is not how we transfer information between systems, but rather how we describe our product in a way that facilitates this information transfer. Having a unified structure for our products is a step in that direction, and BOM is a method which could be used to aid this.

The presented demonstration tool shows an after-the-fact implementation of BOM generation. However, as more commonly seen in CAD tools from other industries, the use of BOM is an integrated part of the work flow for designers and engineers. As such, for adoption within industrialized house-builders, the questions of who creates the BOM and when are relevant.

This study shows a demonstration where an E-BOM is generated, using a traditional BOM structure. One of the strengths of BOM is however the ability to adapt to different views depending on the application. As such, further studies are of interest where the E-BOM is not only generated, but also transformed into other forms, such as the M-BOM to support manufacturing. Furthermore, with the use of product platforms and a product-oriented perspective, industrialized house-builders using predefined solutions could benefit from using alternative structures, such as the Modular BOM, in efforts to more efficiently derive products. Furthermore, the composition chosen for the E-BOM in this study is limited to only showing one structure. If we are to follow the view of an E-BOM as a functional decomposition of a product, then there is a need to identify what that entails for the context of industrialized house-builders.

The concept of implementing BOMs in the context of industrialized house-builders is seen as showing promise in the search for methods by which we structure information in our IT-systems throughout the value chain. Its use in the manufacturing industry is described by previous research but in the context of industrialized house-building it is more of a novel approach. This study shows how an implementation could be performed where BIM data is used as an information base, however, this study is only a glance at the topic and there is a need for further studies to better describe its use in the context of industrialized house-builders. As such, future research should include topics such as: identifying the owner(s) and user(s) of BOMs, in order to know who defines them and how they are consumed; what different representations of BOMs (e.g. E-BOM, M-BOM) could be used and how they should be structured; how BOMs could be used to bridge IT-systems (e.g. BIM and PLM) in order to support design and production of houses.

Abstract –

The cost of the operation stage in a project life cycle is much higher than that of other stages in the building lifecycle. Efficient use of facility management can save money. However, the information of the traditional facility management cannot effectively be employed, which in turn affects the quality of the facility management. The emerging technology of building information modelling provides an opportunity to overcome the difficulties of utilizing the information stored by means of facility management. In this paper, the Revit@ platform has been used to build up a BIM model relating to the facility management. Through the Revit API, computer implementation has been developed, based on the programming language C#. This computer implementation can extract the information regarding the costs of equipment from the BIM model. Such information can be further analyzed to support decision making.

Keywords –
BIM; Facility Management; Secondary Development; Economic Analysis

1 Introduction

It has been well known that a significant part of the expenses of the life cycle of a building occurs during the operational stage. [1-3]. Almost all activities during the operations need considering the information of facilities. However, the information cannot be effectively employed by means of traditional facility management. Gallaher et al. [4] indicated that US$15.8B are lost annually in the U.S. Capital Facilities Industry due to the lack of adequate interoperability. As a matter of fact, the market of facility management in China faces the same problem. Hence, the effective use of detailed facility information in a building becomes the rising issue.

Meanwhile, with the advancement of the national development strategy in the informatization of civil engineering, modern technologies have been continuously applied to architecture, engineering, and construction industries in China. One of the promising technologies, Building Information Modelling (BIM), has been in the spotlight since it was introduced. The phrase "Building Information Modelling" is used to describe virtual design, construction, and facility management [5]. BIM provides one model that can store all building information for facility management.

Many research studies have shown the applications of the BIM technology to facility management. For example, Akcamete et al. [3] proposed an envisioned approach for integrating historical information in BIM to support visualization and spatial analyses of various maintenance activities in a facility. Wang and Zhang [6] demonstrated a case study of the maintenance activities for air conditioners in a building by means of a building information model. Liu and Issa [7] proposed a method that can automatically exchange the information of maintenance between building information models and Computerized Maintenance and Management Systems (CMMS). Yu and Li [8] combined the use of Revit@ and Access@ to establish a facility management system that can conduct not only the classification, assignment, and extraction of information, but also the query, location, and economic analysis of information. A case study has been carried out to verify the feasibility of their facility management system.

This study uses BIM technology for facility management along with the economic analysis of facilities. To take the efficiency of the analysis into account, the computer implementation was developed through the Revit@ API to give feedback on the cost analysis of a specific facility in a BIM under the same platform. A case study of a facility has been demonstrated in this paper. 3D building information model of the facility was first built from its 2D drawings. The computer implementation for the cost analysis was then applied to the 3D BIM.

2 Method

In this study, Revit@ was chosen to be the research tool, because it is one of the most popular BIM software in China. In addition, it equipped with a friendly and positive development environment. Based on the environment, the computer implementation was developed by using C# programming language. The flow chart of Revit@ secondary development is shown in Figure 1. Through an Add-In Manager plug-in which existed in the original installation package, the computer implementation was applied to the information of a BIM built in the same platform of Revit@ for the cost analysis of facilities. Results of the cost analysis can further help a facility manager in decision-making.

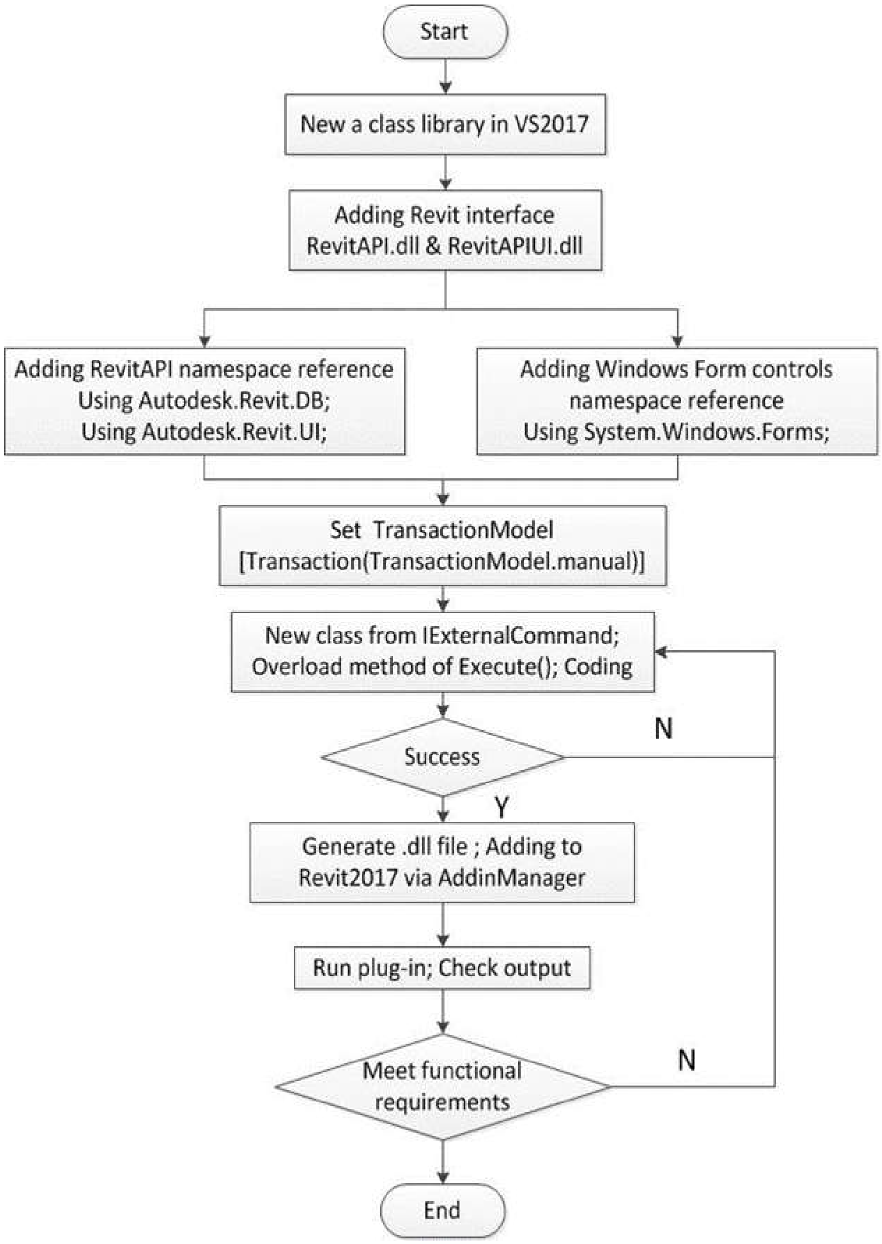

Figure 1. The flow chart of Revit@ secondary development

This computer implementation for the cost analysis is related to the principles of engineering economics, such as the economic life, the time value of money, and so on. A brief introduction is following:

In the first place, the following three points should be satisfied.

(1) The operation cost of equipment can be recorded and then statistically analysed;
(2) The annual interest rate is constant; and

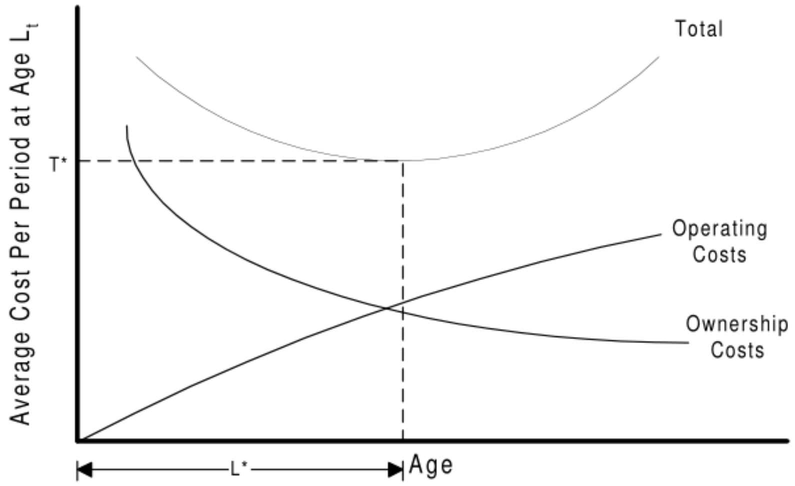

Figure 2. Economic life diagram

(3) The cumulative cost of the equipment in the future can be compared to a reference cost.

Mitchell [9] mentioned that economic life is based on decreasing ownership costs with the increase in operating costs. As shown in Figure 2, economic life gives the minimum value of the total costs on the curve at the point of an optimum age. The total costs consist of ownership costs and operating costs. Usually, the ownership costs merely consider initial costs and depreciation, regardless of salvage value, and the operating costs only take the costs of maintenance, repair, and operation into account.

Park [10] mentioned that "The time value of money means that a dollar today is worth more than a dollar in the future because the dollar received today can earn interest." Hence, the time value of money is one of the key factors in the economic analysis. Table 1 lists some important formulae used for the cost analysis of facilities.

In addition, Park [10] mentioned that the annual equivalent cost (AEC) criterion provides a basis for measuring the worth of an investment by determining equal costs on an annual basis. For the sake of simplification when using the life of various facilities for analysis, this study mainly used the two formulae in Table 1 to convert the original cash flows into the annual equivalent flows.

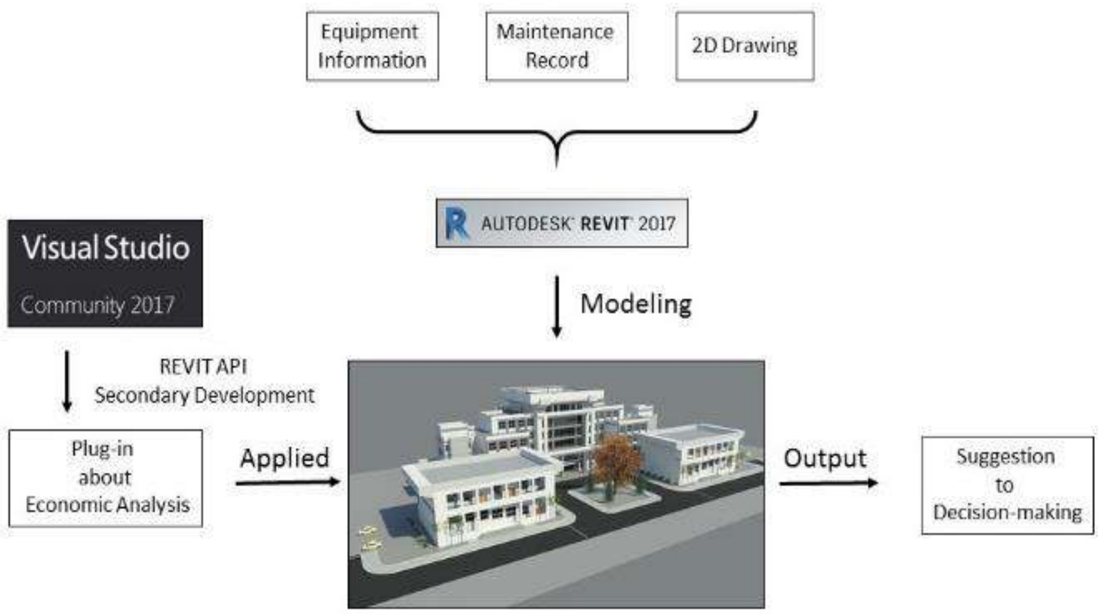

Figure 3. The application procedure of the computer implementation

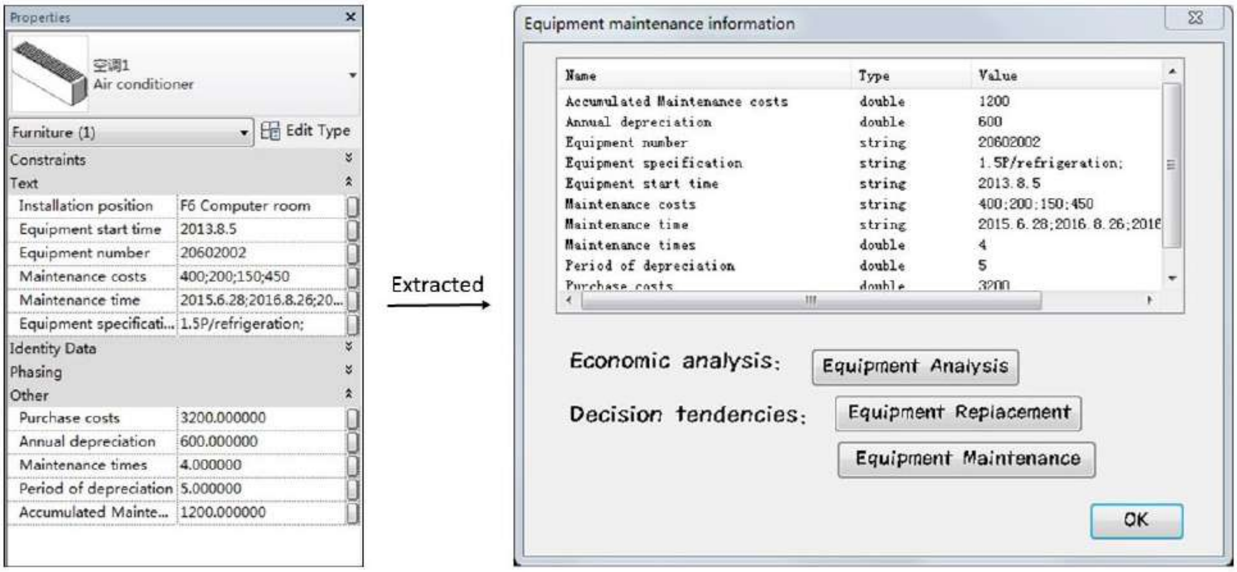

Figure 4. The main interface of the computer implementation.

Table 1. Some important coefficients related to economic analysis

Factor Notation	Formula	Cash Flow
Present worth (P/*F*, *i*, *N*)	$P = F(1+i)^{-N}$	Capital recovery (*A*/P, *i*, *N*)	$A = P[\frac{i(1+i)^N}{(1+i)^N-1}]$	
3 Results

The application procedure of the computer implementation is illustrated in Figure 3. Once a building information model has been built, the computer implementation in the procedure can automatically extract the specific equipment information. Shown in Figure 4 is the main interface of the computer implementation. The left window of Figure 4 displays the partial information of the equipment in the BIM. The right window of Figure 4 displays the main interface of the computer implementation, on which the upper and the lower parts illustrate respectively the information extracted from the BIM and the functions of several application modules.

The main function of the "Equipment Analysis" module is to analyse the status of the selected equipment for supporting the maintenance planning decisions. In case the facility manager considers replacing the equipment, the "Equipment Replacement" module can help to make a right decision. When the equipment is broken, the "Equipment Maintenance" module gives rise to the analysed results based on the costs of the repairs and maintenance for the equipment. A window appears in Figure 5 resulting from the analysis of the "Equipment Maintenance" module for an example.

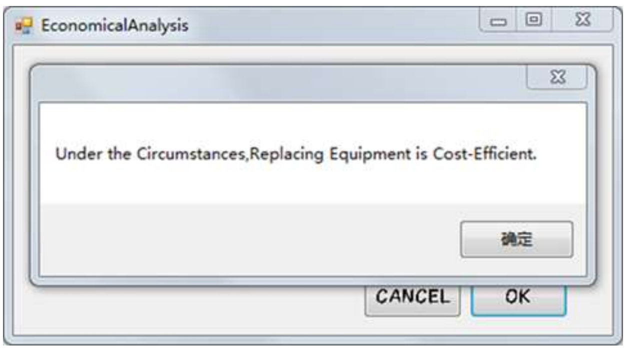

Figure 5. An analysis module result.

4 Conclusions

In China, most of the maintenance work in a facility is reactive. This practice is not effective from the perspective of facility management, because the reactive maintenance typically increases the costs of repairs and maintenance. To reduce the number of the reactive maintenance, there is a need for supporting the planned maintenance work. The emerging technology of building information modelling provides an opportunity to support such work. BIM can collect the information of facilities during their life cycles. As a matter of fact, the proposed method can be globally used unless the selected BIM software does not have an open development environment.

In this study, the computer implementation for the use of a BIM to analyse the costs of equipment was developed using the programming language C#. This computer implementation can simplify the process of the cost analysis to further improve the efficiency of decision-making. In addition, it can provide the secondary development of a building information model with some experiences in a future.

Interactive visualization for information flow in production chains: Case study industrialised house-building

G. Jansson[a], J. Mukkavaara[a] and T. Olofsson[a]

[a]Department of Industrialised and Sustainable Construction, Luleå University of Technology, E-mail: gustav.jansson@ltu.se, jani.mukavaara@ltu.se, thomas.olofsson@ltu.se

Abstract –

Predefinitions in house-building platforms is developed as routines to manage project building information models over to production data by documents and digital drawings. Visualisation of the information flow in the industrialised house-building process is hard to track and information are often presented as islands, seldom described in the flow for the entire process. Interactive visualisation, using game technology, has open up for new applications of data -transformation, -visualization and -simulation of project information which is less studied in the context of industrialised house-building. This paper tries to address this issue via a combination of game engine technology and the predefined industrialised house-building process. The game engine technology allow development for end-user demands and functionality to express and visualise values for the daily planning and execution of processes. In a case study approach the development and analysis of four building projects were studied and chosen to the range of product platform predefinitions. Based on object structure for different views, models and the related metadata were visualised with an immersive virtual environment prototype. The prototype, based on game engine technology, was developed to manage incoming building projects variations that followed house-building platform predefinitions. As a visualising tool of engineering, on-site planning and production process the game engine technology simulates and visualize views on product structures, production information, assembling and operation instructions by interactive functions in the game environment.

Keywords –

Game engines; industrialised; house-building; information flow; visualization

1 Introduction

Industrialised construction companies are described in a range from high level of prefabrication to fully on-site construction [1]. The range of predefinition of the product affects how to manage a design process in construction and how information systems support the progress with human knowledge of the work. Visualising planning, as the artefact of planning construction projects in flow-oriented work, are used instead of traditional resource-planning with schedule techniques [2].

Using game technology in virtual environments has the potential as a communication tool for architects to customers to understand the house-building process [3-6]. By providing virtual models across extended supply chain representations Whyte et al [7] argue that combined visualisations are evolved through practices in reified and hybrid forms in fabrication, assembly and on-site work. Industrialised house-builders has developed their information flow using drawings and instructions in documents. BIM-software are used to speed up modelling of house-building projects, and design automation is used to provide template-based configuration functionality for example regarding the interfaces between wall-to-wall, wall-to-floor, and wall-to-ceiling. Other configuration in the BIM-software could be generation of studs, boards and stud-cutting around doors and windows. Automation between design and production has focused on robot and machine control since the beginning of the nineties [8]. Even if BIM-software with data for production has been around since the start of the millennium only a few applications for visualising information flow has been evaluated and implemented in house-building for factory production [1].

In the development of information systems for industrialised house-building processes the aim of this study is to describe how interactive visualisation could visualise the information flow for different views in the house-building production chain. To reach and confirm the research aim, the following questions about interactive visualisation in industrialised house-building has to be answered:

In the chain of information flow, how can progress be visualised by game technology through variation of different information views?

How can interactivity be used to visualise changing scenarios for BIM data in a factory production setting?

2 Frame of reference

Communication of building concepts is often based on rendered pictures, sketches, drawings and documentation by text where lights and movements is hard to compresence for decision makers in the early stages of design [3, 5]. Visualising the third dimension from 2D-descriptions demands experience and training [6, 9] and the static 3D-view do not enable expression of different perspectives for a specific place and a specific time [9]. Since the nineties the evolvement and application for building projects with virtual reality (simulated virtual environments based on physical environments), augmented reality (physical environments augmented by virtual input) and immersive virtual environment (user interaction supported within virtual realities) has become technologies that not only focus on design aspects but also on the life-cycle visualisation and simulation of a building project [10]. The immersive virtual environment enables possibilities for reviewing alternatives in the realisation process of a project before it becomes physical reality [6]. BIM-models are constantly becoming more detailed which opens up for opportunities to use game technology for VR visualization, but this also creates problems for a seamless use without further optimization. BIM-models are created to describe buildings in detail and many 3D models extracted from BIM models are too big and complex to be used directly in real-time visualizations [11]. Because of this, it is still difficult to integrate VR as appropriate tools during the design process [12]. The introduction of a new generation of VR glasses has made the situation even more challenging, though these new types of VR devices offer enormous possibilities in terms of realism and sense of scale they are also much more demanding when it comes to real-time rendering performance [12].

Industrialised house-building in Scandinavia has developed their processes from manual production to automated production lines in factories. Standardisation of house-building platforms that manage component, process and relations describing different market positions and relates to how the company organisation could arrange production planning [8]. Using design automation in industrialised house-building is described by Sandberg et al. [13] as a chain of engineering activities in the design work. By the use of software, configuration through parametrisation of building systems generation of components up to building is possible [8]. Balancing resource and flow efficiency is an important issue for industrialised house-building companies [14]. The use of standardised workflow with single unit flow is identified as efficient for operation in factory production [2, 14].

3 Methodology

This study was designed in a qualitative research approach based on interviews and collecting data by archiving data in drawings, documented rules in platform predefinitions, and production routines. The case study approach gives opportunity to reach value rich information from the combination of interviews and deeper knowledge from cases [16]. Semi-structured interviews give opportunity to follow answers from respondent and to develop the insight in for the research [17] where three technical managers at the studied company were chosen. Interviews with focus on both product concepts with predefinitions and IT-structure to manage object designations created the design phase in description documents and BIM-models. Industrialised house-building in Scandinavia is based on high levels of predefinitions in platforms or a combination of predefined products that are modularised in combinations. To reach the variation of predefinitions of house-building platforms two projects from two companies were chosen to facilitate the range from high levels of predefinitions to medium levels of predefinitions. The studied context is based on two volume-module production companies that has 15 years of experience of of-site production based on platform-products in their production.

Company 1 has a capacity of 2 000 apartments per year and a turnover of 100 million euro have reached a speed in production of about 60 volume units per week with two production units served by one design organisation. Company 2 has a capacity of 700 apartments per year with a turnover of 30 million euro and have reached a speed in production in about 40 modules per week with three production units served by one design organisation. Selection of building projects focus on volume module variation, general object selections and medium complexity for client choices. Volume modules with varies in dimensions from 3.1x6.2x2.8 meters to 4.2x9.1x3.1 meters in width, length and height.

Software selection were based on CAD software, databases and game engine platforms that are frequently used in general but also ones that enabled functionality of transforming object related information with relations. To develop the IVE, a prototyping approach was used. Development was done according to interview results, platform predefinitions and with one reference project in one production unit as a start. The prototype section of the study did not aim to find the most efficient application of software for an IVE, but rather to describe different scenarios of the information flow that could be developed further and as a foundation for flow oriented analyses of objects.

There is an increasing interest in articulating methods used in the field of IVE development for application in the construction industry [9, 11, 12]. Analysis of the

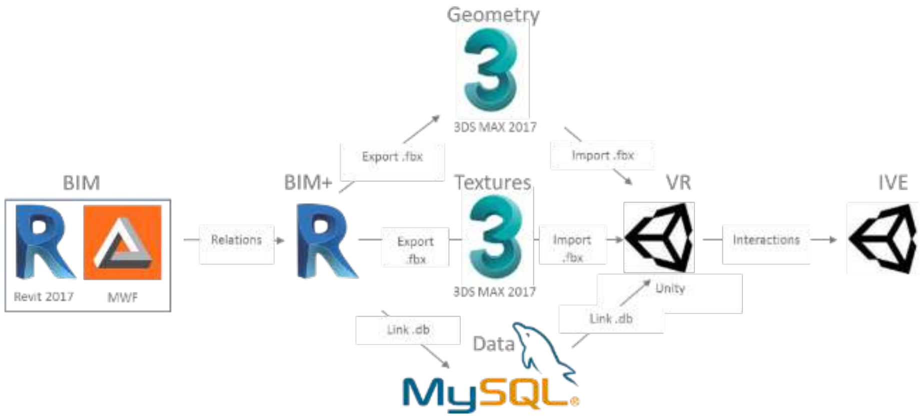

Figure 1. Transformation process of industrialised house-building BIM to IVE.

results were therefore made to provide insights to aspects included in visualising information flow using IVEs.

4 Game-technology for information flow

Describing the value chain of information was setup using game-technology to describe different process stages of managing information. BIM-models constitute an information base for communication of information between stages in the chain from design to production. The traditional use of drawings from design to different stages has until now been used as the primary communication from BIM-models. To enlighten the possibilities of managing information from BIM-models, without the transformation to drawings, the aim for describing a continuous flow of information was to set up a structure of product views and the communication of product transformation between these views. Game-technology was the enabler to visualise the transformation in the chain for the following views: engineering view, manufacturing sequence view, production process view, and on-site production view.

Implementation of game-technologies was achieved using Unity, a cross-platform game engine, which allows for the creation of applications with 2D and 3D graphics support with interactivity and functionality. Autodesk Revit, together with the add-in MWF Pro Wood for creating timber structures, worked as BIM-generators for the selected building projects (see Figure 1). Using a custom add-in for Autodesk Revit, written in C#, the BIM-models were developed further to BIM+, where extensions of the possible relationships between objects were implemented. The relations that were implemented for the house-building structures where the relations included-in and consist-of, e.g. a stud could now be described as included-in a specific wall, or a volume-module could consist-of specific walls, floors and ceilings. The add-in used calls to Autodesk Revit's API in order to extract data regarding the different elements in order to determine their relationship in one of two different ways: through attributes, or through geometrical analysis. As some elements already contain relationships, e.g. a window has an attribute which links it to its host, these relationships could be derived directly from the BIM model. Other relationships which are not already present, e.g. which wall a stud belongs to, were subject to a geometrical analysis. This analysis used the geometries of elements to determine geometrical intersections in order to identify relationships. These relationships were later used to give names to, and to track objects of buildings, volume-modules, elements, components and details in the visualization process.

In order to produce a 3D representation of the BIM models in the game engine, a solution where passing the geometry and materials from Autodesk Revit through Autodesk 3ds Max was used. This method was used as importing FBX-models directly exported from Autodesk Revit failed to provide the materials and textures found in the BIM-model. Using Autodesk 3ds Max as a middleware also provides the possibility to optimize the geometry and materials (see Figure 1).

Like with other game engines, Unity is limited in its ability to directly read metadata from BIM and CAD-tools. As such, to facilitate this transfer an information link was created through the use of a database. In this instance, MySQL was used as the database management system as it has the possibility to meet Autodesk Revit's database link interface and also to serve Unity with data through the use of custom scripts written in C#. In order to link metadata between the BIM model and the representation in the game engine, the unique element id that is generated for each element in Autodesk Revit was chosen as a common denominator.

As the geometry for the BIM model is exported, each object is given a name that contains the unique element id. Equally, the database that is populated from Autodesk Revit also contains a reference to this unique element id in each entry. Using this method, the geometry and metadata could be linked within the game engine.

The combination of the visual representation and a database containing the metadata, produces a virtual environment of the BIM model. The separation of geometrical representations, materials, and metadata as the three types of input sources became the method of transformation through the game engine development process (see Figure 1).

Linking design, manufacturing and production data from the BIM+ model into the virtual environment became the enabler of object structures that follow the building project through the entire life cycle. Geometry and material models were updated manually by traditional export/import using the format FBX. In this type of communication for information flow, the methods of combining transformation scripts through the use of unique object identifiers became central to the ability to first separate and then combine in the IVE prototype.

4.1 Interaction between and in building stages

The building stages in industrialised house-building with prefabrication of timber volume modules, when an order is set, is divided into the following visualisation views: engineering view, manufacturing sequence view, production process view, and on-site production view. The engineering view describes the building from its functional perspective with timber volume structures and space objects. Here, the interactivity in the game engine was programmed to give a variation of choices for changing between predefined views and fly-trough features and visualisation of combinations of space and physical objects. The transformation from engineering view over to the manufacturing sequence view visualises in which sequence each volume module were planned to be assembled on-site. Functionality was programmed here so that a user could select a volume module and get information corresponding to the current view. This can be seen in Figure 2 where data for the specific assembly sequence are presented, where the first number represents a sequence ID (23, 24, 25, 26) and the second number represents an object ID for each volume module (502, 503, 504, 505).

The production process view shows the transformation from the manufacturing sequence to a visualisation of the flow of volume modules and elements in a factory. In the production process view, interactivity were developed to visualize different product assembly lines with stations and visualising BIM metadata for the volume or element object at the station in the specific time (see Figure 3.). Alternative flows of assemblies lines were built in with Unity functionality based on a list of instructions and derived from the manufacturing sequence. From that list the both the main line (volumes) and sub-lines (elements) were programmed in C# for the specific flow. The number of elements in each volume and number of stations in the sub-lines gives the enter time

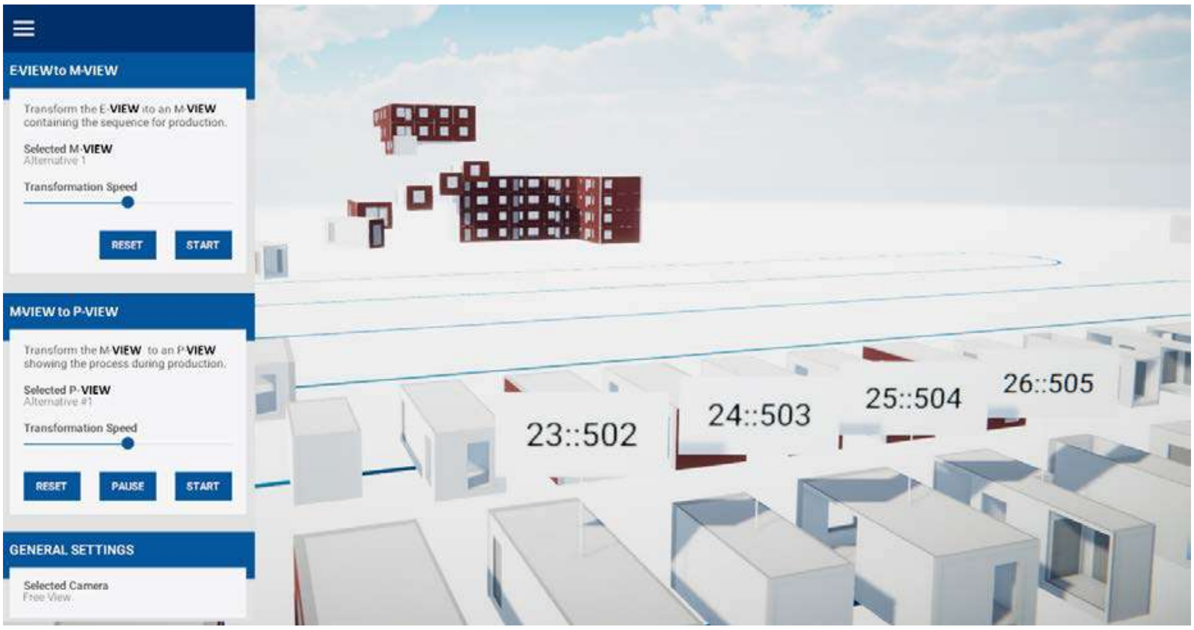

Figure 2. Visualisation of transformation from engineering view to manufacturing sequence view in the IVE prototype showing object ID and sequence ID.

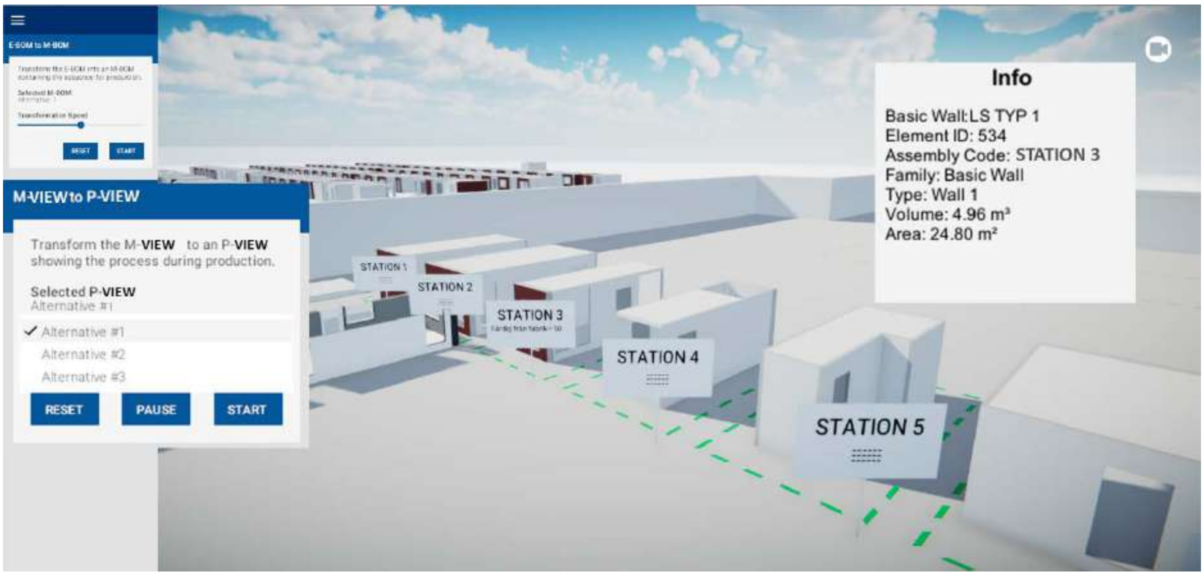

Figure 3. Visualisation of an alternative dialog and showing BIM information output with station related information in the factory production view in the IVE prototype

(instruction.Type==ProductionInstructionType.Enter) for each object for the flow. For a continuous flow from the list each object (volume, element) were asked to move to next station if they have entered the production line (instruction.Type==ProductionInstructionType.MoveTo) and ends with a general predefined pause for all stations in the main line. The entire flow of volume objects is then ended in the factory production process view if none of the two above conditions is not set (instruction.Type==ProductionInstructionType.Exit).

Lastly, the on-site flow shows the transformation of ready volume modules from the factory being assembled in the specified manufacturing sequence with a set site assembly time for each volume. In all instances of the transformations, interactive functionality was used in the game environment to combine object data and visualise different scenarios according to variation of projects, number of stations in assembly lines, production speed (pauses) and site assembly time. Possibilities to start, stop, reset and change the speed were provided. As such, the user is given the opportunity to control the events occurring within the IVE prototype.

The result shows that the use of game engine technology as a communication tool gives spatial understanding of both structural and space geometries, regardless of professional expertise. By exploring an environment in the IVE prototype, it comes very close to the experience of a full-scale model. The use of a game engine powering the IVE prototype provided the underlying tools to simulate and analyse processes in virtual environments. The environments allowed high interactivity and real-time performance, which meant that the goals for each stage could be evaluated before real production.

4.2 Building scenarios and metadata

Two building project scenarios of information flow were evaluated to the developed IVE prototype. The two projects were evaluated for two different assembly sequences and according to three production units (factories). Functionality with the Canvas tools in Unity gave the possibility to create user interfaces with controls such as buttons, dropdown menus, and sliders can be implemented to enable user-control over an environment. Interactive functionality for selection of assembly sequences were programmed in as drop-down menus with the two assembly alternatives in the Engineering to Manufacturing dialog (Figure 2). The three alternatives of production units were implemented using the same technique for the Manufacturing to Production dialog (Figure 3). Each building object in the IVE prototype were prepared with links to present object information for each view. An example is that the engineering view only visualise object ID, and in production view a number ofdetailed information were visualised that related to original BIM-data. If the Revit-model were to be updated with new metadata, the included links would facilitate propagation of the updated metadata to the IVE prototype.

5 Analysis and discussion of the results

Although the focus is primarily on resource efficiency, the significance of flow efficiency in house-building production is increasing [14] and systems that support and visualise the progress through production becomes needed. The open game engine technology, with a global network of solutions, gives possibilities to develop interactivity in the environment [12] and to visualize and simulate processes with product models for house-building through the entire production chain. The interactive visualisation in the case scenarios has to manage a variation of single project information to the variation of repeated process information. Simulation with IVE functionality has in this study shown possibilities for prefabricated house-building systems to visualise alternatives both for production units (factories) and also for the assembly order to prepare for building site. The spatial models with related data visualise the process in the IVE prototype as almost real objects, and as according to Heydarian et al. [10] the life-cycle perspective is important for all stages in the realisation of buildings.

Object structures with the relation of included-in and relates-of became a needed feature for the simulation of object flow in the visualisation. House-building processes with prefabrication of volume-modules uses the hierarchy in their planning of factory production in object assemblies from components up to volume modules. This serves not only the information flow but also the material flow that has to be managed in parallel.

Visualisation of different stages in different views of a production process gives an analytical method for planning production. By using both interactivity for input variables (as manufacturing sequences, production lines, and flow speed) the use of IVE enables a tool for analyse planning and simulate building process progress from a production perspective.

As the study shows, and also Whyte et al. [7] means, that total interaction and photorealism is not always necessary to make decisions through the process. The detail level should instead be adjusted according to the situation in which the IVE prototype is used. The study showed that platform predefinitions affects the information flow both on product and process information, which is central for how game engine could contribute by the interactive visualization in house-building production. A high level of predefinition of the product visualises the combination of object and process information in the IVE wile less predefinitions requires a lot more work before objects could be implemented in the IVE environment for flow analyses.

6 Conclusions, limitation, and future work

By highlighting the interactive functionality for flow it was concluded that game engine technology is applicable in industrialised houses-building on a spectrum from interactive visualisation in design, production and simulation of site assembly flow. To describe how IVE could visualise the information flow for industrialised house-building, the prototype presents the importance of alternative functionality for different views, as production processes in factory but also to the variety of assembling sequences. To visualise different views of the production progress, with game technology, the study shows how the combination of geometries, textures and data that are linked and could be updated by automation. Interactive functionality in the IVE prototype shows how the link between BIM and IVE could be updated to different scenarios by using extern databases and internal functionality in the cad and the game engine. To manage house building project for production a high level of predefinition of platform predefinitions speeds up the development of links between BIM and IVE.

The evaluated methods of IVE development for industrialised house-building could be interesting for on-site productions where standardised production work is applied and the need for visualising information flow. Limitations of two companies in this study constrain the generalisation of a prototype but enlighten the possibilities to understand possibilities to use BIM for IVE in a flow oriented production perspective. The transformation process of BIM to IVE describe a separation of geometry, textures and data with object tags as enablers for automated combination of models in the IVE prototype. This technology could be useful for other simulations, like supply chain flow of production materials or resource planning which are in relation to the studied scenario in our case.

Out of the four scenarios in the case two of them were modelled in ArchiCAD with the application Archiframe, for timber structures. Possibilities to evaluate the method for other cad-platforms is of interest for the API programming of relations and database connection, but not the purpose in this case.

Abstract –

Information management for Urban Facility Management (UFM) is a key enabler for a more sustainable built environment [1]. This paper presents a further development of a case study research concerning the implementation an innovative UFM service. The UFM process is enabled thanks to a robust data engineering approach and Information Technology (IT) tools, based on Database Management Systems (DBMS) and Geographical Information Systems (GIS). The proposed methodology allows to streamline the survey phase enhancing the UFM services already in place, according to a continuous improvement logic. The scope of the research concerns the implantation of effective facility management methodologies, [2] through the use of current Information Communication Technologies (ICTs). The case study research concerns a business district in San Donato Milanese, Italy. After two years since the kick-off of UFM service, thanks to data provided by the UFM company operating in this context, authors aim at presenting advantages of adopting the proposed methodology. Information available concerns cost, technical historic datasets and budget CAPEX data until 2019. This information is georeferenced and processed through geo-spatial algorithms, in order to obtain spatial analysis and representation for monitoring and improving the UFM service. In conclusion, it can be stated that the proposed approach can improve UFM process fostering information management among stakeholders and reducing operational expenditure.

Urban Facility Management, Data engineering, GIS, Information Management

1 Introduction

Management of the built environment is characterised in the last years by the increasing of the complexity of physical assets, as well as the high number of stakeholders and the pervasive use of Information Communication Technologies (ICTs). Real estate is providing constantly a huge amount of information which must be collected, managed and exploited for the optimisation of the management process and for the achievement of a more sustainable built environment.

Facility Management can be intended as an effective strategy for restoring performance of assets to a proper level of quality, in order to provide a good environment for human beings, within the sustainability framework. This concept, despite being wide and opening to further specifications and insights, can be extended to the urban environment. Accordingly, Urban Facility Management (UFM) can be implemented to provide an integrated array of services supporting operation, fruition and valorisation of urban goods [3].

This paper presents an update of a case study research carried out in 2015 concerning the support for the implementation of an UFM service in San Donato Milanese, Italy [4]. For this purpose, an information system supporting the survey phase has been developed. Information are gathered and managed thanks to a Data Base Management Systems (DBMS) jointly with Geographical Information Systems (GIS). The outputs of the process are thematic maps, used for leading strategic decisions on prioritisation of maintenance and restoration interventions in the neighbourhood. The system has been employed in the kick-off stage of the UFM service. The survey and reporting tool has been applied and partially embedded in management procedures of the company appointed for the implementation of the UFM service.

In §4 a quantitative and qualitative analysis of data concerning the maintenance cost and investment undertaken on the management of the urban precincts is presented. These analysis, show that, thanks to the implementation of the system, cost for corrective maintenance decrease, despite a different trend can be highlighted in the last year of analysis (2017). The paper concludes with some insights and further development of the methodology and the whole research. Moreover, drawbacks and limitations are highlighted.

2 Data engineering for UFM

Urban OM&R can be intended as a set of actions carried out to keep or restore performances of urban goods to an adequate level [5]. Therefore, they are primary issues in management of the built environment. Moreover, OM&R can be encompassed in a wider framework, namely the Urban Facility Management (UFM), which comprehends a series of services, procedures and actions for enhancement of operation, fruition and valorisation of the urban goods in order to achieve a better quality of the built and open environment [3][6]. Considering an overarching strategy of resource saving, these issues acquire outstanding relevance, to foster sustainability of buildings and, more in general, of the built environment [7].

Different players in the real estate, belonging both to the private and public sector, contribute to the management and production of information. The public player on one hand assumes a role of legislator providing guidelines and frameworks concerning the types of information that must be collected, recorded and certified for validating building procedures and operations. On the other hand, it produces and preserve itself a great amount of data. Thus, it assumes a double characterisation. It can be considered a supervisor, since it has a responsibility in terms of compliance checking of reliability and accuracy of information requested to the private player during design, execution, use and management phases of buildings. While executing this role, it must be also compliant with the rules and codes developed for the purpose [8]. As a consequence, the public player plays both a proactive and coercive role.

In the same context, it is needless to say that private player is forced to produce compulsory documentation related to its real properties. Moreover, it is appointed for the management, updating, and conservation of this information.

Nevertheless, it is not always easy to assess and determine the responsibility and compliance with codes and laws. Therefore, in those situations where the uncertainty increases, tools for information management acquire a key role both at the building and territory level.

For reducing uncertainty in OM&R, the authors identified a set of information both for building and urban precincts that should be taken into account. These core information collections are called *Building Logbook* and *District Logbook* [9]. Table 1 and Table 2 list the main information contents of the tools cited above.

Table 1 information categories and contents of the Building Logbook [9].

Section	Information to be collected
Building registry info	• Concerning the urban registry information and the updated internal subdivision in sub-units.
Information about the property, management and tenancy	• Updated documentation on ownership, • updated documentation on tenancy and related contracts and agreements, • documentation concerning the management structure, appointed to the management of the building (concerning leasing contracts and technical management contractors).
Technical info on building elements	• Building breakdown, • description of technical, typological and functional characteristics of components,
Operative info for management and maintenance	• Documentation related to technical, administrative and economic management of the building, • safety and certification documentation.

Table 2 information categories and contents of the District Logbook [9].

Section	Information to be collected
Urban and building registry info	• General information about the neighbourhood, • quantitative data and reference to infrastructures, urban facilities and buildings, • urban planning info.
Population registry info, property management and tenancy	• Data on the population of the neighbourhood, • data on city users, • data on management entities.
Technical info on urban goods and elements	• Location, • ownership/responsibility/manager, • geometric info,
Operative info for management and maintenance	• technical condition, • instructions/procedures/guidelines for maintenance and management, • safety measures, • plan/program for maintenance.

As can be seen, the information required by the two core information collection is rather wide and complex. Moreover, it can be considered as dynamic collection of data, updating time by time whenever a changing at the building or at the district level happens. The Building and the District Logbook should be used for the reduction of the uncertainty in transaction and use phase, since they can be considered as risk prevention tools for technical, economic and legal issues in management of the built environment. Through their use, crucial information could be easily found used as proof of compliance with laws, building or urban performances etc.

When the scale of the intervention is the neighbourhood, the District and the Building Logbooks should be used jointly, in order to enable the stakeholders to timely access information. In the following paragraphs a description and update of a case study concerning the implementation of a UFM service is described. This experience must be encompassed in the framework described above, especially for what concerns the implementation and management of the District Logbook for the sections titled *Technical information on urban goods and elements* and *Operative information for management and maintenance.*

3 Case study

The system, has been applied, fostering the setup of an Urban Facility Management (UFM) service for Quartiere Affari in San Donato Milanese, Milan, Italy.

The purpose of the information system, concerns the speed-up of the survey phase. Thanks to its possibility to manage a great amount of information, a Geographical Information System (GIS) has been adopted. GIS potentiality is enhanced through the joint use of a Database Management System (DBMS). These tools are integrated with a survey module, mounted on portable devices (e.g. smartphones and tablets). Exploiting the aforementioned tools, it is possible to ease and systematise the urban environment's assessment process. Accordingly, the times for urban components' detection have been significantly reduced. In Table 3 key data of the survey campaign are summarised.

Table 3 Survey key data

Description	Data
Tot. failures detected	476 (297 failure forms)
People involved	4 people in 2 groups
Roads	Approx. 2.500 m
Square	Approx. 9.000 m^2
Average survey time for 100 linear meters	1:00 h
Duration of the survey campaign	1 week

The survey has been carried out on the neighbourhood, to collect data concerning the status of urban components, identified according to a breakdown structure previously defined [3]. Information collected concern:

- typology of the pathology detected,
- different levels of necessity of intervention (from long term to urgent),
- safety for users,
- pictures of the pathologies on the urban elements,
- comments [10].

Information are gathered thanks to the use of a mobile application developed for the purpose and stored in a web database (*Assessment* phase in Figure 1).

Figure 1. Survey process schema. Phase 1 Assessment

Data are then georeferenced using a GIS platform. In the *Data analysis* phase (Figure 2), information collected during the survey campaign has been processed and organised both through quantitative and spatial analysis. Combining these two types of analysis it has been possible to spot the most critical urban components and urban precincts (phase *Data output* in Figure 2).

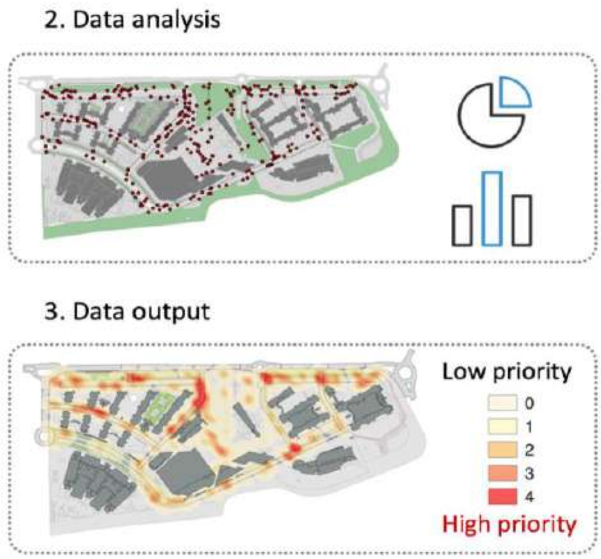

Figure 2. Survey process schema. Phases 2 Data analysis and phase 3 Data output

Identification of most critical entities, allowed to prioritise maintenance and repair interventions [4]. Most critical areas are highlighted in Figure 2 *Data output* thanks to a map showing the concentration of pathologies of components in a circle of 20m of radius.

Thanks to the analysis performed and described above, it was possible to identify that the crossroads are the most critical technological units presenting also issues related to safety for users (therefore, more critical). Following a descendent level of priority of intervention, urban drainage system is identified as second most critical technological unit. As for what concerns the crossroads, also this entity is subject to a high level of stress, especially if located in roadways characterised by heavy vehicular traffic. The third most critical technological unit is the walkway. Spatial analysis concerning the concentration of degradation in a radius of 20m has been carried out and combined with quantitative analysis. While the trends in degradation of technological units described before is confirmed, this data processing allowed to identify, the precise location where the degradation phenomena appear [4].

4 Maintenance costs analysis

The survey phase has been carried out in 2015, thanks to the information system described in the previous paragraphs. After that, the company in charge, developed the investment and UFM plan. Thanks to a collaboration with the UFM company, we could access the cost and technical historic datasets and budget data employed for the implementation of the intervention needed for bringing the maintenance and functional status of the neighbourhood in optimal condition. Moreover, the UFM company, partially integrated its management and survey procedure with the assessment and framework provided by the authors. Despite the complete adoption of new technologies and procedures, as recursive procedure to be carried out periodically, can be considered as a long term process, the cost trends in term of OM&R expenditure, confirm an improvement over the years.

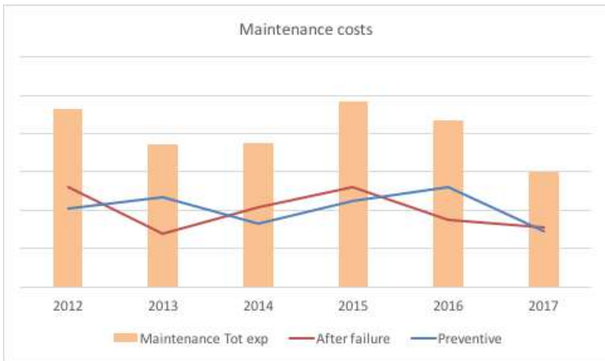

Figure 3. Maintenance expenditure trend from 2012 to 2017.

The cost chart in Figure 3, represent the trend of maintenance expenditure from 2012 until 2017, namely the period in which the UFM company has been appointed. As can be seen, the cost trend of the after failure maintenance (in red) and preventive maintenance (in blue) show a higher investment in preventive maintenance in 2012, namely the starting year of the UFM contract and in 2016, after the survey and assessment phase carried out by the authors. Nevertheless, in 2017 can be spotted an increase of the expense of the after failure maintenance. In 2017 can be also spotted an increase of the expense of the after failure maintenance, despite the total maintenance expenditure assumes the lowest value since 2012.

Lower investments in maintenance are compensated by high investments in CAPEX. Area in the neighbourhood identified through the survey as most critical in terms of safety for users, intensity and concentration of degradation phenomena etc. have undertaken a refurbishment process. In Figure 4 are represented the cost trends in term of investments for the rehabilitation of the areas described above and for maintenance (corrective and preventive). The trends depicted in the chart show that a higher CAPEX injection in rehabilitation of the urban areas, corresponds to a decrease in maintenance expense. Unfortunately, preventive maintenance expense forecasts for 2018 and 2019 are not available.

Figure 4, on the other hand shows an interesting trend for total CAPEX injection for years from 2016 to 2019. For privacy reasons, CAPEX, as well as the maintenance expenditure magnitude, is not reported in this paper as precise amounts but as a percentage of the total CAPEX injection during the investment period (2016-2019). The representations in Figure 5 and Figure 6 show a correlation between the localisation of failures, detected during the survey, characterised by the safety issue attribute and the urban precincts where more intensive investments have been dedicated.

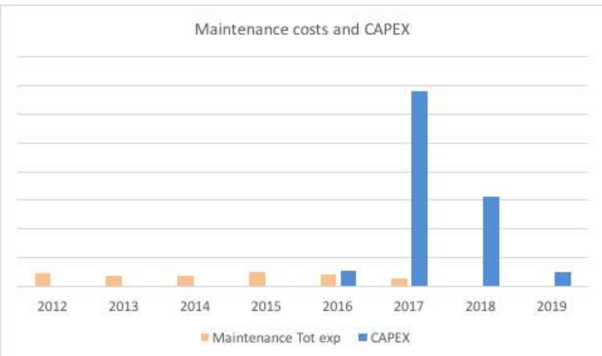

Figure 4. Maintenance expenditure (2012-17) and investment trend in refurbishment (2016-19).

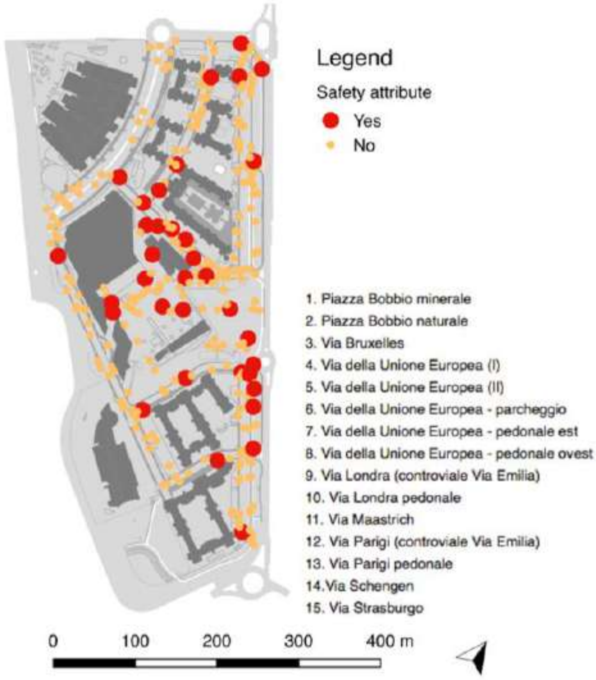

Figure 5. Localisation of failed components with safety attribute

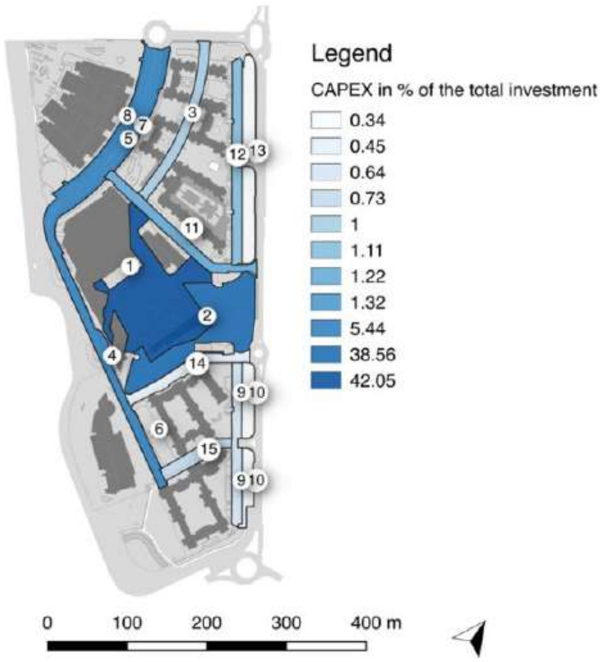

Figure 6. Localisation of CAPEX investments in percentage of the total

InTable 4 are summarised the number of detection of failed urban entities characterised by the attribute safety, in the urban precincts represented in Figure 6.

Table 4 Number of detections with safety attribute in the urban areas

Code	Area	Safety detections
1	Piazza Bobbio - minerale	9
11	Via Maastricht	6
10	Via Londra pedonale	4
3	Via Bruxelles	3
14	Via Schengen	3
2	Piazza Bobbio – naturale	2
9	Via Londra - controviale Via Emilia	2
12	Via Parigi - controviale via Emilia	2
13	via Parigi pedonale	2
4 – 5	Via della Unione Europea	1
15	Via Strasburgo	1
6	Park via Unione Europea	0
7	Via della Unione Europea - pedonale est	0
8	Via della Unione Europea - pedonale ovest	0

Among these areas precincts 1 and 2, corresponding to the neighbourhood's central square are receiving more than 40% of total investments on the period considered. This peculiar situation is due to the fact that being a spaces frequented by many users during the day, the degradation phenomena where more critical than other urban precincts, thus they required a higher injection of capital for the refurbishment intervention. Moreover, this higher amount of resources is due also to the extension of the area (approx. 9.000 m^2). Other peculiar situation can be highlighted for what concerns the precincts 4, 5, 6, 7, 8 Corresponding to via dell'Unione Europea. Despite in this area can be found only one detection presenting the safety attribute, it is the third more expensive precinct in terms of CAPEX injection (5.44%). This is due to the fact that though not affected by degradation with safety attributes for users, the number of detection is rather high.

Nevertheless, it must be taken into account that the only economic data, does not provide a dimension to the kind of refurbishment or restoration intervention carried out. Accordingly, it is necessary to combine these evaluations with others (technical, qualitative etc.) in order to obtain a more comprehensive picture of the whole neighbourhood's status. These further datasets could be obtained thanks to the recursive implementation of the survey phase. To conclude, it must be highlighted that Figure 4 does not represent the geographic representation of the total CAPEX. Values of investments on underground parking has been neglected, since they have been considered as separated entities for the whole development of the case study research.

5 Discussion and conclusions

Through the description of the case study research and thanks to the collaboration with the company appointed for the UFM implementation, it has been demonstrated how the precise definition of the information contents to be collected and management during the survey phase and for carrying out the UFM, it is possible to make informed investment decision of OM&R. This experience demonstrates that, adopting the survey system and the related procedure for assessment and data handling, UFM services can be better organised and performed faster, nevertheless, thanks to its modular structure, it allows the integration of different thematic modules [11]. Therefore, GIS software allowed to import information detected during the survey in thematic maps, exploited to define the level of degradation of some urban areas and to guide maintenance interventions. The system developed is dynamic and flexible and is updated through IT tools which take advantage of relational databases. Moreover, it can be considered as a risk prevention tool from both client and supplier point of view.

The system, despite being a powerful tool for data collection and analysis in the built environment, so far, lacks of integration with Building Information Modelling (BIM) editor software, even if it can be considered as compliant with the information management addressed by BIM procedure [12]. Thus, the system, can be considered as a first step toward the development of a more comprehensive Asset Information Model (AIM).

The methodology for economic assessment of the benefit in the adoption of the proposed system is based on the comparison between the quantitative data analysis against the spatial analysis allowed by the use of the GIS platform. This approach allows to describe and analyse cost performance trends in a wider and a more complete way. The economic expense for after failure maintenance and preventive maintenance can be related to the condition assessment of the neighbourhood, showing interesting trends before and after the survey has been carried out. Nevertheless, it was not possible to analyse the trend of the CAPEX injection, related to the current status of the urban areas. Only an assessment concerning the status as of 2015 compared to CAPEX budgeted from 2016 to 2019 has been possible. This is due to the fact that, despite the survey process to be implemented through the proposed system has been partially embedded in the procedures of the UFM company, it is not completely and periodically carried out. The process of adoption of new procedures in the well-established corporate practices is typically a long term process.

In conclusion, it can be possible to sketch an overlook of the proposed system concerning the integration of the core database with further modules belonging to different disciplinary fields. For this purpose, a case study concerning the possibility to exploit information collected during the survey for obtaining urban sustainability assessment is being implemented [11]. This case study demonstrates the possibility to exploit methodology underpinning the implementation of the system, within the context of the Neighbourhood Sustainability Assessment Tools (NSA) [13]. When management OM&R is addressed at the urban level, one of the keywords to be taken into account is complexity. For this reason, the system can be further developed, through the integration with a module for community involvement in urban maintenance prioritization [10]. Nevertheless, allowing users belonging to a given urban area to detect anomalies on the urban environment, requires robust data handling procedures, to be developed jointly with the implementation of the community involvement module.

This experiences show the potentiality of a structured data engineering for management and control of UFM service. Nevertheless, more testing and further validations in case studies are desirable. This will allow to integrate the proposed methodology and system in a more and more effective process for management of the built and open urban environment.

Acknowledgements

Authors would like to express their deepest gratitude to GEA S.r.l. for having allowed us to test the model on site and for having made their data available.

Abstract –

Recently, the accurate prefabricated Curtain Wall Modules (CWM) used as building facade are gaining popularity around the world. However, the conventional manual procedure for installation of CWM is dangerous for labour work. More so, it is a time consuming and expensive task. Automation of the CWM installation using a cable robot is an alternatively faster and safer method. The cost saved due to shorter installation time would compensate for initial investment costs of the robotic systems. However, for CWM installation, the cable robot and its modular end-effector (MEE) need to perform several tasks such as positioning within 1 mm accuracy, drilling, installing bracket (connectors), and handling and positioning the CWMs. However, there is no such robotic solution currently available on the market. As a probable solution to CWM installations, the European project "HEPHAESTUS" is designing a cable robot-based automatic system capable of 1 mm positioning accuracy, while performing other tasks such as drilling on the building. Meanwhile, it could carry nearly a tonne in payload in an outdoor environment. As a design phase in this paper, five different conceptual scenarios for such complicated automatic installation process conducted by a cable robot are introduced. The possible concepts are assessed using the Delphi method. Finally, the accuracy, safety, and installation time of the selected scenarios are comparable to the conventional manual procedure of CWM installation. In the future, these systems further improve within the HEPHAESTUS project framework.

1 Introduction

The construction industry plays an important role worldwide. Many countries consider it as a large part of gross product, which supports high employment rates [1]. Although construction companies use numerous apparatus onsite and offsite to enhance productivity, still several duties remain for manual workers [2]. One of such tasks that requires high labour effort in construction sites is the installation of curtain walls. This task poses serious risks for manual workers, since this task is done on the edge and on top floors of incomplete buildings. In addition, manual curtain wall installation is a slow operation. Numerous labour forces working long hours make the manual curtain walls installation highly expensive as well [1], [3], [4]. Therefore, automatic installation of curtain walls increases safety and productivity [5] , [6].

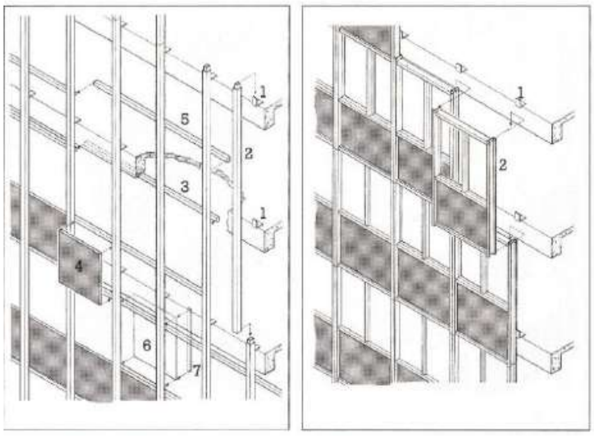
In the call for proposals from the European Union: *ICT-25-2016-2017 - Advanced robot capabilities research and take-up* [7], the *HEPHAESTUS* project [8] got founded in *innovation and action* scheme. The consortium of the project consists of three research institutes, one university and five companies. Nine members of the consortium are from different European countries namely Germany, Spain, France, UK, Italy and Norway. This project addresses novel concepts for facilitating the cable robots in the construction sector, which currently has a minor usage. The focus of the project is on curtain wall installation as a high risk and critical construction task. This paper is within the frame of the HEPHAESTUS project that aims to solve the challenges mentioned above.

In this study, we first discuss state of the art (chapter 2), followed by an introduction of the five possible scenarios for the automatic installation of curtain wall modules by cable robots (chapter 3). Next, the scenarios assessed using the Delphi method are highlighted (chapter 4). Finally, the assessment results leading to preferred scenarios are concluded.

2 State of the art

2.1 Curtain wall

A curtain walls is an exterior envelope of the building which does not carry the vertical loads of the building roof or floor. It sustains its own weight in addition to imposed loads such as wind, and transfers these forces to the building. It provides benefits such as daylighting and reduces the overall weight of the building [2]. There are two types of curtain walls shown in Figure 1.



Unitized and stick curtain wall system

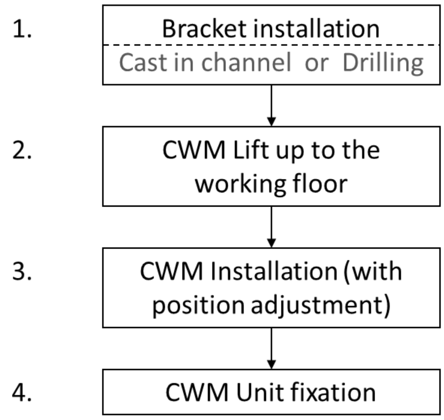
Figure 1. Left: Assembled on site, "stick". Right: Pre-assembled into rectangular panels, "unitized". [Picture rights: courtesy of AAMA [10]]

1. Type one is the stick system, where the installation of metallic frames and glass panels is carried out on site [9]. Most stick systems consist of horizontal rails and vertical mullions. When mullions and rails create such a grid on site, glass panels are often inserted, although other materials can also be used.
2. The second type is the unitized (modular) system. In a unitized system the curtain wall modules (hereafter called CWM) are pre-fabricated and assembled with pinpoint accuracy in the factory. The assembled module includes the rectangular aluminium frame and inner glass. A connecting part, i.e., bracket, will help to affix the module onto the buildings.

Figure 1 shows the two different types of curtain wall. The figure also shows that unitized system installation needs fewer steps on site. Therefore, the unitized system is selected for automation process and is the subject of this paper from now on.

2.2 Conventional CWM installation

The standard conventional CWM installation is a manual procedure, which occurs in four phases (see Figure 2). Step 1 of curtain wall module installations encompasses Bracket installation. There are two general ways of bracket fixation on the concrete slab of the building: cast-in channel and drilling. The Cast-in channel system is the most common technique for unitized system installations in new buildings.



Sequences of CWM installation

Figure 2. Conventional steps for a CWM manual installation process.

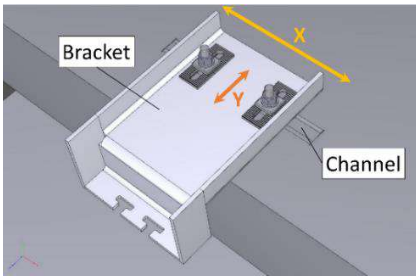
For the installation of cast-in channel systems, the first step is placing the cast-in channel on the framework, followed by welding it onto the steels bars before pouring the concrete (Figure 3 - up). The next step is manually removing foam from the cast-in channel (Figure 3 - bottom), followed by placement of the bracket (Figure 4). The adjustment of the bracket proceeds until its positioning meets the adequate pre-defined location.

Cast-in channel system

Figure 3. Preparation of cast-in channel system [Picture rights: courtesy of Focchi SPA [11]]

In a drilling system, the drilling points are first measured, and the absence of rebar under the aforementioned drilling points are checked before

drilling. If there is rebar under the drilling point, the drilling point will be changed accordingly while carefully considering the range of bracket adjustment allowance. Then, two holes are drilled in their proper positions. Finally, the bracket will be fixed using screws in the appropriate areas using anchors.
The bracket should be installed within an accuracy of 1 millimetre. In a cast-in channel system, the adjustment of the bracket position is possible in two directions (Figure 4). In a drilling system, the alteration is possible in only one direction because of the absence of a channel.



Bracket adjustment

Figure 4. Two possible direction of bracket adjustment while installing [Picture rights: courtesy of Focchi SPA [11]].

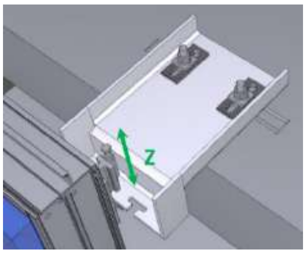
During bracket installation, its position will be controlled and checked by use of measurement systems such as a total station. In a manual setup, the placement of the bracket is critical because the final position of the CWM relies on the bracket location. The positioning of the bracket is likely not to be further re-adjusted.

CWM installation

Figure 5. Conventional installation of a CWM, possible dangers for labours - the number of workers involved in the installation process [Picture rights: courtesy of Focchi SPA [11]].

After the production, assembly, and control of the curtain wall modules in the factory, the modules are transported to the construction site and stored. At this step, it is assumed that the brackets are already fixed in their planned positions and are ready for hosting the CWM. In step 2, cranes lift the CWM to the working floor. The CWM can also be elevated to the working floor using an elevator (if available on site). Nevertheless, cranes handle the CWM’s weight during installation, while workers manipulate the CWM and adjust its position accordingly (step 3, see Figure 5).

Workers on the site guide the CWM into the bracket and adjust the CWM’s height via a specific part of the CWM (Figure 6). Finally, when the correct position of the CWM is confirmed, it will be fixed (step 4) and the installation of the next CWM starts.



CWM level adjustment

Figure 6. One direction of CWM adjustment during installation [Picture rights: courtesy of Focchi SPA [11]].

Each bracket hosts two adjacent curtain wall modules while bearing half the weight of each CWM, and each CWM is supported by two brackets, i.e., each bracket handles the full load of one.

2.3 Automated CWM installation

Multiple types of automated equipment for automatic curtain wall installation exist. One good example is a patented method by Brunkeberg Systems AB [12], which uses a dedicated railing system and a specially designed CWM to install the façade from the outside of a building. However, rail installation is conventional in this method. S. N. Yu *et al.* [2] used a mobile robot from the inside of a building to automate façade installation. However, they only managed to automate step 3 (Figure 2) of the standard CWM installation. J. Činkelj *et al.* [4] developed a telescopic hydraulic system that reaches the building façade from the outside followed by nailing of the façade panels to the building. This tele-operated system is specialised for sandwich panels, but not for CWMs. K. Iturralde *et al*. [13] proposed a Modular End-Effector (MEE) concept for use in automatic panel installation. Nonetheless, the proposed MEE is still at the conceptual level. These robotic systems, nevertheless, have some limitations.

In the HEPHAESTUS project (a subject of this paper), all the four steps (Figure 2) in CWM installation are considered to be fully automated, but not tele-operated. To reach this novel goal, a cable driven parallel robot (known also as cable robot) hosting a modular end-effector is the selected robotic system. A cable robot system has several advantages: (a) it could carry heavy objects based on cable load capacities, (b) the workspace is a design parameter and could be chosen big enough to cover the whole side of the building. Moreover, other features of cable robots such as the degree of freedom, speed, and adaptability could be beneficial [14]. In cable robots, flexible cables are used as actuators of parallel manipulators. One end of each cable is connected to a platform hosting the MEE, and the other end is reeled in or out by a motor-driven winch. The MEE is a specially designed mechatronic system, which moves to different floors of the building by the help of a cable robot. Briefly, a cable robot carries the MEE to the desired position and the MEE performs the rest of the tasks (e.g., drilling). Figure 7 shows a conceptual cable robot and the platform hosting the MEE. However, the Figure does not reveal the details of the MEE.

Cable robot

Figure 7. Conceptual view of a cable robot (Orange) working on a building. The platform hosting the MEE is coloured red.

2.4 Development process

In the HEPHAESTUS Project the requirements for the system together with existing technologies have been studied. The HEPHAESTUS Project revealed that the series of tasks in CWM installation is one of the critical issues that need to be addressed. Therefore, in this paper, mainly the sequence of the tasks is researched. In order to find the most suitable workflow procedure, first, five possible scenarios were defined and analysed by the Authors. Secondly, these five scenario were introduced to the whole project consortium. Next, based on the Delphi method for gathering expert opinion, all project partners participated in an assessment process. Finally, as a result of the assessment process, the preferred scenario is introduced in this paper.

3 Description of the installation Scenarios

The previously defined scenarios distinguish themselves in their different workflow of tasks. Although all the five different scenarios fulfil the CWM installation requirements, they require different technologies and provide various outputs. Table 1 shows the different steps to be taken in each of the five scenarios. All these phases are automated by the use of a robot unless mentioned otherwise.

Table 1. The sequence of tasks undertaken in the different Scenarios

	Scenarios				
	1	**2**	**3**	**4**	**5**
Steps					
Drilling the hole in precise location		1			4
Drilling hole with rough position			1	1	
Placing anchor in bracket	1	2	2	2	
Adjustment of bracket position	2	3	3		
Placing bracket	3	4	4	3	
Placing anchor in building					5
Fixing the bracket on the building	4	5	5		6
Measurement			6	4	
Creating interface bracket (Manual or by external device)			7		
Adjustment of CWM connection part (Manual)				5	
Mounting Bracket on the CWM(manual)					1
Placing and fixing interface bracket			8		
Placing CWM	5	6	9	6	
Placing CWM and bracket together					2
Adjustment of CWM and bracket together					3

Following, in this chapter, those scenarios are defined and their advantages and disadvantages are discussed.

3.1 Scenario 1

The first conceptual scenario follows the same workflow as the conventional installation process; for installing the CWM in new buildings, the placement of a "cast-in channel" before pouring the concrete is necessary. Afterwards, a bracket is accurately placed and adjusted. Finally, the curtain wall module is draped over the bracket. The accuracy of installing the façade relies on a precise bracket installation.

Advantage: This is the closest scenario to the existing installation methods. Therefore, solving this scenario would mean getting closer to the needs of the current market.

Disadvantage: The complexity of the tasks is considerable. The MEE system would need to achieve several tasks such as levelling of the bracket's nuts simultaneously.

3.2 Scenario 2

In the second scenario, it is considered that there is no cast-in channel available. Hence, drilling is required. First, the drilling position is calculated, then the robot will check if there is re-bar under this planned position. If this is the case, the position will be adjusted considering the bracket adjustment range. If there is no re-bar, the drilling process does not require an additional recalculating step. After this recalculation, two holes for each bracket are drilled automatically by the robot. From this point onward steps are similar to the scenario 1.

Advantage: It improves the adaptability and versatility of the system, because a cast-in channel system may not be provided in all constructions (assuming e.g., renovation process or steel construction), but drilling could be used in almost all constructions.

Disadvantage: There is some additional complexity. Attention to re-bar of the concrete, which should be recognized before drilling, especially if slabs are post tensioned.

3.3 Scenario 3

This scenario is based on using a correction interface for (mostly) each of the brackets. It is an alternative to have the adjustment flexibility in the fixing or drilling process. The idea is first installing the bracket roughly, and then with help of an interface, correcting any small misalignments. Considering the construction nature, (for example, concrete slabs are not always well aligned) some misalignments are hardly avoidable. Therefore, this scenario solves it by using a uniquely made interface for each bracket.

Advantages: This is a rapid installation case if the interface can be ready on-time. Furthermore, drilling position is selected roughly.

Disadvantage: It is Expensive. CNC or an additional machine on-site would be required. Other rapid prototyping methods such as 3D printing for the manufacturing of the interface may not be strong enough. Challenges of rebar recognition on drilling process exists, too.

3.4 Scenario 4

In this scenario, similarly to scenario 3, the hole is drilled roughly in range of a few centimetres. And the bracket is installed within that rough position precision. The adjustment for the exact position of CWM is handled by an adjustment module on the CWM. On the CWM, there is a part to be connected to the bracket. This part normally is fixed on the CWM, but in this scenario the CWM is re-designed to make this part adjustable. After rough placement of the bracket, its position will be measured and the connecting part on the CWM will be adjusted manually on the ground to correct the misalignment caused by rough installation position of the bracket. In contrast to conventional installation methods, adjustment capability transfers to a connection part of CWM. In conventional methods, adjustment happens directly on the bracket.

Advantage: The advantages are same as in Scenario 3.

Disadvantage: Adjustment module on CWM could not be mechanically strong enough to carry the load. It is better to have it fixed and not adjustable, considering mechanical stiffness. There might be a problem during the placement, hence non-parallel movement of the CWM may be necessary, which can jeopardize the fitting process. Challenges of rebar recognition on drilling process exists, as well.

3.5 Scenario 5

In this scenario, it is given that the bracket and the CWM first combine with each other, which could be considered as one module hereafter. Secondly, the combined modules are carried to the desired position by the cable robot, and next they are adjusted on their correct position within 1 mm accuracy. The further steps: drilling, placing anchor and fixing the bracket finish this scenario. When the bracket is installed on the building, it is carrying the CWM, which is the main difference of this scenario from the others.

Advantages: The CWM module is used as a physical pattern.

Disadvantage The slab's current geometry is unknown. Therefore, it may be impossible to level the bracket. Challenges of rebar recognition on drilling process exists, as well.

4 Assessment

After presenting five scenarios, one of them should be selected as the preferred scenario. To select the most profitable one regarding the requirements of the system, an assessment process is carried out in this research. In this chapter, first the assessment methodology is introduced then the corresponding procedure and results are presented.

4.1 Methodology

The assessment process and the selection of the preferred scenario in this project is a decision-making problem. In many decision-making cases, the decision needs to be taken based on multiple attributes to select an alternative from the feasible ones. This is the principle of Multiple Attributes Decision Making (MADM). It contains multiple decision attributes and multiple decision alternatives. The aim of the method is to make the decision considering all attributes [15][16][17]. One of the methods to do so is the Delphi method developed by Helmer and Dalkey [18] (around 1950s) to systematically use the expert's opinions. Decisions based on several experts' opinions are usually more precise than the individual opinion of each of the expert [19]. The Delphi method is a group communication process, which gathers the experts' ideas via survey letters or, in our case, via an assessment table. In contrast to other methods, Delphi applies multiple iterations (uses feedbacks) to develop a consensus of opinion concerning a specific topic [20]. The Delphi method begins with sending the same open-ended questionnaire to each of the Delphi participants (experts) and asking for their first thoughts and comments about the questionnaire. This is the first round. After collecting responses, this data will be converted to a well-structured questionnaire to be used in a second round. It is acceptable to start the method from round two if such well-structured questionnaire is already available [21]. In the second round, each expert receives a new questionnaire and is asked to review and sometimes to rank it in order of priority. In this round, area of diversity among opinions are identified and some consensus starts forming. In round three, each expert receives the questionnaires that includes opinion and rating of other experts in the previous round. They are asked to revise their rating and specify their reasons. In round four, usually the final round, the consensus of opinion, and any remnant of items exists, is presented to the experts. It should be mentioned that the number of Delphi iterations could vary from three to five.

In this paper, the Delphi method is used to assess the previously proposed scenarios. The group of experts as Delphi participants are project members. On behalf of each organization of HEPHAESTUS consortium, one person represents the organization's thought. So, nine experts are involved. First, an assessment table is provided as a questionnaire, where scenarios could be assessed by provided indicators.

In the first round, the assessment table and the scenarios' explanations were sent to experts and they were asked to share their first thoughts on the scenarios and indicators of assessment tables. After receiving the first comments, they were considered and included in the scenarios and the table. In round two, new well-structured table and scenarios returned to the experts. The experts shared their new revised ratings in the assessment table while they knew the others' opinions, as well. Finally, in the fourth round the final assessment table based on consensus of experts' opinions was presented. All experts agreed on that and it was accepted as the result of the Delphi method.

The following section presents indicators, which are used in an assessment table. The section after next describes the assessment table.

4.2 Indicators

The cable robot must perform certain tasks. The main task is to install a CWM in a building structure. For that purpose, some specific criteria for the cable robot were marked:

- **Cost of the proposed systems**
  Initially the presented solutions must rely on the possibilities of the end-users, the CWM installers and the contractor companies. It should compete with conventional manual installation.
- **Simplicity and ease of accomplishment**
  There are several ways to perform each task to make the overall system work. The simplest way is preferred, because it eases the design process and makes the job for an end-user simpler.
- **Technological availability**
  The proposal must rely on previously tested technologies. However, scientific development is required in cases such as a specific visual system for bracket placement. The extra developments should be avoided as much as possible.
- **Accuracy and Repeatability of the robot's path**
  The cable robot is responsible for the CWM installation. Therefore, its position accuracy plays a key role in installing the bracket and the CWM correctly.
- **Adaptability to different construction sites**
  The cable robot should be adaptable to multiple construction sites. The target buildings are commercial and office buildings. In such cases, they are made of steel or concrete structural frames with on-site concrete slabs. The cable robot system will be designed to install the curtain wall panels in facades without balconies, as it is the case of most commercial and office buildings. Indeed, a cable robot is well-known for easy reconfiguration, since pulleys and drums can easily be placed in different position and are adaptable to complex systems.
- **Matching to conventional unitized CWM**

products
If scenarios require major changes in the current product (the Curtain Wall Module and bracket) for being installed by the cable robot, this might be a problem for future marketing of the robot. Therefore, matching the system to the conventional bracket and the CWM system will ease the future marketing and is considered as an indicator of the most successful robot.

- **Possibilities of Multi-functionality (cleaning, repair, etc.)**
The cable robot should be configured for accomplishing multifunctional tasks, the project primary task (installation of CWM) plus possible optional tasks (such as cleaning or painting). The optional tasks are generally easier compared to the primary task.

4.3 Assessment result and preferred scenario

In order to assess each scenario quantitatively, each indicator has a specific maximum value as seen in Table 2 in parentheses.

Table 2 Assessment table of the Scenarios

	Indicator (max- value)	Scenarios 1	2	3	4	5
Demonstrators	Cost of the proposed systems (20)	15	15	10	10	15
	Simplicity of the system and ease of accomplishment (20)	10	10	10	15	10
	Technology availability (20)	15	15	10	15	10
	Accuracy and Repeatability of the robot´s path (20)	15	15	10	5	5
Future feasibility	Adaptability to different construction sites (10)	5	5	5	5	5
	Matching to conventional unitized CWM products (5)	5	5	2	2	5
	Possibilities of Multi-functionality (5)	5	5	5	5	5
	TOTAL (100)	70	70	52	57	55

The indicators are divided into two types: demonstrators and further feasibility. Since demonstrator is the primary goal of the HEPHAESTUS project, the respective indicators have a greater maximum value. If the project is successful for the demonstrator task, it could fit for simpler applications as well (e.g., cleaning). The weights (maximum value) of indicators are mentioned in parentheses. The maximum value represents the maximum score a participant could give a specific scenario. The higher the value, the better the project goal in terms of that indicator. For instance looking at Table 2; scenario two has higher value compared to scenario three considering first indicator, which means scenario two better fits to the project goal regarding costs. Simply it could be translated such that: scenario two is at the end cheaper by experts' opinion compared to scenario three. The sum of the weights is 100. Each scenario finally will gain a total value between 0-100, the closer to 100 the better the scenario fits the project goal considering all indicators. All consortium partners in the HEPHAESTUS project have participated in the assessment process by the Delphi method. Table 2 is the final table of round four using the Delphi method confirmed by experts.

5 Conclusion

The results in Table 2 show that scenario 1 and 2 achieved the highest value and are the preferred scenarios. However, the MEEs in scenario 1 and 2 need further development in the direction of modularity. Ideally, the MEE should be modular enough for both situations, despite the need for some modifications. Additionally, scenario 2 is interesting from a technical point of view; it makes use of drilling, and can therefore be used for renovations on old buildings with no cast-in channel. Another aspect of the preferred scenarios is to perform bracket installation and to carry the CWM, distinctively. The modules in charge of moving the CWM and the ones responsible for installing the bracket do not have to be run at the same time by the cable robot, therefore reducing the typical load carried by the robot.

In the next research phases of the HEPHAESTUS project, the authors will further improve and develop these selected scenarios.

It is worth noting that the details of the "detail how to do systems" will be defined in the next stages of the project, which deal more with the design of the system. After completion of the design, the system will be built and tested in a real world.

Abstract

Attached tower crane is globally used in the high-rise construction to transport components vertically and horizontally. To reduce cost and improve overall efficiency, the tower crane should be well located to move heavy materials. This paper proposes an optimization algorithm to identify the optimal type and location of attached tower crane with proper location of material supply point. The algorithm concerns four main models:1) tower crane location generation model to define alternative type and area for allocating crane.2) supply point location model for selecting all potential area to establish supply point.3) tower crane optimization model to get the ideal location of tower crane and supply point. 4) 4D simulation model to evaluate and visualize the optimal layout scheme through BIM. Then, a practical case, in China, is described in order to demonstrate the outputs obtained by the optimization algorithm. Later, three typical situations of construction site are discussed based on the case. The results reveal the rule that the trolley sliding movement is weightier than the jib rotation movement when considering the optimal layout scheme.

Keywords –
Attached Tower Crane; Optimal Algorithm; Site Layout; BIM

1 Introduction

Construction site layout planning is a tough task that has to be determined at the early stages of construction, and suitable site layout can significantly improve the construction efficiency [1]. Equipment cost might be in the range of 10% to 40% of overall construction cost [2]. Therefore, having an optimal layout of equipment (e.g. tower crane) and material supply point will be conducive to shorten schedule period and reduce cost [3].

As for types of construction equipment, tower crane is the most prominent construction machinery in the construction market, not only for their large size, but also because they played a prominent role in transporting components vertically and horizontally [4]. In addition, tower crane is the most expansive type among these construction equipment types [5].

With the accretion of population during urbanization process, the number of high-building is increasing especially in China and this phenomenon leads to the widespread uses of attached tower crane. The crane, allocated close to the building boundary, significantly improves the lifting capacity of cranes. Therefore, the selection and allocation of attached tower crane has been the main concern of the construction of high-rise building.

2 Literature Review

Current study has put forward a lot of different ways to find the optimal position of tower crane, which is mainly based on simulation and mathematical algorithms. Based on achieving minimal collision of tower cranes, Zhang et al. [6] proposed the method of calculating hoist travel time firstly which laid the foundation for later study. C. Huang et al. [7] improved the equation by adding not only formulas to calculate vertical transporting time but also a parameter α to reveal the location specific effect in different construction sites. Subsequent study completed simulating the hoisting process and separated into load mode and unload mode [7]. In 2017, Justin K. W. Yeoh et al. [8] took multiple stages and the concept time into account to a better solution.

Most of previous researches prefer using mathematical algorithms to allocate optimal layout planning. C. M. Tam et.al [9] applied genetic algorithm to optimizing supply point and tower crane location. Later, GA-ANN model, combined genetic algorithms and artificial neural networks, was introduced to solve

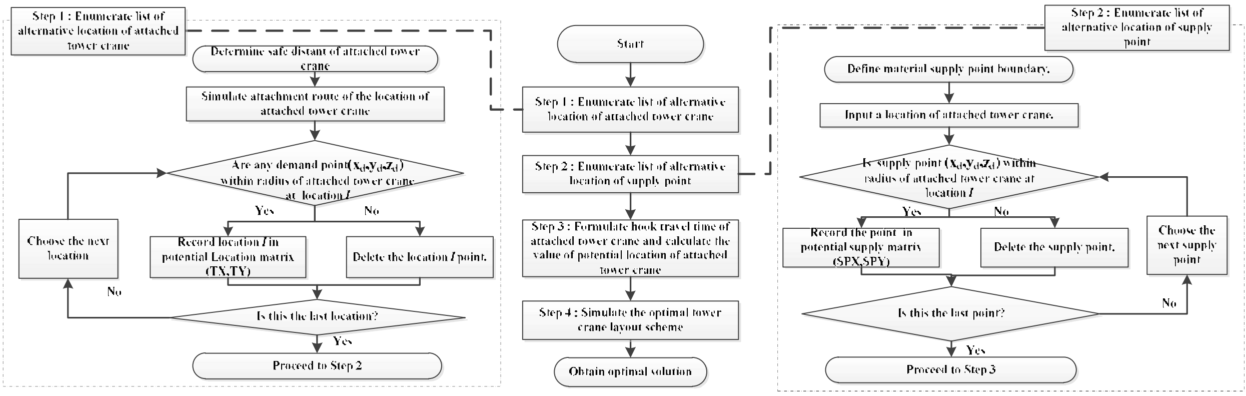

Figure 1. Flowchart of attached tower crane optimization

the same problem [10]. Another modern application for the problem, involving mixed-integer linear programing technique, was introduced by Huang et al. [11]. With increasing focus on construction layout planning, Javier Irizarry et.al. [12] applied geographic information system (GIS) and building information modeling (BIM) to solve the problem which visualize the potential conflicts. And Particle Bee Algorithm (PBA), combined particle swarm optimization (PSO) and bee algorithm (BA), involved to get the optimization location of demand points and supply points [13]. Then, Jun Wang et.al [14] used firefly algorithm for generate optimal layout planning and BIM technology to input data and visualize layout scheme. Mohamed Marzouk et.al. [15] developed a decision model for tower crane selection and location based on BIM and GA.

In previous study, scholars mainly discussed material demand point, supply point, location and lift capacity of tower crane that based on the object of minimal operating time, cost and collision between tower cranes. Practically, tower crane with high lift capacity means using less time to transport the same quantity components than lower ones. However, this also leads to increased costs which is proportional to the rent time. Thus, it is essential to select the suitable type and optimal construction layout planning in different construction which is the purpose of this paper

3 Attached Tower Crane Optimization Model

Finding optimal tower crane scheme involves four steps as shown in Figure 1. Firstly, a tower crane location generation model is introduced to produce all alternative tower crane location. Secondly, a supply point location model is generated, finding all potential material supply point. The next is an optimization model to search optimal exact location of tower crane and supply point. Finally, the outputs are evaluated and visualised through BIM.

3.1 Module A: Tower Crane Location Generation Model

To illustrate the constraint of selecting and locating tower crane, several analogies has been drawn on from the previous study. As shown in Figure 2, D1 and D2 represent two demand points where need the same type of components, while the component in D3 is lighter than that in D1, which means M1=M2>M3. And R1, R2 and R3 stand for the radiuses of the maximum area to ensure the crane lift the load of the demand points respectively. Ideally, each crane has its own fixed lift capacity and the radius of the component is inversely proportional to the component mass. The lighter the component is, the further the jib is, which leads to R1=R2<R3. In order to insure the crane to deliver all components to demand points, the crane has to be positioned in the overlapping region.

According for the attributes of attached tower crane, the crane needs a safe and short distance to be located and operated. This distance can be obtained by practical experience. Therefore, attached tower crane should be located in the junction of the overlapping region and attachment route.

3.2 Module B: Supply Point Location Model

Comparing with the tower crane location generation model discussing above, supply point location also has two limiting factors. On accounting for the distance between attached tower crane and the building, the supply point lays behind the crane. Another factor is similar to the principle discussed above. Each potential crane location can have its alternative supply area, as shown in Figure 3.

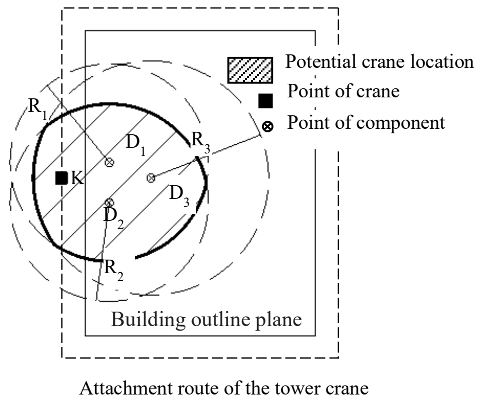

Figure 2. Possible crane location

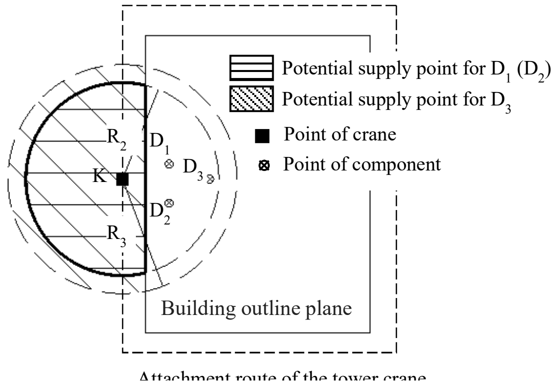

Figure 3. Possible supply point location

3.3 Module C: Tower Crane Optimization Model

Attached tower crane lift components in supply point S (x_s, y_s, z_s), transporting it to demand point D (x_d, y_d, z_d). This movement process of attached tower crane is consist of vertical movement and horizontal movement. On the other hand, the hoisting process can be divided in two main situations: (i)With load (ii) Unload.

3.3.1 Vertical Movement of Attached Tower Crane

Vertical movement can be separated into two parts, the vertical lift movement and descent movement. In order to avoid the collision between the components and building, there is a safe height h_0 above demand point. Eq. (1) and (2) calculate the travel time of vertical lift movement and descent movement respectively where v_{h1} represents hoisting speed of hook (m/min). When attached tower crane is back to supply point for starting the next delivery, the crane is under unload condition. The different between with load and unload is the velocity of hook.

$$T_{v_1} = \frac{|z_d - z_s| + h_0}{v_{h1}} \quad (1)$$

$$T_{v_2} = \frac{h_0}{v_{h1}} \quad (2)$$

3.3.2 Horizontal Movement of Attached Tower Crane

As mentioned in Zhang et al. [6] model, the horizontal movement contains two motions: (i) linear motion of the trolley;(ii) the rotation of the jib. Figure 5 shows the relationships among location of the crane, demand point and supply point, including the radial and tangential movements of the crane jib. The relationships can be calculate using Eq. (3) - (7).

$$\rho_D^K = \sqrt{(\mathrm{x_d} - \mathrm{x_k})^2 + (\mathrm{y_d} - \mathrm{y_k})^2} \quad (3)$$

$$\rho_S^K = \sqrt{(\mathrm{x_s} - \mathrm{x_k})^2 + (\mathrm{y_s} - \mathrm{y_k})^2} \quad (4)$$

$$\rho_S^D = \sqrt{(\mathrm{x_d} - \mathrm{x_s})^2 + (y_d - y_s)^2} \quad (5)$$

$$T_\omega = \frac{1}{v_\omega} \arccos\left(\frac{\left(\rho_S^D\right)^2 - \left(\rho_D^K\right)^2 - \left(\rho_S^K\right)^2}{-2 \cdot \rho_D^K \cdot \rho_S^K}\right) \quad (6)$$

$$T_r = \frac{|\rho_D^K - \rho_S^K|}{v_r} \quad (7)$$

$$0 \le arccos(\theta) \le \pi$$

Where T_ω= time for trolley movement; T_r= time for jib rotation; v_ω= slewing speed of jib (rad/min); and v_r= radial speed of trolley (m/min).

Practically, the movement of the jib rotation and the trolley sliding runs simultaneously to transport component efficiency. The parameter α represents the degree of synchronization between the movement of jib rotation and trolley sliding. The assignment of α is between 0 and 1 that stand for full simultaneous movement and full consecutive movement. The parameter β_r and β_ω represent the first movement of the

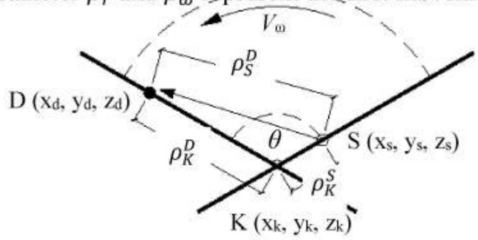

Figure 4. Horizontal operation process

$$T_h = \alpha[\beta_r T_r + \beta_\omega T_\omega] + max\{(1-\alpha)[\beta_r T_r + \beta_\omega T_\omega], \beta_\omega T_r + \beta_r T_\omega\} \quad (6)$$

When α=1， β_r=1， β_ω=1， or α=0， β_r=1, β_ω=0, or α=0， β_r=0, β_ω=1, the results of Eq. (6) are same as the results of that of Zhang [6].

3.3.3 Total Travel Time of Attached Tower Crane

In the same consideration of parameter α, the parameter γ is added to express the degree of synchronization between the vertical lift movement and horizontal movement. Furthermore, the hook travel time is determined by many factors such as site conditions and the proficiency of operators. Hence this paper adds the parameter μ_k to reveal the degree of difficulty in alternative crane location K for the operator to manipulate ranging from 0.1 to 10.0, which may be diverse in different combination of demand and supply points.

$$T_{i,j.l}^{o}(x_s, y_s) = \mu_k\{\gamma T_{v_1} + max\{(1 - \gamma)T_{v_1}, T_h\} + T_{v_2}\} \tag{9}$$

In conclusion, Eq. (1) - (9) define the calculation of hook travel time when delivering a single component. Besides, in practical, there would be loading time, unloading time and waiting time during the whole process of hoisting. Therefore, the total time of a building hoisting scheme could be defined as Eq. (10).

$$T_{t_n} = \sum_{i=1}^{I}\sum_{j=1}^{J}\sum_{l=1}^{L} T_{ijl}^{o} + T^u + T^w \tag{10}$$

Where I refers to the total number of the components, J refers to the total number of the floor, L represents the total number of type of the component.

3.4 Module D: 4D Simulation Model

Owing to the abstract outputs from above model, it is tough for site manager to fully understand the result and make wise decisions. Furthermore, conflicts and restrictions in spaces are difficult to display in 2D or 3D layout planning. Hence, the purpose of developing this 4D simulation model is to evaluate the credibility of the mathematical model outputs and space restrictions.

The inputs of this model come from three parts: 1) the outputs of tower crane optimization model including the location of attached tower crane and supply point with proper type of the crane.2) the coordinates of demand point and material comsumption.3) model library concerns 3D building model, construction schedule and 3D construction site model. The outputs of this model are the final layout scheme which will be implemented in reality.

4 Case Study

The proposed optimization model was used in the construction of a 23-story single apartment in Chongqing, China. The high-rise building is a footprint of 34.8 X 11.7m using attached tower crane. In addition, the types of the cranes used in this case are QTZ63, QTZ80 and QTZ125, and the numbers after "QTZ" means the max load moment of that type of tower (unit: KN/m). According to practical experience, the distance between the building boundary and tower crane is assume to be 4 meters which is the same between the location of tower crane and material supply points, as shown in Figure 5. Owing to the significant shape of attached tower crane and components, the possible position of tower crane and supply points is described in one-dimensional coordinate as particle distribution.

The results of module A, produced by MATLAB, displays in Figure 6. QTZ63 and QTZ80 are only able to deliver components to cover all demand points in part of the attachment route, while QTZ125 has potential location in all of the route. Depending on whether the attachment route, the situation can be divided into two parts: (i)full-filled which achieves the object; (ii) part-filled which attached tower crane locates in part of the attachment route. Practically, tower crane and material supply points locate on the basis of the experience that the tower crane should satisfied the farthest demand point with the heaviest component. And the full-filled situation simulates this realistic scenario. Thus, QTZ125 is the optimal type of attached tower crane in this project using practical experience. Meanwhile, QTZ63 and QTZ80 are another choice based on this mathematical model. As shown in Table 3, choosing

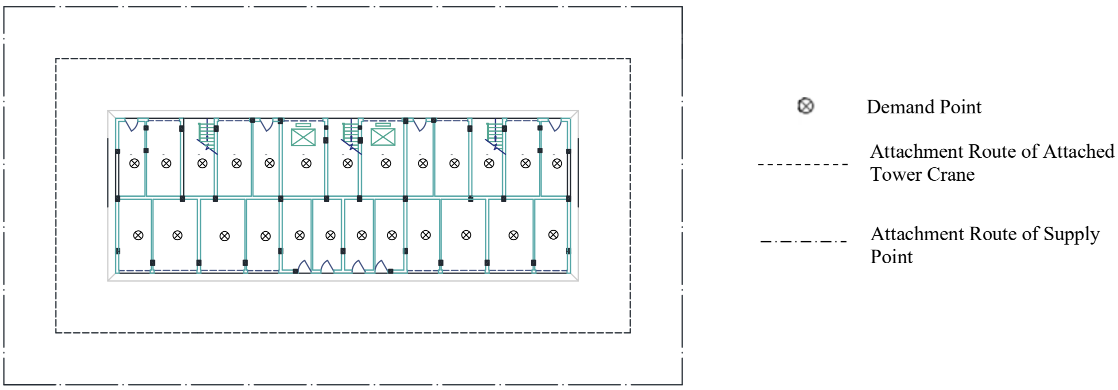

Figure 5. Site layout of case study

QTZ63 is a better solution that reduced the total cost of QTZ125 by 42.57%. Finally, the outputs are proved feasible in practice by Module D, and display in Figure 7.

Table 1 Coordinates of demand points and weight of the section to be transported (Standard floor)

5 Discussion

Each project has its individualism optimal layout planning because of the different constraint among the construction site. Exploring the main influencing factors and the changing rule of time in different situations is helpful to find the optimal layout planning. Practically, the supply point may be fixed in one position on account for the other facilities layout (e.g. steel cut machine), or there is no constraint of the allocation of supply point and tower crane. The experiments are based on the full-filled mode that is able to reveal the all-round output of the layout. In addition, the mass of the demand point distribution is symmetrical in left and right.

Situation I: Material supply point is right behind attached tower crane.

As shown in Figure 8 (a), the filled black pentacle refers to the optimal location of attached tower crane in the center of top attachment route. The line chart shown in Figure 8 (b) is the total delivering time of each attached tower crane location, and when the crane lays on the bottom and top of the attachment route, the total time will be shorter than that it in the right and left. The reason is that the high-mass component distributing mainly on the top line of demand points, so the distance to all demand points gets the minimal travel time.

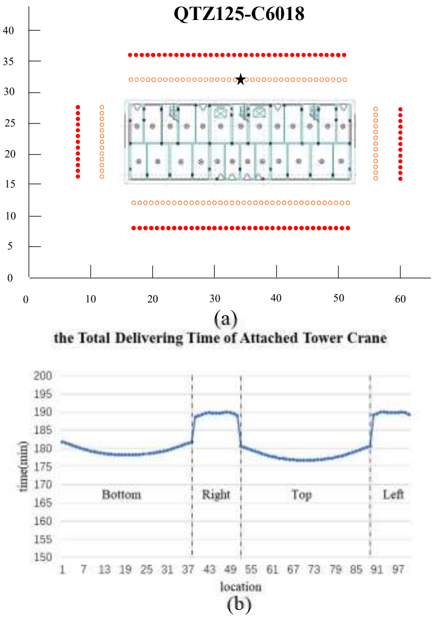

Figure 8 Results of situation I

Situation II: under no extra constraint when define the location of attached tower crane and supply point.

For this part, the layout planning reaches a state of relative ideal that may achieve in the early planning stage. As illustrated in Figure 9, the green triangle refers to the optimal metirial supply point when the tower crane located on the black filled pentacle. In addition, the left green triangle is corresponding to the left black pentacle.

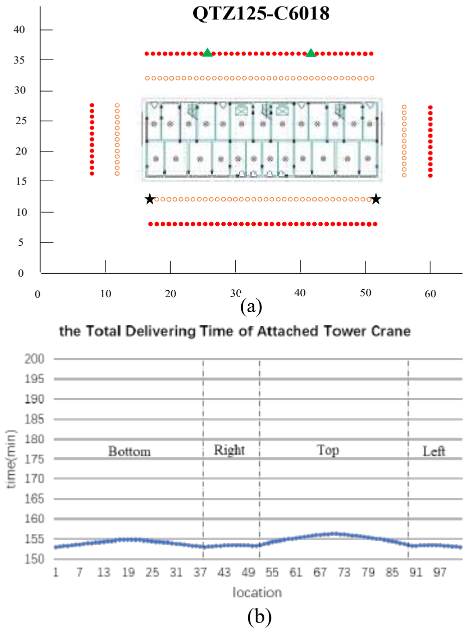

Figure 9 Results of situation II

Situation III: Supply point is fixed.

In order to comprehensive discuss this situation, this part is divided into three typical conditions:

1. fixed the supply point in the center at the bottom of attachment route;
2. fixed the supply point in the center at the left of attachment route
3. fixed the supply point in the angular point of the attachment rout

As shown in Figure 10-12, the optimal location of attached tower crane usually locates in another side of the attachment route, but not so far from the fixed supply point. The fixed supply point plays an important role in layout planning. Furthermore, when the crane lays right above the fix supply point, the total delivering time reaches the highest.

Among those situations, the line chart of situation II is the smoothest line and reaches the minimal time which indicates the importance of considering the layout planning in early stage. Meanwhile, it is a bad choice to lay attached tower crane just above the supply point that always leads to a costly result.

According to the proposed model, the mainly direct factors of the total travel time are the trolley sliding movement and jib rotation movement that influenced by the angle θ of ρ_D^K and the difference of ρ_S^K and ρ_D^K, respectively. And the optimization layout planning is to achieve a balance between the two factors.

Contrast with situation II and III, situation I is waster money which θ isn't able to less than 90 degrees while the difference of ρ_S^K and ρ_D^K is the same with others. Therefore, when solving the layout planning problem, the angle is a more important than the difference.

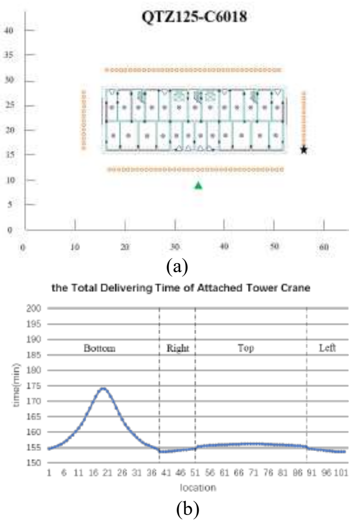

Figure 10 Results of situation III(i)

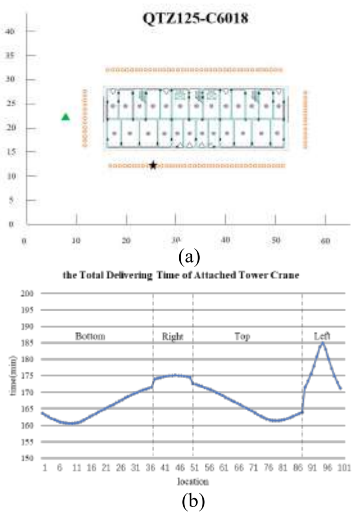

Figure 11 Results of situation III(ii)

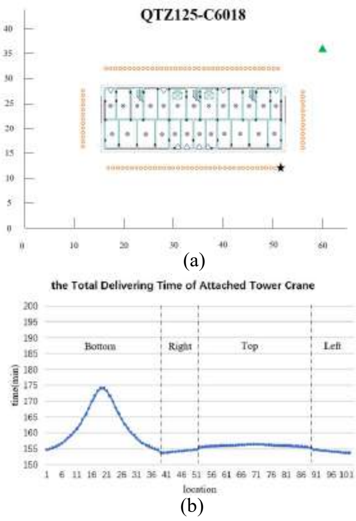

Figure 12 Results of situation III(iii)

6 Conclusion

This paper analyses the relationship among attached tower crane, demand point and material supply point, then simulates the movement of hook travel. Based on mentioned above, an optimization model is generated in order to select the type of attached tower crane and find the optimal location of the crane and material supply point based on finding the minimal cost. Furthermore, to evaluate and visualise the outputs, simulating the layout planning to ensure the optimal scheme is feasible and guide the site manager fully understand it. Finally, this algorithm leads to a more cost-efficient result than the traditional method that determined based on experience.

Compared with current study, the object of this study is attached tower crane, and this paper is more pertinent because it concerns the crane features as constraints when determine the layout planning. In addition, this paper discusses the main influence factors when positioning attached tower crane and supply point. Based on the practical case, many experiment has been done and reveals a few rules. The experiments are divided into three typical situations according to realistic site construction and aim to analyses the influence essential factors in layout planning. The results show that the angle between ρ_S^K and ρ_D^K is more important than the difference of ρ_S^K and ρ_D^K.

Abstract –

Simulation and predictive models to verify the energy performance of new or retrofitted existing buildings strongly need tuning procedures based on energy monitoring in the operational phase, thus to avoid performance gap concerns. The value chain of an uninterrupted information for energy models based on design data (e.g. for new buildings) or on paper documents and additional surveys (e.g. for existing buildings) is crucial to perform a reliable design optioneering process. The present research applies a BIM2BEM approach to provide a public administration with a model for facility management (i.e. BIM) and a model to assess energy improvement and check the choices (i.e. BEM), as a pilot project on school buildings renovation. Schools are frequently out-of-date buildings in harsh need of structural and energy refurbishment and public administrations require consistent economic evaluations considering the payback time of the proposed solutions. Additionally, O&M (Operation & Maintenance) costs should be included in a life cycle evaluation of the buildings. Two schools with different layouts and configuration adopted as case studies to compare energy simulation to actual consumption. The workflow empowers the energy simulation results highlighting the accuracy of energy modelling in different situations and it introduces possible tuning strategies to decrease uncertainty.

Keywords –

Predictive models; energy retrofit; BIM, interoperability.

1 Introduction

Nowadays, digitalization of design processes is BIM-based and allows an uninterrupted information chain [1] promoting a consistent energy model based on design data through BIM2BEM (Building Information Model to Building Energy Model) procedures enabled by gbXML interoperable format [2]. Furthermore, the possibility in existing cases to compare the predicted results with actual energy consumptions is imperative to identify suitable tuning criteria for energy models that always differs from real use [3]. The proposed BIM-based framework could empower in the whole life cycle an accurate evaluation of the building changes that are key factors to manage the asset and to guarantee the economic feasibility of renovation strategies [4]. The research aims at investigating how to use the BIM methodology for existing building management and how to implement energy retrofit strategies based on performance analysis by means of dynamic simulations accomplished through BEM. The main innovation and value is the interoperability of the models that allows to guarantee the conformity of the information in the design and evaluation environments. The possibility to extract the energy model from the BIM model is a step towards an optimized workflow that is not currently implemented in the practice when design and energy evaluation are always running on parallel tracks [5]. The performance gap that affect the energy simulation in comparison with actual performance in the running phase often heavily affects reliability of the models and time and cost are wasted to understand where is the misleading factor. Many factors collaborate on performance gap, however variability of occupancy, weather data, modeling assumptions and real performances of the building referred to designed and modeled ones are the main issues to be addressed [6]. The possibility to reduce the discrepancy of information and to define the reliability of simulation models is thus fundamental for AEC sector and to reach the nZEB goals. Different uses of the buildings are more or less prone to these errors and educational facilities are a very interested field of application because of the relevance of the thermal behavior of the building related to comfort conditions and learning performance of the users. At national level the school building stock is highly inefficient, as the 75% has been realized before energy laws [8][9] and thereby it is outdated and in need of retrofit and structural interventions [13] [14]. In the paper a new methodological approach is proposed defining BIM model for existing buildings and translating data to BEM models. A comparison of energy simulation and real consumption is used to understand the reliability of the model in different building configurations and to define tuning procedures that can be based on sensing and IoT.

2 Methods and tools

The use of the BIM methodology in combination with BEM energy analysis software for existing buildings is implemented in order to carry out preliminary analyses for renovation strategies and maintenance interventions to improve performance and reduce energy consumption. The data transmission between the two digital environments is guaranteed by interoperability which is the ability of a system to cooperate and exchange information with other different systems in a more or less complete and error-free way with the aim of optimizing resources reliably even between non-homogeneous information systems, both in software and hardware. This issue is becoming increasingly important when we talk about BIM-oriented design. The interoperability between BIM and BEM is a quite new issue and there are not many operational suggestions available for relocating data from architectural to energy models [7]. The data transfer process makes possible to keep the value chain of the information reducing discrepancies and possible inconsistencies contributing to exacerbate the performance gap, and increase time and cost of the realization.

2.1 Workflow

The analysis path uses Autodesk Revit as BIM authoring tool and IES VE as BEM dynamic simulation software (Figure 1). The architectural spaces defined in Autodesk Revit are defined as bounded analytical spaces and thus translated as thermal zones in the BEM. Analytical spaces are objects used to define and analyze of volumes that have thermal characteristics and specification allowing to store information about that thermal zone (e.g. occupancy rate, ventilation rate, temperature set points, etc.) to perform static and dynamic analyses on heating and cooling loads. The BIM model adapted for energy simulation should be enriched with data about thermal characteristics of the envelope, thermal specification for loads and parameters of the thermal zones and plants efficiency and typology. In this way it is possible to enable load calculation in the BIM environment or dynamic simulation in further simulation environments (directly into Green Building Studio or through *.gbXML file in IES VE, Design Builder, etc.). In the present research a workflow BIM2BEM through gbXML is adopted to eventually simulate the thermal behavior of two case studies.

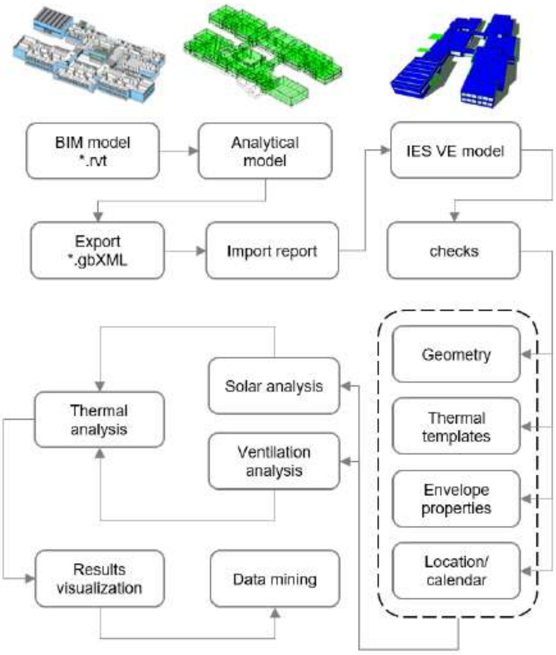

Figure 1. Workflow for interoperability BIM2BEM.

2.2 Scope and research problem

In the case studies the BIM methodology has been proposed to the public client (the Municipality of Seregno, Northern Italy) in order to manage the existing school building stock. The BIM2BEM path has been adopted to simulate different condition of the schools during time (and with refurbishments adopted in comparison with original situation) and to evaluate the advantages of different design options for further energy retrofit strategies (design optioneering). The information coming from the BIM database have been translated into the BEM simulation model to perform dynamic simulations. It is also possible to go back to enrich the BIM model with BEM calculated values for thermal spaces enabling a bi-directional information flow. In the present research the main scope was map the interoperability process and to test the reliability of energy model in comparison with energy consumption data through a data mining process.

2.3 Data mapping

The interoperability process needs a strong control and detailed data mapping to assure consistency of the model with the real conditions of the building spaces. The importing process through gbXML file is accompanied by an IES VE report showing the encountered problems and the measures taken by the software to fix them. The report also lists the presence of architectural holes in the external envelope, making impossible to carry out the energy analysis. The report is thus a first step to evaluate the process, however, a specific data mapping has been defined through *error sheet* to guide the process for further implementation of the methodology (Figure 3Figure 2).

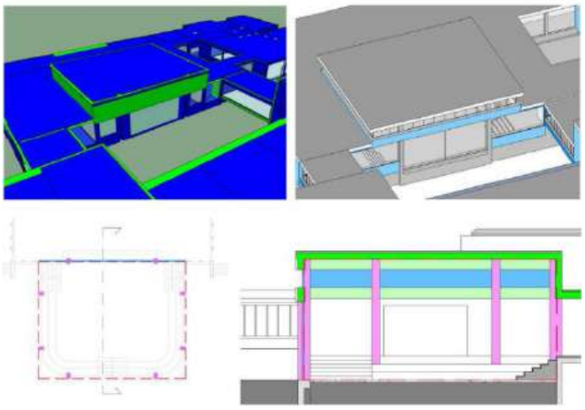

Figure 2. Specific data mapping of the import errors through BIM2BEM and suggestions for the simplification of the energy model.

3 Case studies

The research started with the analysis of the educational facilities in the municipality of Seregno, northern Italy where 11 educational facilities dating from 1900 to 1987 are located. The municipality of Seregno is located near to Milan in the province of Monza and Brianza and it is one of biggest cities strongly developed between ’80s and ’90s. the greatest part of the expansion of the city dates in the ’90s and the quality of construction about energy performance cannot be considered high due to the low level of insulation introduced by the national energy laws in 1976 [8] and 1991 [9]. The thermal transmittance that can be assumed for public buildings realized in that period ranges between 0.8 and 0.6 W/m^{2}K for vertical opaque envelope and 3.5 W/m^{2}K for transparent surfaces. Nevertheless, the school buildings have been previously realized as reported in Table 1, this means lower values that can be assumed about 1.1 W/m^{2}K for opaque envelope and 5.7 W/m^{2}K for transparent surface where no retrofit occurred [10]. The school building stock in Seregno is representative of the characteristics of the 62,000 national schools, that have a total annual energy consumption is about 11’630 GWh (i.e. 70% for heating and 30% for electricity). The specific heating and hot water consumption for public schools is about 180 kWh/m^{2}year whereas the requirement for new construction is less than 40 kWh/m^{2}year, according to current standards [11] and EU Directives [12]. The community of Seregno has 44,875 inhabitants. Given the high density of population, a growing number of schools have been developed over the years, both public and private, and currently the following structures are located in the territory:

- n. 9 nurseries;
- n. 3 kindergartens;
- n. 7 primary schools;
- n. 6 secondary schools of first grade;
- n. 7 secondary schools of second grade.

Among these 32 structures, 11 public schools where energy bills were available have been selected.

Table 1 School Facilities in Seregno, Northern Italy.

n.	Year	School Level	Floor configuration
1	1900-1920	Primary (Stoppani)	2	1920-1940	Primary (Cadorna)	3	1965	Secondary (Mercalli)	4	1969	Kindergarten (Nobili)	5	1970	Secondary (Manzoni)	
6	**1972**	**Primary (A. Moro)**	7	**1973**	**Kindergarten (H.C. Andersen)**	8	1974	Multilevel (Gianni Rodari)	
9	1975	Nursery (Aquilone)	10	1976	Nursery (San Carlo)	11	1987	Secondary (Don Milani)	
A first analysis has been focused on maintenance costs and BIM-based management strategies while for the present research, 2 case studies among these schools have been chosen to develop a detailed analysis in order to compare the dynamic simulation about thermal behavior with data on the actual consumption. The comparison aims at underlining the level of reliability of energy models and the discrepancy introduced by standard simulation setup compared to actual thermal behavior of the school buildings. The realization of the BIM model with different stages of evolution during time and with different architectural and retrofit development has been useful for the municipality to store information about the historical evolution of the assets. The interoperability path allows also estimating and verifying the energy consumption in the life cycle. Among the 11 schools two case studies has been selected considering the listed criteria:

- area > 1000 m^2;
- construction year;
- morphology;
- interventions occurred over time.

The two case studies are part of the same school complex, the "Aldo Moro" Comprehensive Institute: they are the Primary school “Aldo Moro” (n. 6 in table 1) and the kindergarten “H.C. Andersen” (n. 7 in table 1). It is worthy to note that the 82% of the school is configured in blocks with a distribution corridor, and one or two sides of classrooms. There are only two cases in which a different use and a more complex organization of the space can be guessed. The corridor-classroom distribution is the main traditional configuration that can be found in the national school building stock. A new concept of school related to pedagogic needs is addressed by the two different cases (n.5, n.7 in Table 1). The traditional primary school A. Moro has been simulated in two versions describing the upgrade introduced in the last 2 years regarding envelope retrofit to be compared with energy bills and the complex school kindergarten “H.C. Andersen” has been simulated in the original configuration and with the following extension, (i.e. 1/4 of the space was added during refurbishment).

3.1 Traditional school with a distribution corridor and one side of classrooms

The primary school “A. Moro” presents a traditional distribution of the educational spaces and it has been retrofitted by improving thermal resistance through an insulation layer for the opaque envelope and substituting the windows to increase thermal performance of the transparent envelope. The building has two main blocks in which different uses are hosted. The north side hosts the classrooms section while in the south block the gym, offices, auditorium and canteen are located (Figure 3).

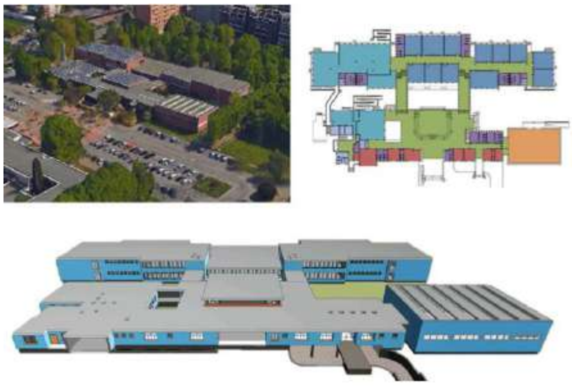

Figure 3. View of the Primary School “A. Moro”, floor area with functional spaces and BIM model.

The modelling process started with a detailed BIM model which included the two stages of implementation of the school: the original envelope configuration and the refurbished one. The refurbishment focused on the envelope increasing the energy performance of transparent and opaque envelope. Specifically the interventions have been: the windows replacement and the increased resistance of the opaque envelope by adding a polystyrene insulation layer.

3.2 Complex school with classrooms around a hall used as informal educational space

The kindergarten “H.C. Andersen” is the most significant complex school in the list of table 1. It has an L shaped ground floor, which has been extended with a fourth squared pavilion giving a final compact squared shape to the whole school. The school has ne floor and as can be seen in Figure 4, the floor plan has the classrooms located in different sides facing a wide common space as connection and distribution. It has also a didactic role for social skills improvement because for children it is very important to exploit informal spaces and learn how to exchange information in a sort of indoor playground. Therefore, the school configuration is a square with a central common space with skylights to bring the daylighting in the central area. A BIM model with the first configuration (L shaped) and the updated configuration (Square shaped) allowed the translation of the information to the energy simulation software. Once all envelope stratifications had been arranged in the BEM model and the correct association of the delimiting building components for each thermal zone has been checked, it is needed also to verify that the envisioned use of the rooms as set out in Autodesk Revit has been maintained. The energy software assigns to the rooms the specific use, which is closer to that defined in the BIM model. The verification of a multiple selection of rooms can be performed through the building manager tool. The database manager is used to set customizable profiles of each thermal (i.e. 7.30 a.m. to 6.30 p.m. for the school spaces and 10.00 a.m. to 1.30 p.m. for the kitchen, Saturday, Sunday and public holidays have been excluded).

Figure 4. Aerial view of the kindergarten “H.C. Andersen”, floor area with functional spaces and BIM model.

3.3 Interoperability process assessment

For both the case studies, problems in the data transfer process have been faced starting with the partial loss of information of the bounding elements of the single thermal zones.

A complete interoperability process should allow the import into IES VE of all the setups defined in the Autodesk Revit model. A partial interoperability is still a good result nevertheless the goal is to develop a workflow that could be easily managed and automatically replicated. Thermal zone delimitation and settings, envelope constructions, use of the spaces, schedule and thermal plants are the fundamental information to be included in the thermal model. Many information are missed if specific modelling strategies are not adopted in the BIM model. As first the internal partitions such as walls, floors and roofs should have active the local delimitation parameter in order to create the correct thermal zone.

In order to overcome specific losses of information about material stratification a fixing downstream procedure can be adopted selecting in detail the element and checking the assigned material and possibly adjusting the stratification directly in the energy simulation software. If the envelope type is transferred from BIM to BEM, a step forward is to check the integrity of the correct layering of the opaque envelope because material layers with no thermal definition in BIM are lost in the translation. This can occur for example for plaster or some substrate.

The problem can be solved by editing the envelope layering adding or replacing the missing layers with existing materials in the libraries or creating new materials. The adjustment and bug-hunting process is a time-consuming hard task. When the model has been completed in all its parts and the correct link between the various elements has been verified the energy simulation can be successfully performed. The results of the energy simulations have been compared to the energy bills in the last three years to confirm the accuracy and measure the uncertainty of the predictive model referred to actual energy use.

4 Results

Energy simulation of the two case studies have been performed in the four configuration (i.e. two for each case study) simulation the existing situation of the schools, before the retrofit and before the extension.

The predicted energy consumption related to the envelope but also to the thermal plants specifications have been compared with the energy bills collected in the archive of the Seregno Municipality.

The main results of the research is thus to emphasize the potential of the optimization process introduced as methodology that uses BIM data to simulate the building energy performance and can be directly compared to existing actual data with a confidence interval to be estimated. The successfully application of the methodology enables and speed up the process providing reliable results and thus potentially consistent economic feasibility evaluations.

4.1 Energy evaluation of the traditional school

In the case of the "A. Moro" school, which has a traditional layout configuration, the energy gave monthly results according with the actual energy bills although a standard setting of the indoor space has been adopted. The standard setting includes data about internal gains, people density, ventilation rates, temperature set points and time schedule that are derived by commonly adopted value for the traditional building use. The more traditional distribution of school with spaces organized as commonly adopted since 1900 has less discrepancy compared to complex and innovative solutions and thus it can be expected that some parameters could not be equally fitting in the traditional and complex schools of the case studies.

Coming back to the "A. Moro" school, in Figure 5 the comparison between the original version and the retrofitted building is shown. The envelope solutions introduced clearly enhance the thermal behavior in the winter period. It is worthy to note that while the most complex "H. C. Andersen" school required to make conscious alterations to the templates changing from the standard data setting to a specific custom definition, for the traditional primary school no additional tuning was needed to obtain a result with an acceptable percentage gap between simulation and energy bill (Figure 6).

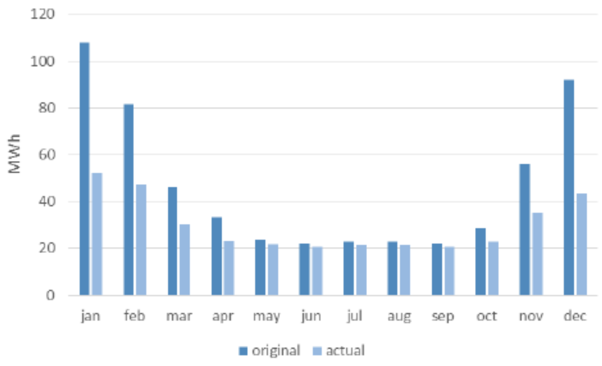

Figure 5. Primary school “A. Moro”: energy consumption simulation of in the original situation and the retrofitted version.

Figure 6. Primary school “A. Moro”: actual energy bills compared to energy consumption simulation and the percentage gap between simulation and real data.

The acceptable uncertainty level is also due to the geometry of the spaces, which inevitably affects their use and also they have been designed with a specific vocation. Actually, the corridor facing the classrooms is not conceived as a place of permanence of the students, it is a simple element of distribution and connection and its size is not exceeding the tolerance of an aggregated energy use and setting. On the contrary, precisely because in the kindergarten "H. C. Andersen" there is neither a need nor an obligation to keep pupils in classes, the school has been designed with a central internal space conceived as a wide circulation space that is also a covered playground suitable for expression of sociality. Consequently the space is constantly used to host the different activities carried out in the school and the children have the possibility to relate with a different space that seem a square or an open space for events with a zenithal daylighting that is far from the traditional enclosed learning space of the classroom. Hence, the configuration of school building should also take into account the specific needs that the different types of pedagogic training require. The school is not indeed a kindergarten however in the setup of simulation and in the assumption the same standards are often supposed.

4.2 Energy evaluation of the complex school

The kindergarten “H.C. Andersen” increased its energy consumption in 2014 when the new section of the school has been realized. In Figure 7 the energy bills and in the original situation (L shaped building) and in the following three years are reported. The average value has been also added as currently adopted procedure to compare energy simulation to actual consumption.

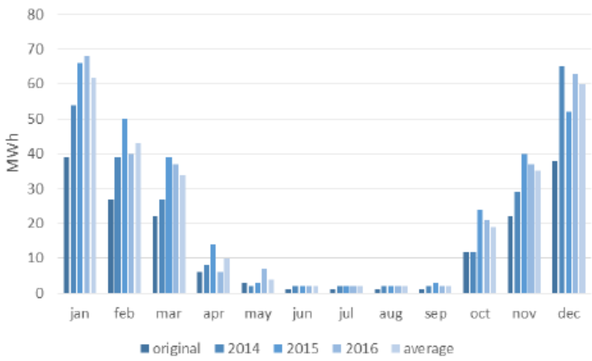

Figure 7. Kindergarten “H.C. Andersen”: energy consumption simulation of in the original situation and during the following three year of operation phase.

The first simulation using the BIM based data has been enriched in the BEM setup with standardized value of people density for the occupancy schedule, nevertheless the particular configuration of the central space defined a different scenario. For that reason the first result diverged from the energy bill of about 40% and therefore a fine tuning of the model have been performed. The standard people density equal to 0.5 people/m^2 adopted for standard school is suitable for classroom spaces however in the complex school case study the central space is used with a lower density that is not comparable to the standard value however educational activities take place. The schedule of use were also re-defined to address this different occupancy rate into the space. Furthermore, a higher temperature compared to the standard value, due to the children presence and the space in which the fan coils are not effective into heating the core part of the school has been established. With this fine tuning procedure and measures the percentage of discrepancy decreased to less than 20% compared to the three years average value of the energy bill (Figure 8). A detailed assessment of users' flow has not been introduced in this stage of the research however could be interesting in future research development. Could be useful to stress that the level of the school and the methods of use are not too flexible, although obviously some uncertainty of the results is linked to the variability of occupant attendance to the classes.

	original	2014	2015	2016	average
energy bill	174.38	243.86	297.19	286.92	275.99
energy consumption	123.07	230.36	230.36	230.36	230.36
percentage gap	29.4%	5.5%	22.5%	19.7%	16.5%

Figure 8. Kindergarten "H.C. Andersen": actual energy bills compared to energy consumption simulation and the percentage gap between simulation and real data.

5 Conclusion

The aim of the research was to explore the possibilities of comparing building consumption directly to predictive models realized through an interoperability BIM2BEM process. The digital twin of the building allows creating an archive of the retrofit interventions and a database for the asset management in the life cycle. The BIM model also permits the transfer of the stored information to other platforms adopted for specific energy assessment and simulations. Through the BIM2BEM interoperability path, an uninterrupted information chain is created generating additional value and ensuring process consistency. By means of predictive models, adjusted and customized during the different phases of the building's life cycle, it is possible to evaluate the design optioneering in an analytical way enabling conscious choices based on results whose accuracy must be verified and double checked.

It is particularly important to give reliability to the process in order to verify the simulation results to critically understand the thermal behavior of buildings. It is very important to ensure the accuracy when approaching existing buildings the need to be upgraded. In fact, the economic feasibility of the retrofit interventions is strictly related to the accuracy of energy savings that can be predicted in the design phase. Too often the energy intervention are not supported by reliable energy calculation and declared NZEB are not NZEB, are not that efficient and the goal is unattended. In the school is also crucial to assure that indoor conditions will be comply with standard comfort level to implement and support learning performance and users' development. Finally, a complete interoperability process needs to be ensured in order to promote reliability and to improve the information management in the BIM2BEM process. The manually implemented part is an adjustment which decreases the level of detail of the BIM in order to reduce the errors in the BEM. This process requires accuracy and simplification not involving crucial elements to assess the thermal behaviour of the building.

Acknowledgments

The authors would like to mention and thank Arch. Manuel Mancosu and Arch. Laura Canonico for the setup of the models and the fundamental work on the simulation process. The research starts from the work of Eng. Federico Gulino, where documentation about the Seregno school building stock has been collected and analyzed. A special thank goes to the Municipality of Seregno for the support and cooperation in collecting data and availability of materials.

Abstract –

Building management systems monitor and control building performances in real-time. Most control systems, which have been developed in the last decade, achieve the required performances relying on a centralised and hierarchical framework. In the regular operation phase, these systems are usually able to efficiently reach their goals, whereas they often fail to stick to pre-determined targets in the presence of unforeseen disturbances. As a matter of fact, traditional control systems suffer complex unforeseen scenarios that cannot be modelled by the analytics and knowledge integrated in these systems, because hierarchical systems strive to keep full control at any level.

As an alternative, holonic management systems, which have been successfully applied in the manufacturing field, can tackle this type of drawbacks. The flexibility of their elementary units, the holons, makes it possible to avoid the rigid structure of hierarchical systems so as to respond quickly to disturbances and dynamically re-arrange their structure.

In this paper, a first holonic computing structure is developed for indoor comfort management in an office room. The structure developed can drive both the operation management phase and the medium- and long-term measurement of performances. The former is implemented by means of a sequence of specific minimum cost actions which is based on the overall throughput effectiveness (OTE) metrics. The latter exploits the same OTE metrics to suggest corrective and improvement actions. Finally, OTE diagnoses are re-directed to a BIM model to support decision making for long-term improvement actions on the building facility.

Keywords –

Intelligent Buildings, Building Management System, Holonic System.

1 Introduction

Building management is the process of monitoring and controlling the operating systems within building facilities. In the case of indoor comfort control, it includes heating, air conditioning, ventilation and shading units. Most commercial control systems, which have been developed in the last decade, achieve building indoor comfort relying on a centralised and hierarchical framework. Their hierarchical structure is usually made up of the following top-down layers: data acquisition, data transmission, data interpretation, performance evaluation and optimisation [1]. Strict master-slave relationships between layers imply top-down control decision, whereas bottom-up status reporting is implemented [2]. In the operation phase, hierarchical building management systems are usually able to reach their goals in an efficient way and with no faults, whereas they fail to stick to pre-determined targets in the presence of disturbances. In fact, traditional systems cannot pursue the assigned task if any unforeseen events occur. Their rigid structure makes it very difficult to tackle unexpected scenarios. As low-level modules have to consult higher hierarchy levels in case of a disturbance, their reactivity becomes weak. Furthermore, global decision-making is often based on obsolete information [2].

In this paper, a first holonic computing structure based on CPS technology is developed for the indoor comfort management in a room used as an office in a large public building. The operation management is managed by a control based on the measurement of the effectiveness of every device intended as a unit of the system of systems which applies a well-defined sequence of specific minimum cost actions. During simulations, an overall throughput effectiveness (OTE) metrics measures the subsystems' performances and drives corrective actions for their enhancement [3]. Finally, suggestions, history and lessons learnt from the OTE evolutions are re-directed to a BIM model to support decision making for the improvement of the whole building performance and design.

This paper is organised as follows. Section 2 provides a literature review of the holonic approach that was adopted in the present research. Section 3 describes the case research methodology. Section 4 provides a description of the case study. Section 5 shows the simulation results. Section 6 is devoted to conclusions.

2 Literature Review

The holonic concept, which is the basis of holonic management systems, was introduced in 1967 by Koestler [4]to explain the evolution of biological and social systems. Likewise, in the real world, where almost everything is at the same time a part and a whole, each holon can be part of another holon [2]. In fact, the word holon is the combination of "holos", which in Greek means "whole", and the suffix "on", which suggests a part [5], [6], [7]. In the manufacturing field, holons are autonomous and cooperative building blocks, since they can both control the executions of their own strategies and develop mutually acceptable plans [2]. Furthermore, holons consist of an information-processing part and often a physical processing part [2], [5], [6]. The former is responsible for high-level decision making, collaborating and negotiating with humans and other holons, while the latter is a representative of its linked physical component and responsible for transferring decisions and instructions to it [5]. According to Koestler, a holonic system or holarchy is then a hierarchy of self-regulating holons that function (i) as autonomous wholes in supra-ordination to their parts, (ii) as dependent parts in subordination to control at higher levels, and (iii) in coordination with their local environment [2], [4], [7]. Therefore, holonic architecture combines high and predictable performance, which distinguishes hierarchical systems, with the robustness against disturbances and the agility typical of heterarchical systems [6]. In this way, systems' resilience is guaranteed.

The agent, which in latin is "a person who acts", is a software-based decision making unit embedded with internal knowledge. Unlike holons, no such separation of physical and information processing parts exists in agents' structure. Furthermore, whereas holons can themselves be made up of other autonomous holons, agents do not immediately apply the recursive architecture [2], [5]. A multi-agent system is made up of two or more related agents [2], [7].

Cyber-physical systems, in the manufacturing field, are systems of collaborating computational entities which are in intensive connection with the surrounding physical world [8]. The interaction between physical and cyber elements is of key importance to the purpose of this paper. As a matter of fact, cyber-physical systems, similarly to holons, consist of a cyber part and a physical part. This shared feature makes holonic paradigm a suitable approach for constructing and modelling a CPS system in the form of a holarchy. Therefore, on the one hand, a CPS system permits bidirectional coordination of virtual and physical levels and, on the other, the holarchy, with its flexibility, guarantees evolutionary self-organisation or, in other words, resilience [5]. Moreover, CPS systems provide an opportunity for changes in the physical structure to be captured and reflected in the virtual model. Conversely, changes in the virtual model can be communicated to sensors embedded in the physical world [9], [10]. To implement these concepts in real world applications, agents are key enablers, since they act as decision-making and communication entities with agents embedded in other holons and also humans [5], [6]. Holonic management systems, which have been successfully applied in the manufacturing field, can constitute a novel technology to tackle unforeseen scenario variations. Indeed, the autonomy and cooperation of their elementary units, the holons, makes it possible to avoid the rigid structure of hierarchical systems and therefore respond quickly to disturbances [2].

3 Research Methodology

The holonic computing structure developed in this paper involves three development environments, Matlab®/Simulink®, SQL and Revit® (see Figure 1). The Revit® environment concerns the BIM Digital Model (BIM DM, see Section 3.2), as the interface of one of the numerous BIM softwares available on the market, such as Autodesk® Revit®. The Matlab® and SQL environments share the Decision Support Tool (DST, see Section 3.3), which has the function to assess the system of systems' effectiveness and suggest a list of possible corrective actions.

In addition to the DST, the SQL environment involves the BIM Relational Model (BIM RM, see Section 3.2), i.e. a relational database that acts as a bridge between the DST and BIM DM and has a double function. The first function is to update the DST when the BIM DM changes. The second one is to store effectiveness data received from the DST to run building diagnoses. The BIM RM and BIM DM exchange data in both directions, thanks to the Revit® DB-Link plug-in. In this way, the SQL and the Revit® environments are connected.

The Matlab® environment consists of the Supervision Policy (SP, see Section 3.4), the Virtual Simulation Laboratory (VSL, see Section 3.1) and the

DST block.

The measures taken from the VSL provide feedback (delayed by 1 step in order to be realistic) for the decision support tool. The DST evaluates and updates the OEE of each cell by means of SQL queries, then it updates the OTE in all the system's tree and suggests a list of possible actions to the Supervision Policy. Among the actions suggested by the DST, the Supervision Policy selects and applies the one to be carried out in the Virtual Simulation Laboratory based on some internal logic/intelligence.

In Figure 1 all these entities and their relationships are depicted.

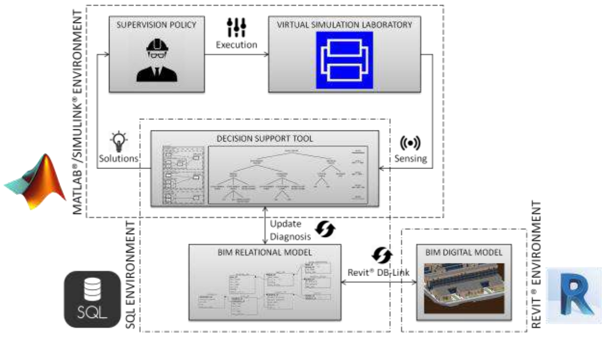

Figure 1. The architecture of the holonic computing structure developed based on CPS technology.

The holonic computing structure developed and implemented by integrating Simulink®, SQL and Revit® environments makes it to carry out any type of desired simulations away from the site.

3.1 Virtual Simulation Laboratory

The Virtual Simulation Laboratory is in charge of replacing and emulating the real building by using a detailed building model. This model was developed in the Dymola® programming environment, which is based on the Modelica® Language. Traditional simulation tools for thermal modelling are usually domain-dependent modelling environments. Whereas, Modelica® brought in relevant innovations allowing for equation-based modelling using program-neutral model description, domain-independent solution methods and the capability of exporting models as Functional Mockup Units (FMU).

The building model used in this work is built upon the open-source Modelica® "Buildings" library [11] and it has the level of detail that is necessary to analyse the behaviour of each device and sub-system belonging to the building. For the purpose of this paper, but without loss of generality, a model of the building restricted to the third floor is considered. However, a preliminary comparison of the comprehensive model with the one restricted to the third floor showed negligible differences. The model was then translated and compiled as a FMU so as to be embedded in the VSL through the Functional Mockup Interface (FMI).

By exploiting the capability of the FMI Kit for Simulink®, provided with Dymola® 2018, the VSL was integrated in the cyber physical system depicted in Figure 1 as an FMI block in co-simulation mode. The selected control inputs for the VSL are three actuator inputs normalised between 0 and 1: the shading level (SL), the fan coil level (FCL) and the window level (WL). The variables measured are both from indoor and outdoor. Indoor measures taken from the controlled room are: air temperature, relative humidity, CO_2 concentration, cooling power, AHU air flow rate, number of people. Outdoor measures are collected by a weather station included in the VSL which provides: air temperature, relative humidity, barometric pressure, wind speed and solar radiation on the horizontal plane.

3.2 BIM Relational and Digital Model

In this paper the BIM Relational Model and BIM Digital Model are two sides of the same coin, the practical and the formal side, respectively. The BIM DM of the building under analysis was developed using Autodesk® Revit® and then translated into its congenital relational structure, namely the BIM RM. Hence, the BIM Model works as a repository of any types of data that belong to the building analysed.

The connection BIM RM-DST, as mentioned, provides the opportunity to define and update the scheme of the DST after changes to the building. In addition, the same link provides, in the other direction, the possibility of auto-diagnosis of the holonic management system developed. Actually, the BIM model becomes a repository of the facility history or of the potential actions of improvement concerning the building. Indirectly, a bi-directional communication channel is set up, i.e. a learning phase of the VSL from the BIM repository and the storage of real-time data from VSL into the BIM model.

In order for this to happen, the relational potential of the BIM has to be fully expressed. The underlying BIM representation of the information can be leveraged and further extended to create a mapping between a relational database. Note that the full Relational Model (RM) is intended in the sense described in [12]. In the RM everything is a relational variable (*relvar*). Tables, attributes and database schemas cannot usually be operated relationally. In current SQL-based database management systems (DBMS), these operations are implemented with non-standard host language proprietary extensions for the specific DBMS implementation. By a homomorphic mapping between

Table 1. OTE metrics computing formulas in recursive form adapted from [13].

Interconnection type		OTE of parent holon	R_{th} of parent holon	Q_{eff} of parent holon
Series		$\frac{\min\left\{\min\limits_{i=1,\ldots,n-1}\left\{OTE_i \cdot R_{th,i} \cdot \prod_{j=i+1}^{n} Q_{eff,i}\right\}, OTE_n \cdot R_{th,n}\right\}}{\min_{i=1,\ldots,n}\left\{R_{th,i}\right\}}$	$\min\limits_{i=1,\ldots,n}\left\{R_{th,i}\right\}$	$\prod\limits_{i=1}^{n} Q_{eff,i}$
Parallel		$\left(\sum\limits_{i=1}^{n} OTE_i \cdot R_{th,i}\right) \Big/ \sum\limits_{i=1}^{n} R_{th,i}$	$\sum\limits_{i=1}^{n} R_{th,i}$	$\frac{\sum\limits_{i=1}^{n} Q_{eff,i}}{n}$
Assembly		$\frac{\min\left\{\min\limits_{i=1,\ldots,n}\left\{OTE_i \cdot R_{th,i} \cdot Q_{eff,a} / k_{a,i}\right\}, OTE_a \cdot R_{th,a}\right\}}{\min\left\{\min\limits_{i=1,\ldots,n}\left\{R_{th,i} / k_{a,i}\right\}, R_{th,a}\right\}}$	$\min\left\{\min\limits_{i=1,\ldots,n}\left\{\frac{R_{th,i}}{k_{a,i}}\right\}, R_{th,a}\right\}$	$\frac{\sum\limits_{i=1}^{n} k_{a,i} Q_{eff,i}}{\sum\limits_{i=1}^{n} k_{a,i}} Q_{eff,a}$
Expansion		$\frac{\sum\limits_{i=1}^{n} \min\left\{R_{th,e} \cdot OTE_e \cdot k_{e,i} \cdot Q_{eff,i}, R_{th,i} \cdot OTE_i\right\}}{\sum\limits_{i=1}^{n} \min\left\{R_{th,e} \cdot k_{e,i}, R_{th,i}\right\}}$	$\sum\limits_{i=1}^{n} \min\left\{R_{th,e} \cdot k_{e,i}, R_{th,i}\right\}$	$\frac{\sum\limits_{i=1}^{n} k_{e,i} Q_{eff,i}}{\sum\limits_{i=1}^{n} k_{e,i}}$

the BIM and its relational representation, we obtain the opportunity to develop new structured types that make it possible to record relational information and data. For example, in a BIM entity, it is possible to completely record the real-time history of parts of the building equipment as obtained from sensors. Moreover, it is also possible to record a tracking of the BIM structural changes over time. With data mining, knowledge extraction and representation techniques, some information can be grown upon, enriched, and a reasoning system can be integrated into the relational model of the building. This allows us to make BIM the core of short-term control and medium- and long-term design evolutions and adaptations on the building endowed with intelligence.

As a first experiment, the best available technology on DBMS has been used as a proof of concept. In order to interact bi-directionally with the BIM, the building digital model has been mapped to an SQL Server DBMS using the Revit® DB-Link plug-in. It permits the flow of information between Autodesk® Revit® and the DBMS in both directions. In this way BIM is updated with changes applied from the reasoner or the controller, and receives the real-time data from the virtual or physical models or the sensors. A workaround to the limited relational possibilities has been temporary created by extending some of the basic elementary BIM attributes with a numeric type that creates a primary key to some relations that can store real-time data tables or even a complete (nested) database schema.

3.3 Decision Support Tool

The operation management, as anticipated, is led by a pervasive control of the effectiveness of the system of systems. In other words, during simulations, an overall throughput effectiveness (OTE) metrics measures the subsystems' performances and drives corrective actions towards their improvement [3].

The distributed performance metrics, inherited from the manufacturing field, defines the overall factory effectiveness (OFE), the overall throughput effectiveness (OTE) and the overall equipment effectiveness (OEE). These parameters, whose values are between 0 and 1, are effectiveness indexes referring respectively to the highest level, intermediate levels and the lowest levels of a system's performance. The OEE metrics of one of the lowest production equipment is defined as follows:

$$OEE = A_{eff} \times P_{eff} \times Q_{eff}, \tag{1}$$

where the availability efficiency A_{eff} captures the deleterious effects due to breakdowns, the performance efficiency P_{eff} captures productivity loss due to reduced speed, idling or minor stoppages, and, finally, the quality efficiency Q_{eff} captures loss due to defects [3]. Subsequently, by applying the formulas in Table 1, the effectiveness of every system's cells is determined.

Note that OTE is a recursive function of OEE. This means that OTE is equal to OEE at the leaves of the recursive system's tree. OTE expression depends on four fundamental types of interconnection structures: *series*, *parallel*, *assembly* and *expansion*. In Table 1 we adapt the formulas and the structures from [13] that determine the four kinds of interconnection.

The parent-children relationship affecting elements located at different levels of the system is explained focusing on the assembly that is associated to the active thermal source (see Figure 2 and Figure 3). Once the OEE of the "children" fan coil unit (FCU), shading (SHA) and *assembly* cell (a_{ATS}) are defined, the OTE of the "parent" active thermal source is calculated using the *assembly* formula in Table 1. This is the procedure by which the whole systems tree is compiled with OEE/OTE values. Afterwards, by means of the Event-Condition-Action (ECA) calculation model described in [3], the DST provides, for each iteration, a list of suggested corrective actions.

The development of the structure of the DST follows two necessary and practical steps. The first one consists in defining the system's scheme with semantics. It could be defined as the closest representation to the humans' way of thinking (see Figure 2). Subsequently, the previous scheme is translated into the system's tree, defined, conversely, as the closest representation to the computing structure (see Figure 3). The system's tree shows the reconfigurability, scalability and robustness typical of holarchies, in other words, resilience. Indeed, it can be adapted to environment changes. At any level of it, the tree instance can be changed or dynamically reconfigured on purpose.

Both the system's scheme in Figure 2 and that in Figure 3 are made up of *cells* (the leaves of the tree) whose semantics is described as follows:

- TC: thermal conduction affecting external room's partitions;
- FCU: fan coil as a piece of equipment that is able to provide a cooling power;
- SHA: shading as a device that is able to reduce solar radiation, providing a fraction of it;
- LEA: air leakage through external room's envelope;
- WIN: window as a piece of equipment that is able to provide a moisture content variation and air flow;
- AHU: air handling unit as a piece of equipment that is able to provide a moisture content variation and air flow;
- a_{ATS}: room's mixing capacity of cooling power from thermal sources, function of room's shape and whose specific proportion is defined by k;
- a_{TS}: room's mixing capacity of cooling power from thermal sources, that is a function of the room's volume and whose specific proportion is defined by k;
- a_{HS}: room's mixing capacity of moisture content from humidity sources, function of room's volume and whose specific proportion is defined by k;
- ACR: air change rate defined by the amount of fresh air flowing in the room and its volume.

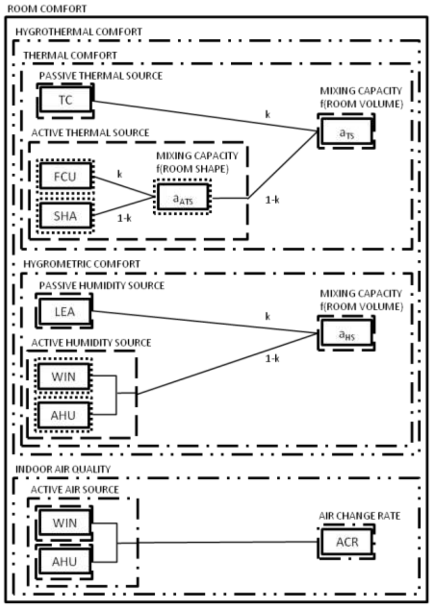

Figure 2. System's scheme developed for the case study.

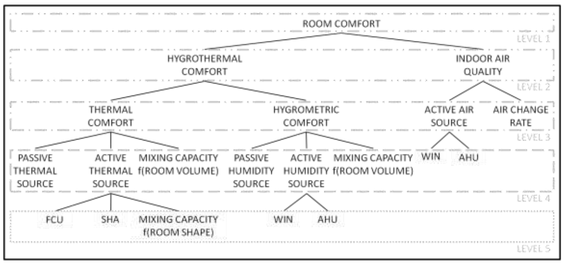

Figure 3. System's tree developed for the case study.

3.4 Supervision Policy

The Supervision Policy (SP) represents an intermediate step between the DST and the VSL (see Section 3.3and Section 3.1) whose function is similar to the one of a manager. Indeed, this entity selects, among the actions suggested by the DST, the action to carry out or leaves the status unchanged (no action). Hence, the SP defines the criterion by which the system acts or does not act. In addition, this "manager" has the ability to learn from the past (i.e. from the BIM, see Section 3.2). The effects obtained during the previous days suggest confirming or changing corrective actions.

In the simulations discussed in Section 5, the policy assumed for short-term operation management sets:

- high priority to thermal comfort (achievable by means of shading closing/opening and fan coil unit power on/off), average priority to indoor air quality (achievable by means of window opening/closing) and low priority to hygrometric comfort (achievable by means of window opening/closing). This means that, if actions are suggested for each sub-system, the first action field is thermal comfort, the second one is hygrometric comfort and the third is indoor air quality. This assumption does not imply that a field action is less important than another one, since the time step of each iteration is short (i.e. 5 minutes);

- higher priority to shading closing than fan coil unit power on and higher priority to fan coil unit power off than shading opening, in order to pursue thermal comfort according to energy saving principles;
- that a lower-priority action will be carried out in the following iteration if the related low performance persists;
- that if a higher-priority action is already running, the selection skips to the lower-priority one;
- that if more than one action for the same sub-system is suggested, the highest gain action is selected.

4 Case Study

Eustachio is the building where the Faculty of Medicine of the Polytechnic University of Marche, Ancona, Italy, is located. This is a large and multi-purpose building composed of two main blocks that create a clear division between the main fronts: the north and the south ones. It is equipped with a traditional building management system (BMS). The heating system is a two-pipe type and the air-handling system serves the north and the south fronts separately. Consequently, the building has some symptomatic discomfort problems like, for example, too high temperatures during winter, too low temperatures during summer, while mid-season temperatures are out of control.

In this paper, the focus is on one office room (i.e. room no. 90), located on the third level of the south front and used as an office (Figure 4). Its net surface is approximately 19 m^2 and the three-module window is about 7 m^2 large, with one module operable. The air handling unit in room no. 90 causes just air recirculation, since the humidifier does not work. The fan coil unit is a FC200 type and, for the purpose of the paper, only its cooling function in the summer season is considered. In addition, a shading system is also included. The actual BMS manages the cooling phase triggering both the fan coil unit and the shading device at the setpoint temperature of 26 °C.

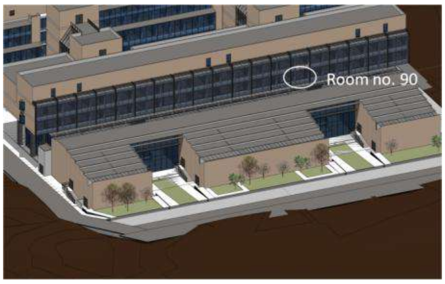

Figure 4. Room no. 90 in a 3D view of the Eustachio building's BIM digital model.

5 Simulations Results

The holonic management system, described in this paper is experienced for the month of June 2016. In this period, weather data define really dynamic boundary conditions able to strongly urge the system. The simulations for this representative scenario aim to prove the system's ability to perform short-term operation management in real time and diagnoses of building with regard to medium- and long-term refurbishment. Such diagnosis ability differentiates the holonic management system at issue from common BMS.

5.1 Operation Management of Building

The holonic management system accounts for building operation, regulating shading level (SL), fan coil level (FCL) and window level (WL) towards indoor comfort. In other words, it can put into practice instructions from the DST, i.e. suggested actions to reach system's improvement, according to the supervision policy (see Section 3.4). Although simulations were carried out for the whole month of June, in this paper only the simulation results of one day are discussed. The following charts show simulation results for the 17th of June. When operating temperature T_{op} exceeds the setpoint T_{set} (see Figure 5.a), the system reacts at first by closing the shading (see Figure 5.b, SL = 0.900) and then switching on the fan coil unit (see Figure 5.e, FCL = 1.000). The shading remains closed longer, giving priority to fan coil unit power off, according to the supervision policy aiming to save energy. When indoor relative humidity RH_i is far from the setpoint RH_{set} and, at the same time, outdoor relative humidity RH_o can help to improve it (see Figure 5.b), the system reacts by opening the window (see Figure 5.f, WL = 0.056). Finally, the system reacts to room overcrowding, which causes too high CO_2 concentration (see Figure 5.c), by opening the window (see Figure 5.f, WL = 0.112).

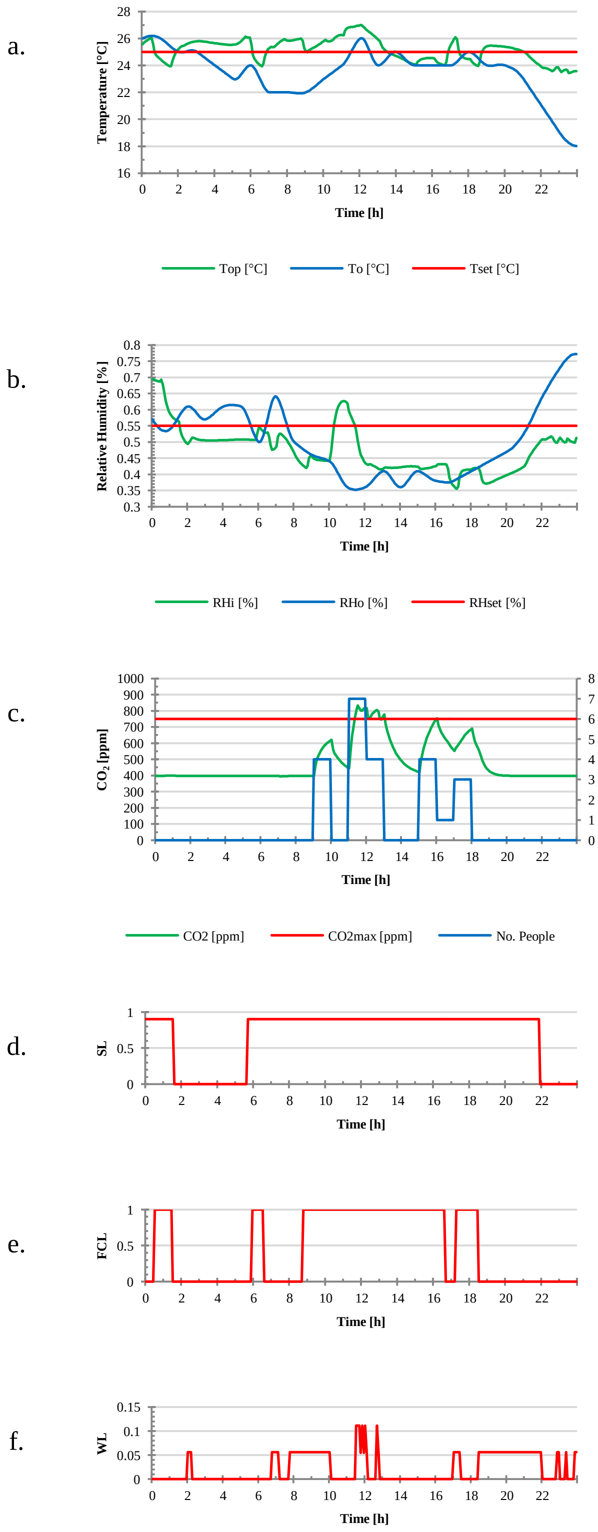

Figure 5. Operation management results for the 17th of June. Trends of a) temperature, b) relative humidity, c) CO_2 concentration vs number of people inside room no. 90, d) shading level (SL), e) fan coil level (FCL) and f) window level (WL).

5.2 Diagnosis of Building

The holonic management system makes it possible to carry out diagnoses on buildings by focusing on the system of systems' and cells' effectiveness mean value. In fact, BIM RM (see Section 3.2) can:

- store system of systems' time data, such as OTE/OEE time values, creating a repository of the facility history;
- store and re-direct their mean values, which are continuously updated according to the last iteration, to the BIM DM (see Section 3.2) in order to visualise them inside Revit® environment (e.g. during refurbishment design of building).

Low mean values of OTE and OEE highlight entities that cannot pursue the assigned target towards room comfort. Figure 6 shows OEE monthly mean values (June 2016) for the system's *cells* (the leaves of the tree) whose semantics is described in Section 3.3. The histograms point out the highest effectiveness of Indoor Air Quality sub-system. In fact, the room assumed as case study has a good air change rate (OEE_{ACR} = 0.90) and window ($OEE_{WIN(IAQ)}$ = 0.76) and air handling unit ($OEE_{AHU(IAQ)}$ = 0.86) ensure a satisfactory ventilation in June. Whereas, the room's external partitions are not effective in terms of thermal conduction (OEE_{TC} = 0.16) for indoor thermal comfort, since they are made of glass and metal. The shading (OEE_{SHA} = 0.19) and fan coil unit (OEE_{FCU} = 0.32) show possibility of improvement, since the former can be extended to the whole glass façade (both the transparent and the glazed part) and the latter can be boosted up. Results about hygrometric comfort point out how the window ($OEE_{WIN(HC)}$ = 0.67) and air handling unit ($OEE_{AHU(HC)}$ = 0.62) ensure a good enough contribution to optimal indoor relative humidity and room's external partitions are not effective, because of air leakage (OEE_{LEA} = 0.34).

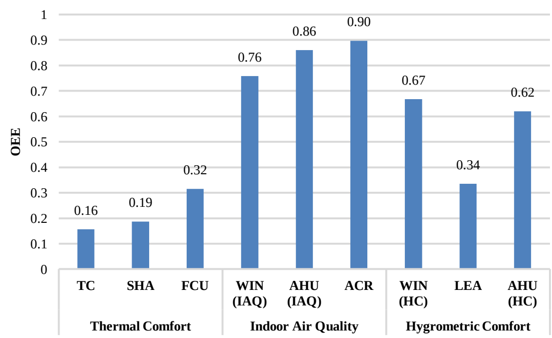

Figure 6. OEE monthly mean values (June 2016).

6 Conclusions

The holonic computing structure, which involves Matlab®/Simulink®, SQL and Revit® development environments, is experienced in a room used as an office. This computing structure works in two directions, the short-term management of building operation and the medium- and long-term diagnoses and refurbishment. In fact, the system shows its ability to reach a target, managing different parameters and devices and following an agreed policy. Besides, the connection of the above mentioned environments ensures diagnoses of buildings based on data history regarding system of systems' effectiveness.

Abstract –

As an elementary part of building projects, construction logistics encompasses planning, control and monitoring functions to ensure the flow of materials and people on the construction site. Furthermore, it includes the management of storage areas and site facility planning. Despite its importance, the implementation of construction logistics often does not occur systematically. In practice, the project phases in which its planning and implementation take place as well as the considered degrees of detail differ significantly depending on the project conditions, such as the projects' complexity, involved stakeholders or the scope of the construction project.

In this paper an approach is presented that facilitates a systematic and holistic planning of construction logistics over all project phases on basis of lean construction principles. To achieve this, the coordination of all domain-specific stakeholders (e. g. construction logistics planners, site managers, contractors) is essential. As a work basis, construction logistics planners can create a specific digital construction logistics model (CLM) derived from the digital architectural model. This CLM can be used to schedule deliveries and storage areas, as well as logistics related information (e.g., delivery dates, storage areas, escape routes, waste collection points or construction site equipment elements).

Construction logistics has to be generally accepted as an own domain-specific role during and especially in the beginning of construction projects to ensure the regarding of all necessary processes and requirements towards the construction logistics.

1 Introduction

A way to optimize processes is to use the methods and tools of the Lean Thinking (LT) approach. Their application allows the optimization of processes aiming at minimizing waste and increasing efficiency. By this approach, an optimally use of resources is facilitated. In order to switch from the conventional to a LT-based working method, an analysis of the processes as well as economic and technological aspects have to be carried out first. The approach of adapting LT methods to the construction industry has been investigated since the early 1990s. For this purpose, the International Group for Lean Construction (IGLC) was founded in 1993 [9]. Although this process of implementing LT in the construction sector has been going on for nearly 30 years, it is only applied in a minority of projects. Recent studies pointed out that the application of the Building Information Modeling (BIM) methodology can facilitate the implementation of Lean Construction (LC). The thereby rising synergies can lead to the generation of a significant additional value [13].

This paper examines the construction logistics as one crucial part of construction projects in the context of the interaction between BIM and LC. It is based on the results of a master thesis [10] written at the Institute of Numerical Methods and Informatics in Civil Engineering (IIB) at Technische Universität Darmstadt. It forms a starting point for further research. The overall goal of this future work is to investigate how the holistic integration and linkage of both approaches over all project phases can improve the projects' results as well as facilitate a more cooperative way of interaction between all stakeholders.

Due to the high demands towards construction logistics, construction projects in densely built-up areas are regarded as a field of application; Resulting constraints are, for example, the limited amount of space available inside and outside of buildings or the tense traffic situation in the surrounding area of the building site. According to [17] "Interruptions caused by breakdowns, clean-up and rearrangement, material search, ways and transports" cause a share on all activities of 33.4%. Optimization of construction logistics can thus contribute to cost reduction, improved adherence to deadlines and, in general, to improving the organization of construction sites.

2 State of the Art

2.1 Building Information Modeling

The Building Information Modeling methodology is applied more and more frequently in construction projects. Furthermore, steps towards the implementation of a legal framework for the public sector in Germany are made. According to [6], BIM should be considered and applied in all public infrastructure projects in Germany from 2020 on. Pilot projects, such as mentioned in [16], have already been planned and implemented according to this methodology. As one main type of output of the BIM methodology building models serve the purpose of digital information management on which, for example, simulations, clash detection checks (between specific domain models) or visualizations can be performed.

On the part of the executing companies, the benefits of this methodology are increasingly recognized (in particular as a data basis for later operation, e.g., Facility Management) and specialized working groups are set up in companies like Strabag, Hochtief or Zechbau. By linking to tendering programs or scheduling software the automation of processes is facilitated and thereby quality can be improved and costs reduced.

2.2 Domain Models and Level of Development

In literature, several concepts to define and classify domain-specific models are outlined. According to [12], a domain-specific partial model is a trades-specific model that contains all information provided and required by a planner. These sub-models can serve, for example, as basis for the coordination of issues regarding different trades like clash detection issues. Depending on the stored information, a distinction is made between the BIM dimensions 3D (geometrical data), 4D (3D + Dates), 5D (4D + Costs), 6D (5D + Life Cycle Data) and 7D (6D + Facility Management Data). In general, these models can be understood as nD-models which can be extended by any kind of information needed within a specific domain or project. [2] states that sub-models differ in their domain (specialist perspective), zones (spacial structure), degree of detail and phases (period of observation). In this paper, a domain-specific model is classified according to the requirements defined in [15]. It distinguishes between Level of Geometry (LoG), Level of Information (LoI), Level of Coordination (LoC) and Level of Logistics (LoL). In the following, the contents of a specialized Construction Logistics Model (CLM) are described in more detail on the basis of the LoL. The LoL reflects the spatial and temporal development level of the logistics processes. All components of the digital building model are put in a temporal and local context with regard to their delivery to the site and their assembly.

2.3 Lean Thinking

One approach to optimize processes and thereby workflows is the adoption of Lean Thinking - including the underlying principles and tools - to the construction industry, known as Lean Construction. LC focuses on the value created from the perspective of the client; by means of continuous optimization and the reduction of waste, the proportion of value-adding activities is to be maximized.

Lean ideas have so far not been applied uniformly to building projects. A major problem with current construction projects is still the waste of various resources and their uneconomical handling. Nonetheless, there are examples from the residential and office construction sector in which the use of lean methods (Takt planning, Takt control, process optimization) led to the minimization of waste and an increase of the cost-effectiveness [7].

2.4 Construction Logistics

Construction logistics as an integral part of the value chain of construction projects must be planned, controlled and managed carefully. In the implementation of large-scale projects, it is already frequently involved in early project phases [16]. In small and medium-scale construction projects, on the other hand, it is often not taken into account until late or even not at all. In contrast to other disciplines, it is not always perceived as an important and independent component of construction projects.

This so far low prioritization of construction logistics, but also its increasing importance, is reflected in the German Official Scale of Fees for Services by Architects and Engineers (Honorarordnung für Architekten und Ingenieure, HOAI), for example. Until 2011, there was no basis for billing the services of construction logistics in Germany, as the HOAI does not include a service profile for the technical planning of construction logistics. This was first made possible by the introduction of [1].

3 Building Information Modeling and Lean Thinking

As recent researches show, overlaps between the two approaches of Building Information Modeling and Lean Thinking can be found on various tiers. Figure 1 illustrates an excerpt of them. Synergies arise which can lead to improvements in a variety of use cases [14].

On an abstract level, both approaches contain principles that complement and can be combined with each other. At the company level, tactical management must already work towards implementing both approaches throughout the company. There are also major overlaps in the objectives of BIM and LT.

At the operational level, project management based on LT and using the BIM methodology must be implemented. Practically, this can be done with different tools. The concept of the Lean Construction Logistics Management, described in the following chapters, covers one part of this topic. Further information and general considerations on the linkage of BIM and LT and the resulting increase in value in construction processes can be found, e. g., in [11], [5], [13] or [3]. Most of recent studies are focusing on the investigation of these synergies on an abstract and theoretical level. The research at IIB has the goal to investigate approaches that promote a holistic implementation of LC and BIM in practice by the example of construction logistics.

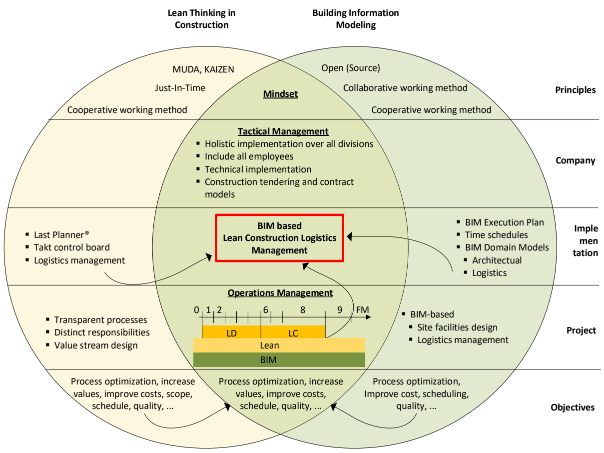

Figure 1. Synergies between Building Information Modeling and Lean Thinking

4 BIM-based Construction Logistics as Part of a Holistic Lean Construction Implementation

For a holistic implementation of the LT approach in construction projects, acceptance by all project participants as well as an implementation in all disciplines and across all project phases is a prerequisite. For this purpose, different tools and methods of LC are suitable.

The types of waste in the construction industry illustrate the importance of construction logistics. For example, the reduction of material stocks, waiting and transit times or the most efficient use of space offer great potential for optimization.

This paper therefore shows an approach for a BIM-based planning and implementation of construction logistics and gives examples for where to increase the value in construction processes in accordance with LC.

4.1 Structural Implementation

Shortly after project initiation, the project management has to consider the role of construction logistics. Only this early integration allows a holistic integration of construction logistics. In addition, all disciplines involved must be taken into account in logistics planning. From the development of the first planning concept and the known constraints, the development of a basic logistics concept can be started. Such a concept must be coordinated with the construction management processes and dependencies as well as with the implementation of LC. It is then worked out and refined over the further project phases.

Construction logistics must also be taken into account in the subsequent project phases. For example, construction logistics services must be subcontracted, which requires a contract specification. In particular, it must define a lean-based implementation. For example, suppliers and contractors need to know that they have to coordinate their production and assembly on site with a clocked schedule and change over to Just-In-Time (JIT) delivery and assembly.

In the execution phase, construction site management must be able to monitor and control the implementation of planning on the construction site. In addition to the implementation of lean methods and tools, a prerequisite for this is the provision of all necessary information.

4.2 Information Management

As in all other spheres of construction projects, comprehensive and well-structured information management is essential for construction logistics. According to the LC approach during all project phases

- the right recipient needs
- the right information
- in the right quality
- at the right time
- in the right scope.

Table 1 gives an overview with examples of information that arise in the context of construction logistics and must be linked to a digital building model. For example, the scope described in [1] can be used as the basis for identifying the relevant information. In section 5, a concept is presented which describes the data storage of all building-related information in a specialized model for construction logistics. Appointments, costs and other types of information (e.g. communication) must be linked to this.

Table 1. Examples of construction logistics specific information according to project phases based on [1]

HOAI phase	Information
1	Available space (property), Transport Connections, Neighbourhood restrictions
3	Building logistics concept: presentation of personnel, machinery, material and waste streams
5	Traffic concept, construction site equipment after construction phases, storage areas for supply and disposal, operating areas

4.3 Logistics Stages and Storage Area Management

Considering construction logistics, it is possible to diversify into the logistics processes up to the construction site (supply logistics), on the construction site (construction site logistics) and away from the construction site (disposal logistics).

The processes up to the construction site include transport, transhipment and storage (TTS). The transport can be optimized, for example, by delivering according to the requirements of the construction site (JIT) and operating interim storage facilities (e.g. logistics hubs).

Logistics away from the construction site consisted mainly of waste disposal processes, since in contrast to stationary industry the distribution of goods is not necessary. Here, new structures are needed on the construction site that enable the waste to be collected and disposed of in an orderly manner. In this way, disposal costs can be reduced, recyclable materials can be reused more efficiently and, in general, the construction site can be kept tidy.

Looking at the logistics processes on the construction site, in addition to receiving and distributing goods, storage area management can be identified as a key competence for a smooth and undisturbed construction progress. Due to limited space on the construction site and in the building itself, these must be planned efficiently and depending on the construction process. For this, detailed phase plans must be worked out, which locate the individual storage areas over the course of the construction process. Additional marking of the storage areas reduces search times and a pre-planned placement of these can reduce travel times. Corresponding requirements for the characteristics of the storage areas must be taken into account in advance. A software concept is presented in section 6.

5 Approach

The approach presented in this paper aims towards the development of an innovative and holistic implementation for planning, controlling and execution of construction logistics over all project phases. Thereby, the early integration of construction logistics in building projects shall be facilitated. As mentioned in chapter 1, in this paper first considerations are presented to serve as a basis for further and more profound research.

The focus lies on a construction logistics model, which is derived from an architectural building model. Besides the geometry and semantics of the underlying model, this CLM encompasses all information concerning construction logistics presented in chapter 5.1. According to the BIM methodology, the CLM must be created in an early project phase and then maintained over all subsequent project phases.

For enabling logistics planners, site managers and suppliers to work with this CLM, a software tool needs to be provided that extends existing software applications. One of its tasks is providing the opportunity to create relations between the building model and the construction logistics schedule. Especially construction site supply and disposal as well as storage and transport operations on the construction site have to be taken into account in this context. This application serves as a central construction logistics information management system and is extended by a digital storage area management.

Figure 2 shows the scope of the concept called Lean Construction Logistics Management (LCLM) introduced in this paper. In the following sections the relations between scheduling, construction logistics and the CLM are presented.

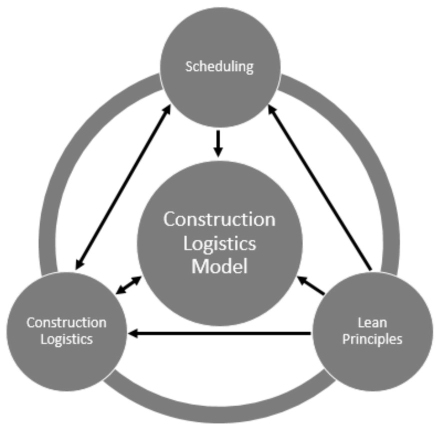

Figure 2. Overview of the LCLM Concept

5.1 Construction Logistics Model

5.1.1 Components

The CLM contains a large amount of geometric and semantic information. Besides the building itself, geometric information include site boundaries, additional floor plan information and object geometries. In addition, the model can have geometric information about the construction site equipment with storage areas, assembly areas and traffic routes. The object geometries include the components to be stored, construction aids and construction equipment.

In addition to these geometric representations and information, various semantic information is necessary for the construction logistics planning. Information about routes, costs and time connections are needed. In addition to construction roads, the routes include pedestrian routes and emergency escape routes. In the inner city environment, the area around the construction project should be included in the logistics planning for delivery. A detailed environment or city model can be used for this purpose. In addition, a logistics hub can be designed in advance if required.

All this information forms the basis for optimizations based on calculations and simulations. For example, the optimization of routes facilitates a reduction of way distances and travel times. Equally, an optimal use of the available space leads to more efficient storage and material distribution and, in general, a tidy construction site.

5.1.2 Requirements

In addition to the geometric and semantic components of the domain-specific model, there are further requirements that are important for construction logistics. For an integral planning of construction logistics, which takes into account the entire progress of the project, it is necessary to link the individual components with the corresponding (logistics) processes from schedule planning. This approach allows the planning to be adapted to the construction process and thus possible conflicts can be avoided.

There are also requirements regarding the information to be stored. These must always be available in the correct level of detail. The most important information includes details on measurements, materials and equipment. The dead weight, transport weight and dimensions are essential. Building geometries and storage areas must also be described in sufficient detail.

Depending on the specialist discipline, other domain-specific models must be included in the planning of construction logistics. For example, geometric framework conditions may exist from the HVAC or carcass construction.

5.1.3 Model Uses

After the comprehensive creation of such a specialized CLM, it can be used in different ways. On the basis of the partial model, collision checks can be carried out with other specialist models in order to detect collision points (paths, areas, dimensions) in planning and to work out countermeasures. Corresponding collision checks on the transport route to the installation site are mandatory.

Furthermore, digital planning methods can be used to carry out a storage area management system that improves the construction process and tidiness on the construction site. Efficient storage space management minimizes travel and search times. The digital planning also enables the control and management of construction logistics. Based on the stored information, a digital construction logistics manual and phase plans can be derived. By linking it to scheduling, simulations can be executed and multiple scenarios evaluated. To examine the flow of goods on the construction site and to control it, the model can be combined with a goods control system, extended by the time component. By using a goods control system, all goods receipts (inbound deliveries) can be checked and logged. This serves for documentation and quality assurance. The use of RFID technology has already proven to be a common practice in (construction) logistics.

5.1.4 Project Context

Information management plays a crucial role in the execution of projects throughout all project phases. In order to ensure a smooth and trouble-free project flow, principles of collaboration and project standards must be agreed upon. As digitalization in the construction industry progresses, contracts must also be adapted and expanded. Common practice is the definition of BIM-related content, such as roles and stakeholders involved, use cases, information exchange, software to be used, etc., in a BIM Execution Plan (BEP). On the part of the client, Employer's Information Requirements (EIRs) are drawn up. These should be laid down as an integral part of the contract between the client and the contractor.

Information generated during the construction process can be classified in accordance with the LoG-I-C-L scheme (see 2.2) [15]. Depending on the scope of the project and the specialist disciplines involved, it is not sufficient to store the construction logistics exclusively by defining a LoL in distributed specialist or domain-specific models. Rather, as explained in the previous sections, a CLM must be created which contains all the information that is directly within the sphere of influence of construction logistics. This domain-specific model must also be unequivocal and completely defined in a BEP, for example, according to the LoG-I-C-L schema. It must be coordinated with all other specialist models.

5.2 Scheduling in the Context of Construction Logistics

Scheduling places the individual work processes in a temporal context and includes the construction logistics processes. The time schedule can be based on the structure as shown in Figure 3.

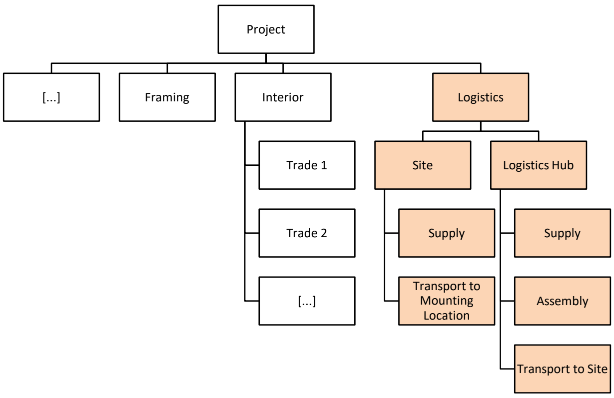

Figure 3. Suggested structure of a construction logistics focused time schedule

One way of classifying the logistics processes is to differentiate them spatially according to construction site and logistics hub, as well as according to their activities in delivery, assembly and transport to the installation location. This structure results from the approach that different stakeholders are responsible for the individual logistics processes. The example structure mentioned above is applicable to all projects with a logistics hub, for example in the inner city area. The structure can be extended to include the provision of construction machinery, taking into account a construction yard. However, the structure can also be reduced by the logistics hub in order to map only the basic logistics processes. It must be adapted to the specific logistical project needs.

5.3 Linkage of Scheduling to the Construction Logistics Model

The connection of scheduling to the CLM can be done, for example, by storing an unique activity identifier on the relevant components. This means that all information is available centrally in the model or is linked to it. The required materials are stored in the schedule as the corresponding resource of the respective operation. By linking the individual processes, interdependencies between building operations are modelled and the execution of construction work is optimized in terms of time. The connection allows a time-dependent observation of construction logistics processes and storage areas in the model.

5.4 Application of Lean Principles

Figure 2 shows that the application of the LC principles influences the scheduling, the CLM and the construction logistics. They are forming the basis for all underlying processes from creation of the first architectural building model to the processes during the execution phase.

The application of lean principles in the construction phase is well known by tools like a Takt Board or principles like Last Planner®. Also in the design phase, the development of a building model can be based on lean ideas. For example, short cyclical design reviews can help to identify issues. Thereby, countermeasures can be taken in an early stage. This approach is called Lean Design (LD) or Lean Design Management.

6 Implementation

6.1 Construction Logistics Model and Time Scheduling

In the following implementation, the specialist model bases on an architectural building model, which contains information on the structural shell and interior finish. The buildings' design follows the LD approach. An architectural model serves as data basis for the developed CLM. Figure 4 shows the floor plan of this model. It consists of four takt sections with the same structure. In addition, the needs of HVAC and other trades must be incorporated into the planning of construction site logistics and, accordingly, into storage area management. This integration will be part of future work.

The shown example building is a reinforced concrete skeleton construction with a steel-glass curtain wall and interior walls made of plasterboard. The elevator and staircase cores are made of in-situ concrete.

Autodesk Revit software was used for modeling. Each object has a comment field within its properties. The connection to a testing schedule is implemented in this module. The comment field is used to include the operation IDs from the testing schedule. In this way, a component can be assigned to several processes. The information of the activities can be accessed via the stored IDs of the processes in the CLM. This enables a time-dependent space management straight from within the CLM.

Furthermore, the model also includes an outsourced logistics hub and the transshipment point on the construction site. The placement of the logistics hub is not geographically correct in the context of site supply, but serves to visualize the TTS processes. The core components of the model are therefore:

- Geometric and semantic representation of
  - Storage areas
  - Ground plans and terrain model
  - Objects to be stored (building materials, components, auxiliary equipment, etc.)
  - Logistics hub
  - Construction site equipment incl. transshipment point
- Linkage of the detailed time schedule for execution and a derived time schedule of the construction logistics
- Different model versions depending on the project phase with the right information content (LoG, LoI, LoC, LoL)

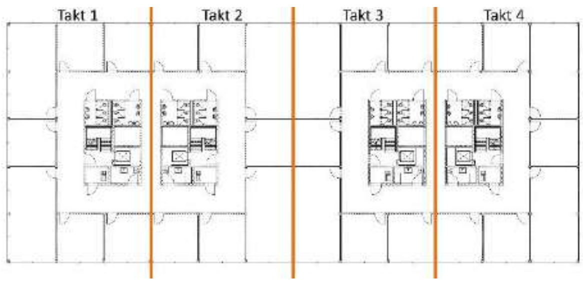

Figure 4. Floor plan showing four takt sections

The time scheduling is structured according to the structure shown in the section 5.2. It is designed in a high level of detail so that it can be used to control the construction progress during the execution phase.

6.2 Lean Construction Logistics Management

Based on Autodesk Revit, an AddIn was created that includes an interface to time scheduling and enables the creation and administration of storage areas. LCLM essentially comprises the following functionalities:

- Linking of tasks from a schedule to components
- Placing storage areas in the floor plan
  - Manually by user
  - Automatically by an algorithm
- Displaying Information about storage areas
- Generate target/actual comparisons with regard to the material delivery
- Display material and components of an operation in the model
- Simulation and visualization of the construction process

6.3 Limitations

There are proprietary software tools available for linking digital building models with time schedules and further information sources (e. g. Autodesk Navisworks, RIB iTWO or ceapoint desite MD). These were not discussed in this paper as well as in the underlying Master's Thesis [10], because the software to use was restricted to Autodesk Revit, Microsoft Project and non-proprietary libraries, like MPJX. Furthermore, a detailed classification in the overall project context becomes part of further research.

7 Conclusion and Outlook

7.1 Conclusion

This paper introduces an approach that puts construction logistics more firmly into the focus of the entire construction process. The role of logistics planning is already taken into account in selected (major) projects. The CLM supports and simplifies logistics planning. Thus, it also promotes the integration of construction logistics for smaller-scale projects.

In contrast to previous approaches, in which only 3D or 4D models are created, the presented construction logistics domain-specific model is integrated into the entire BIM process and not only as a side product, which does not interact with other specialized models and from which no information is returned. By integrating a LoL in all other domain-specific models, the relevant logistics information from these models is also taken into account. The CLM is used for the data storage of building-related logistics information and is linked to schedule planning via software. For this purpose, an AddIn was developed which allows the assignment of processes directly in Autodesk Revit. The basis for this tool is the application of LC, which aims to reduce waste in all processes of planning and execution of the construction project. The presented software supports this by optimizing transport routes and modelling objects of construction logistics, such as storage areas or construction materials.

7.2 Outlook

The approaches and ideas presented in this paper must be further elaborated and examined. The effort required for the creation and maintenance of a construction logistics domain-specific model over all project phases must be determined based on practical examples. In this way, the added value of the described approach can be proven.

On a superordinate level, new ways of thinking must be accepted and applied in the construction industry. In addition new cooperative contract and business models must be promoted, which already build on Lean Thinking and the BIM methodology from the beginning of the project.

Abstract –

Unmanned aerial vehicles (UAV) have gained tremendous interest in the construction management domain as a platform for progress monitoring, safety supervision, quality inspections, and overall job site logistics. With the continued growth of UAV application within construction domain, it is essential for construction program graduates to develop a general understanding of UAV operations, regulations, and integration with other technologies as a part of their construction curriculum. This document presents an exploratory case study to identify the potential opportunities and challenges of integrating a UAV and photogrammetry module into a building information modeling (BIM) undergraduate-level course. Photogrammetry and BIM integration with UAV have been selected as the use case because of their widely-used applications in construction domain. The module learning objectives as well as the technical components of flight operations, knowledge tests, and photogrammetry workflow integration are discussed in detail. This module provided an opportunity for students to obtain hands-on experience on both software and hardware sides of the UAV, Photogrammetry, and BIM integration. This allowed the students to successfully assess and implement these technologies in a realistic practice exercise. Challenges were found with the time required for student to be sufficiently effective pilots to perform the UAV flight operations under the hardware limitations of the study. Additional blockades were recognized during the integration of federal aviation administration (FAA) UAV regulations within the module. The contribution of this case study is to provide a better understanding of integrating the use of UAV and photogrammetry within an undergraduate construction curriculum.

UAV, Photogrammetry, Education

1 Introduction

The use of Unmanned Aerial Vehicle (UAV) technologies in the construction domain has been continuously growing over the past decade. Academicians and industry professionals have presented tremendous interest in this technology as new technological advancements have decreased the cost, and increased the reliability, flight time, and manoeuvrability of UAVs. Construction professionals seek for safer and more efficient means for conducting their construction management operations and UAVs might be a platform to facilitate them with their tasks [1].

Some recent applications of UAV technology include: building or safety inspection [2,3], progress monitoring [4,5], damage assessment [6], site mapping and surveying [7, 8], building maintenance [9], among others. Most studies consist of two basic steps: UAV data acquisition, and data processing and analysis. UAVs equipped with various sensors have been used to capture visual, thermal or geographical data, then make use of the data to evaluate the condition of target structures or sites. Photo-/video-grammetry has become a widespread technique employed to process and analyze aerial photographs or videos. In such photo-/video-grammetry techniques, the data captured by UAVs has been mainly used to generate point cloud data for applications such three-dimensional modeling [10] or distance measurement [11].

As these applications become more generally employed in practice, a need has arisen for university-level courses that integrate them as part of their curriculum. Efforts have been done in STEM fields to integrate these technologies in their curricula. Mechanical, electrical, and computer engineering, have concentrated on the hardware and software design of the aircraft [12, 13]. In geomatics, the educational aspect of UAVs has focused in geospatial thinking, where the students collect aerial images for remote sensing and image processing purposes [14-16]. Nevertheless, UAV and photogrammetry technology integration in construction management education remains largely unexplored in the construction literature. This paper investigates this integration by using a case study where these technologies are integrated into an undergraduate-level course as a hands-on module.

2 Research Motivation and Scope

The construction management domain is currently undergoing a vast technological and institutional transformation with the adoption of visualization tools such as BIM, and virtual reality (VR) [17, 18]. In the educational context, these innovative technologies have been successfully integrated into several program curriculums using various teaching modules that follow core construction concepts [19]. UAVs offer reductions in work load, risk, and overall cost of some construction operations [3, 20] and over the last few years, this technology has become very popular in the construction domain. Although UAV technologies might have been used by various construction management programs, there are no publications in the construction literature that addresses the pedagogical challenges and opportunities present in the implementation of these technologies in construction management education.

This study discusses a hands-on module aimed to enhance students learning about UAV technology for reality capturing purposes and how it can be used for building information modeling. Without this type of hands-on learning experience, students would have to gain these skills during their internships or after graduation. In this paper, an analysis of the module components (flight evaluations, knowledge tests, and photogrammetry workflow integration) are discussed. Additionally, the pedagogical opportunities and challenges would be explained.

3 Module Design

The module has been designed for the undergraduate-level course BCN4252: Introduction to Building Information Modeling at the University of Florida based on empirical experience of current construction practices in the United States. The course focuses on advance BIM (Clash Detection, Quantity Takeoff, Site Development, Walkthroughs) and related construction technologies (VR, AR, 360-degree photography, UAVs, Photogrammetry). In the course, 7 sessions are dedicated to UAVs and Photogrammetry. These sessions are divided into two major components: knowledge development and hands-on training. During knowledge development sessions, the basic concepts relating to the UAV applications, operations, regulation are introduced. The relationship between UAV and photogrammetry is described by providing practical examples of the integration of these techniques in the BIM methodology (e.g. surveying, mapping, inspection, progress monitoring, and clash detection). Additionally, software and techniques used to generate these point clouds are discussed within the construction domain. In the hands-on training, student perform UAV flight operations using a UAV to generate point clouds through the employment of software workflows. These actives have several learning objectives and expected outcomes that would be discussed in this section.

3.1 Learning Objectives and Expected Outcomes

In the knowledge development sessions of the module, students are expected to understand the definition of UAV, differences between fixed-wing and rotary-wing UAV, key components on a rotary-wing UAV, description and advantages of UAV autonomy features such as waypoint navigation, obstacle avoidance, auto-takeoff and return home. The students are also expected to gain basic understating of UAV regulation in relation to airspace classification, operation requirements and flight restrictions. In addition, students should have been able to define photogrammetry, identify their advantages and shortcomings, and evaluate the incorporation of these techniques into construction-related applications.

In the hands-on training part of the module, students are expected to perform various UAV flight operation tasks and understand the fundamentals of UAV safe flight. Students are also instructed to generate three-dimensional models using recorded photographic data obtained from UAVs, integrating a photogrammetry software workflow.

3.2 Flight Operations

This section of the module evaluates the students' UAV flight skills. The evaluation consists of three different flying tasks, where the students fly the aircrafts above a linear path with three stops – two on each end, one in the middle as shown Figure 1. Stops are marked as numbered circles. A mannequin head is placed in between each of the paths and elevated to a height of four feet by a platform. The students exercise ascend, descend, yaw, roll, and capture pictures or videos using UAV during the flight operation.

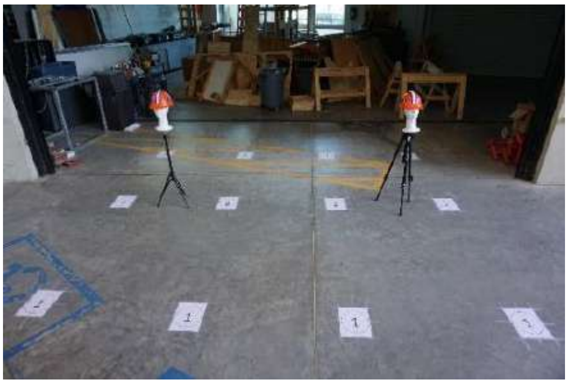

Figure 1. Flight Operation Exercise Area

The difficulty of maneuver in each task increases progressively from beginning to end, which simulates a typical flying session on construction site. Takeoff and landing are included in all tasks as they are critical every time a UAV is flown. To perform the tasks, students use the Syma 5X aircraft, which is equipped with a Full HD camera sensor. The selection of this aircraft was mainly driven by the cost, but other factors such as reliability and maneuverability were considered. Figure 2 displays each task to be performed by the pilots. Initially, task 1 requires the pilot to controls the UAV to take off, ascend, then land on the same location. During task 2, the pilot controls the UAV to take off, ascend, yaw 360 degrees, then land the UAV on the same location. In task 3, the pilot controls the UAV to take off, ascend, yaw 90 degrees then roll to the next stop and land UAS on the circle. Then, the student control the UAV to take off and ascend again, direct the camera to the object, capture a video, roll to circle 3, then land UAV.

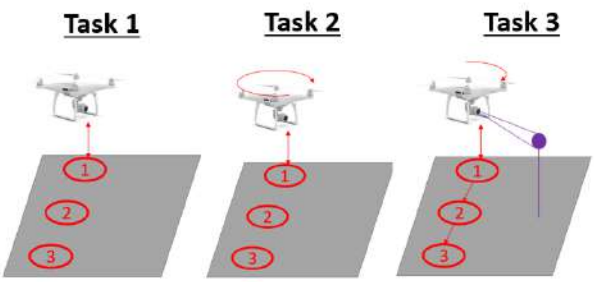

Figure 2. Flight Operation Tasks

Before the test, an ungraded preliminary practice session is provided for the students to familiarize themselves with the operational characteristics of the aircraft selected for the study. Students are divided into four groups, each corresponds to a path within the testing area. Each path is dedicated to two students, who share one UAV and six batteries. Each student at each path has approximately 10 minutes to practice each flight task.

During the test, the students are divided into four groups. Each group is assigned to one path and had one visual observer that evaluates their flight performance. Students pilot the UAV employing the techniques acquired during the preliminary session and are graded by the visual observers based on a Likert scale that measures the performance of each task in a five-point scale, ranging from poor (1) to excellent (5). The students also provide open-ended comments on each task during the evaluation session.

3.3 Knowledge Test

In the United States, the regulatory agency Federal Aviation Administration (FAA) is responsible for setting the standards for commercial aerial operations throughout the country [21]. During 2016, the FAA set in place a standard for commercial operations of UAVs. Commercial pilots must obtain a certification to perform aerial operations, including those performed in the construction industry. The FAA requires for pilots to pass an evaluation regarding UAV regulations, airspace, weather, loading, performance, and operations to get accredited. Analogously, the European Aviation Safety Agency (EASA) have proposed a framework for the operation of UAVs under the A-NPA-2015 [22], classifying the UAV operations as "*Low-risk operation – 'open' category*" which encompasses "*small drones under direct visual line of sight operated within safe distance from persons on the ground and separated from other airspace users*" [22]. Nevertheless, the EASA is still under review and has not presented a final publication with the general ruling as December of 2017. The knowledge section of the module is created to discuss UAVs, these regulations, and their previous applications.

Throughout this part of the module, students are expected to gain a basic understanding of concepts relating UAVs, their applications, safety challenges, and regulations. To evaluate their comprehension of the material, a knowledge test is designed, containing 14 questions in all these topics. The test has five categories as follows:

- The concept of UAV
- UAV technical requirements
- FAA basic regulation and how it might relate to construction domain
- Current applications of UAVs in Architecture, Construction, and Engineering domain
- Safety challenges of using UAVs onsite

3.4 Photogrammetry Integration

For this study, a three-step photogrammetry workflow is used to help the students in their point cloud generation process (Figure 3). The initial step (1) of the workflow requires the extraction of the keyframes for the videographic data captured with the Syma 5X aircrafts that contain the mannequin head. To achieve this, the VLC media player (free and open-source) software is employed to attain screen captures of the keyframes in the video files. On the second step (2), Autodesk Recap® is used to generate the point cloud. The extracted keyframe images are imported into Autodesk ReCap® cloud-based software. An RCS (Point Clouds) file is obtained after processing, containing the mannequin head and the surrounding environment. Using the Autodesk ReCap® desktop software, the point cloud is cleaned with the objective of separating the surrounding environment and targeted object (mannequin head). In the last step (3), the cleaned RCS file is imported into Autodesk Revit ®, where it is scaled relative to the model, and positioned for display in an RVT (Revit Project) file.

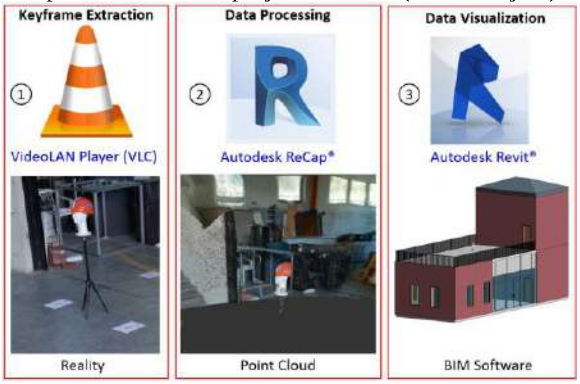

Figure 3. Photogrammetry Workflow

3.5 Data Sampling and Collection

For each section of the module data was collected from the students taking the course. In total, 11 students took part in this part of the module, performing all the tasks corresponding to each section. The data collection was done using the following criteria:

- Flight Operations: The students were evaluated by an observer based on their UAV flight performance using a five-level Likert scale: poor, fair, average, good, excellent. The evaluator graded the students' performance according to the tasks defined on section 3.2.
- Knowledge Test: The number of correct answers were collected from the quiz to evaluate the understanding of the participants regarding UAVs in the construction domain, its usage, and the FAA regulations.
- Photogrammetry Integration: In this section of the module, keyframe images obtained and RCS and RVT files were collected from the students. Each component was evaluated according to its completion and representation accurateness.

4 Results and Discussion

4.1 Participant Demographics

In the sample data collected for the study, it was found that subjects were mostly male (91%), with a minority of female (9%). The average age of the participants was 22 years, with a maximum of 24 years and a minimum of 21 years. All the students (100%) were in the senior year (4th year) of their university education. Generally, the students (82%) reported to have between one and five years of work experience in construction management, and the remainder (18%) informed less than one year of experience. Most of the students stated to have excellent or good eyesight (73%).

Overall, most of the participants did not have any experience with radio controlled (RC) cars, boats, or airplanes (64%) with none of them having any experience. with operating UAVs either in their personal time or at work. Many of the students also had an average knowledge of UAVs in construction (73%) and understanding of FAA regulation (55%).

Figure 4: Students performing flight operations

4.2 Flight Operation

The data collected from the flight operation performed by the students reveal that overall, as the difficulty of the maneuvers increase, the performance decreased (Figure 3). Task #1 - *UAV to take-off, ascend, and land*, was the highest scoring task on average, rating above "*average*" in the Likert scale, but it presented a wide dispersion (Mean: 3.2, Median: 4.0, IQR Low Bound: 1.0, IQR High Bound: 5.0). The evaluators noted that several of the participants experienced issues performing the maneuver as the UAVs "*do not go straight up and down*". Moreover, the evaluators also noticed that if "*the UAV [front] is facing the user, the maneuver difficulty may increase*", which indicates that it was challenging for the participants to identify the front side of the UAS in relation to their positions.

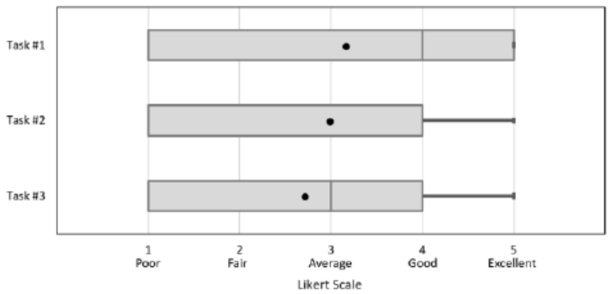

Figure 3. UAS Fly Tasks Grading

Task #2 - *UAV to take-off, ascend, yaw 360 degrees, then land*, was rated "*average*", displaying a wide distribution of scores, and leaned towards the lower end of the scale (3.0, 4.0, 1.0, 4.0). The evaluators commented that most students "*could not perform the 360-degree rotation*", as the UAV was "*hard to control*". Task #3 - *UAV to take-off, ascend, yaw 90 degrees, then* *rolls, captures a video, and land*, presented below "*average*" scores (2.7, 3.0, 1.0, 4.0), with a wide distribution leaning towards the low end of the spectrum. This was the most challenging task in the set of flight manoeuvres. The evaluators commented that the UAVs were "*drifting all over the place*". Additional comments were provided that identified issues with the recording of the video, as the UAV recoding light indicator would "*flash red light [recoding on] and then immediately go back to green light [recoding off]*"

Additional comments were provided by the evaluator immediately after the flight maneuvers were done, reporting hardware issues such as "*had to reset the UAV several times to reestablish the control link*", "*the UAV is very hard to keep steady*", and "*batteries change interrupted the UAV flight*". Additionally, the evaluators observed that "*more time practicing would be beneficial*" and that the participants that did not attended the practices session before the evaluation session had a lower overall performance.

Following the UAV flight operations, the participants reported the total workload required to perform the tasks using the NASA TLX [23] assessment tool (Figure 4). The participants indicated that the mental demand required for the flight tasks was above average (Mean: 11.5, Median: 14, IQR Low Bound: 6, IQR High Bound: 16) with high variability. It was observed during the flight maneuvers, that the participants required their full attention on the task to perform them according to the prescribed requirements. The physical demand reported by the participants was well below average (4.9, 5.0, 2.0, 7.0) with a narrow distribution of responses. The UAV operation required minor physical effort as there are radio controlled aircrafts. The only physical effort required was the manual set-up of the aircraft on the markers. The participants expressed that the temporal demand was below average (8.0, 8.0, 6.0, 11.0) with a narrow distribution. This indicates that the participants did not felt highly pressured in terms of the time or pace required for the tasks.

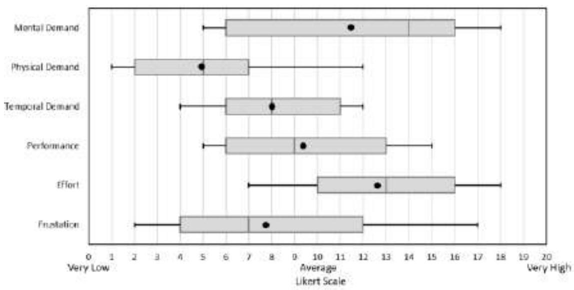

Figure 4. NASA TLX Grading

The participants reported that their overall performance of the task neighbored the average score, but this measurement present a wide distribution of responses (9.4, 9.0, 6.0, 13.0). This indicates that the average participant perceived to be successful in their task performance. Moreover, the participants indicated that the effort required to perform the task was above average (12.6, 13.0, 10.0, 16.0) with a narrow scoring distribution. Finally, the participants indicated a below average level of frustration (7.7, 7.0, 4.0, 12.0) with respect to the tasks. This suggests most of the participants did not felt irritated, stressed, or annoyed during the UAV flight maneuvers.

4.3 Knowledge Test

The knowledge test that the study participants took after the flight maneuvers, revealed that in average participant scored 18.2 out of 20 points with a standard deviation of 1.74. As shown on Figure 5., 45% received the maximum score for the evaluation. Overall, the questions that most participants answered erroneously were related to UAV and its flight height under the FAA regulations. This indicates that the participants had some difficulties understanding basic FAA regulations and their significance in the construction domain. Other questions that were incorrectly answered by the participants were mainly related to the concept of UAV and its application in the construction domain.

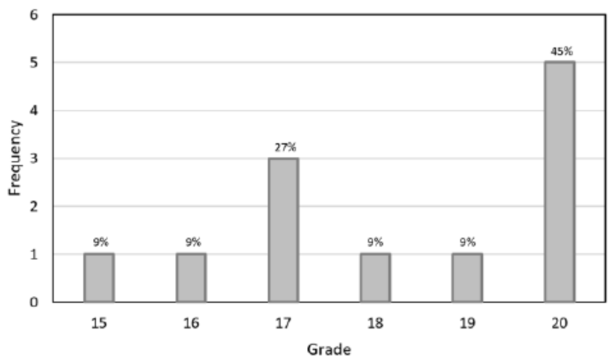

Figure 5. Knowledge Test Results

4.4 Photogrammetry Integration

After the participants concluded the flight operations, the videographic information was extracted from the UAVs, for posterior analysis using the workflow established on section 3.4 The video was successfully split into pictures by the participants using VLC MediaPlayer®, creating an average of 186 keyframe images in JPEG format.

The images were input into Autodesk ReCap® for processing, obtaining RCS format point cloud as a result. Within the same software, the participants cleaned the point cloud as contained the environment surrounding the target object, so that only the desired object remained. The resulting RCS file then was imported into an

Autodesk Revit® architectural model, where the point cloud was scaled to proportional measures to the model. The key issues reported by the participants related to the software the cloud-based software Autodesk ReCap®. Multiple uploading and processing errors of the images were found, mainly caused by the number of input images into the platform.

5 Research Limitations

This research has three major sources of limitations: (1) sample size, (2) participant experience-based limitations, and (3) hardware limitations. (1) The sample size for this study was very limited, containing only 11 participants analysed in the results. This implies that the observations presented in this study cannot be used to generalize beyond the sample population. As this is an exploratory study, the focus aimed to provide general overview of the variables and factors affecting the topic by directly reporting the lessons from the teachers, evaluators, and participants. Consequently, these lessons may not be representative for all instances or conditions in construction management UAV and photogrammetry education.

(2) The participants of the study did not have any experience flying UAVs excepting the preliminary practice session. The flying operation were directly affected by the deficient piloting skills of the participants during the evaluation session. This presented difficulties to obtain usable footage for photogrammetry application. (3) The UAV hardware used for the operation does not provide in-flight stabilization of the aircraft, which requires constant user input to maintain a leveled aircraft. Moreover, the UAV is equipped with a low-end camera without a gimbal, producing photos and videos only up to Full HD resolution. This introduces additional complications for inexperienced pilots to keep a fixed target focused for a reasonable amount of time, and further limits the quality of the 3D models to be produced from the photogrammetry process. With the intention of simplifying the flight operations to control for these variables, the UAV were flown in low altitude without any obstruction, wind or precipitation, (reducing the risk of losing control and crash), which is not representative of real-world fly conditions. With the same intention, the participants monitored the UAS closely in distance, making the tasks less challenging.

6 Opportunities and Challenges

The integration of UAV and photogrammetry in a BIM course module presented insightful pedagogical opportunities and challenges for undergraduate construction management education. The hands-on approach presented on this module enabled students to experience the common hardware and software-related problems professionals might encounter during the application of UAVs for generating point cloud data. The flight operations of the UAV provided a method for the students to experience the problem-solving skills necessary for a pilot to successfully obtain aerial imagery. Establishing a control link, battery life time constraints, and spatial awareness for UAV control were some of the identified factors that affected the students flight operations. Moreover, students understood BIM software interoperability limitations, as they were required to recognize the appropriate file formats for the manipulation of point clouds. Overall, students recognized the necessity for general troubleshooting knowledge in relation to the hardware and software involved in the technical workflow.

The challenges observed in the integration of these technologies into the module related to the UAV (flight, hardware, knowledge) and the photogrammetry software utilized for this study. This module comprised only twelve hours of lecture and lab time, which limited the time needed for the students to practice their flight skills. Only a two-hour session was employed for the students to physically perform the UAV manoeuvres, followed by the evaluation session. Another crucial factor that reduced the efficacy of the students' performance was the UAV hardware. The Syma 5X aircraft used in this study do not possess an automatic hovering feature, increasing the difficulty of any operation that requires steady image capturing. Moreover, constant supervision of the flight operations by the instructors is required, which effectively limits the number of students that can simultaneously fly the UAVs while achieving the learning objectives of the module. This level of supervision could be lowered by providing UAVs with more automated features, simplifying the flight tasks the students are required to learn. Nevertheless, the understanding of the image collection workflow still requires instructor guidance.

The UAV FAA content for the module was also hard to be integrated as this module did not aim to provide an exhaustive overview of regulations and pilot certification. Nevertheless, this module attempted to provide sufficient information to create awareness regarding UAV operations to the students. Only the three major topics that comprised the FAA Part 107 certification were covered at a basic level (regulations, airspace & requirements, and weather), but many other topics were left out. Finally, the software utilized to create the point clouds also generated challenging situations. ReCap® has the advantage of allowing cloud-based processing of the images, reducing the computational power required from the students' computers, but makes difficult the evaluation of errors that might occur during the point cloud creation process due to the limited feedback provided by the platform. Additionally, this software limits the number of images that can be uploaded to the platform, allow a maximum of 250 images.

7 Conclusions and Further Study

The use of UAVs and photogrammetry techniques within the BIM context has become generalized in the construction industry during the recent years. This has generated a necessity for program graduates to have a practical understanding of UAV operations, regulations, and integration with other technologies. This paper describes the opportunities and challenges observed in the implementation of UAVs and photogrammetry module in an undergraduate-level course. During the flight operations, knowledge tests, and photogrammetry workflow integration, data was collected to obtain insight on the design of the module. From the analysis of the data, it was found that the students had an overall "*average*" performance flying the UAVs, while they were highly constrained by the UAV hardware used in the module and the limited amount of piloting experience. Additionally, the photogrammetry workflow presented challenges during the point cloud generation due to limited amount of control and input that students and teachers had on the photogrammetry process.

Further investigation must be done to validate the findings of this study. Data sampling over various semesters is recommended to obtain generalizable results. Moreover, in the subsequent data collections, the hardware of the UAVs should also be improved to remove some of the limiting factors presented on this study. Additional practice sessions are recommended to improve the mastery of the students piloting the UAVs. Future research should explore the effects of the introduction of UAV/Photogrammetry module in program graduate education by assessing how valuable the skills obtained on the course are in relation to industry practice.

Abstract –
Throughout history, waves of industrial revolutions have disrupted established manufacturing methodologies. Traditional construction processes have been transformed by new means of creating objects and computing information. The manufacturing of steel is no exception to this trend. Past methods for the creation of steel included hot forming (casting, extruding and welding), cold forming (subtractive milling, bending and rolling) and cold connected assemblies (bolts and rivets). All these methods create certain constraints to the application, form and function of steel elements. Developments within fabrication technologies bring a new dimension to the possibility of creating complex geometries in steel manufacturing. This article explores the use of new technologies including additive manufacturing as well as composite joints, and highlights the integration of new robotic programming paradigms for architectural production.

Typical 3D printing technologies create objects by incrementally adding layers of material in order to create a final part. Employing robotics does not only allow for fabrication on a larger architectural scale. The flexible configurations of the robotic arm, with its six degrees of freedom, allows for the additive manufacturing of elements on top of existing structures or surfaces.

Within this article we create an overview of fabrication technologies for joining steel, as well as their influence on architectural design. We explore how new technologies enable the creation of new design possibilities, through the increased flexibility of robotic fabrication.

1 Introduction

Construction technology has a significant impact on the design and performance of architectural projects. The evolution of materials and methods of production has enabled the Architecture, Engineering and Construction (AEC) industry to design and build projects of increasing complexity, form and function. As new techniques develop, the industry integrates these innovations in order to push the boundaries of construction capabilities. This trend can be seen in the history of architecture as low rise buildings evolved into the skyscrapers that define modern skylines. The impact of manufacturing technology has a determinant role in shaping architecture. Many examples can be identified that attest to this connection whereby shifts in capabilities transform the AEC industry at large.

Advances in construction technology shape the design of architecture, from new digital information workflows to innovative fabrication processes. The current wave of fourth industrial revolution is now taking shape and architecture is again evolving. New levels of intelligent automation, and the increasing connectivity of information networks are creating more ambitious and efficient structures than ever before. The power of designers to computationally optimize designs is matched by new means of manufacturing complex components. This trend is amplified by new methods of collaboration, from algorithmic design to Building Information Models.

The development of new processes for using machines and materials is an important aspect of realizing innovative architectural ideas, from robotic fabrication to new methods of working in steel and composites. These advancing capabilities are combined with increasing ambitions for architecture that are cost competitive and efficient to assemble while still achieving high levels of performance, sustainability and geometric complexity. With this evolution in mind it is helpful to consider examples of architectural forms which encompass these transitions in process.

We can observe the evolution in architectural process by juxtaposing projects from the past with those from the present in order to see the impact of new means of construction. It is important to keep in mind that while technology may change there are many constants that remain. These constant conditions run throughout the course of architectural history to add a shared context to construction efforts. Each building for instance must negotiate a balance between form, function and structure in order to find a means of creating space which efficiently meets its design requirements and can be built within its constraints of technology, time and budget.

The Eiffel tower demonstrates this balance in a truly iconic way. By utilizing the height of the times existing technology and manufacturing methods this structure embodied the benefits of steel construction. From its structural definition of form to its rapid construction schedule, this tower became synonymous with the city of Paris and an age of advancing architecture. The form takes advantage of repetition as its symmetry allowed for the preparation of parts to have repeatability and structural integrity that could be calculated by hand.

In contrast to the Eiffel towers symmetry we can consider the ArcelorMittal Orbit, an observation tower designed for the London Olympic Games. This tower is a complex creation of non-symmetrical geometry in which each part is uniquely created according to a digital model. The asymmetric form was made possible through the utilization of computational design tools and advanced structural analysis software. The principles of structure, construction considerations, and the desire to create an iconic experience to represent a city are common to each project while the impact of digital design and fabrication processes can be seen to considerably increase the complexity of the built form.

A further example of the impact that advancements in technology has on architectural projects can be found in the evolution of thin shell structures. Engineers such as Richard Bradshaw were key figures in designing thin shell structures that utilized the strength of form to optimize structures. These designers required a deep understanding of structural analysis, hand calculations and the geometries required to create such impressive forms. New digital design tools, methods for iterative structural analysis and file to factory workflows that design for mass customization have empowered designers such as Marc Fornes to reimagine the shell structure as a highly complex geometry comprised of thin sheets of material that derive great structural integrity from the form of the construction.

Works produced by Marc Fornes, such as Minima | Maxima, create shell structures through continuous surfaces which draw their structural integrity from both the geometry of the construction and the aluminum laminate weave it is constructed from. This increase in design complexity continues the tradition of creating impressive structures that consider construction methods early in the conceptual process in order to integrate design and fabrication. These workflows seek to optimize a project and increase its ability to be constructed efficiently in light of bespoke geometry.

The integration between design and fabrication tools continues to grow. In the future of construction, digitalization will be the central interface in the supply chain. The integration of robots and automation technology can improve the competitiveness of the construction industry, which lags behind other industries in regards to increases in efficiency and productivity. The integration of digital processes has significantly advanced the tools of architecture in a short amount of time.

A concept for furthering this trend was commissioned by the BMVi in 2015. To guide the integration of modern digital processes and technologies in the planning, construction and operation of buildings envisages a step-by-step plan for the introduction of BIM [1] was developed. Building Information Modeling or Management (BIM) is ideally used to digitally create and manage information regarding the physical and functional properties of a building over the course of its entire lifecycle, from design, to construction, to occupancy and operation, to its eventual decommission. BIM serves as an information source and database for interdisciplinary collaboration between all parties involved. Currently, BIM is utilized mainly during the design stages of an architectural project and does not yet sufficiently integrate machine production. In many cases a BIM model must be rebuilt in a shop level tool or set of drawings before physical production of parts and assemblies can proceed.

These developments also affect the steel construction industries. New flexibilities within the digital tool chain of design to production also require new flexibilities in the fabrication processes. While casting of metal is a relatively cheap process especially for mass production, the fabrication constraints exclude a number of parts. Even though 3D printed sand molds already extended this process and allow for the creation of undercuts and can be created without draft, this is still a relatively time consuming process, which requires a high lot size to be efficient.

On the other hand, subtractive milling, generally limited to 3 axis of freedom, creates a high waste factor. Other limitations are inherent in this process including the creation of undercuts or parts that require tooling from all sides. While five axis CNC machines are able to create undercuts and CNC technology overall is distinguished by very high accuracies, they do not achieve the same flexibility as a robotic milling solutions both in workspace as well as reachability.

Within the field of forming through bending or pressing often times stencils need to be used. The high forces within the process require stiff machinery and therefore prevent the use of more flexible robotic solutions. However, the field of single point incremental forming has shown that robots are able to create a wider range of parts but only with materials up to a certain thickness.

Within this paper we take a closer look at direct additive manufacturing technologies such as welding for joinery, as well as incremental welding for part creation and hybrid processes which allow the use of composite materials for joining of steel parts. While flexibility can be achieved in every part, this often leads to higher fabrication times. We therefore focus on flexible joints for prefabricated parts.

2 Robotics in Steel Construction

Currently the construction industry utilizes automated production systems almost exclusively for prefabrication. Specialized systems for the production of standardized components are limited in flexibility and costly to obtain and operate. These systems often require specialists to program and are designed to repetitively execute movements without mass customization or variation. Feedback from these processes is generally not communicated to the design process. Sensors and intelligent dynamic adaptivity are also not the normal method for correcting errors in tool paths or part placement. While these methods are used in other industries, it is only recently that research aimed at bringing these processes into the architectural workflow. By considering these initiatives, we can observe a variety of further-reaching approaches that stand on the borderline between research and real-world use.

Over the last ten years, robotics has made its way into architecture schools all over the world. Conventional industrial robots serve as universally applicable machines. The possibility of combining abstract movements with various tools opens up a wide range of possibilities for individualized production.

Early projects incorporating robots into the architectural process explore the changing design to fabrication workflow and the exploration of possible tooling strategies [2]. Through cooperation with the construction industry, these efforts resulted in highly individualized objects as demonstrations of this new file to factory robotic strategy. Pioneering projects such as the exhibition hall of the Landesgartenschau of the University of Stuttgart [3], [4], the roof of the experimental hall for digital production at ETH Zurich [5] or the work of the Institute for Timber Construction of EPFL Lausanne [6] can be seen as demonstrator for the creation of complex high performance geometries particularly in timber construction.

Beyond digital prefabrication, there are various efforts to bring robotics to the construction site. Advances in drone and machine vision technology have fueled the use of these systems in stocktaking and inspection, as well as in construction documentation and analysis [7]. With these approaches, there are still far-reaching questions regarding the level of detail and sensible interfaces for rectifying deficiencies.

While manually controlled construction machines have long been at work on construction sites the future will find a greater integration of semi - autonomous or even fully autonomous machines involved in construction site logistics for civil engineering [8]. Lessons learned from other industries, such as agriculture, mining, automotive and aerospace will help to adapt technologically advanced manufacturing methods for use in the construction industry.

In the field of steel construction, semi-automated systems for welding were developed at an early stage, or systems for sheet metal forming were adapted from prefabrication to be used on construction sites [9]. Systems for in-situ production have different approaches to operation when compared to use of robotics in prefabrication. One example of the conversion of conventional construction machinery from prefabrication to on site application, is the Hadrian X brick building robot [10].

In research projects industrial robots are brought to the construction site as prototypical systems [11], [12]. However, such robots are not yet suitable for use beyond proof of concept development due to programming difficulties, safety issues, lack of contextual awareness and the low payload handling capabilities of robots used in research compared to those that may be used in production. For similar reasons, different directions of development are emerging for lightweight steel and metal construction. While the focus of robotic applications in steel construction will probably remain in the factory, development options for assembly will open up the field of robotics in lightweight metal construction.

Steel construction is one of the most common trades at work in the architectural enterprise. The steel industry is characterized by a high degree of prefabrication. This construction method has influenced the planning and execution process and led the industry towards an approach more traditionally seen in mass manufacturing as efficiencies of scale are utilized in order to bring down production time and costs while still increasing quality. To achieve this objective, the steel construction industry uses digital tools at every stage from design to production. This integrated, process-related planning already leads to BIM-based construction planning [13], which is highly demanded but rarely comprehensively implemented.

Automation has not only found its way into the planning process, but also into production. Not only serial or small series of steel components and modules are processed in specialized saw-drilling or welding systems, partly with industrial robots, but also individual productions. The robot has been used for a long time in industries where "exactly repeating" activities are characteristics of manufacturing. However, a robot-oriented further development of the steel construction production has to deal with facts such as very different component weights and sizes, a large number of primary materials, batch size 1 series and relatively large tolerances [14].

Despite the high level of automation, there are further potentials for the use of robotics in prefabrication. Where previously specialized stand-alone machines and associated software have been in use, more flexible systems and a higher-level view of the working structures can offer considerable advantages.

In construction steel production, the material flow, the recording of pre-material (tolerances), welding, cutting and drilling, the assembly sequence etc. are required for robot development and programming. Clearly, these things must be geared to the special requirements of steel construction and lightweight metal construction.

3 Prefabrication

In addition to subtractive manufacturing, assembly and joining, construction research also shows approaches to additive processes. The 3D printing of concrete is propagated by different companies for the printing of entire walls or even houses [15]. Others use 3D printing, partly with robots, to produce formwork and reinforcement [16]. The first experiments on the vertical application of mineral substances with robots are carried out at the RWTH [17]. In steel production, additive processes such as deposition welding or coating with robots could also gain in importance, since they enable complex geometries that are difficult or impossible to produce by subtraction [18].

Conventional prefabrication processes can be made more flexible, cheaper or even possible in the first place by using robots. For example, collaborating robots can bend a hot wire and guide it through polystyrene blocks to create moulds for free-formed concrete parts [19]. In cooperation with the Institute of Welding and Joining Technology, the Chair of Individualized Production in Architecture at the RWTH Aachen University is concerned in particular with further-reaching automation potentials and parametric factors of classical welding technology.

Arc welding processes are of particular interest for the production of large metallic structures [20], [21] due to their significantly higher melting capacity and comparatively lower plant and operating costs. As early as in the 1980s, generator shafts with a component mass of up to 225 tons were produced additive using the submerged powder (SAW) process. gas metal arc welding (GMAW) is much more mobile and flexible than the submerged arc welding process. In particular, the use of energy reduced short arc processes makes it possible to manufacture complex to highly complex metallic components in an additive manner. The LASIMM project relies on the collaboration of robots for fully automated additive and subtractive component production. In this case, the arc-based additive manufacturing is carried out by industrial robots in combination with machining, whereby a parallel kinematic structure is used here due to its increased stiffness [22].

Highly complex structures can be produced by incremental spot welding. A robot-guided GMAW torch places spot welds in any orientation on top of each other, thus creating structures of almost any size and complexity. Parametric models allow for the development of systematic approaches to design of robotic tool paths. In this way the robotic path, welding strategy: speed, angle, duration, weld height and resulting executable code can be programmatically updated to adapt to the mass customization of bespoke architectural elements. The parametric nature of the process empowers the robot with the ability to dynamically adapt to input provided by sensors. Figure 1 details experimentation in robotic wire arc additive manufacturing (WAAM) at the at the Welding and Joining Institute (ISF) of the RWTH Aachen. Figure 2 illustrates some of the results.

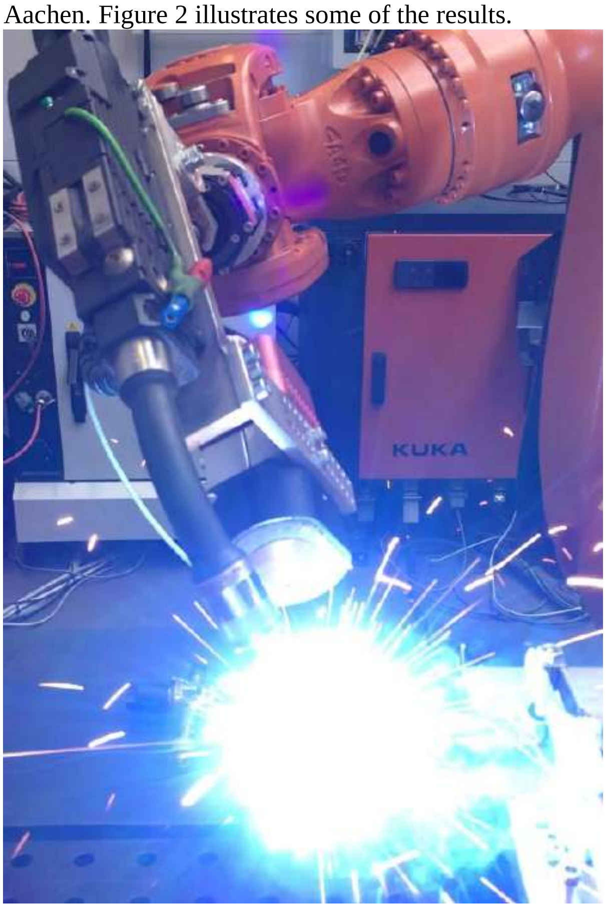

Figure 1 Robotic Incremental Point Welding

The development of additive manufacturing through the robotic fabrication of incremental point welding in steel can lead to advancements in construction technology and new ways of mass customization of bespoke geometries.

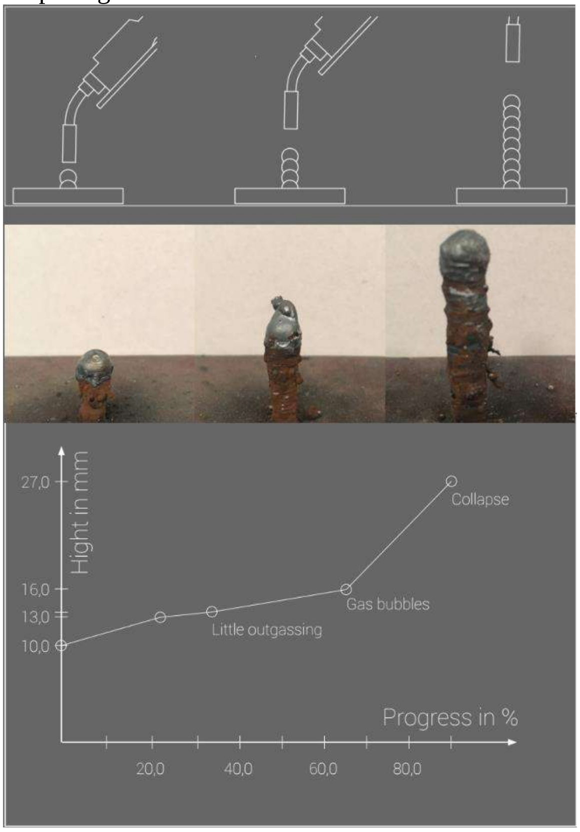

Figure 2: Incremental welding results

Another application area for flexible robot applications is the application of pin structures by means of CMT pin welding on complex shaped surfaces as illustrated in Figure 3. By a combination of targeted current conduction and the dynamic movement of the welding wire, it is possible to reproducibly create pin structures on metallic surfaces. This process opens up a multitude of possibilities for the production of composite components made of different materials.

Possible fields of application are metal-concrete composites for bridge construction or metal-CFRP composites for high-strength lightweight construction applications [23], [24].

The advantage of the high flexibility of GMAW welding can only be fully exploited if a suitable concept for implementing a complex adaptive path planning is available at the same time. In addition to a comprehensive analysis of the factors for an optimal development of the pin through the welding process, potential applications have been identified. A direct on-site production of composite materials is of particular interest, as this opens up new possibilities for the renovation of existing steel structures.

In order to provide the necessary flexibility, the process was transferred from a 3-axis positioning machine to an industrial robot with six degrees of freedom. A KUKA KR3 with a particularly high speed of movement was used. This makes it possible to flexibly design the distance of the pins in order to reduce the heat dissipation in between two weldments.

Figure 3: CMT pin welding with KUKA KR3

By increasing the degree of freedom, it is also possible to work on individually shaped metal surfaces. In order to enable the measurement and installation of the robot on site quickly and flexibly, a new robotics-based process for measuring surfaces was developed. Due to a direct communication between the planning tool and the robot controller, surface parameters at important points can be measured directly with the robot. Using these points, the surface description is used directly for the further path and process planning of the robot. In particular, the measurement can be carried out directly with the robot and reduced from a complete spatial positioning to an adaptation of individual parameters based on the working direction.

In the long term, innovative manufacturing processes will lead to a far reaching change in industrial prefabrication in the construction sector. This will not only lead to the development of new production facilities, but will also lead to a new planning and construction process. Due to the large dimensions of a building, modular components will continue to be in the foreground. Up to now, quite complex plant technology has been used which represents closed systems in terms of both hardware and software. The possible flexibility of the robot is limited here. As a universal tool carrier, it should be able to carry out various work steps, e. g. post-processing of the seams as required or combine more flexible process steps such as plasma cutting, notching and welding.

The demand for more flexible machine and software platforms will increase in the near future. The desire for individualized construction and increasing demands in terms of recyclability and reusability necessitate a rethinking of the concept of integral and differential construction. Prefabrication will have to be more agile. The aim of developing adaptive and flexible machines must extend the capabilities of people in the form of intelligent assistants. A transfer of experience from man to the digital machine is a sustainability strategy that allows companies to keep their manufacturing knowledge safe and free up resources for new developments.

4 In-Situ Fabrication

The main challenge for the work on the construction site is to support people in their work with machines. In addition to occupational safety, health protection and a shortage of skilled workers caused by various factors, the closing of the digital gap in the construction process is the driving force for innovation in this area. Since the construction site is currently dominated by machines without intelligence, there is great potential for improvement. However, this is also associated with high technical challenges.

Factory settings allow for a conclusive prior planning of fabrication. The construction site requires a new level of intelligence within the programming, that takes into account all possible and often unpredictable events and is therefore beyond the scope of current technologies. Simultaneously the construction environment does not constitute a completely unknown fabrication environment as is assumed in the field of service robotics. Over the course of multiple planning phases and experts integrate a high amount of basic information into digital tools. However, changing environmental influences and constant structural changes in the working area of the machines do not occur in the industrial factory environment.

This requires an intelligent use of planning knowledge in combination with easy configuration and adaptability on-site. Most sensors used in production are still not suitable or in most cases not as reliable in construction environments. Within the field of CMT Pin welding we implemented a new paradigm for in process surface measurements, which tries to combine the capabilities of robotics with human planning knowledge. Instead of measuring on a point by point basis a group of control parameters is combined with a parametric geometric surface model as illustrated in figure 4. Within a configuration program the robot movement approaches a number of sample positions.

Manually the distance and angle to these positions is adapted, which in turn inform a parametric surface model used for the welding process. Figure 5 shows the process in detail. After measurement of the surface within the planned constraints and parametric model the placement of each pin is then executed automatically. Depending on the complexity of the surface and therefore the used parametric model the configuration phase requires a much lower number of adaptation steps then an adaptation of each weld position.

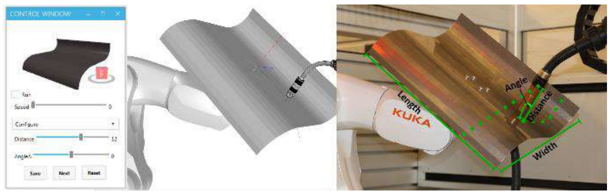

Figure 4 Link between parametric model & physical objects through robotics, with measurements through visual inspection

This allows the in-situ configuration based on parametric geometric models inside the parameter space instead of requiring and adaptation of the robot trajectory space. While in turn also informing the design and reducing sensor based adaptation to a local level.

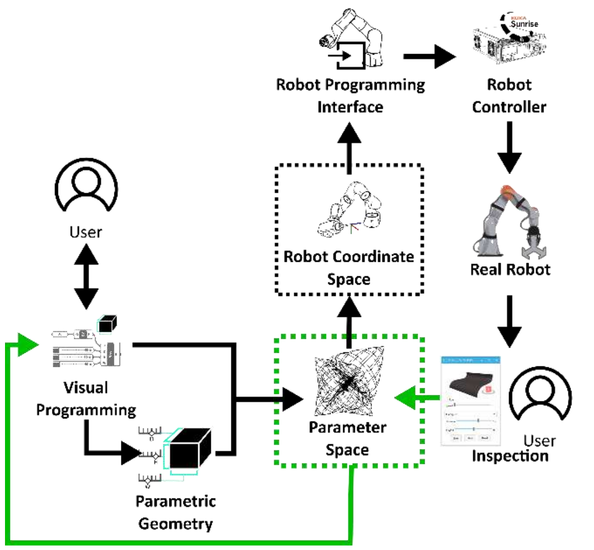

Figure 5 In-Situ parameter space adaptation in pin welding

While alternative approaches require a full scan of every part, the process can be optimized just by a distance measurement to ensure optimal fabrication while overall part position and dimensions are informed by interconnecting parameters within the robot coordinate space. Figure 6 shows the quality difference in aligned and unaligned pin welding.

Within other projects [25] for the assembly of timber structures the chair for individualized production in architecture used similar means of employing planning knowledge in combination with force torque sensors for localized measurements.

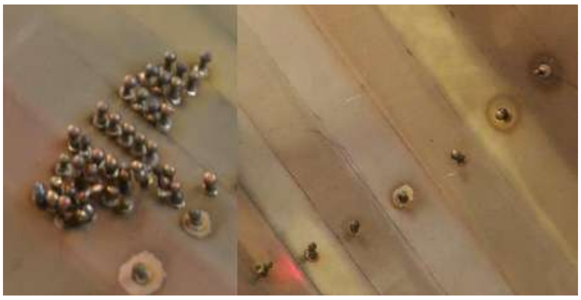

Figure 6 Pin welding with & without surface alignment

5 Approach for Planning and Scheduling

Due to the extensive changes both in prefabrication and in-situ production, it is necessary to adapt digital planning, working methods and organizational structures to changing circumstances. An important aspect here is the area of tension between the possibilities of industrial prefabrication of modular components in the factory for customized individualized application on the one hand and a targeted exploitation of site factors at the construction site, such as shortened transport routes, the use of local resources, assembly without devices and local production methods on the other hand.

This requires further development of agile planning methods and an uncertainty management for the building sector, which encompasses the entire construction process of a building from the beginning of the planning to the final acceptance of the finished building. Possible changes need to be evaluated at any time in a comprehensible way with regards to their effects (construction time, costs, etc.) according to the criteria of Lean Construction. Utilization can be increased due to the ever-increasing networking and the resulting improved possibilities of production planning and monitoring. In the event of planning or construction changes, both points provide the possibility of forecasting and initiating the costs and times of a necessary just-in-time production. The rigid structure of the production facilities in steel construction and the enormous specialization of workstations has so far prevented a high degree of individualization and the efficient production of small batch sizes and individual parts. However, the demand for this from architects and users of buildings is steadily increasing.

Here, the use of robots can achieve significant added value. If one understands the industrial robot as a machine for the assumption of stressful or highly precise motion sequences, a multitude of universal, adaptive tasks can be carried out with it, which only requires the development of adaptation to on-site factors and material- or product-specific process sequences. The same robot can take over a wide variety of sub-processes and minimize the organization and transport costs. The juxtaposition of bulky, locally tied special machines can be replaced by a flexible, multifunctional workspace. In order to further increase the degree of flexibility of such a highly adaptable workspace, mobile and stationary robots can be connected by means of intelligent, modular process flows. In addition, the wide range of movements of robots compared to conventional linear or gantry mounted machines enables simple and fast adaptation of standard mass production processes to the manufacture of highly individual components with complex geometries within the scope of mass customization. In addition to increasing the efficiency of the process and the cost-effectiveness and sustainability of buildings, further areas of application for steel construction are thus opened up and can lead to a general increase in production in the sector.

6 Usability and Adaptation

In order to guarantee a fast and continuously adapted development of new process sequences for individual, unique components, the handling of machines and machine programming must improve considerably with the help of adaptive software and intuitive operations. Up to now, the development of production processes and adapted machines has been in the hands of machine builders and computer scientists, leading to the accumulation of various special software. The adaptation of complete or individual process flows cannot usually be carried out by the steel constructors themselves, but only in consultation with specialists. This not only leads to unnecessarily long conversion and adjustment times for existing factories. It also prevents the seamless, direct integration of the existing material and process know-how of the steel constructors and other parties involved in planning into the production process. Uniform, intuitive software can lead to planners, employees and technicians of the steel construction companies being able to develop and map their production processes themselves in ever faster cycles. Stronger, interdisciplinary interaction between different disciplines for effective integral planning and BIM should be urgently implemented.

The software plug-in KUKA|prc (parametric robot control) [26] is a model for intuitive robot programming in the creative industry. The universally usable basic structure of the software enables a simple, geometry-dependent path planning of the robot as well as the smooth integration of further design and material parameters up to the optimization of the arrangement of work pieces in the working space of the robot to improve the production time. This is also what inspired the described process adaptation used within the described pin welding process.

The proliferation of such an open, intuitively operated system could, in turn, not only increase the efficiency of a single trade union, such as steelwork within the construction industry, but could also bring about the linking and simplified monitoring of the entire construction and planning process of a building. This offers advantages above all in the cross-facility production of highly complex, multifunctional components and building modules and saves the time-consuming assembly of individual parts on the construction site.

7 Conclusion

Even though theoretically there is already a high degree of automation in steel construction, high investment costs and extensive factories make it affordable only for large companies. Scalability of workspace through the flexible use of robots and intuitive, open software systems can be solutions here. The challenge for industrial scale applications will be to combine individualization, which is important for the construction industry, with process reliability. It is already becoming apparent that in the field of robot-assisted manufacturing, topics such as the standardization of interfaces can only be solved jointly and pre-competitively.

Innovative researchers such as MX3D [27] and the RAMLAB (Rotterdam Additive Manufacturing LAB [28] are developing the incremental welding of additive manufacturing. This approach lays down lines of welds to build up a three dimensional object. This method creates challenges for determination of structural integrity as the heating and cooling phases of each additive layer varies in terms of distance and durations. Fundamental research into the robotic fabrication of 3d printed steel is being undertaken. This research has the goal of analyzing the material characteristics and structural qualities of 3d printed metal deposition in order to optimize and speed up the process including the integration of adaptive methods informed by sensor data and predictive models.

The development of additive manufacturing through the robotic fabrication of 3d printing in steel can lead to advancements in construction technology and new ways of mass customizing bespoke geometries both on-site and in factory settings. This paper provided a first foundation for future architectural developments to build upon. Through a consideration of this technological innovation, both present and future potential applications, considerations, constraints and benefits of this new methodology were analyzed. This included a discussion on future challenges and opportunities, ranging from fundamental questions in need of analysis, as well as the possible applied opportunities that suit the unique capabilities inherent in the robotic 3d printing of steel.

The intersection of automation and material innovation can lead to new paradigms of architectural construction. Future industrial revolutions will continue to disrupt existing standards of practice. This paper brings to light the potential of steel's future in order to provide a milestone by which to measure our progress to date and plot a path into the future with respect to new methodologies for creating steel structures.

Abstract -

One of the major challenges of a real-time autonomous robotic system for construction monitoring is to simultaneously localize, map, and navigate over the lifetime of the robot, with little or no human intervention. Past research on Simultaneous Localization and Mapping (SLAM) and context-awareness are two active research areas in the computer vision and robotics communities. The studies that integrate both in real-time into a single modular framework for construction monitoring still need further investigation. A monocular vision system and real-time scene understanding are computationally heavy and the major state-of-the-art algorithms are tested on high-end desktops and/or servers with a high CPU- and/or GPU- computing capabilities, which affect their mobility and deployment for real-world applications. To address these challenges and achieve automation, this paper proposes an integrated robotic computer vision system, which generates a real-world spatial map of the obstacles and traversable space present in the environment in near real-time. This is done by integrating contextual Awareness and visual SLAM into a ground robotics agent. This paper presents the hardware utilization and performance of the aforementioned system for three different outdoor environments, which represent the applicability of this pipeline to diverse outdoor scenes in near real-time. The entire system is also self-contained and does not require user input, which demonstrates the potential of this computer vision system for autonomous navigation.

Keywords -

SLAM; Context awareness; Real-time integrated system; Robotic computer vision system; Construction monitoring

1 Introduction

A mobile robot operating in the physical world must be aware of its environment. A large part of this awareness is about estimating spaces (i.e., of mapping) and the robot's location (i.e., localization) [1]. In the absence of external localization aids, the robot must be able to build a map and, at the same time, localize itself in the same partially built imperfect map [2]. The robot must be "contextually aware" of its surroundings, meaning that the robot must be capable of sensing different objects and making situation-specific decisions based on them. This is achieved through object recognition via semantic segmentation, which enables the generation of a spatial map of the obstacles and the traversable space of the environment. This work can also boost autonomous robotic applications to achieve a higher degree of automation in construction monitoring and personalized safety, which have high rate of interest among researchers in this area [3–8].

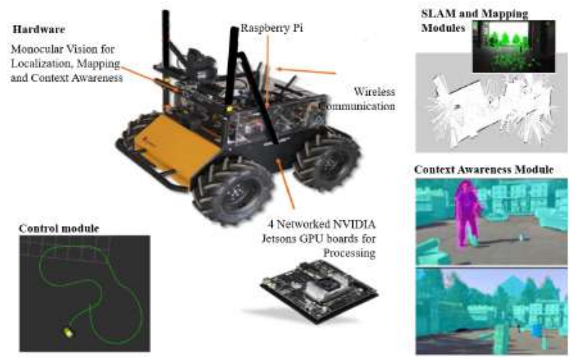

Figure 1. Overview of system components- hardware, control, SLAM, context awareness and mapping

The recent advance in powerful and portable processing units have enabled analysis of complex data streams in real-time. These small processing units with high-computing capabilities are well-suited for environmental monitoring using a combination of cameras, microphones, and sensors for temperature, air-quality, and pressure [9–11]. Still, there are a few well-set platforms that combine the state-of-the-art hardware with accessible software and opensources. This paper proposes an integrated mobile robotics agent that is capable of processing localization, mapping, scene understanding, and control and planning. The proposed integrated system uses multiple NVIDIA Jetson TX1 boards [12], each handling a specific task. The low-power consumption and integrated GPU make the Jetson TX1 an ideal candidate for running the aforementioned processes in real-time. As illustrated in Figure 1, the sub-tasks are control, simultaneous localization and tracking (SLAM), image segmentation (denoted as Context Awareness), mapping. For validation, three case studies that captures three different outdoor scenes are performed to evaluate the system's robustness, performance, its integration, and, therefore, its feasibility of the future development of an autonomous ground robot.

This paper is organized as follows: Section 2 presents a literature review on SLAM and scene understanding which are the primary sub-tasks in this approach. Sections 3 describes the system overview and hardware modules of the proposed system. Section 4 describes the approaches taken to perform the above-mentioned pipeline. Section 5 presents the system evaluation and results. Section 6 ends this paper with the conclusions and future works.

2 Background

2.1 Monocular SLAM

In a dynamic environment, human eyes can quickly and accurately provide visual information that our brain uses to map and understand the environment. A robot must also know with a high degree of certainty, where it is located in the environment. Only if this occurs, can it localize itself with respect to the map, which is essential for tasks such as navigation and motion planning. Likewise, using cameras, robots get visual information and they can generate maps of their environment. For building a good map, accurate localization is needed and for accurate localization, a good map is necessary. This chicken and egg problem is what SLAM aims to solve [13].

Initial approaches focused on 2D maps using a laser scanner or LIDAR [14]. The advantage of such approaches was the speed of mapping and the lower computational cost. However, LIDAR-based approaches suffer when there is a lot of heat and reflective surfaces that affect the laser [15]. Also, 2D approaches are unable to capture the scale of the obstacles. With an increase in processing power and development of better algorithms, the use of cameras for SLAM became more feasible.

When it comes to monocular vision-based SLAM, ORB-SLAM [16], Direct Sparse Odometry (DSO) [17] and LSD-SLAM [18] are the widely used algorithms. ORB-SLAM is a feature-based method, while LSD-SLAM is a direct method based on color intensities in the image. Relying on feature extraction, feature matching, and visual odometry, maps are built, but the drawback is that the map is accurate only up to a scale. There are several methods available in the literature which can achieve this task in real-time [16, 18–21]. The approach discussed in [16] is the most appropriate for the current task due to its speed and ability to run in real-time on the TX1. The point cloud and odometry of ORB-SLAM is not directly usable as their units are not in real-world scale. Hence, one of the tasks is to transform the unscaled odometry to real-world units. In this work, the SLAM Module provides the odometry and tracking state to the Context-Awareness and Control Modules.

2.2 Scene Understanding

The literature in object recognition is very rich, and yet growing. The goal of making the robot contextually aware can be achieved through recognition of the objects and taking decisions based on such insights. Either object classification or scene segmentation can be used for scene understanding purposes. Scene segmentation, while being more computationally intensive, provides more precise results, especially near the boundaries of objects.

Even though, convolutional neural networks (CNNs) had been utilized for a long time [22], they seemed to be hard to use for bounding-box object classification up until 2014. This was when an image region proposal scheme was combined with CNN's as classifiers and was able to outperform other object detection frameworks [23]. Later versions of R-CNN object detection were introduced to resolve some of the R-CNN's limitation, such as training pipeline complexity and slow test-time [24, 25]. Fast R-CNN [25] sped up the inference time by a factor of 25. In this method, computation of convolutional layers was shared between region proposals of an image. Faster R-CNN [24] inserted a region proposal network (RPN) after the last convolutional layer. By this change, the method required no external region proposal which improved computational speed up to 250x.

High computational load is one of the main limitations for (CNN)-based frameworks for semantic segmentation. [26] proposed a semantic segmentation framework using fully convolutional networks and utilizing existing classification networks, such as GoogLeNet [27] and AlexNet [28]. This method transfers learning approaches via fine-tuning of pre-trained models. [29] is also based on a very large encoder-decoder model performing pixel-wise labeling which suffers from a tralarge number of computations.

MobileNets [30] and Enet [31] are computationally lighter convolutional networks. ENet is designed to run on embedded boards with a focus on distinguishing roads from the rest of the scene. These capabilities make it suitable for autonomous robot navigation in outdoor (and particularly construction) sites.

3 System Overview

The monocular vision-based approach in the current study is described in this section. Figure 2, shows the

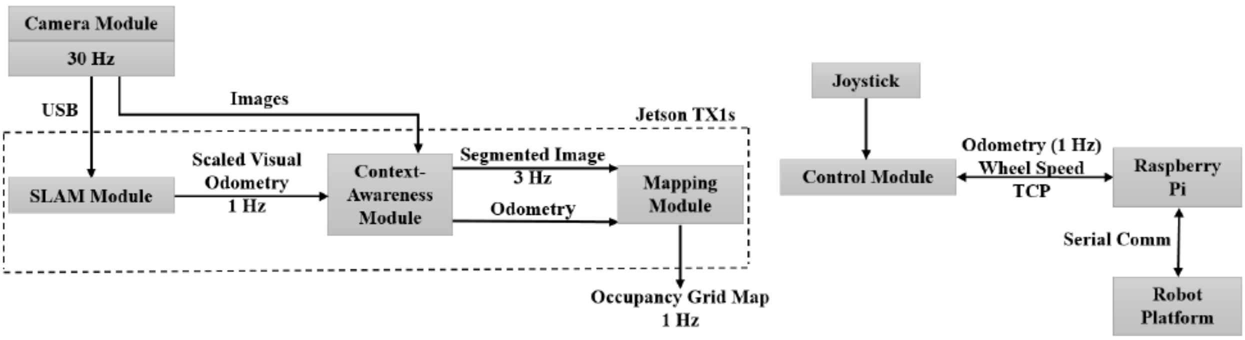

Figure 2. Monocular vision-based general pipeline

integration of aforementioned modules. The SLAM Module sends the scaled odometry to the Context-Awareness Module. The Context-Awareness Module processes the images using a scene segmentation scheme and generates a 1-D array. This array indicates the obstacle boundary which are inputs to the Mapping Module. The Control Module receives the control commands from a joystick and passes them to the Raspberry Pi. Robot Operating System (ROS) [32] is used in this research to simplify the data exchange process between multiple modules.

Figure 3, illustrates the hardware used in the proposed system which are; A Clearpath Husky A200 [33], NVIDIA Jetson TX1 [12], Raspberry Pi, Wi-fi enabled router, and a Microsoft Xbox controller. The controller is connected to the Control Module and is responsible for manually controlling the robot for initial mapping of the scene. This happens by sending this information to the Raspberry Pi through a TCP socket and the Raspberry Pi sends back the wheel encoder information. The Raspberry Pi can also operate a kill switch to stop the motors in case of an emergency. In Figure 3, There are four NVIDIA Jetson TX1 boards. Each module runs on one board to minimize logistics and integration time. A network via router on the robot connects all the Jetson boards.

4 System Description

The main goal of this research is the integration between SLAM Monocular Module, Context-Awareness Module, Mapping Module, and Control Module. This integration leads to the generation of an occupancy grid map of the environment which forms a spatial map of obstacles and traversable space of the scene. In this section, other capabilities of these modules are explained in detail.

4.1 Real-time visual SLAM with scaled odometry

The provided odometry to the Context-Awareness Module cannot be used directly. To solve this issue, the proposed approach in [34] is implemented to get the scaled information between visual odometry and wheel odometry. Both odometry are calculated for the entire path and then a closed-form solution is generated. Finally, The scaling matrix between wheel odometry and visual odometry is found and updates every second. The final odometry output that other modules can use is published as a ROS topic at a frequency of 1 Hz, as shown in Figure 1. Figure 4, shows scaled ORB-SLAM in red compared to unmodified SLAM in blue which shows that the scaled ORB-SLAM improves the trajectory. The unmodified SLAM is not able to detect the simple turn or even moving in the straight line.

4.2 SLAM and Context-Awareness Modules contribution to provide segmented images

The next step is to provide images and synchronize scaled odometry to the Context-Awareness Module for the segmentation of ground plane and obstacles. Contextual Awareness Module provides the intelligence and aids in decision-making while in motion. It strives to improve a general awareness of the environment by enhancing the visual information from the monocular camera.

Creating the segmented images and preparing them to be used by Mapping Module consists of three steps; pixel-wise semantic segmentation, filtering the segmentation vector, and perspective transformation. The segmentation model Enet [31], is used to produce a pixel-wise semantic segmentation map per image. The segmentation vector is a 1-D vector along the horizontal axis that represents the distance to the closest object at each point. Finally, a perspective transformation is implemented to convert from image to the world coordinate system. This information is used by Mapping Module to create the occupancy grid map of the environment.

4.2.1 Pixel wise semantic segmentation

The pixel-wise labeling task assigns a label to every pixel of the image. This typically requires models that are computationally heavy, with a lot of parameters. Due to

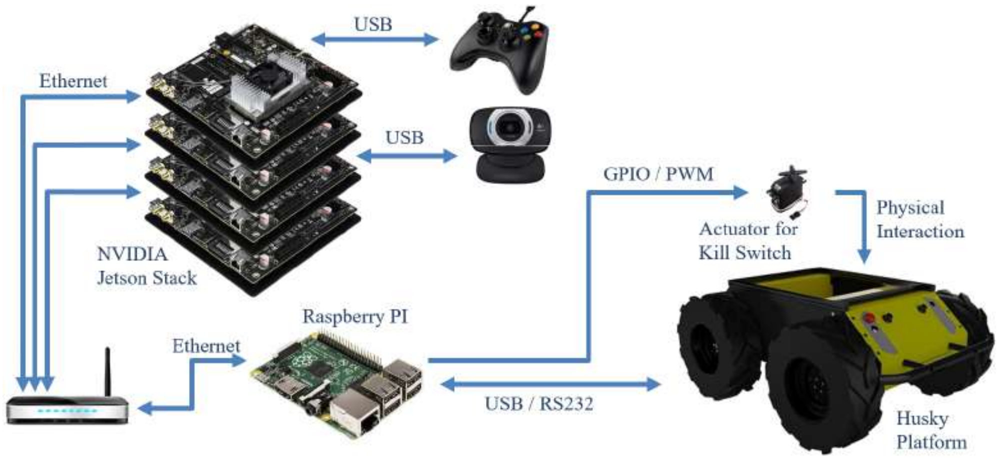

Figure 3. Physical diagram of components in the platform. The channels used for interactions between the different physical modules are labeled in blue.

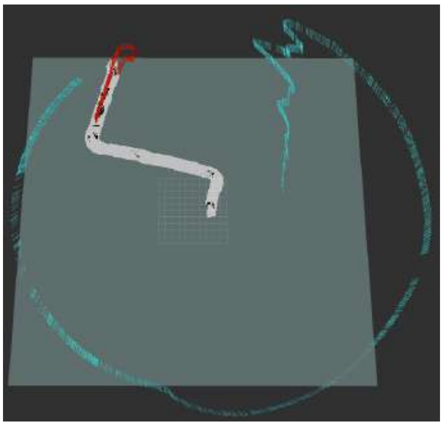

Figure 4. Scaled ORB SLAM odometry (red) vs. unscaled ORB SLAM odometry (blue)

the limited computing capability of the Jetson, a smaller model (ENet) is chosen with a slightly lower accuracy, but fast enough for near real-time performance. ENet method for semantic segmentation [31] is designed to work on embedded boards and in the current research this method is implemented on the Jetson TX1 with image input size of 512×256, at speed of 10 fps (much faster than other models such as Segnet and FCN [26, 29]).

The labeled pixel-wise data are input to ENet during the training phase. In this research, a scripting file is implemented to easily label images with freehand drawing. 1000 images, captured from multiple videos, are sampled and labeled manually. Grey-scale images with pixel information being the class label and size similar to input image size are used for training the network. Five labels are used for labeling as shown in Figure 5: object, road, person, sky, and unlabeled.

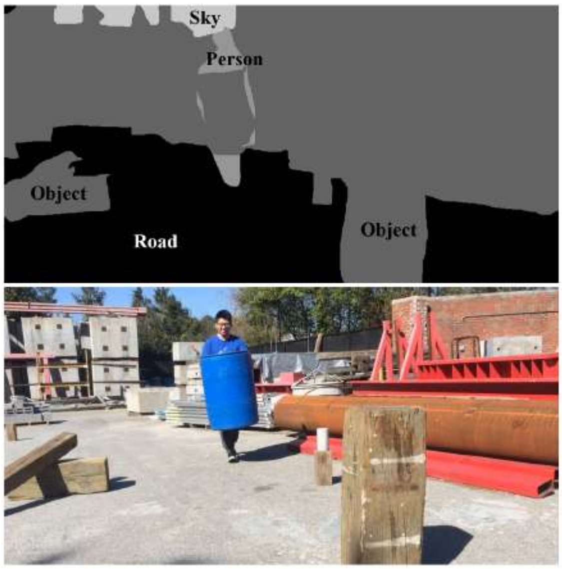

Figure 5. Different labeled classes

The training process includes 2 steps. First, training the encoder part. The input images for encoder training has a size of 512×256 and the size of output labeled map is 64×32. The model is trained for 300 epochs with a batch size of 10. Second, training the decoder part on top of the encoder to convert the intermediate map into the same dimensions as the full image.

4.2.2 Filtering the segmentation vector

The robot can move safe in the places that are known as road in the image. First of all, a 1-D vector is computed which provides the first instance of the obstacle when going through the bottom (the blue line in Figure 6). The filter is tuned to only include objects that are within 2.5 meters of the camera. Also when the vector is vertical it probably means that it is not actually the base of the object so it should not be included in the occupancy grid. To this end, points with the high gradient (more than one) in the x-direction are filtered out. The red segments in Figure 6, indicate filtered segments which are plotted as obstacles.

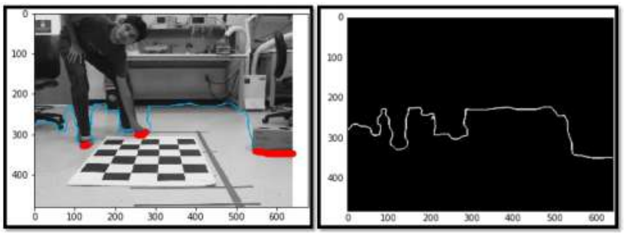

Figure 6. Red dots indicated filtered points to be considered obstacles

4.2.3 Perspective transform

The 2D image coordinates are transferred into physical distance values from the base of the robot using perspective transform. In the proposed system, the location and orientation of the camera are fixed related to the robot. Hence, a fixed perspective transform from specific focal length and camera position can be used for the whole process of mapping the pixel locations to its real-world locations (see Figure 7).

In reality, the perspective transform matrix is little different with the transformation matrix in Figure 7. The reason is, the origin starts from the top of the image, not the camera itself. Also, it is necessary for the pixel mapping to be symmetric on the left and the right sides of the robot, but the camera is not exactly in the center of the rectangle.

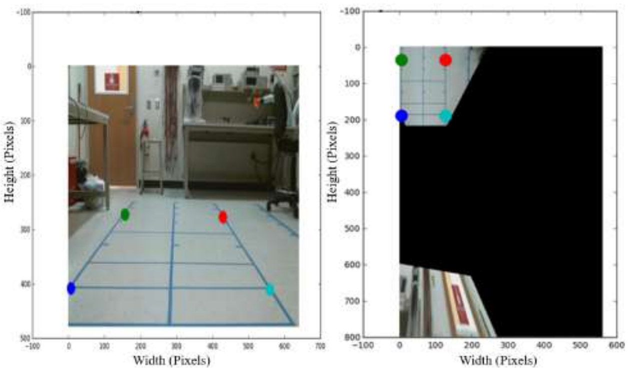

Figure 7. Left: Original image, Right: Perspective transform

4.3 Occupancy grid map creation

The Mapping Module uses the segmentation results to provide an occupancy grid map. The aforementioned obstacle position vector from Context-Awareness Module is processed to find the lower boundary of close obstacles. Next, the perspective transformation matrix helps to find the real world obstacle locations. Finally, the position of obstacles is plotted on a local rectangular map with 1.1m wide and 2.5m long and the global map incrementally updates by using the local map (see Figure 8).

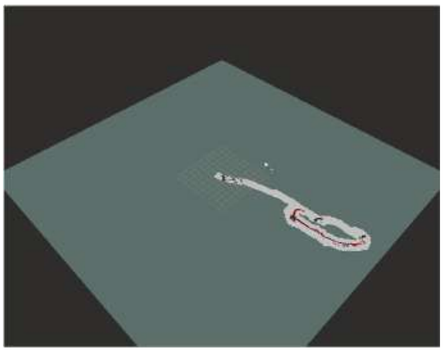

Figure 8. Global map

4.4 Publishing tracking state of ORB-SLAM for SLAM and Control Modules integration

It is necessary for the SLAM Module to know whether or not ORB-SLAM has initialized tracking. The Context-Awareness Module is not able to segment the images if the SLAM Module loses track. Also, the Mapping Module needs the images from SLAM Module to update the global map and the SLAM Module can only send the images in the tracking state. SLAM Module publishes following states: waiting for images, not initialized, tracking, and tracking lost. Providing this information for Control Module enables the robot to retrace its path in case tracking was lost. [35] shows the tracking state in the ORB-SLAM Module.

5 System Evaluation and Results

The proposed system is tested in three different outdoor environments with various object and weather conditions as shown in Table 1. The Figure 9 shows a representative image of the environment and a screenshot of the occupancy grid map during its generation. The RVIZ tool of ROS is used to visualize the occupancy grid map. The red line in the image is the trajectory of the robot and the grey rectangles represent the mapped areas.

The focus of the validation in this research is on the integrated robotic system which brings multiple components together and runs in real-time. The videos of the

Table 1. Environment description

Evironment Type	Object Type	Weather Condition	Video Length (minutes)	Number of processed frames (pipeline rate of 1 Hz)
Parking space 1	Car, curb	Cloudy	12.7	762
Construction site	Wooden planks, trash bin, cement slab	Cloudy	15.15	909
Parking scene 2	Trash bins, utility cart	Sunny	9.5	570

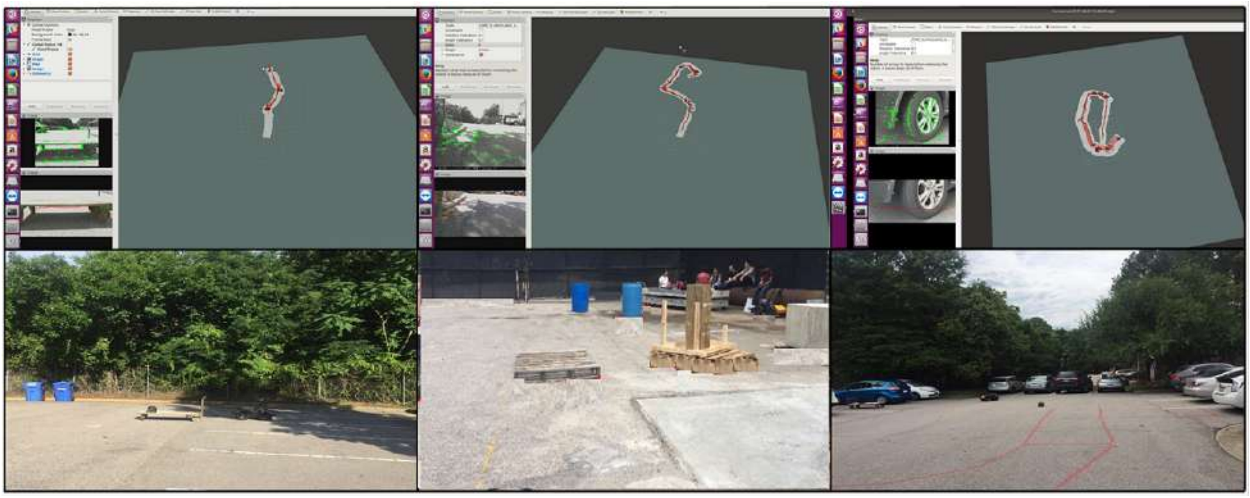

Figure 9. Image of the environment (bottom) and its corresponding occupancy map (top).

whole pipeline demonstrate the capabilities of this integrated system in near real-time [36–38].

The computational load on the Jetson boards is also presented for future systems and pipelines (see Table 2). Since the Jetson board has a quad-core processor, the percentages for the CPU are within a range of zero to 400. The CPU usage of ORB-SLAM is very high, but the scaling process in SLAM Module requires light computing. Figure 10, shows that the Context-Awareness Module runs heavily on the GPU. When an image is passed over to the ENet network, a segmented image is produced and is shown as a spike in the GPU usage in Figure 10. This process publishes the boundary-position vector at the end of processing. The hardware usage for Mapping Module is not significant and it shows the potential of implementing more than one module on one Jetson.

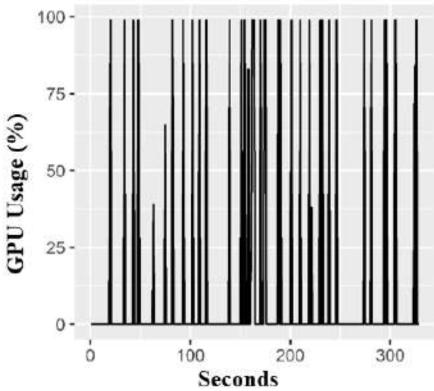

Figure 10. Context-Awareness Module GPU usage graph (%)

global Map	54
local Map	18

6 Conclusion

This paper presents an integrated mobile robotic system that runs multiple vision-based components in real-time. The proposed system implements monocular SLAM and contextual understanding of a scene, which creates a 2D spatial map with detected obstacles. This system showcases the importance of a modular framework which can include latest SLAM and Context-Awareness algorithms in a plug and play format. This system is effective and can be run in real-time on multiple embedded platforms that are integrated as a system. The proposed system is a step forward in making intelligent and contextually aware robots ubiquitous. The results also demonstrate the potential for enabling a computer vision system for autonomous navigation.

Some of the possible extensions and improvements to this projects are documented as follows. For instance, the proposed system does not have an effective way to deal with a large area to be mapped in real-time. A potential solution is to remove older parts of the global map and will be investigated in the authors' future work.

The use of higher resolution input images with more features will result in better tracking and mapping. To ensure that the algorithm still runs in real-time, the feature extraction and matching parts can be moved to the GPU. This will allow us to get better results in a dynamic environment.

The computational load put on each Jetson board shows that the module corresponding to the segmentation task runs heavily on the GPU. The size of the model and high memory usage along with the need for real-time performance restricts the speed of the Husky [39]. Improving the segmentation model in order to reduce the computational load in the Context Awareness Module will address this issue.

Abstract –

The Building Information Modeling (BIM) is getting more and more common into building construction, but it hasn't been developed into underground work so far, although it would be very useful. Indeed, underground works strongly interact with their environment, and with many different stakeholders, whose data are partitioned into their own field. In this paper, a study dedicated to the development of a new decision support system is presented: it is a 3D visualization interface dedicated to worksite's technical management.

This tool is focused on tunnel boring machine (TBM) projects. Its main assets are:

-To have a 4D (3D + time) model, built in real time thanks to the connection to different databases of the worksite.

-To integrate data that comes from different fields such as: TBM excavation parameters, geological data (3D block model describing the lithology and rock alteration), buildings, tunnel as-built, stations, geotechnical and structural monitoring (settlement for example).

Until now, there has been no integration of these data into one single tool, making analyses of their mutual impact on each other quite complicated and tedious.

Keywords –

TBM; 3D modeling; 4D modeling; Visualization; Monitoring; Decision support system; Information management

1 Introduction

CAP is a system for tunnel boring machine (TBM), navigation, guidance, and data acquisition and survey. It is also a subsidiary company whose clients are TBM projects (Vinci and other general contractors).

The navigation module is based on automatic and periodic measurement of the real-time position relative to the tunnel alignment (using a total station).

The guidance module is composed of the steering console controlled by the pilot and the automaton leading to the action of the pushing rams and other actuators.

All the sensors data are stored into a database which can be used for surveying; including real-time analysis and monitoring.

This core system of the TBM is central to the worksite activity. However, it is not the only one needed. Indeed, the geology and geotechnics studies are not included; as well as the structural monitoring (such as the vertical settlement induced by the passage of the TBM).

These other systems are based on their own software solutions, with separate data representation. It means that a TBM worksite is driven by partitioned systems: there is not a global tool to integrate the crucial data throughout the project.

In addition, there is for now a lack in 3D representation for the linear infrastructures, and especially for linear underground works (geometric design tools, and data structures). The creation of Industry Foundation Classes (IFC) dedicated to underground works is at its early stage [1].

These are the reasons why we decided to carry out a study with the aim of developing a new software for CAP system which would integrate data not only related to the TBM, but also to the other systems and available 3D models (for visualization purpose, not for navigation).

The research conducted herein has led to the creation of a 4D (3D + time) interface for data visualization and automatic tunnel modeling. However, it should not be considered as a BIM tool.

It has been developed in Unity3D and is in the prototype and demonstration stage. It has not yet been deployed/marketed on TBM's projects: which is what we aim to do (from one root software, making different projects for each worksite/client).

The data used in this case study is a real project: Rennes (France) metro line B (under excavation between

2015 and February 2018).

The rest of the paper is structured as follow. Section 2 presents the inputs that we wanted to integrate and how we worked on to do so. Section 3 describes the integration processes driven by a maximum of automation. Section 4 describes the implemented tools. Section 5 presents the feedbacks of the operators who would be the users of this system.

2 Inputs

2.1 TBM digital model

For the TBM modeling, 3ds Max has been used for its convenience for computer graphics design. Indeed, the head (cutting wheel, shield, tail, articulation jacks, pushing rams, erector segment) is geometrically conform to the blueprint, but the rest of it is only computer graphics representing an earth pressure TBM. It has then been textured, and rigged to enable its animation.

The Figure 1 represents its head, and shows the cutting wheel, the shield (separated in two by the 14 articulation jacks), and the 14 pushing rams (the jacks pushing on the concrete rings).

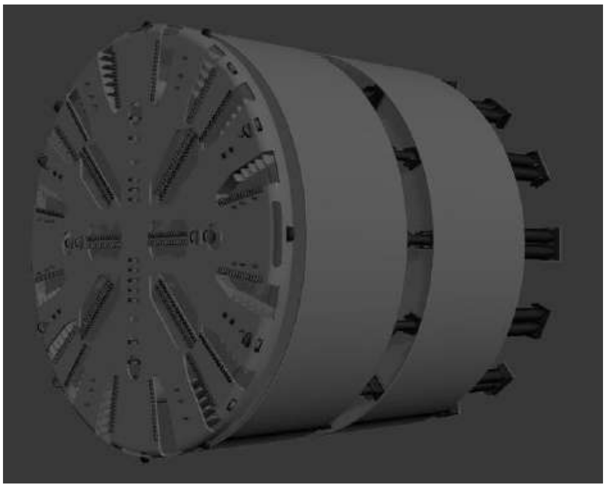

Figure 1 : Model of the TBM head

2.2 TBM parameters

CAP stores all its sensors data (it usually represents around 1000 parameters, including computed ones) in a relational database with a one second timestep. For this study, only around 60 seemed relevant to use.

The data needed for spatial representation of the various parts of the TBM are the articulation jacks and pushing rams extensions; and most important, is the curvilinear abscissa of the cutting wheel on the alignment of the tunnel (chainage).

The other data are the main excavation parameters: energy, speed, torque, speed, jacks pressure, etc.

2.3 Geological block model

The geology of the project has been modelled by interpolation of rocks interface identified into the drilling logs. The limits in between two given layers are considered as 3D points. The process consists in computing an interpolated surface passing through that points: giving a 3D model of the border of that two layers.

This is performed over all the drilling logs description, for each lithological rock interface. Additionally, the rock alteration profile can be modelled.

This leads to the generation of multiple 3D surfaces [2], constrained by the modeler, to its geological and/or geotechnical interpretation: the common constraint is to give a preferential orientation and dip of the layers. This 3D geological output has been generated using Eureka software (Maptek).

For automatic integration of the 3D geological data, it has been chosen not to use these 3D surfaces directly as inputs. Indeed, the objective was to map a mesh (ground) with geological information extracted from the 3D model; the most automatic process is to use a 3D block model composed of voxels (volumetric data). This geological block model has been computed from the 3D surfaces (Eureka software output) using Vulcan software (Maptek). The size of the cells has been set to 0,5m x 10m x 0,5m to fit the orientation and dip of the layers (E-W 70° S).

The Figure 2 shows the alteration profile of: a) two 3D surface meshes interpolated from the drilling logs information b) a cut in the block model obtained in Vulcan.

a) 
b) 
Figure 2 : a) 3D surfaces and drilling log in Eureka b) cut in the 3D block model in Vulcan

2.4 Structural monitoring

The structural and deformation monitoring is crucial for ensuring the stability on top, at the passage of the TBM. It is mainly automated, thanks to the setup of many different sensors (extensometers, inclinometers, total station / prism target etc.). On the ground, vertical settlement and differential vertical settlement is monitored.

Specific companies ensure this monitoring, centralizing in real-time into a database all the sensors data; analyzing them and computing rules and threshold for trigger alerts. They also provide software solutions for communicating to the worksite these monitoring results with GIS maps showing sensors and their values. Arising from this tool, the operators are facing many different maps and graphs, corresponding to different infrastructures, orientation, levels, etc.

We chose to represent only the vertical settlement; in the area where the settlement induced by the passage of the TBM can occur: 30m before the cutting wheel, as far as 100m after the cutting wheel (after the passage).

2.5 Tunnel alignment

A tunnel alignment does not have a 3D geometric description, because it is defined in projection plans. In the horizontal plan (x, y), it is composed of straight segments, clothoid, and circle arc. In the vertical plan, along the tunnel alignment – that is the 2D alignment previously defined – it is composed of straight segments and parabola. This geometric data is what is used to compute the position of the TBM relative to the tunnel alignment (thanks to the topographic polygonation and automatic total station tracking of the TBM).

The first extension for the IFC5 (dedicated to infrastructures) – the IFC Alignment [3] – has not been so recently released, but, to our knowledge, has not been deployed on linear infrastructures projects so far. It is connecting to GIS-like modeling, and will be the base for IFC bridge, IFC rail, IFC road and IFC tunnel [4]. While IFC Bridge is on progress for many years [5], the work on the IFC Tunnel has just started (in 2017 in France, via MINnD national project [1]).

We did not used IFC Alignment format; but simply the geometrical information of the tunnel alignment to compute a series of 3D points. A one-meter resolution of the chainage has been chosen; which is a greatly satisfactory precision: the 300-meter minimum radius resulting in 0,4mm maximum distance between circle arc and one meter segments.

The Figure 3 displays the tunnel alignment made of 3D points, in horizontal plan.

Figure 3 : tunnel alignment in horizontal plan

2.6 Stations BIM models

We had to our disposal the BIM models of the stations in IFC 2x3 format. These are LOD 300 BIM models (level of detail), and are segmented in subtrades which enables the integration of civil works only. These models have been exported via Revit in FBX format, keeping only the geometry and not the metadata. The Figure 4 displays one digital model of the project.

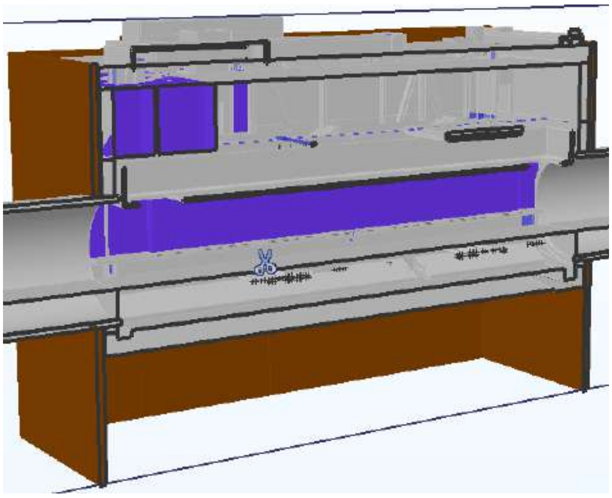

Figure 4 : BIM model of one station

2.7 City buildings model

Virtual 3D city models can be obtained from multiple techniques: photogrammetry (satellite, aerial or close range) and laser scanning (aerial or terrestrial laser scanning) [6].

After acquisition, the modeling can end up on different data: raw meshes, segmented post-processed models (like as-built buildings models with a certain level of detail). The standard file format for geographic information system (GIS) applied to cities is CityGML.

CityGML open-source data, including 3D models, are available for many big cities (for example Lyon metropolis, France [7]). These data are very relevant to integrate in a 3D application since they are segmented in sub elements, which can be used for interaction.

However, for the city of Rennes this data is not available. We decided to use satellite photogrammetry data composed of a unique mesh, including some artifacts, and vegetation (which is not the desired focus).

The Figure 5 shows a part of that mesh.

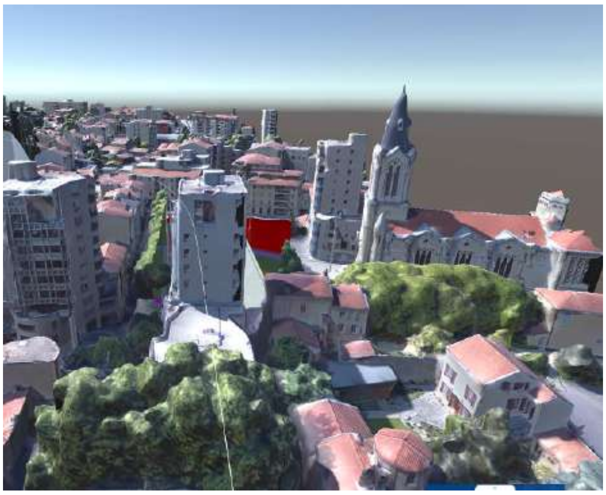

Figure 5 : City mesh

For further development, we would consider using CityGML models for the reasons mentioned above (which, if not provided in open source by cities, can be bought from dedicated companies).

2.8 Ring (tunnel lining segment) digital model

For tunnel modeling, the elementary object is the concrete ring. It has been designed on Inventor, based on the blueprints of the project. Its geometric features are detailed in section 3.3 p.4.

3 Integration into a Unity3D software

3.1 Integration overview

The inputs are integrated into a Unity3D software with maximum automation (for further projects to be created most efficiently). The TBM model is positioned and animated thanks to the TBM parameters, accessed via a http query on CAP database.

The digital models (static) were integrated into Unity3D using FBX format.

The geological block model is at the frontier between static and dynamic data: an update in the model is automatically integrated into the software (part of the Streaming Assets, with no need to get back to the Unity Editor). The methodology for its integration is developed in Section 3.4.

The Figure 6 illustrates the overall integration in the software. The verification is quite basic: the problems we encountered were due to bad georeferenced data (the worksites often use multiple coordinate systems); which are easily detected (visual check).

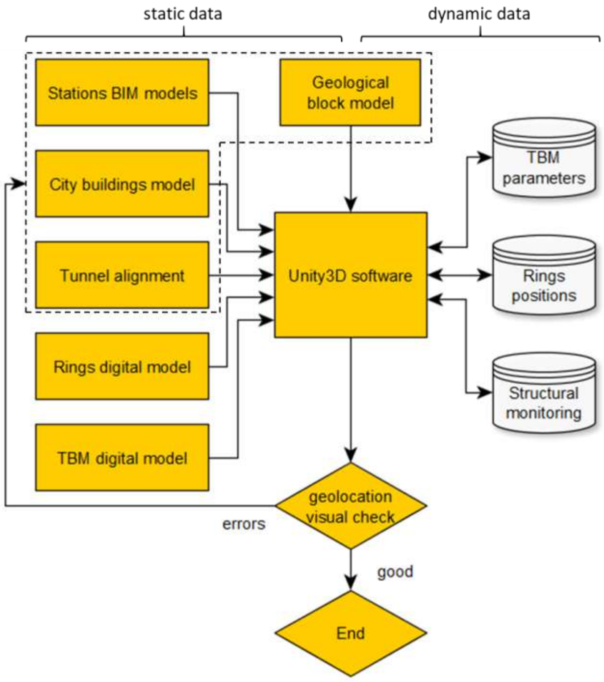

Figure 6: Inputs integration and verification overview

3.2 The choice of Unity3D

Unity3D is a game engine and an integrated development environment used to develop video games and simulations for computers and other devices. It is increasingly used in many industries applications.

Developing plug-ins onto BIM software would have been more complicated than using Unity3D (if not impossible); and it seems more likely to become obsolete with development on a specific software.

There are also convenience reasons that naturally led to choose Unity3D: drag-and-drop functionality, C# scripting. Unity3D being multi-platform is something valuable too: our software is only built on a computer application, but AR or VR may have a use for this tool.

Additionally, its widespread use in the field of 3D industrial application makes it an appropriate solution to plug in with other similar tools.

3.3 Automatic tunnel modeling

The real-time storage of rings position enables the automation of tunnel modeling. The json answer to the http query on the database is structured as follows: ring number, ring type (there are two types of rings: 1,3m thick and 2m thick), and angular position of the key segment. Besides, the chainage of the first ring is given.

A ring is composed of different segments (seven in our studied project). They form a cylinder cut at its borders by planes which are not orthogonal to the axis of the cylinder (forming a trapezium if looked at in the right projected plan, cf. Figure 7).

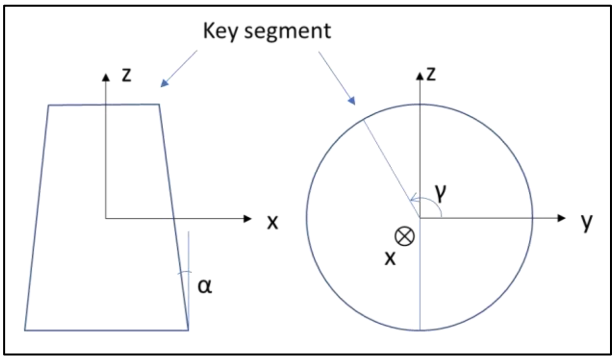

Figure 7: Drawing of a concrete ring

From the chainage of the ring, we can compute five degrees of freedom (DoF) thanks to the tunnel alignment data. The sixth one is given by the angular key segment position (γ) which is incremental.

This information is satisfactory to instantiate the sequence of ring models centred on the as-designed tunnel alignment, and with the true key segment positioning. Since the segment positioning is not defined by the construction survey, we can consider that as being a semi as-built modeling of the tunnel. The scripting of this part, and the frequent database connection (0,1Hz), makes it an automatic and real-time modeling tool.

Moreover, as time information for the pose of rings is stored in the database, we gave the possibility to watch its evolution over time (making it a 4D model). In addition, a metadata has been added on the segment models to link it to the document management system (DMS) of the project relative to the quality survey of the rings and to the traceability of their manufacturing.

The Figure 8 represents a part of a ring sequence seen from inside, and in which we can navigate. The ring number is displayed, as well as the segment numbers (the key segment is displayed with darker color).

Figure 8: Semi-as-built tunnel model

To obtain a full geometrical as-built of the tunnel, the real (as-built) tunnel alignment should be integrated.

M. Lu et al. computed an as-built of the tunnel from the position and orientation of the TBM [8]. However, the tunnel is moving a bit after the TBM passage (it is usually going up at a centimeter order of magnitude, due to the subtraction of the TBM weight). That's why topographic surveys are necessary to precisely measure the as-built tunnel alignment (the deformation of the rings is also measured). These data were unavailable at that time, therefore we tested another technique to obtain the as-built tunnel alignment. It has been computed using only the first ring position (for which the 6 DoFs are known), and the sequence of angular key segment position.

Based on the drawing of Figure 7, we can write the angular differences between ring N and ring N+1 (spherical coordinates) as follow in Equation 1-3.

$$\theta_{N+1} - \theta_N = \alpha(\cos\gamma_N + \cos\gamma_{N+1}) \quad (1)$$
$$\varphi_{N+1} - \varphi_N = -\alpha(\sin\gamma_N + \sin\gamma_{N+1}) \quad (2)$$
$$\alpha = arctan(l/2D) \quad (3)$$

γ being the angular key position; θ being the angle from x in the (x,y) plan of the ring frame; φ being the angle from z; l being the tapering of the ring; and D being the diameter of the ring.

We computed it on a dataset – in the cartesian coordinates system of the tunnel alignment – and compared it with the as-designed tunnel alignment. The Figure 9 shows the difference between these two alignments, along with their distance to the first ring.

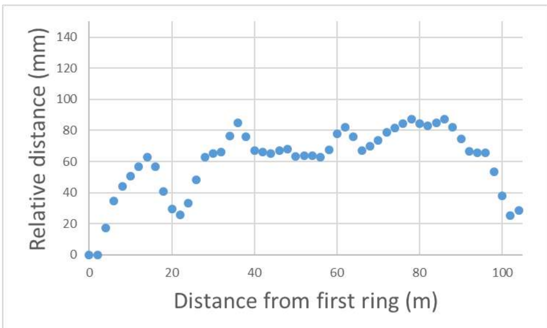

Figure 9: difference between tunnel alignment and computation from ring sequence

These values (around 7cm) are too big to be the true distance between as-built versus as-designed alignment. We suppose that the difference is due to the elasticity at the interface of the rings (rubber sealing).

For as-built alignment computation, we should either use the technique developed by M. Lu et al [8], or wait for the topographic survey to be done. The presented technique is of no use on its own, but could be used in complement with a topographic survey (for computation between the measured rings).

3.4 Creation of a ground mesh with display of geological information

For representing the geological block model data, we choose to create a ground mesh. This method is lighter for rendering computation than a volumetric rendering of the topological data.

The process of the mesh generation is based on “naïve surface nets”, a simplified version of “marching cubes” process [9]. It consists in meshing an implicit surface in a discrete distance field defined in each point of a 3D uniform grid. The size of the grid has been set to the smallest size of the block model cell.

The geometry of the model to mesh is defined by Constructive Solid Geometry (CSG) operator. This simple and fast process consists in combining closed surfaces thanks to Boolean operators (union, intersection, subtraction) [10].

For creating the ground mesh, we combine:

- A cube representing the edges of the ground.
- The surface of the tunnel defined by its polyline dilated to the radius.
- The simplified envelops of the stations by convex decomposition.
- The level at the surface of the ground. The implicit surface of the ground is defined by the distance of a point to the weighted neighbors projected on the weighted normal of the neighbors [11]. The neighbors search is optimized thanks to a KDTree (knnflann).

The surface mesh is then generated by surface nets method; which guaranty one quad per cell, rendering a color information for each cell without the need for creating textures, and wrapping/unwrapping them on the mesh. The drawback is the number of triangle to display, but it is still lighter than a volumetric rendering.

The color information (corresponding to a geological information) is rendered by “vertex color”. We define a color on each vertex of the mesh, thanks to the geological block model, and the color of the triangle is interpolated.

The Figure 10 displays the result of that process on the project dataset, including TBM and tunnel model.

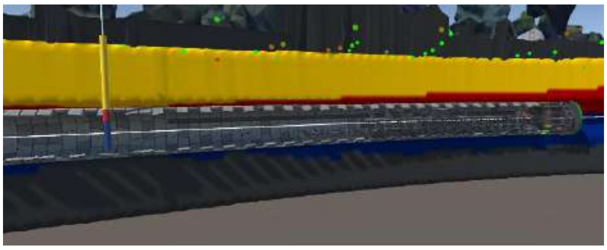

Figure 10: Ground mesh with geological colour information

3.5 Other integrated inputs

The Figure 11 shows the vertical settlement: each monitored target being represented as a sphere colored by its settlement value: green (0mm) to red (-3mm). The big white sphere represents the position of the TBM’s cutting wheel. This is a straight forward integration, relying on a database query.

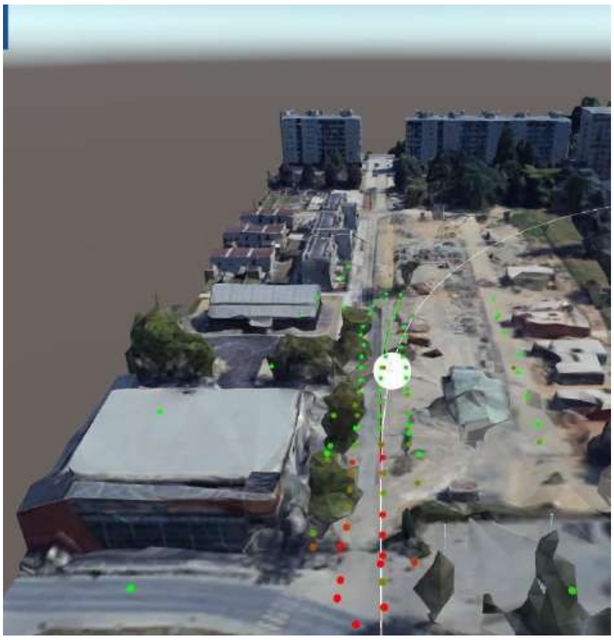

Figure 11: Vertical settlement monitoring

The Figure 12 displays the positioning of the TBM (head and rear cars) thanks to the chainage information, articulation jack extensions, and tunnel alignment. The rings are also represented.

Figure 12: TBM positioning on the tunnel alignment

All this information being stored in databases, it is possible to visualize it over time such as for the tunnel modeling. However, in this prototype software, it has not been fully integrated with data over time. It will need some optimization not to overload the internet bandwidth of worksites with high frequency queries.

3.6 Resource-efficiency compared to data weight.

We worked on optimizing the size of the meshes. The original versions were much heavier than the final ones presented in Table 1.

Table 1. Mesh vertices number classification

Element	Vertices	Triangles
City	1 166 626	2 060 814
Ground	286 167	558 185
Station 1	12 646	51 104
Station 2	78 116	245 079
Station 3	49 293	105 205
Station 4	34 377	94 639
Station 5	27 397	96 300

When testing the run of the built application, it has been noticed that we are far from overloading the processor (Intel Core i7-7500U). Around 40% of its resources are used (cf. Figure 13).

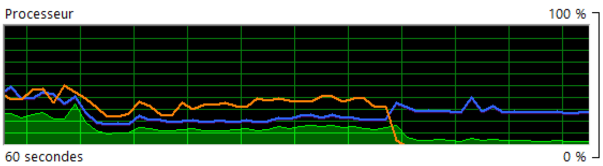

Figure 13: Processor resource (orange curve)

However, a full worksite can be much bigger than this scene (this represents only 1,4km of the 9km of Rennes project). Without optimization on data visualization (such as GIS rendering optimized with the distance of the camera), it will be overloaded. This subject will be addressed on further studies.

These performances do not guarantee every possible project with the same mesh volume: it relies also a lot on other parameters, like the textures. Additionally, a changeover on WebGL could be asked (which would need to do some compromises).

The geological block model represents 87 728 935 points. Instantiating a cube GameObject for each point would have led to over than 2 billion vertices.

4 Implemented tools

4.1 An interpolation of the surface vertical settlement

To give a better representation of the vertical settlement local data, we decided to compute 2D map over the surface of the project, inspired by the interpolations usually employed for level interpolation [12]. The result presented on Figure 14 has been done using an inverse distance weighting interpolation (IWD). We should consider studying also other interpolations to analyze what fits best, because we did not find articles on that specific topic.

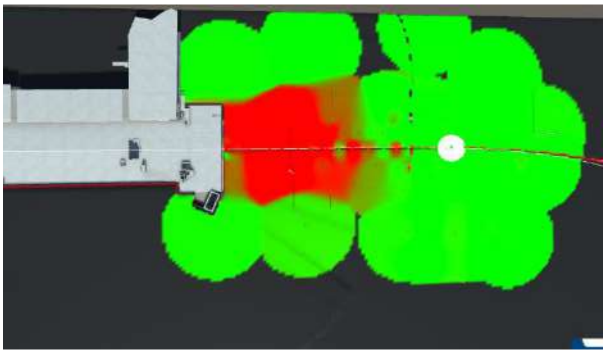

Figure 14: Interpolated vertical settlement map

4.2 A cutting functionality crosswise of the tunnel alignment

Usually, the geological (and potentially geotechnical) drilling logs interpretation does not end up with the computation of a 3D model for underground worksites. In most cases, it is manually interpolated over the longitudinal vertical cut of the tunnel alignment. That's why the only visualization of the geological data along the longitudinal cut does not have a strong value added.

The crosswise cuts, on the contrary, are not usually produced, except for specific areas where it is required. To differentiate from what already exists, we implemented a cut functionality crosswise of the tunnel, positioned by the user. It is a 2D raster geolocated that gets the data from the 3D block model.

Additionally, it represents the interpolated vertical settlement along its cut segment (the settlement value has been multiplied by 1000 so that it is visible). The Figure 15 displays an example of a cut.

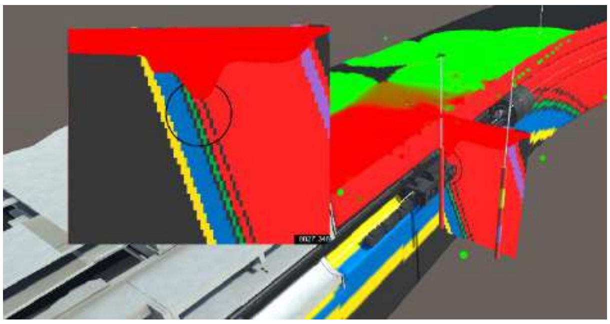

Figure 15: Crosswise cut

5 Feedbacks from the worksite operators

This prototype software has been presented to many worksite operators (technical management) to have their feedbacks. From their point of view, having global information represented in 3D is very valuable. They consider this potential tool as a decision support system that would ease representation of a big amount of data that can't be naturally seen in the real world (because underground). Indeed, the environment, the geology, and the TBM behavior (amongst others) are impacting for the decision making (such as the confinement pressure). Furthermore, the overall visualization can help understand/interpret soil behaviors (e. g. structural monitoring behavior explained by a geological analyze), leading to a better response. It would be particularly helpful when they are facing an incident, and needing to take a quick and efficient decision.

Opinions are diverging when it comes to discuss who the user would be. Everyone agreed that it would be used by technical management, in the office; but some say that it could also be used in the TBM, by the pilot.

Something specific has been noticed, and is important to highlight. From what we know, 3D geological block model is not used in the construction industry (unlike in the oil and gas or mining industries). Operational teams are not used to its scientific representation, and can find it inaccurate since it leads to knurled edges on the cuts, whereas they usually analyze cuts with smoothed interpolation in between drillings logs data. That's why it is necessary to well explain this representation before deploying such data.

The interviewed people also agreed on its limitations: it will not substitute from the other data representations, and software solutions. This new tool aims to ease the overall comprehension of the worksite and better its representation for the operators. It will not enable high end analysis of specific data, for which the existing tools are satisfactory.

6 Conclusion

This study resulted in the development of a functional prototype software of a 4D visualization tool dedicated to underground projects including a TBM: merging data that are usually partitioned into their own field.

We consider that it is a successful proof of concept of what can be done using the data to our disposal from worksites (3D models, and database information) for global 3D integration thanks to Unity3D. The main limitation to broadly deploy this software on worksites equipped with CAP system is the need for manual integration of the data; despite the efforts for maximum automation (such as station texturing, and database connections). This will be further investigated for creation of new projects quickly and efficiently.

One of the problem we faced during that study is the lack of clean, structured data; in addition to the multiple coordinate systems used. For further work – development or deployment – we would ensure that the exchanged data with the worksite are well specified, until BIM become widespread in the underground projects.

Abstract –

Extracting knowledge from data on near hits (aka. close calls) might warrant better understanding on the root causes that lead to such incidents and eliminate them early in the risk mitigation process. While a close call is a subtle event where workers are in close proximity to a hazard, its frequency depends–amongst other factors–on poor site layout, a worker's willingness to take risks, limited safety education, and pure coincidence. While existing predictive analytics research targets change at strategic levels in the hierarchy of organizations, personalized feedback to strengthen an individual worker's hazard recognition and avoidance skill set is yet missing. This study tackles the bottom of Heinrich's safety pyramid by providing an in-depth quantitative analysis of close calls. Modern positioning technology records trajectory data, whereas computational algorithms automatically generate previously unavailable details to close call events. The derived information is embedded in simplified geometric information models that users on a construction site can retrieve, easily understand, and adapt in existing preventative hazard recognition and control processes. Results from scientific and field experiments demonstrate that the developed system works successfully under the constraints of currently available positioning technology.

accident investigation; building information modeling; close call; construction safety; data mining; education and training; hazard identification; location tracking; near miss; predictive analytics.

1 Introduction

Better understanding the root causes that lead to an accident is important to protect construction personnel from similar mishaps in the future. Unfortunately, most of the current accident investigation methods focus on supplying valuable information after the fact, once a person has been injured or killed. Accident investigation reports, as explained in [1], are often (purposely) brief and only a few pages long [2]. Fatality assessment and control evaluation (FACE) reports are one example of a practiced method of an investigation [3]. They typically contain factual information, for example: a description of what happened, the actual results of the event, the persons involved, the equipment or material involved, the activities preceding and during the event, the date, time and place of the event, any emergency actions taken, some pictures of the event situation, and the immediate remedial actions taken.

While the contributions of this study do not substitute any of the existing investigation approaches that are in place, it tackles the topic more pro-actively. In the ideal case, the proposed method will support existing processes with new information to close calls that has not been available before. As [4] has previously outlined, construction safety has to happen at the right-time. Thanks to emerging technology, detailed information on close calls can be recorded and analyzed near real-time. The generated information then can be used for predictive analysis and even immediate mitigation.

This paper first reviews the existing research body on close calls in construction. It explains the proposed algorithm for quantitative analysis of close call events in construction safety. Scientific verification through simulation and validation using real field experiments follow. The results demonstrate the functionality of the developed algorithm and software user interfaces. A discussion and an outlook for future research conclude the paper.

2 Background

2.1 Definition of close calls

Several researches in construction describe a close call as an event that almost resulted in an accident. Too close proximity between a pedestrian worker and a known hazard is one of such events. However, there is no research that provides a scientific definition of the exact characteristics of a close call [5]. According to [6], a close call can be part of a sequence of events that result in anywhere from minor to major accidents. Therefore, close calls should be recorded and followed-up with a close call reporting program. Such programs, in an ideal case, measure safety performance and reduce the probability of accidents. However, the success of close call reporting crucially depends on the participation of persons to report near-misses, which can lead to inconsistent or false results [7]. Due to the often complex contractual organization of projects, construction companies often face difficulties in implementing effective close call reporting and analysis programs.

2.2 Reporting and analyzing close calls

Heinrich's safety pyramid (aka. the accident triangle) provides an early example for separating close calls (called therein near misses) from actual accidents [8]. Fast forward and decades later, the results from a survey by [9] suggest that employees from companies with high health and safety ratings perceive their own safety, zero harm, and continuous improvement in health and safety as very important. In the same study, construction hazard identification, including close call reporting, ranked 10th out of 38 topics which shows the general acceptance of such a system. [10-11] then discussed the strengths and weaknesses for a qualitative (matrix) and quantitative (index) near-miss management system. They focused on how close call reporting and filtering could be implemented to minimize both missed near-miss reports and unnecessary reports. Their design consists of four separate phases: Event identification and reporting, event assessment, prevention measure application and follow-up actions. Among other noteworthy research that followed, [12], for example, established a database consisting of feature vectors (values that represent information on an incident) for close calls, filled with data from common written incident-reports, viewing close calls as events which lead to an accident.

Today, under often self-motivated initiatives for establishing leading indicators for safety, pioneering owner and contractor organizations highly encourage the (voluntary) reporting and analysis of close calls by everyone involved in a project. Databases with restricted access exist where close calls are entered manually or via guided user interfaces (GUI) on mobile devices. Such recent examples from modern construction sites demonstrate the advancements that have been made for reporting and investigating incidents. In brief, the reasons for this change can be summarized twofold: (a) driving organizational change in safety culture by rethinking existing and establishing new processes and (b) taking advantage of sophisticated technologies to record and analyze real data. Our work therefore focuses on low-severity, high frequency injuries. It does not necessarily translate to high-impact, low-frequency events.

Among other research studies, the most closely related previous study was performed by [13]. It describes a method called Proximity Hazard Indicator (PHI). PHI successfully detects spatial-temporal (proximity) conflicts between workers and construction equipment using real-time location sensing (RTLS).

2.3 Summary

Practiced close call reporting and analysis rely on manual data gathering efforts. Using only manual reports as a source of information has several disadvantages. Some of the issues presented in the following help explain the problem:

1. *Size of the problem:* The number of reported close calls is probably smaller than the true number (i.e., personnel may not report close calls fearing retaliation or a drop in productivity).
2. *Standardization:* Accident investigation reports vary by country and are kept general to inform the entire organization and sometimes even the industry. An open-access benchmark which is based on high quality (anonymized), near real-time data and available to every construction site or personnel is missing presently.
3. *Data availability and processing:* Processes depending on manual data lack the necessary level of detail (i.e., unlike the airline industry for the past decades or unmanned autonomous vehicles just recently, trajectories of construction equipment are often neither recorded nor analyzed).
4. *Collaborative planning:* Though BIM offers the construction industry a method to plan, build, and operate infrastructure or buildings, standardized tools for construction safety (and health), site layout or work station planning are missing (i.e., most projects perform modeling efforts with BIM manually at low or moderate detail and only on an as-needed basis).
5. *Safety culture change for labor and management:* Since close call reports may include sensitive information to an incident [14], person(s) reporting them might impact labor-management (i.e., workforce vs. supervisor, management) relations and organizational fairness.

3 Proposed method

The proposed method intends to change the close call reporting and feedback process. As introduced earlier, close calls are typically reported when a human witnesses or participates in an event which compromises or threatens to compromise the health or safety of a person or the environment. If necessary, a person may conduct first efforts to prevent an accident or a further incident. The person notifies their supervisor or safety coordinator on site directly or using a close call reporting application on a mobile device (i.e., if permitted on site: smartphones or tablets) (see Figure 1).

Figure 1: Close call reporting, analysis, and personalized feedback process

Some general information about the event is shared once the case reaches the corresponding safety professional within an organization (a knowledgeable person). Afterwards, a problem-solving peer-review team consisting of workforce (who are trained in operational skills), safety professionals (who are trained in root-cause analysis), and management (who are trained in continuous-process improvement) will heighten the awareness for the seriousness of the case within their own organization. Various means exist to learn more about the risks and how to mitigate them, for example, calling for dedicated close call review meetings, department safety meetings, one-on-ones with workforce or supervisors, or involving a neutral third party. The team, while protecting employees from blame [15], finally recommends corrective actions. At this point, well-working close call reporting processes in practice (should) ensure timely feedback to the person(s) who reported the incident in the first place.

The proposed close call reporting and analysis, and personalized feedback process takes advantage of remote sensing and information modeling to automatically record the circumstances that lead to close calls. By attaching a RTLS device on every resource (pedestrian workers, equipment, and material that was a-priori declared hazardous), their then available trajectory data will be analyzed in BIM to locate close calls.

The proposed methods used in the new workflow are explained next in more detail. It is followed by a detailed investigation into the theoretical verification of the proposed methods using first a simulated data set in a fictional construction setting and thereafter (after ensuring the methods work successfully) several realistic data sets for experimental validation on live construction sites. As a note, the initial selection of simulated over realistic data permitted the verification of the proposed method under ideal (repeatable) conditions. In the simulated setting, a fictional building information model and trajectory information was assumed for the artificial pedestrian workers' and equipment travel paths.

3.1 Trajectory data to construction resources

Construction resources are physical objects and spaces that are required to finish a construction process. In this research, the term construction resource refers to (a) the pedestrian workforce, (b) construction equipment, and (c) objects or structures of temporal or final state. The number of any of these resources in the scene under investigation can be one or many. They can also be static or dynamic in nature. Pedestrian workers as well as equipment are moving frequently, while temporary objects, such as scaffolds or hazardous materials like gas bottles, are mostly static and stay in one position. Other examples of static or as-built structures which can be hazardous are unprotected edges in elevator shafts or leading edges in high-rises.

Construction resource data is defined as a term to summarize boundary data from building information modeling and trajectory data from trajectory logging files. Trajectory or position logging devices frequently store a resource's relative position and the current time, namely timestamps, inside a log-file [16-17]. The logging frequency and additional logging information like battery status both depend on the type of device. In this research, a frequency of one event per second (1 Hz) is assumed to simplify the following calculations.

3.2 Protective envelopes

To automatically detect and analyze close call events between *resources*, additional descriptive information for each individual resource involved in a close call event is necessary. For example, its precise position and *boundary* information define a *protective envelope*. For the reason of simplicity, all data presented in this study is kept to two-dimensions (2D, plan view). As a result, the protective envelopes come in shapes of circles or polygons. The number of the involved resources as well as their parameters, i.e. the size of the protective envelope called the *safety distance*, are set in advance based on the previous research findings by [18]. Trajectory information and building information model complement this chosen approach. The size of its safety distance and its shape are based on the following assumptions:

- *Pedestrian workforce:* A circle with a radius of 1.5 m is selected. This value is based on the average distance a human walks in one second, reacts, and comes to a complete stop [18].
- *Construction equipment:* A protective envelope for equipment must be wisely chosen considering several of its operating parameters. These include, but are not limited to: operating speed, angle of operation, and articulation. Even external factors, such as ground conditions, might be included into calculating a machine's breaking distance. While [19] has shown that multiple hazard zones for equipment are advisable to avoid a hit, generally a fixed value decided by a user is added around the equipment's known bounding box.
- *Temporary object:* The size of a protective envelope for temporary objects (e.g., safe storage of gas bottle) is determined according to rules and regulations set

by governments and local authorities [20]. The resulting shape is a resized version of the existing boundary.

- *As-built structure:* Many structures, once they are erected and remain on site, might also require protection. Guardrails, for example, preventing workforce or equipment from falling to lower levels typically have protective envelopes associated to them. Their safe installation is also regulated by official regulations or company best practices [20].

3.3 Close call event and analysis

Currently, there exists no common definition for close calls [5-6]. A close call, as defined in this research, is a proximity event between one or several pedestrian workers and a hazard, leading to an endangerment of the workers. Also, a close call as it relates to a too close proximity event between two resources A and B is defined as an overlap of their protective envelopes at positions $P(A,t)$ and $P(B,t)$. When using trajectory data, there are two possible approaches towards categorizing close call events: (a) to categorize every proximity event as a separate close call or (b) to combine consecutive occurring proximity events to a single close call. The latter is the more sensible choice for this study.

For each proximity event, a proximity event buffer is created to store information for later processing. This information includes timestamp a [yy:dd:hh:mm:ss], position [m], velocity [m/s], and orientation [°]. Information on the distance [m] and facing direction [°] towards the other resource is also stored. In the example shown in Figure 2, a piece of equipment has been traversing too close to a gas bottle.

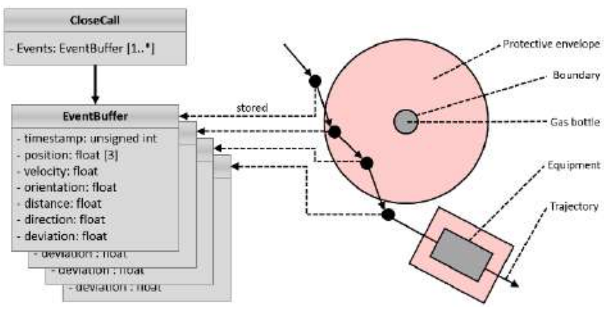

Figure 2: Close call EventBuffer class diagram

For two resources A and B, a close call detection algorithm (1) analyses their trajectories and (2) checks for each *timestamp* $t \in T(A),T(B)$ if their protective envelopes overlap. If an overlap is found, a new close call gets created and a proximity event buffer is assigned to it. Every consecutive proximity creates a new event buffer which is added to the same close call. If no further overlap is detected, the close call is completed and the next proximity will create a new close call. As the trajectory data only consists of coordinates and timestamps, *velocity, facing direction, distance, and orientation* must be calculated separately.

For each close call a radar plot is computed showing the weight values for velocity, duration, deviation, distance, and orientation. Values to these weights visualize the severity of the different aspects that contributed to the close call event. The higher the value points in the radar plot, the more the aspect contributed to the endangerment of the resource. Velocity and length during the close call event (see Figure 3) give a user a brief overview of a resource's safety performance. As suggested by [16] personalized feedback or other change (i.e., selection of other equipment or type, modification to site layout plans) can be issued and future performance monitored until the issue is resolved.

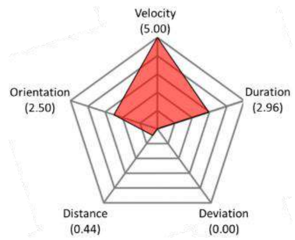

Figure 3: Factors leading to a close call

3.4 Close call visualization

The computational analysis of the gathered data starts with the examination of all single event buffers. From there, it abstracts and combines these information into more general statistics. As the level of detail drops with this generalization, a Guided User Interface (GUI) displays the construction site layout on a map, general construction site statistics and an overview to all construction resources, separated by type. A heatmap, if selected by the user, shows the location of close calls (see Figure 4). It covers statistical data as well as a brief overview on all resources being present at the construction site and involved in close calls. This GUI might be used by management to derive a quick performance overview on close calls for one construction site.

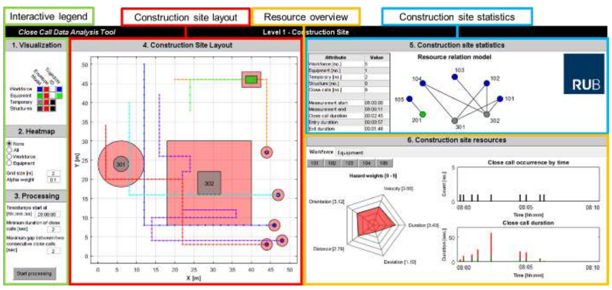

Figure 4: Guided user interface for close calls

4 Verification of method

To verify the method, close calls among few resources were artificially generated. Details were discovered, for example: the course of close calls, individual resource- and hazard-statistics, a heatmap as well as comprehensive construction site safety statistics.

Industry expert input asked to find intuitive answers to typical safety-performance-related questions:

- Which are the areas where close calls occur frequently?
- Which workers or pieces of equipment are involved in a close call and are there any particular differences in the safety performance among them?
- How does a worker react on entering a hazard zone, when might the worker recognize to be at risk, and how will the worker react upon detecting it?
- Which ways exist to leverage the newly generated information for continuous safety performance improvement, e.g. in safety education and training?

The artificially generated data set (called scenario) is based on known trajectories (straight lines) where the ground truth is known and evidence available is used to verify the close call analysis algorithm. This scenario included five workers that traverse a construction site in a continuous manner, facing two temporary static hazards and one dynamic vehicle. Each worker simulates a behavior which addresses one of the different hazard weights. To raise the orientation weight value for a worker, for example, the vehicle creates a close call in a workers' blind space. All trajectories are straight lines. This permits simplicity in the verifying process of the algorithm. A heatmap displayed in the GUI further allows the evaluator to spot the close calls.

Some more specifics to the scenario: one pedestrian worker (A) traversed the site at a speed of 2 m/s (at a maximum allowable speed limit of 1 m/s). A second pedestrian worker (B) was a too short distance towards the hazards (301 and 302). A third pedestrian worker (C) simulated a behavior which should result in a high deviation weight. The duration weight was tested by pedestrian worker (D). Pedestrian worker (E) was confronted with a traversing vehicle (F) to verify the orientation weight function. The heatmap functionality was verified by comparing the trajectories with the hazard locations on the map (see Figure 5).

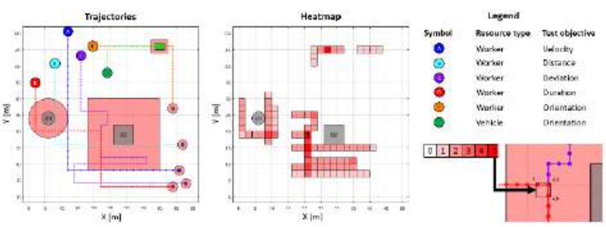

Figure 5: Guided user interface for close calls

The weight radar plots for all resources (team) are displayed in Table 1. The data can be explained as: velocity (high), duration (long), and orientation (vehicle approached from the rear) of the observed close calls in the artificially generated data set were high. The other criteria played a lesser role.

Table 1. Results to close calls from artificial data set

Criteria	Performance
Radar Plot	Velocity (Ve)	3,00
Duration (Du)	3,43
Deviation (De)	1,10
Distance (Di)	2,79
Orientation (Or)	3,12

5 Experiments and results

To validate the close call data analysis algorithm, datasets from a construction sites were analyzed. The following sections cover the pedestrian workers' individual performances and the overall construction site safety performance. Discussions including future work follow.

5.1 Data from building construction site

A dataset was gathered on a real building construction site where several pedestrian workers were present at an elevated work level. A restricted workspace was located inside the work area. Although the protective guardrails around the leading edges met the required safety standards, the present supervisor estimated it as insufficient (asking his and subcontracted personnel "to stay away from the edges"). The close call analysis algorithm aimed at analyzing the trajectories of 4 workers for potential close calls near the leading edge and/or unauthorized entry into the restricted work space.

As shown in Figure 6 (see the grey areas in plan view) the restricted space and the leading edges were modelled as individual objects using BIM. UWB served as the sensing technology for recording the trajectories of the personnel. UWB allowed to allocate a specific ID to every worker. The information in Figure 6 displays the individual trajectories (in blue color) and, by applying the developed close call algorithm, the resulting heatmap (in a range of red colors) for every worker. The images indicate several close calls, mostly towards the southern and eastern sides of the work environment.

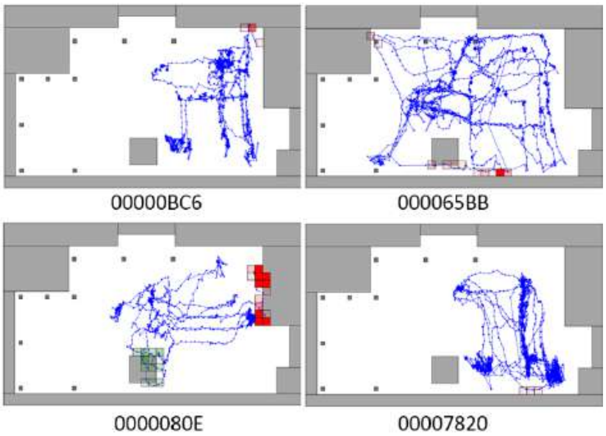

Figure 6: Individual close call performance

The analysis the generated hazard weight radar plot for the pedestrian workers' team performance gives further insights into the observed close calls (Table 2). Many of them were related to very close distances to the leading edges.

Table 2. Results to experimental validation

Criteria	Performance
Radar Plot	Velocity (Ve)	2.69
Duration (Du)	2.00
Deviation (De)	2.64
Distance (Di)	**4.46**
Orientation (Or)	2.83

5.2 Personalized feedback

The data generated in this research might be used to give safety professionals the required facts to take corrective actions that protect the human workforce. While multi-lingual manual reporting cards for close calls may still exist in the future, they have–as outlined before–shortcomings in practice (e.g., incentives, collection, and feedback cycle). A successful transformation to digital recording and feedback is possible and yet has to be investigated in the future in much more detail. A conceptual digital feedback card would, for example, need to be tested for simplicity and acceptance by the workforce (Figure 7). While intrinsically safe mobile devices are required for industrial construction applications, recording and analysis via Internet-of-Things solutions like [21] exist to reduce the time needed in the feedback cycle. The foreman would then have new information in toolbox meetings available for use in safety awareness training.

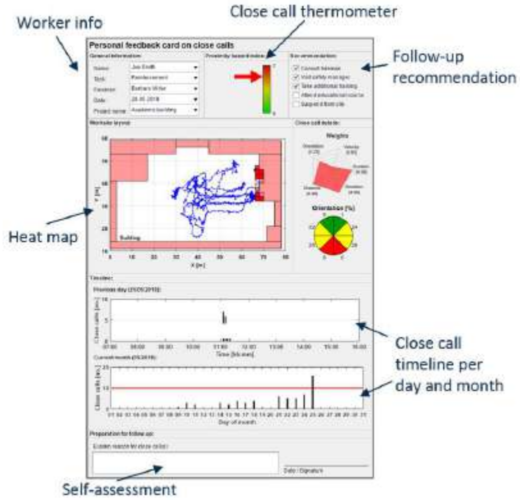

Figure 7: Conceptual display of digital close call reporting and feedback card

6 Conclusions

This study presented an algorithm for the quantitative analysis of close call events in construction. A process of collecting trajectory data as a valuable construction resource was introduced and a graphical user interface was presented that provides safety personnel with automatically generated safety information on close calls. The proposed algorithm was successfully verified first in a simulated and later in a field realistic work environment.

Although the developed method provides useful information on both artificial and real trajectories that cause close calls, the performed calculations are based on several assumptions. They rely in particular on the performance of RTLS. While many type of sensors provide RTLS data (i.e. computer vision, wireless), existing measurement errors may not qualify these (yet) for commercial application in the harsh construction environment. Though [18] demonstrated that errors with UWB can be below 1 m for each positional data log, RTLS technology must also withstand ethical concerns of tracking workforce and be effective in acquisition, use, and maintenance. The latter issue could be solved by targeting worthwhile business applications at the same time, e.g. logistics for indoor work environments. However, most of the existing RTLS still faces major hurdles and demand new sophisticated solutions to operate successfully in such complex work environments.

On a similar note, the developed algorithm considers trajectory-related information only. Although it tackles a complex question, when are workers safe/unsafe based upon their location and the situation, it uses fixed safety distances. Their current size relies on empiric findings.

Though all of these assumptions made still add new functionality to existing close call management processes, additional research is necessary. For example, the presented hazard weight calculations are based on simplified values. Field-based observations are likely necessary to complement the definition of terms and calibrate the weights accordingly. This then may solve whether a close call was a true close call. Options to expand the dataset for such purpose exist. For example, data fusion including new data points from proximity alert sensors that are able to automatically record close calls between pedestrian workers and heavy construction equipment [22-25] could serve future research agendas well. To enhance personal awareness of every worker, a port to safe test bed environments within mixed reality environments would enhance more realistic education and training scenarios, providing users with much needed personalized feedback [26].

Abstract

The Architecture Engineering and Construction/ Facility Management (AEC/FM) industry plays a significant role in the development of economy. In recent years, the wide application and development of Building Information Modelling (BIM) promote the development of informatization and digitalization of AEC/FM industry. However, due to the limitation of a one single tool and lack of understanding of single source of truth, the problems of the industry cannot be solved completely. Therefore, the revolution and innovation of industry can be stagnated. Internet of Thing (IoT) and blockchain can be considered as two technologies that can be integrated with BIM for AEC/FM industry. The aim of this paper is to understand and analyse the basic principles and the applications of these three technologies in AEC/FM industry through literature review. With the integration of these three technologies, the virtual and realistic object and data during the whole building lifecycle can be managed and stored in a security, transparency and convenient decentralized common data environment (DCDE). Finally, a theory named, Cup-of-Water theory is presented.

Keywords –

BIM IoT blockchain AEC/FM industry whole building lifecycle

1 Introduction

In recent decades, the development of global AEC/FM industry is slow compared with other industries, such as manufacture industry, aerospace industry or financial industry. This phenomenon results from low digitalization, loose collaboration and ineffective management methods in most building projects. Hence, it is of significant importance to use new technologies to improve the productivity and efficiency in all phases of a building project, including design, construction and operation and maintenance stages.

BIM, which represents one of the key technologies in revolutionizing the AEC/FM industry, is expected to stimulate a major change to this conventional industry with lots of waste, low productivity and low efficiency. BIM not only provides advanced visualization tools and real-time information synchronization, but also realizes multi-disciplinary collaboration and comprehensive management for a building project lifecycle. Increasing number of AEC/FM firms are having transition from CAD to BIM [1]. It can be estimated that more and more innovations will occur in the future as the building information can be easily recorded, queried and transmitted in a common data environment (CDE).

IoT is a network which allows the data collection and exchange of real objects supported by Internet or traditional telecommunication network. It is possible to use IoT to make building components to be on the network in a unified form [2]. Construction management can then be optimized since materials, equipment and other objects can be traced.

Blockchain technology is a decentralized ledger database, which is initially adopted as a bottom structure of Bitcoin system. It has a well performance on data updating, storage and protection [3].

The objective of this paper is to investigate how these technologies can interact with each other and produce new applications that can benefit AEC/FM industry. Through review and case studies, the principle, technical advantages and applications of each technology are reviewed. Based on those information, the author makes classification with regard to interaction forms, and discuss the advantages and limitations of different ways of interaction. At last, a new theory is came up with to demonstrate the integration of these technologies and how they affect a building project.

2 BIM based Building lifecycle

The lifecycle of a building, mainly contains several processes including the programming, conceptual design, detailed design, analysis, documentation, procurement, fabrication, construction, construction logistics operation and maintenance, renovation or demolition [4]. Due to the characteristics of a construction project, rich technical content, long construction period, high risk and many stakeholders, the project requires systems of good management over the lifecycle of a building. Life-Cycle Management (LCM) has been developed as a business approach for managing the total life-cycle of products and services [5].

With the integration of BIM, some problems of the traditional LCM such as lack of effective information sharing, and the efficiency of the LCM indeed increased significantly [6]. The BIM models contain actual information of the building including the geometric information and non-geometric information such as material for building components, weight, price, procedures, scale and size [7]. Information management aim to provide the right information, in the right format and quantity, at the right time, to the right person, and at reasonable cost [8]. BIM can provide semantically rich digital building models at each process of the project in the whole building lifecycle and the object-oriented concept is utilized to improve the efficiency of the information management in the building lifecycle [9].

A construction project has many stakeholders. With the development of BIM, many questions and problems of BIM application are put forward during the collaborative work. Thomas [10] indicated some legal issues including the ownership of the building model, the modification rights, the distribution rights and the liability for changes or errors. Meanwhile, how to manage copyright protection and how to protect digital intellectual property are also the questions that should be of concerned for relevant stakeholders. Due to the data and information exchange between each stakeholder, the trust and networking costs are also two problems of BIM application currently [11].

3 IoT

IoT is a network of internet-connected objects that able to collect and exchange data using embedded sensors [12]. It mainly includes three key technologies. The first one is sensor technology. It can be used to convert the analog signals to digital signal. The sensors include the infrared sensor, global positioning system and other information sensing devices. The second is RFID tag. It is a kind of sensor technology combining wireless RF technology and embedded technology. Third is Network Embedded System Technology. It is a complex integration technology integrated with computer software and hardware, sensor technology, integrated circuit technology and electronic application technology [13].

4 Blockchain

4.1 Definition and principle

Blockchain technology is most commonly known as a technical base of Bitcoin system. It allows the transfer of ownership of valuable things by binding the digital currency with rights to an asset [3]. The success of bitcoin trading attracts people to explore the theory of blockchain and relate it to other fields, such as IOT, supply chain, smart contracts. In substance, blockchain is a decentralized distributed ledger database using peer-to-peer network. The data on blockchain is maintained by every node on the network, and every user preserve total history of all transactions. This mechanism eliminates the existence of central administrator. In other words, no third party would participate in the network to supervise and manage user data [14].

When user performs a transaction on their computer, which is recognized as a node in the network, the node should identify whether this transaction is valid based on rules of protocol. If this transaction deemed valid, it would be relayed on a new block. Some nodes with strong computation power would put a number of transactions together and encrypt them into a block. Due to the nodes which made encryption requires a lot of energy, money and time to operate machine to calculate hash number [15]. It resulted in the difficulty for anyone who wants to attack the network for they need to expend more to decrypt the block [16]. After transactions are assembled and new block is enclosed with a header called timestamp, the new block is added to the end of the longest chain and referenced to the preceding block. This made the time sequence of the chain clear so that less resource would be wasted due to the delay of P2P network [17]. Once the chain is updated, the new chain would be announced to all nodes on the network and every user had the same copy of ledger of transactions.

4.2 Categories of blockchain

There is always misunderstanding that all the blockchains are opened to any parties in the world so that information storing on blockchain might have privacy problems. Actually, this case refers to the most commonly seen category of blockchain, which is named public blockchains. Besides, blockchain includes two more categories: Consortium blockchains and private blockchains.

4.2.1 Public blockchains

On public blockchains, any individual or organization all around the world can send transactions and the transaction can be verified to be valid. Everyone involved in this peer-to-peer network can take participation in the consensus process. Public blockchains enable users to handle their transactions in a simple manipulation. However, the network might be slow sometimes due to too much load on it.

4.2.2 Private blockchains

On private blockchains, the network demands an invitation and must be validated by either network builder or certain rules assigned by network starter. Each transaction is recorded by the approved parties or entities, instead of all participants in the network. The blockchain creator would normally set up a permissioned network, which defined authority of participants in the network [18].

4.2.3 Consortium blockchains

Consortium blockchains are also called simply hybrid blockchains, which combines the public and private blockchains. The transaction recorders are preselected in an internal group, and the production of block is determined by all these preselected nodes [19]. The rest of access nodes just participate in the transaction, they do not interfere with the Bookkeeping process, and anyone could query the limited information on the blockchain by accessing the specified API provided by the blockchain network.

4.3 Technical advantages of blockchain

4.3.1 Decentralization

Blockchain network uses distributed storage instead of a central storage system. There is no central governor on the network, which implies the consensus could be reached without centralized control. The right and responsibility of any nodes are equal, and the data in the system should be preserved by all the nodes with maintenance function. Decentralization make the transaction on the blockchain complete without extra third parties. Consequently, it provides a reliable ledger platform which eliminate the credit risk of involvement of intermediate parties [20]. At the same time, decentralization has spared the burden whenever database administrator should make decisions on protocol rules. The participants on blockchain could make specified protocols according to property of business.

4.3.2 Peer-to-peer network

Peer-to-peer network is a network system without central server and exchanging information by user groups. It realized the information transfer between each two nodes on the blockchain [21]. Unlike central network systems with central servers, each user terminal of a peer-to-peer network is both a node and a server function. In the blockchain, each node has a complete set of historical transaction books. The peer-to-peer network of blockchain solves the problem of data correctness caused by a single data source. Each user node has a history record so that the overall database could remain static even one node is attacked.

4.3.3 Immutability

Blockchain always maintains a growing chain, once the information is verified and added to the blockchain, it will be permanently stored. The transaction on blockchain can only be added and cannot be modified. Therefore, the data stability and reliability of the blockchain are much higher.

4.3.4 Consensus mechanism

The consensus mechanism solves the problem of data block being encrypted by any node in the network, so as to prevent the blockchain from being bifurcated, and there always exists the unique longest chain. Because most blockchains are open, the anti-attack and stability of the consensus protocol is critical. Current workload proof (PoW) and equity Certificate (PoS) are two of the most common consensus mechanisms.

4.3.5 Secure encryption system

Taking advantages of asymmetric encryption and hashing, blockchain ensures that transactions cannot be denied and destroyed, and the privacy of user information and records is protected as far as possible.

5 Interaction of BIM, blockchain and IoT

Overall, BIM, blockchain and IoT are advanced technologies in three various categories. BIM digitalizes the building information while IoT connects realistic objects with Internet, and blockchain transmits data on a decentralized network. When considering how these technologies can contribute to a building project, it is difficult to analyse benefits of a single technology. In other words, it is interaction of different technologies that breeds new applications, and therefore improves the way the AEC industry generates single source of truth for digital information. In this paper, the enhancement from interactions of these three technologies can be concluded below.

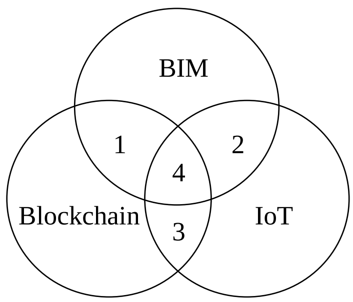

Figure 1. Interaction of BIM, IoT and blockchain
Note:

1. BIM and blockchain: contract, supply chain, modification record.
2. BIM and IoT: green and smart building, construction site safety, e-Commerce
3. IOT and blockchain: Decentralized IOT database, privacy, external collaboration
4. Integration of BIM, IOT and blockchain

As shown above, the interaction of BIM, blockchain and IOT could bring about technical and management innovation throughout the life cycle of construction project. It is necessary to analyse the potential benefits and restriction of these applications following the order as listed above. After that the value of interaction of BIM, blockchain and IoT can be realised.

5.1 BIM and blockchain

5.1.1 Smart contract

In construction project management, there existed many issues relevant to transaction and documentation. First, payment delay or not paid on time have been stressed out as one of the main factors causing conflicts and disputes between each party [1]. Secondly, the traditional contract signing in a construction project required a complex procedure with confirmation of different parties. And the documentation of a contract is a time-consuming process considering various forms of contracts and different properties of transactions. However, smart contract, which is an important innovation enabled by blockchain technology, might be helpful in construction.

Szabo, the proposer of smart contract, described that "smart contract is a computerized transaction protocol that executes the terms of a contract" [22]. It should have several functions that meet fundamental contractual conditions, such as payment and liens. At the same time, smart contract can reduce or eliminate the influence of third party and can improve the efficiency of signing. At that time, digital technology is not mature so that smart contract was only at conceptual level. Today smart contract can be computer program coding based on blockchain system that executes the predefined terms without intermediate. Digital currency like bitcoin or ether are used to achieve payment or exchange with realistic asset.

Compared with traditional contractual ledger, smart contract has several advantages on built environment.

a) As mentioned above, payment not being completed on time is a serious problem causing loosen collaboration and decreased working efficiency. Smart contract can effectively prevent such cases by binding the payment together with contract. Once the work has been done, the fund stored on the contract would be released and sent to a contractor.

b) Smart contract can be executed automatically following its code. It saves a lot of time which people should spend executing or supervising the contract manually.

c) Due to the decentralization property of blockchain, the data of smart contract is of high security and immutability. Further, decentralization eliminates the trust risk from the involvement of intermediate party [23].

d) If the logic and content of contract could be written properly in the program, the software would accurately execute the items step by step. It reduces the possibility of some manual errors.

In BIM workflow, it is a perfect state provided that every contract can be written as a smart contract. However, the workload and technical requirement might exceed the capability of project team to achieve it. At the beginning when project team start using smart contract, it is suggested that smart contract should be applied on some specific transactions, which can raise the efficiency, security and collaboration of a project at most.

a) BIM model management

One of the main obstacles to replace traditional document-based construction process by BIM-based construction process is that information is distributed on more than one version of a BIM model, model reviews and digital documents [24]. It results from fragmented management of model usage, their associated right and ownership of a BIM model. The Using smart contract, each party in a project team can only access BIM model under the permission of such intelligent contract, and their operation can be recorded on the blockchain. By this way, the responsibility and right can be effectively allocated, and information can be integrated on blockchain database.

b) Property and land ownership transfer

In a construction project, there are amounts of property transfer transactions, like equipment purchase or prefabrication procurement. Otherwise, there also exists land ownership transfer events when the building area is modified. It is significant to use smart contract to transfer the property and land ownership since smart contract provides an authentic platform without redundant cost.

5.1.2 Modification record

Due to the immutability of blockchain, the record is permanent [23]. As many people and teams working in one project, the modification of one BIM model at same time is unavoidable. The tamper proof and time-stamped data can be record by using blockchain not only for internal member but also for external collaborators [23,25]. Immutable public record of all model modifications can be stored [22]. With the application of this record the efficiency of the data sharing can be significant increased, the efficiency of management can be improved [26], the collaboration and trust between each participant can be enhanced [23].

5.1.3 Supply chain and logistics

In the traditional construction supply chain, the collaboration between each partner is temporary, the cooperation period is short, and the number of participants is huge. Therefore, the unstable relationship can cause the lack of transparency and traceability [27]. The problem of trust between each participant in supply chain leads to a low efficiency and low level of productivity [28]. The blockchain can be considered to solve these problems through an immutable digital ledger system [29]. This system is authenticated and the information on this system is more reliable than the conventional [26]. Based on the reliable information and without the participation of third party, more companies can be considered to hire as contractors or subcontractors. A reliable, open and competitive market is a positive motivation for the companies and people in the industry [30]. The efficiency of the procurement can be increased [31]. Moreover, blockchain can provide consistent report for each participant in supply chain including owners, contractors and subcontractor. It helps managers to track the progress of the project and the logistics timely.

5.2 IoT and BIM

IoT can be applied in different processes in the building lifecycle based on BIM. In terms of the green and smart building design, some sensors can be used to measure the temperature, air quality, humidity; monitor the location and movement or control the system respectively to provide safety and thermal comfort with limited energy consumption intelligently and automatically [30, 32]. With respect to the application of IoT in construction site, the wearable sensor can be used to monitor the acting of workers to make the workplace safer and more efficient [33]. In terms of the construction supply chains and logistics, the RFID sensor can be used to monitor various aspects of product and their environments [34]. Meanwhile, the IoT have potential to promote the application of e-commerce in procurement process [35]. In terms of the facility and asset management, the IoT can improve the efficiency of O &M; reduce the track cost and process in real time through the RFID technology [36].

5.3 IoT and blockchain

With the development of IoT, the limitations of it is gradually exposed. Firstly, due to the centralized of the currently IoT system, the central database is vulnerable to attack. With the exponential growth of data, the cost for operation and maintenance of database is increased rapidly. Secondly, credit mechanism is hard to build without the third party. The cost of the collaboration work between external partners is high. Meanwhile, the privacy of participants could be leaked via the third party. Based on the characteristics and advantages of the blockchain, the limitations can be solved.

5.4 Integration of BIM, IoT and blockchain

The applications of integration between two of these three technologies are came up gradually. However, the application of integrating BIM, blockchain and IoT is rarely mentioned. One of building maintenance systems based on "Decentralized Autonomous Organizations" (DAO) can be considered as a meaningful approach that adopts BIM, IoT and blockchain technologies in the construction industry. This example shows the feasibility and the value of integration between these three technologies.

5.4.1 Building Maintenance System （BMS） based on DAO

An efficient operation and maintenance system of a building can save labour and management cost as well as reducing health and safe issues. A new building maintenance system based on DAO is expected to perform well rather than existed systems in the future [37]. DAO is the abbreviation of " Decentralized Autonomous Organizations", which is an organization that runs through rules encoded as computer programs [38]. This organization does not have any human governor. It follows completely the rules of a smart contract. On the other side, BMS takes advantages of IoT technology to retrieve the operation information of every building component. Once BMS could monitor the performance of building and get prepared to react to any abnormal conditions based on a fixed contract, a set of troubles on operation and maintenance stage can be solved in an abbreviated time [39].

Supposed an elevator in a large office building breaks down, the sensor from BMS could quickly find the problem and detect which part of the lift got damaged. Then transaction would be uploaded onto blockchain network. DAO could make responses to this event according to the scheme of the smart contract, such as writing facility damage report, connecting with service provider, or purchasing new component with supplier. As a consequence, the broken elevator could soon get repaired and return to operation. It prevents hundreds of staff in the building from having to walk on fire passage, which leads to safety concerns [40].

From this example, it is of great significance to apply blockchain along with IoT during operation & maintenance of a BIM life-cycle. IoT provides the opportunity to access the dynamic data of building while DAO make automatic reaction to any situations based on predetermined programs. The absence of any of BIM, blockchain and IoT technologies could make BMS unable to work.

6 Discussions

In the UK, the Digital Built Britain national strategy describes the plan to create a mature digital economy for built environment and lead to a smart cities, services and grids [41]. It requires a large amount of digital information, new commercial model, interoperable and safety working environment. This strategy indicated that the informatization and digitization are the tendency of the development of the future AEC/FM industry in the UK. As one of most advanced countries in the development of construction and BIM standards, the HM Government's strategy can be used for reference in the global construction industry. Meanwhile, the development of informatization and digitization of AEC/FM industry are also mention in the 13th Five-Year Plan of China. The advance technologies are required for the development of economic and social [42]. Both national strategies can indicate a digitized and informationalized world in the future. Those mass of data and information need to be well managed without wastage, excessive transfer and unnecessary cost burdens [43].

BIM, IoT and blockchain are three advanced technologies that are explored to achieve the informatization and digitization of AEC/FM industry. These three technologies can be considered to be complementary.

Without linking to IoT, the correctness of project data is poor. Considering that a smart contract was made to manage the equipment lease, it is essential to collect the dynamic data of equipment in order to ensure the performance and safety of a machine. The virtual 4D BIM data could only provide some static data such as manufacturer or provider information of the equipment. Manual recording and uploading of these dynamic data of equipment generate problems. For instance, the updating is not real-time, and the data accuracy cannot stay on a prominent level, which could lead to execution error of a contract. Therefore, it can be realised that blockchain technology can improve the trustfulness of virtual BIM data, but the independent interaction of these two technologies still lacks support from real world data. Meanwhile, IoT can improve the level of intelligentization and automation of the supply chain and logistics through sensors and RFID. It ultimately increases the efficiency of these applications with the participation of IoT.

Without blockchain, the integration system of BIM and IoT is lack of security and correctness due to the single source of truth. Due to the various data format between each technology, the information exchange is complex. With the regular format data in blockchain, the collaboration can be more efficient in an integrated system. Overall, with the construction industry, the generation rate of data is exponential from a number of stakeholders along the life cycle of the building. These data and information need to be transferred, stored and shared by an efficient and safe method. Blockchain is a reliable technology to process data. With the blockchain, the data and information can be managed well.

Without BIM, all the information in the whole building lifecycle is hard to be digitized. Paper-based document cannot be used in IoT and blockchain directly. BIM is the first step and the basement for AEC/FM industry to convert and manage digital information through-life.

In conclusions, BIM, IoT and blockchain are complementary. With the integration of these three technologies, the traditional AEC/FM industry can become a digital and informationized industry in a high efficiency and secure environment.

In order to clearly illustrate the interaction of these three technologies and how they rely on each other in a building project, a "Cup-of-Water" theory is came up with to graphically show the importance of integrating them together.

7 "Cup-of-Water" theory

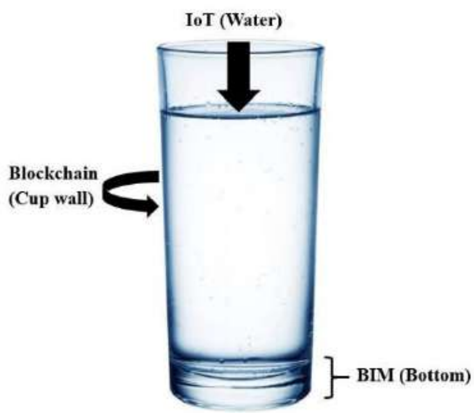

Figure 2. Cup-of-Water Theory

The information carrier, entity and flow can be taken as a cup filled with water, where water is building data and cup is the approach how these data are stored, transmitted and shared.

BIM (Bottom): The management of digital information for whole building lifecycle is the baseline of the revolutionary AEC/FM industry.

Blockchain (Cup wall): Redefinition the method of storage of high value single source of truth for AEC/FM industry.

IoT (Water): The entity of the object and data.

Three components are all compulsory in this system for the industry. Without BIM, the "water" cannot be conserved and managed. The method for regulating the object and data is meaningless. Without IoT, the cup is empty. The system is out of sync with reality. Without Blockchain, the 'water" cannot be conserved and managed in a security, transparency and convenient environment. The integration of these three technologies is the future of the AEC/FM industry.

8 Conclusions

In this paper, the definition, characteristics of BIM, blockchain and IoT in AEC/FM industry are presented through literature review. Then the interaction between these three technologies are analyzed with regard of their applications, benefits and limitations. The integration of BIM and blockchain can improve the safety and efficiency of the contract signing, project modification, asset management and supply chain management. But the applications lack dynamic realistic data of project without IoT. The integration of IoT and BIM brings about comprehensive data in the whole life cycle of a project, but these various formats of data require a stable method to be stored and transmitted. The sole combination of IoT and blockchain without BIM is infeasible because the project data cannot be digitalized. The integration of all these three technologies can access and organize the digital information of building project in the most effective and safe way. An example of building management system based on DAO shows the feasibility of integrating these technologies and huge significance to the building. Cup-of-Water theory is concluded to illustrate the structure of the relationship between BIM, IoT and blockchain during the whole building lifecycle. In this theory, BIM can be taken as "cup base", which is the fundamental of a digital building project. IoT is described as "water", which is entity of object data from the real world. Blockchain plays a role as "cup wall". It is cup wall that preserve water in a transparency, secure and convenient environment. At last, the national strategies of China and UK both promote a digitized and informationalized AEC/FM industry in the future. These three technologies are complementary and the "cup of water" have potential to lead an innovation AEC/FM industry in the future. Currently, the integration between BIM, IoT and blockchain is a complex and diversified process. The detailed methods for integration and integrated system structure need to be further developed.

A review of IoT applications in Supply Chain Optimization of Construction Materials

A. Kumar[a] and O. Shoghli[a]

[a] Department of Engineering Technology and Construction Management, University of North Carolina at Charlotte, USA

E-mail: akumar28@uncc.edu, oshoghli@uncc.edu

Abstract –

. The timely updates and delivery of construction material on a job site could have a significant impact on the overall duration, quality, and cost of the project. The study focuses on analyzing the role of Internet of things in providing a real-time update on the delivery and data for material handling in supply chain management, and review the role of IoT in the function of value addition that it could bring in the form of management of materials and communication to a project.

It is anticipated that within the next decade, the Internet will evolve into a seamless fabric of classic network and networked objects. The use of IoT coupled with smart sensing devices could help in the communication and material tracking with high accuracy and free of noises such as human error, workforce shortage, cramped budget, adverse weather conditions, and other environmental factors.

The study will explore and identify the various remote sensing devices and technologies that could be integrated and utilized into the live data feed for the information update, with a particular focus on the use of internet of things through electronic devices. The system would help project manager in schedule updates and improve material efficiency

Keywords –

Supply chain management; Internet of things; Material efficiency; Construction.

1 Introduction

In recent years, most of the manufacturing and distribution industries have paid much attention to Supply Chain Management (SCM). By adopting and investing money in the supply chain management, the big and renowned infrastructure companies have significantly reduced inventory and logistics costs. In addition, they have marked increment in the speed with which they respond to customer demand, and improved overall company competitiveness [1].

Due to these benefits and successful cases of the supply chain management, many industries are adopting the approaches of SCM and the construction industry is also one of the industries to adopt SCM [2]. The construction industry is usually characterized as a complex industry because of the high variability in construction environments and the complication of the construction process [3]. Despite the recent improvements in construction technology, material management remains an issue that has a lot of scope for improvement in construction projects [4]. It is relatively difficult to introduce SCM to the construction industry, because of the higher costs, longer-term durations, and complicated construction interface. However, SCM for construction materials is essential to have a successful construction management, because construction materials costs make up a considerable percentage of overall construction budget [2]. The use of the conventional practices might circumvent certain problems such as material shortages and suspensions but early and excessive material entry into the site comes up with whole different direct and indirect costs such as repeated handling, interest loss, and storage cost [5]. In absence of management for material supply operations, issues could reflect in terms of extra cost to the overall project budget, schedule update, and quality of the project.

The supply chain management is in the process of massive transformation from manual data compilation methods to the use of new generation of technologies where it is in the process of abolishing expensive and ineffective practices and embracing newer, faster, and efficient technologies and systems such as building information modelling, multi-dimensional scheduling, computer-aided design, and sensing devices to monitor, estimate, and track its progress and provide real-time schedule update and hassle-free management for the construction and built environment.

2 Literature Review

Supply chain management is in the process of meeting with newer technologies. Merlino et al. [6] mentioned that today's supply chain is not the same as past few years and in the recent year supply chain is not only impacted from augmented reality in material handlings and other components, but empowered from the newer technologies such as robotics, artificial intelligence, and big data. These technologies/concepts come under the Internet of Things (IoT) which is on the basis of algorithmic process, production decisions, govern automatic devices, and do forecasting and planning.

IoT could help to bridge the communication and technological gap that exists between two most important associates for the project that exists at the extreme ends of the built environment spectrum i.e. manufacturer and customer. IoT could help the industry personnel to get real-time schedule update with astonishingly precise values that could help the project manager to make better-informed decisions and exercise better control on the overall project.

The IoT uses various interconnected smart sensing devices that communicate and share data to solve a problem such as a schedule updating, material tracking, inventory management, transportation, staffing, and resource allocation in the industry. To overcome the problem, several tools such as Radio Frequency Identification Tags (RFID), Global Positioning System (GPS), Wireless systems, Bluetooth technologies, and high-end cameras could be used to maintain real-time information sharing and data gathering.

A review of some of the prior successful cases of IoT technology applications in SCM are as follows:

- Robotics is already revolutionizing all the operational territories in materials handling, providing new roles as supply chain providers to distribution companies such as Amazon or Ali Baba [6].
- By putting assets and endeavors in supply chain management, firms such as Wal-Mart and Dell have altogether decreased inventory and logistics costs, expanded the speed with which they react to the client request, and enhanced general organization competitiveness [1].
- After the implementation of RFID advancements, Procter and Gamble and Wal-Mart simultaneously diminished the inventory levels by 70%, enhanced service levels from 96% to 99%. These companies also managed to curtail administration costs by re-engineering their respective supply chains [7].
- Supply chain information transmission model based on RFID and IoT was utilized in pharmaceutical industry to realize drugs information retrieval [8].
- Application of IoT technology in textile SCM [9].
- Application of IoT in green agricultural products SCM [10].

2.1 Supply Chain Management in General

The Supply Chain Management (SCM) concept is an important development in the corporate logistics first proposed by Houlihan [11]. The concept underwent several modifications over the period of time and received numerous valuable inputs from various scholars. Supply chain management problem has multiple variables that make it a dynamic problem. An effectual and competent SCM can have a significant positive impact on quality, cost, and duration of a construction project [5].

The Supply Chain Operations Reference (SCOR) model is proposed by the Supply Chain Council in the year 2004. It is an exhaustive business process and performance measuring method designed to meet customer requirement from all perspectives. A supply chain model is developed in a hierarchical manner and used to carry out multi-dimensional equivalent comparisons with respect to performance. The user can provide a standard quantitative scrutiny of process performance by studying the behavior of SCM from the model and implementing adequate plans. SCOR helps to integrate internal and external systems. SCOR can likewise be utilized to assess current corporate performance against contenders, in order to enhance performance [5].

The SCOR model is the first standard reference model of supply chain process whose diagnostic tools cover all industries. The PLAN step is the most important component of the SCOR model which measures integration, process, reliability, and information technology (IT) to deliver a plan.

The SCOR breaks down the SCM process into five functions, namely Plan (P), Source (S), Make (M), Deliver (D), and Return (R). The five modules were arranged into an order of hierarchy based upon the fundamental elements. The demand and supply of the modules were planned and controlled. The various functions such as performance measure, applicable software features, and optimum solution were defined. It was found that SCOR model can help the industry personnel in solving management and optimization problems such as setting up periodic targets, trend determination, and property evaluation. The leading studies of SCM on construction applications and other industries are illustrated in Table 2.

2.2 Usage of Internet in SCM

The primary goal of the supply chain systems is multi-dimensional and includes cost minimization, improved levels of service, upgraded communication among supply chain companies, and raises the flexibility in terms of delivery and response time. By combining internet with the SCM can provide benefit to the industry in terms of numerous cost-saving opportunities and improvement of service for supply chain [12], for instance, traditional logistics practices were very slow due to face-to-face negotiation but owing to internet, the rate negotiation can now be carried out on the internet at a lower cost.

According to Lancioni et al. [12] research, it is shown that based on the ranking, the most popular use of the Internet for SCM is in transportation, followed next by processing, managing vendor relations, purchasing procurement, and customer service. Table 1 represents the ranking of internet applications in supply chain management.

Table 1 Ranking of internet applications by logistics decision area [12].

Application	% Using	Rank
Purchasing/Procurement	45.2	3
Inventory Management	30.1	5
Transportation	56.2	1
Order Processing	50.7	2
Customer Service	42.5	4
Production Scheduling	12.3	6
Relations with Vendors	45.2	3

2.3 Digital Supply Chain

In the era of the global and connected economy, the digital supply chain is becoming a most researched trend and it is also on the ramp to improvement and success [6]. Digital technology is taking place over the traditional operations and now every business has become a digital business and its impact on supply chain management is predominantly great. According to Yan et al. [8], by only applying the traditional way of SCM strategy cannot lead to winning comprehensive advantages in the market competition. Therefore, many companies/industries are understanding the essential factor of these changes and they have already started working to introduce digital technology into their operations, however, just adding technologies into the business is not the answer for all.

There are several digital technologies which could be counted under the Internet of Things (IoT) and could successfully qualify as a future of the supply chain. The digital technologies are:

1. Supply Chain and Augmented Reality (AR)
2. Supply Chain, IoT, and Big Data
3. Supply Chain and Radio Frequency Identification (RFID).

2.4 Augmented Reality (AR) as an aide to Supply Chain

According to Cirulis et al. [13], the prime objective of Augmented Reality (AR) is to augment the real world environment with virtual information that enriches human sense and abilities. AR technology is to combine virtual information with the real world [14]. This technology is usually used in real time and semantic context with environmental elements [13]. AR technology is very common on the TV channels like sports channels. For instance, on the TV sports channel, there would be a score on the captured video and that score is the virtual information that combines with the reality and there are a number of other channels or other daily routines are using AR technologies. Most industries are using this technology to compete in the market and this technology is also used in SCM. AR will provide benefits to the supply chain as listed below [6]:

Picking Optimization: By using AR, any professional can see a ‘digital picking list’ on a heads-up display. Professionals can select a building material and the digital display will calculate and guide them through the shortest and most efficient path through the warehouse for the package to be picked up. This information can also be saved in the Warehouse Management System simultaneously with the help of the cloud computing.

Freight/Container Loading: AR could replace the need for physical instruction because of the heads-up displays (picture google glass visuals). These displays have step by step instructions with the best methodology to load the container according to the size, dimension, and weight of the building material loaded into the vehicle. The information and data through AR can ensure optimum loading and thus help reduce freight cycles of the supply from warehouse to the construction site.

Dynamic Traffic Support: Most transportation vehicles (e.g. trucks) are equipped with GPS navigation, but AR systems are the natural successors. Heads-up and windshield’s displays would allow the driver to re-route shipments in real time without distracting the driver significantly. For example, a truck is loaded with a concrete bags and AR can show the driver critical information including the weight of the concrete bags, gasoline efficiency, the route to the reach to the destination and so on.

Facility Planning: AR can help the professionals to visualize their next facility in full scale even before the construction starts. The project managers can model their workflow through the site, test measurements, and estimate the raw material needed to carry out the various activities. The AR system can also help the planners to select potential suppliers for various building materials while maintaining an online database simultaneously.

2.5 Supply Chain, IoT, and Big Data:

The smart sensing equipment integrated with cloud computing and big data could be the next big thing that could provide a multidimensional solution towards supply chain optimization of building materials. Devices such as RFID, cameras, Laser tags, GPS, Bluetooth LE (iBeacon), Low-frequency LF tags, and Battery Assisted Passive (BAP) tags could be used to for an effective management of a project site. The 24/7 availability of real-time information update accessible on a wide variety of devices enhances the level of performance delivery of the industry and provides a firm base for consistent workflow [6].

Some of the most promising areas for the application of the IoT's and Big data in the construction industry are:

Reduce Reaction Time to Stimulation: The ability to readily meet the demands of a customer is one of the major areas of supply chain optimization. Cloud computing coupled with smart communication devices could help reduce the time lag between the order and shipment of the building material [33].

Inventory management: The inventory at a construction site or a warehouse can be tagged with smart sensing devices such as RFID tags which can help maintain a count of the available stock and also trigger a request for more supplies in case of the stocks getting below certain levels [34].

Prediction of Customer Needs: In the age where the customer satisfaction is of paramount value, smart organizations could use the services of the big data to point out potential customers and customize their product and marketing according to customer needs [35].

Locating construction equipment: The IoT can be used to locate and track the various construction devices such as machinery, excavators, scrapers, drilling machines, cranes, and booms. The tracking system can help maintain a count of the resources allocated at a site and formulate a strategic positioning of the equipment on a job site.

Improving the efficiency of Supply Chain: The cost reduction techniques, spending patterns, and material efficiency will continue to be the top priorities in the supply chain. IoT and big data could be used to improve upon these variables.

Remote operation of machinery: IoT enables the technicians to operate machinery from a distant location so that they could avoid potentially hazardous work conditions. The wireless networking of machinery and devices enables the technicians to carry out their work with the help of remote operated machines and robots.

Supply Chain Traceability: Traceability of construction manpower, material, and equipment is directly linked to risk. Big data and Global Positioning System (GPS) can be used to keep a count of the number, location, and database of the active hours at a construction site [12].

Safety and Risk management: The construction and civil infrastructure project sites can use the smart sensing devices to augment the onsite safety standards. Smart locating, imaging, Laser sensors, and tracking devices such as hawk-eye-vision cameras can be used to ensure the safety of the working personnel on a job site.

2.6 Supply Chain and Radio Frequency Identification (RFID)

The IoT expands the application of RFID as an automatic information collection terminal, RFID system is also included in IoT as an information entrance, because it recognizes the information by reading and processing the metadata which is stored in the RFID tags. Yan et al. [8] stated RFID as a "non-contract automatic identification technology named radion frequency identification, which can identify the still or move entities automatically."

Case scenarios for applying RFID technology in construction project management [36]:

Logistics and supply chain management (LSCM): The typical supply chain means the customer's ordered materials were shipped or transported by transportation vehicles from the factory to the material distributor to the on-site warehouse. In this process for every associated professional (e.g. buyers, project managers, truck drivers and so on) should know all the necessary information such as manufacturer, quality of the product, specification etc. and this could be possible by using RFID tags. Similar to any price tag that can be seen to any product and this has been seen in construction to tag the big components. With the addition of the other technologies like adding Global Positioning System (GPS) and Geographic Information System (GIS) with the RFID can add more accuracy in terms of tracking the construction materials [37].

Inventory Management: Maintaining inventory is a big task and has the particular importance in construction. In addition, by maintaining a good material inventory one can ensure the smoothness of construction process [36] and RFID technology can be utilized to improve the inventory management of construction materials. For instance, by keeping RFID reader in a storage area, it is easier to maintain the inventory because it can read the RFID tags that are attached with the materials and it can automatically update the inventory.

3 Advantages of IoT In Supply Chain

The smart sensing equipment integrated with cloud computing and big data could be the next big thing that could provide multi-dimensional solution towards supply chain optimization of building materials. Devices such as RFID, cameras, Laser tags, GPS, Bluetooth LE (iBeacon), Low-frequency LF tags, and Battery Assisted Passive (BAP) tags. The 24/7 availability of real-time information update accessible on a wide variety of devices enhances the level of performance delivery of the industry and provides a firm base for consistent workflow.

The services of cloud computing and big data can be used to operate, record, and store the raw and processed information from the machines, software systems, sensors, and people. The information stored in the cloud could be accessible through a wide variety of devices such as personal computers, tablets, mobile phones, etc. The information is free from physical limitation of location or time constraints.

The use of IoT coupled with smart sensing devices could help in the communication and material tracking with high accuracy and free of noises such as human error, workforce shortage, cramped budget, adverse weather, and other environmental factors.

Specific information about construction materials that need to be tracked and shared by using IoT technology during the SCM process include:

1. The visualization of the logistic patterns. Track quality, quantity, and cost of the resources. Compare the plans vs actual delivery, and monitor and inspect the delivered product [26].
2. Develop a decision-support system to generate a production and supply plan for the supplier and buyers of steel rebar [2].
3. Handle ready-mix concrete operations by following the position of trucks and observing the motion and status of concrete conveyances in real time [38].
4. Optimize vehicle routing and vehicle scheduling of logistics under uncertain systems [39].
5. Tracking system to improve the work efficiency of scaffold supplies [32].
6. Remote monitoring of the tools and equipment on a job site [40].
7. Facilitating the trouble diagnosis system and maintenance of construction equipment [41].

4 Discussion and Conclusion

In the current scenario, where the human workforce is expensive, scarce, and irregular in terms of performance, the digitization of the workforce and build environment can help the organizations to manage their performance in terms of cost, time, and quality of the end product. An array of smart sensing devices like RFID, LASER technology, BAP tags, and LF tags coupled with communication medium such as the wireless internet network could help boost the overall efficiency of an organization. The smart devices have the capacity to interact and communicate with the environment around them which consists of software systems, machines, devices, and people. Altogether, these systems are capable of providing a customized solution to the problem and help an organization to easily conduct operations such as data compilation, communication, quick response to stimulation and decision making.

The real-time data feed is uploaded to a cloud database and is easily accessible through a vast variety of devices such as mobile phones, tablets, pods, television, and computers. The information available through the digital medium powered by IoT is free from the constraints of location, time, space, adverse weather, human error, and other environmental factors. The real-time data updates can help the project managers and supervisors to track and monitor the operations at a construction site and help them exercise a better control of the overall project.

The ease of application and functions involved with IoT comes up with its own set of unique challenges, the dependency of the entire system over a constant source of power supply can’t be negated. In case of power failure, the whole facility could come down and put the organization into disarray. Additionally, the security of the data compiled through these systems is not theft proof. The digital systems and data are prone to hacking which possess a great security risk to the functioning, efficiency, and organizational structure of a firm. Furthermore, the greatest challenge that the digital systems face is the ever-changing and evolving nature of the technology itself. There are numerous numbers of research-work that constantly goes on into the digital field, this transpires into the technology getting sharper and being different with every passing decade. The change in the technology requires constant upgradation in terms of devices, software, and installation of new systems and training of the handling staff. The technological improvements can put transitional challenges, operational shifts, and financial burden on an organization.

The primary factor with respect to the full deployment of new technological advancements has been as of recently the human one. It is because the gap between innovation and human resources culture has augmented, not diminished. Incompetent plans of progress administration in organizations do not help in filling this void. A ton of work must be done in getting ready new trainers and instructors and the gap must be loaded with new floods of “tech-savvy professionals”, originating from the local digital youthful generations.

Major barriers to the achievement of success of supply chain optimization using IoT incorporates work environment culture, an absence of senior management commitment, privacy issues, improper support mechanisms and the dearth of education of management philosophy. Learning and training at all level in the industry are paramount to beat these boundaries.

Abstract -

This paper describes a method of providing a panoramic image using single image transmission system. In recent years, demands for small robots performing inspection work by remote control are expanded. On the remote control of robots, to provide information of environment around the robots is important for operators. Multiple images are usually transmitted to the operators' sides. In some cases, a large or special image generated from multiple images by image processing units is transmitted to the operators' sides. In order to transmit multiple images, multiple image transmission systems are required. On the contrary, generating special images also require a dedicated image processing unit. However, small robots cannot mount such devices due to size limitation. Therefore, we develop a method of providing a panoramic image using single image transmission system. We assume that robots are too small to mount a dedicated image processing unit or multiple image transmission systems. This system is assumed to target cameras with analog outputs. An image which is different from a previously transmitted image is transmitted every transmission. Before the transmission, a special code is added into each frame to distinguish which camera acquires the frame. We develop a tiny processing board to mount the system on small robots. First, we explain a method of spherical projections to generate a panoramic image. Multiple images are transmitted with single image transmission system after adding the code into the images. Availability of our proposed system is shown by an experiment that providing a panoramic image using two cameras.

1 Introduction

In recent years, demands for robots for performing the inspection work by remote control are expanded. In some cases, these robots perform the inspection work in a narrow space where people cannot enter. The robots are required to be as small as possible. On the other hand, it is also necessary to provide information of environment around the robot for operators. On the remote control of robots, an image acquired from a camera mounted on the robots is provided to the operator. However, to recognize the environment around the robots is difficult with single camera. Therefore, many remote control robots are equipped with multiple cameras. In some cases, a large or special image is combined from multiple images on the robot. An image transmission system is required to transmit an image to the operator from the robot. In order to transmit multiple images, multiple image transmission systems are required. On the contrary, to generate special images requires a dedicated image processing unit. However, small robots cannot apply these methods due to limitation of sizes. We develop a small hexapod robot which is shown in Figure 1 for the purpose of assisting inspection work[1]. The robot is too small to mount USB cameras or multiple image transmission system. The robot is equipped with multiple cameras with analog outputs. A single image transmission system is mounted on the robot due to limitation of sizes. Similarly, the robot is also not equipped with a dedicated image processing unit. Nevertheless, a method of providing a panoramic image is required for the remote control of the small robot.

In this paper, we describe a method of providing a panoramic image using single image transmission system. In order to transmit multiple images quickly using single image transmission system, following requirements are satisfied.

1). All cameras are synchronized.
2). Cameras are switched at the same time that transmission of just one image is ended.
3). Received images can be separated to each camera's image in operators' sides.

About 1), we assume that all cameras are synchronized. Methods to satisfy 2),3), are described in the following. Availability of our proposed system is shown by an experiment of generating a panoramic image by using two cameras. This paper is organized as follows. Section 2 describes related work about providing information on remote control of robots. A method of generating a panoramic image is described in Section 3. In Section 4, a method of transmitting multiple images by a single image transmission system is described. By transmitting

the images in which added a special code, it is possible to distinguish which camera acquires the frame. Section 5 shows availability of our proposed system by an experiment of providing a panoramic image. Finally, Section 6 presents our conclusions and future work.

2 Related Work

In order to recognize environment around robots, multiple cameras are usually mounted on the remote control robots. However, it is difficult for operators to recognize environment around robots by multiple images. A method of combining multiple images to generate one special image has been studied. As a special image, there are panoramic images[2, 3, 4]. The panoramic images can be viewed omnidirectionally from the location of acquisition. Therefore, it is easier for the operators to recognize the environment around the robots by special images than by multiple images. Recently, there are omnidirectional cameras which can acquire panoramic images with one camera. However, the image resolution per viewing angle of these cameras is low. Another special image is a bird's-eye view image[5, 6]. An image looking down the robots is generated by combining multiple images. A bird's-eye view image helps operator to recognize the environment around the robots. In many studies, images generated with combining multiple images are provided on the remote control of the robots.

3 Generating Panoramic Image

3.1 Overview

This section describes a method of generating a panoramic image from multiple images. Multiple images are combined into a single image by projecting the images to a spherical surface. The spherical surface where images are projected on is divided by latitude and longitude. The images are projected to the spherical surface after images are segmented and transformed to accommodate various regions of the spherical surface.

3.2 Coordinate System

As shown in Figure 3, three coordinate systems, which are orthogonal and right-hand ones, are defined for calculation. The robots coordinate system Σ_R is fixed to the center of figure of robots' body. The cameras coordinate system Σ_{Ci} is attached to the camera mounted on the robot. Note that the subscription "i" means the camera number. The projection sphere coordinate system $\Sigma_{section}$ is fixed to the center of the sphere. The vector from O_R to O_{Ci}, expressed in Σ_R, is denoted as ${}^R\boldsymbol{p}_{Ci}$. The vector from O_R to O_S, expressed in Σ_R, is denoted as ${}^R\boldsymbol{p}_S$. The rotation matrix from O_R to O_{Ci}, expressed in Σ_R is denoted as ${}^R\boldsymbol{R}_{Ci}$. In this case, ${}^R\boldsymbol{p}_{Ci}$ and ${}^R\boldsymbol{R}_{Ci}$ is already known according to the specification of the robots.

3.3 Spherical Projection

Image planes are placed at a distance of focal length f_i from cameras. The vector from O_{Ci} to image planes expressed in Σ_{Ci}, is denoted as ${}^{Ci}\boldsymbol{p}_{0i} = [0, 0, -f_i]^T$. Then, normal vector of the image planes, expressed in Σ_{Ci}, is denoted as ${}^{Ci}\boldsymbol{n}_i = [0, 0, -1]^T$. Considering camera attitude and defining vector ${}^{Ci}\boldsymbol{p}$ as any position in 3 dimensions, an equation of image planes is as follows.

$$\boldsymbol{n}_i^T \cdot ({}^{Ci}\boldsymbol{p} - \boldsymbol{p}_{0i}) = 0 \tag{1}$$

The vector of position on the spherical surface ${}^{Ci}\boldsymbol{p}_F$, expressed in Σ_{Ci}, is calculated by Equation (2).

$${}^{Ci}\boldsymbol{p}_F = {}^{Ci}\boldsymbol{R}_R({}^S\boldsymbol{p}_F - {}^R\boldsymbol{p}_S) - {}^R\boldsymbol{p}_{Ci} \tag{2}$$

A vector of three-dimensional position on the spherical surface ${}^S\boldsymbol{p}_F$, expressed in Σ_S is calculated by Equation (3)

Radius of projection sphere r, latitude θ and longitudeϕ is necessary before the calculations.

$$^{S}\boldsymbol{p}_F = [\ r\sin\theta\cos\phi,\ \ r\sin\theta\sin\phi,\ \ r\cos\theta]^T \quad (3)$$

Then, a point which line from camera fixed position to the spherical surface intersects an image plane is calculated. A vector of position on image planes corresponding to position on the spherical surface $^{Ci}\boldsymbol{p}_p$ is able to be calculated from at a point which a line intersects an image plane.

$$t = \frac{\boldsymbol{n}_i \cdot {}^{Ci}\boldsymbol{e}_F}{\boldsymbol{n}_i \cdot \boldsymbol{p}_{0i}} \quad (4)$$

Therefore, a vector of position on image planes $^{Ci}\boldsymbol{p}_p$ is as shown in Equation (5).

$$^{Ci}\boldsymbol{p}_p = t \cdot {}^{Ci}\boldsymbol{e}_F \quad (5)$$

These processes are performed in all regions on the spherical surface. Then, images are projected on regions on the spherical surface. Conditions of $^{Ci}\boldsymbol{p}_p = \left[{}^{Ci}x_p, {}^{Ci}y_p, -f_i\right]^T$ within image planes is,

$$\begin{cases} -\dfrac{w_i}{2} \leq {}^{Ci}x_p \leq \dfrac{w_i}{2} \\ -\dfrac{h_i}{2} \leq {}^{Ci}y_p \leq \dfrac{h_i}{2}, \end{cases} \quad (6)$$

where w_i is the width of image planes, h_i is the height of image planes. When Equation (6) is not satisfied, $^{Ci}\boldsymbol{p}_p$ is removed.

4 Transmission System of Multiple Images

4.1 Overview

This section describes a method of transmitting multiple images via a single image transmission system. One image is able to be transmitted by using the single image transmission system. Another image which is different from previous transmitted image in every transmission is transmitted to transmit multiple images. On the other hand, the received image cannot distinguish which camera acquires the one. A special code is added into the image to distinguish cameras. First, the output signals of analog cameras are described. Then, the timing of exchanging images which are transmitted is shown. Finally, the special code is added into the images.

4.2 Composite Video Signal

This study targets cameras which output the composite video signal. There are some kinds of type. These video encoding processes are different. However, there are not large differences in the structure of the video signals. In the subsequent processing, any type can be applied by changing parameters. In the following, our system is explained by NTSC system which is widely used in Japan. The composite video signal is composed of a video signal and a synchronization signal. The synchronizing signal includes a vertical synchronizing signal, a horizontal synchronizing signal, and a color synchronizing signal. Using synchronizing signals, one frame of images is distinguished.

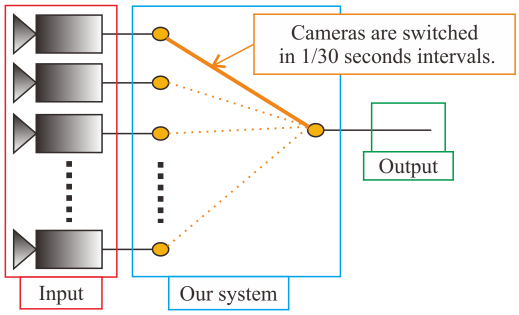

Figure 4. A system of transmitting multiple images using single image transmission system

4.3 A Method of Exchanging the Images

Figure 4 shows that a system of transmitting multiple images. Multiple images are transmitted by switching images which is transmitted in 1/30 seconds intervals. For example, we describe a method of exchanging images by using camera with an NTSC signal. In NTSC system, one image is composed of two fields which are even field and odd field. Each field has 262.5 scanning lines so that one image has 525 scanning lines. One scanning line has one horizontal synchronizing signal. In other words, one image has 525 horizontal synchronizing signal. On the one hands, a vertical synchronizing signal is changed in swapping odd field and even field. After switching the vertical synchronization signal from HIGH to LOW, 525 horizontal synchronization signals are counted to exchange the images.

4.4 Adding a Special Code into Images

A special code is added into images by using active video in composite video signal. Any line of an active video is replaced with the special code. By using the code in the images, a camera which acquires the image is distinguished. The code is composed of two colors which are white and black. By dividing a line into N parts, one line has the values of range from 1 to 2^n. In NTSC system, width of an image is 640 pixels. One line has the values of range from 1 to 2^{640}. Figure 5 shows relation between the code and the numerical value (N = 3). A process of adding binary code into images is shown in Figure 6.

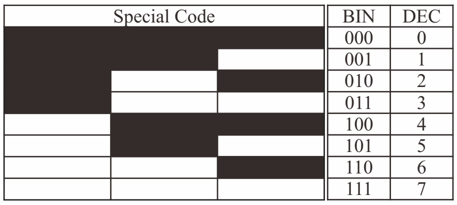

Figure 5. A special code and numerical values corresponding to the code (N = 3)

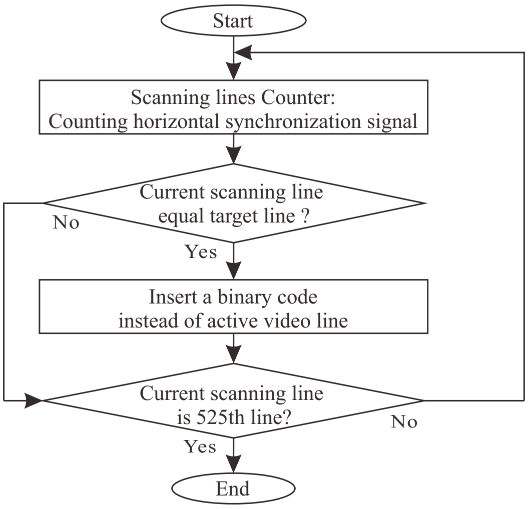

Figure 6. The process of adding a binary code into images

For example, the code is added into the first line of the image. 480 of 525 scanning lines are displayed as images. From 1 to 45 scanning lines are used for different purpose such as subtitle, vertical synchronization. Therefore, the first horizontal line in images can be changed to the special code by swapping 46th scanning line and the code. Figure 7 shows an image which added the code into the 100th scanning line. As a result, the special code in the images have been confirmed.

5 Experiment

5.1 Overview

Being able to provide a panoramic image is confirmed by using our proposed system. In an experiment, two images are transmitted to computer via single image transmission system. Prior to transmitting, the binary code is added into the images by using an experimental equipment. On the computer, the received images are combined into a panoramic image. As a result of the experiment, availability of our proposed method is verified. Problems of generating a panoramic image are also revealed.

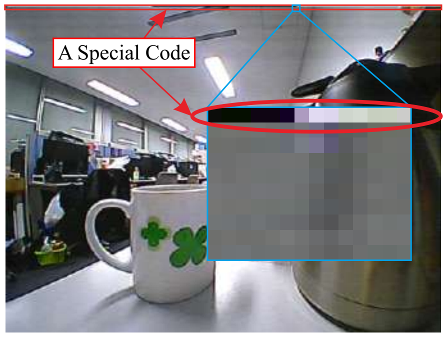

Figure 7. The image which added binary code

Table 1. The specification of computer

Capture Device	PCA-DAV2

Table 2. The specification of cameras

Product name	MINI CCTV CAMERA 205M-WD
Resolutions	640 x 480
FPS	30
Horizontal view angle	about 110 degrees
Vertical view angle	about 95 degrees

5.2 Environment

Figure 8 shows a prototype device which is developed for the experiment. The device is composed of the video signal extractor, the camera exchanger, and the signal counter. The video signal extractor is made by referring to an article[7]. PIC is used for adding binary code and exchanging cameras. Two camera are synchronized before making the experiment. In this case, the two cameras are synchronized by means of injecting a clock signal which created by one crystal into two boards after removing the crystal on cameras boards. If using more than two cameras, clock signals which generated from a clock generator are injected in order to synchronize all cameras. Using the device, a binary code is added into images acquired from two cameras. Images outputted from the equipment are captured in the computer by a capture device. The panoramic image is generated from two images after separating the images. In this situation, one of codes added into the images is black line and the other is white line. Figure 9 shows a simplified image of experimental equipment. The cameras that used in the experiment are shown in Figure 10, and the specification of the cameras and the computer are shown in Table 2. The cameras are fixed to an experimental equipment as shown in Figure 11.

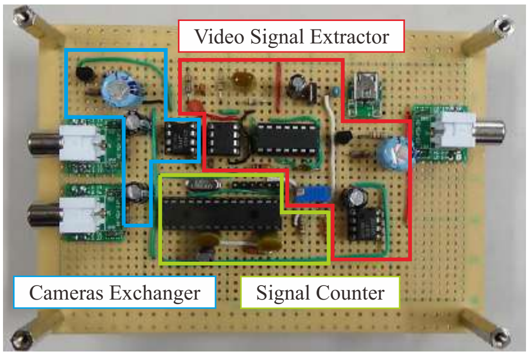

Figure 8. A prototype device to transmit two images using single image transmission system.

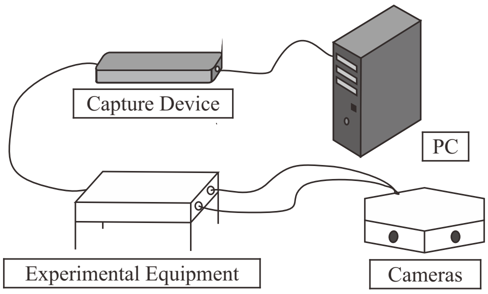

Figure 9. Experimental environment

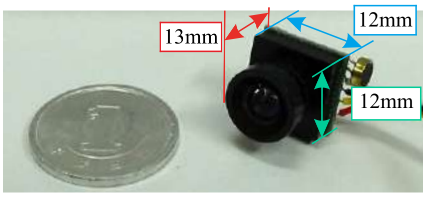

Figure 10. A camera used in the experiment

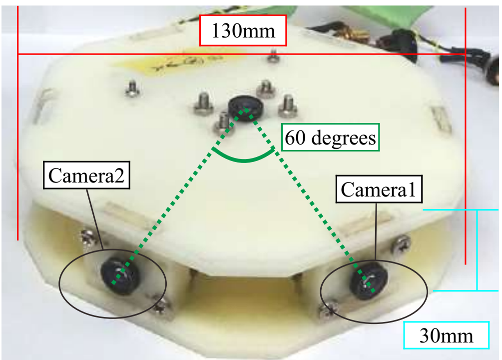

Figure 11. Experimental equipment

5.3 Result

Figure 12 shows the panoramic image which generated by using single image transmission system. It was confirmed that two images can be transmitted quickly and received images are separated to two images. The first line of the image acquired from Camera1 is a black line. Similarly, the first line in Camera2's image is a white line. A special code can be added to the image by using the device. Finally, two images are combined into the panoramic image by spherical projection. Using two cameras, to generating a panoramic image was confirmed. From the above, availability of our proposed method was verified.

5.4 Discussion

The received images are noisier than original images. The image noises might be caused by the video signal amplifier circuit. Our system has two video signal amplifier circuits. In order to reduce noise in images, it is necessary to modify the amplifier circuits. The panoramic image has a problem that a border among the image is not combined continuously. When the camera moves, to generate a panoramic image is difficult due to gap among the projected images. Furthermore, multiple images cannot be acquired from camera at the same time. For this reason, projection position should be changed to combine images correctly. On the other hand, the prototype device which is developed for the experiment is not too small to mount on the small robot. Therefore, to reduce the size of the device is required.

6 Conclusions

This paper presented that the method of generating a panoramic image using single image transmission system. At first, the method of generating a panoramic image with spherical projections was described. Then, multiple images were transmitted using single image transmission system. Prior to transmitting the images, the special code was added into the images to distinguish which camera acquired. Finally, availability of our proposed method was confirmed by the experiment that providing a panoramic image using two cameras.

In future tasks, it is necessary to confirm availability of the our method in the case of wireless transmission. Using more than two cameras, multiple images should be transmitted by the our method. To provide a panoramic image on the remote control, we will develop a remote control system for small mobile robots.

Abstract –

Ensuring high efficiency in construction through advanced planning techniques must be supported by the simulation of construction processes. In previous research, the potential for multi-agent based simulation to support the planning phase were successfully shown with regard to some typical construction tasks. Among the main benefits determined by this approach the following ones were reported: capability of simulating real-world processes and interaction among resources; powerful 3D visualization; optimal sizing of resources. However, those models are not easy to create, because of the absence of built-in blocks and the many relationships among single agents and between agents and context.

In this paper we propose the application of a novel holonic system for construction management, which is a sub-category of multi-agent systems. It combines the high and predictable performance promised by hierarchical systems with the robustness against disturbances and the agility of heterarchical systems. Holons are self-contained, stable, intermediate forms, that can be used to create a bigger whole. By using holons, designers aim to create complex systems that can be reused and redesigned much more rapidly than standard multi-agent systems. The approach was applied to the optimal scheduling of bored piles construction. Hence, a holonic construction execution system for bored piles tasks was developed. The holonic architecture was designed so as to integrate the DMAS pattern for scheduling optimization through stigmergy. The results of this paper showed the easy reusability of our simulation sub-systems and the potentials in terms of automatic optimal planning of construction works.

1 Introduction

Lean construction principles are currently under development in order to improve the productivity of the construction industry. However, this process requires that general lean principles be adapted into practices that are tailored to the characteristics of construction projects. A number of initiatives are known in this field. An empirical study regarding the construction of a large hospital resulted in a set of lessons learned, which can be roughly grouped into three sections: lean engineering, logistics and purchasing, lean construction process [1]. A methodological and very popular approach, which was definitely organized by the lean construction institute, is the last planner system [2]: it helps increase the reliability of a planning system and thereby significantly improve its overall performance. Although really effective, implementing the last planner system in construction organizations over the long-term requires significant support for project teams by dedicated facilitators. Such levels of support are difficult to maintain, but in their absence teams tend to revert to traditional practices [3]. As a result, research is still very active in this field and novel methodologies are object of testing, such as the "kanBIM" prototype, which is a BIM-based workflow information system to help construction personnel implement pull flow strategies [4]. This latest approach highlights the importance of monitoring, control and continuous revision of the work plan, according to the status of work underway. Thanks to the advent of powerful computational tools, optimal work plans can be worked out by means of agent-based simulation approaches. This approach outperforms discrete event simulation, which, in fact, fails to incorporate the inherent variability that arises from the independent construction subjects' behavior as they interact on a construction site [5]. On the contrary, multi-agent simulation is suitable for modelling resources' behavior and interactions in complex settings, like in construction. These models are capable of specifying the characteristic of trade crews, their work methods, the amount of work, workspaces and dependencies between tasks. As a result, simulations encapsulate both variability and uncertainty of the construction workflow [6].

In this paper we study the feasibility of a new reference architecture for construction, that was successfully tested in manufacturing, and that can simulate the construction process. This new system is based on the use of holons, which can organize into holarchies, and own self-configuration and self-organization capabilities, thus resembling the behavior of the resources usually employed on and off-site, which must cope with the high variability and uncertainty typical of construction works [8]. In addition, simulation models are built on top of classes classified as agents, holons and functional blocks, which can be variously combined to perform optimal planning by means of optimization algorithms. In section 2 a brief overview of the scientific background will be provided. Section 3 will report on the basics of holonic systems and of the optimization algorithms we have analyzed. Then, Section 4 will present an application to the optimal planning of bored piles and presents a final discussion.

2 Scientific Background

Renovation works must be scheduled, budgeted and monitored and controlled until the end of work progress. The standard construction practice is commonly done applying diagram methods to sequence activities that are based on work packages defined according to a work-breakdown-structure. Then, progress management usually involves deviation analyses between the actual progress and the initial plan that is constantly being updated and revised. The scarce communication and the absence of automation requires the adoption of standard methods, such as face-to-face meetings and paperwork. This approach has been identified as an inhibitor to increasing productivity and a miscommunication and rework source, which can be improved by means of holonic execution systems. These systems are able to improve communication channels, coordination and cooperation, dynamic management. Also, they can take advantage of BIM-based structured information [8]. Several authors analyzed the great potentials of multi agent-based simulation, thanks to its ability of imitating real world process of systems, where the global behaviour emerges as a result of interactions of single agents [6, 9]. Agents can be active, proactive, autonomous, cooperative, adaptive and mobile. They interact to reach a global objective. However, holons can expose additional important features that resemble the real behaviour of construction execution, i.e. they organize into holarchies, where a system of holons cooperate to achieve an overall goal while negotiating with their own objectives [10]. Hence, they can reliably simulate the behaviour of cooperating agents in construction sites and the dynamics in such distributed operating environments [11] even if parameters change during the work progress [12]. Holonic models were successfully applied in manufacturing control, referring to the PROSA reference architecture [13]. In this application all entities in the “world of interest” were not only represented as agents, but also as entities in the environment, with which they communicate and interact. In addition, the Delegate multi-agent system (DMAS), that is part of holonic systems, allows any holons to delegate a responsibility to a swarm of “lightweight” agents [7]. This feature can be used to find out the optimal work planning prior to the execution phase, and to execute dynamic re-planning during work progress.

Automation in scheduling has been studied in the last three decades and several approaches were experimented [14]. Cased-based reasoning (CB) develops plans by remembering earlier and comparable situations. Genetic algorithms (GA) and neural networks (NN) perform optimization relying on a huge database, so their learning process must be fed by thousands of records. Hence, expert systems (ES, mainly using if-then-else structures) and model based approaches (MB, which simulate the execution process) look more reliable to be applied in construction. However, all these approaches tackle a unique aspect of the scheduling problem: CB is about optimal sequencing, GA on resource optimization and levelling, NN on time-cost tradeoff and optimization, MB on spatial reasoning. Some remarkable examples about MB simulated the construction process either by means of a set of differential equations [15], or an integrated mathematical model [16] or a probabilistic approach [17].

In this paper, we will study another approach and will test it in the execution of bored piles. Our model will conform to the PROSA reference architecture, which includes the DMAS approach, because it allows the re-planning occurring during execution. More importantly, this process allows us to evolve from single-objective optimization towards a multi-objective optimization problem based on ant-colony simulation. In this approach, every objective can be optimized by a different colony, that is cooperating and contributing to the whole process. In addition, every resource involved in the production process is capable of continuously re-planning her schedule as a result from unexpected occurrences, in fact performing dynamic scheduling. Finally, the setup of simulation models can be facilitated by the availability of a BIM model of the designed tasks.

3 Holonic Execution Systems

3.1 Description of Holonic Systems

In this paper we tested the feasibility of using the holonic reference architecture for the simulation of construction execution. The objective of a reference architecture is to specify a generic systems structure, the kinds of system components, their responsibilities, dependences, interfaces, data, interactions, constraints etc…[18]. Then, the reference architecture can be used as the basis for designing any system architecture, which refers to a particular system and focuses on a particular product.

Holonic architectures are made up of holons, which are autonomous self-reliant units, in the sense that they have a degree of independence and can handle contingencies without asking higher authority for instructions. They are stable intermediate forms, that can be used to create a bigger whole [13]. Holons are combined to form holarchies, which combine the positive characteristics of hierarchical and heterarchical systems. Hierarchical systems offer high and predictable performances thanks to their pyramidical structure (although they might lack in robustness). Heterarchical architectures allow for full cooperation between entities, that is arranged by means of negotiation, in fact increasing robustness [19]. Holons can function on their own, which increases robustness and, at the same time, it can function as a part of a bigger whole, forming a hierarchy with other holons for a certain period of time.

The three basic types of holons, which are adopted in the PROSA reference architecture for manufacturing systems, are order, product and resource, whereas staff is optional. Order holons are in charge of accomplishing tasks, they search for solutions and select among candidate alternatives the most attractive one; product holons provide order ones with knowledge about routing and processing sequences that are able to create proper products; resource holons drive their resource actuation and keep their internal state synchronized with the resource through appropriate inputs, such as sensor readings [7]. Holonic systems can operate just in case they include the world of interest, that is the part of reality in which the execution operates. As a result, the architecture of a holon usually comprises both the control system and the manufacturing system (Figure 1):

- The physical processing component, that is part of the world of interest;
- The physical control component;
- The decision making component that is part of the agent.

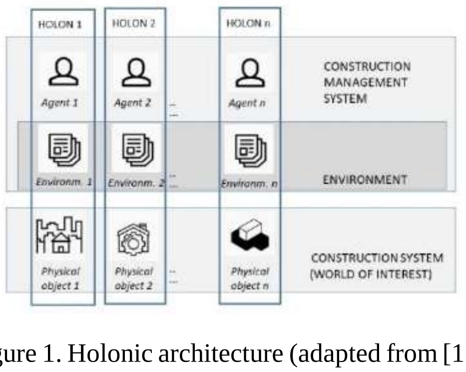

Figure 1. Holonic architecture (adapted from [13])

3.2 Holonic Execution Systems for Construction Management

Most construction tasks are affected by disturbances and variations in their operating environment. As a consequence, work plans that are generated before the process starts, are based on approximate resource performance and predicted operating conditions. For that reason, they need re-planning any time unexpected occurrences cause deviations from what expected. In addition, not two construction sites can be planned in the same way. Hence, multi-objective optimization problems must be integrated in management systems, in order to adapt the crews number and mutual organizations, according to real boundary conditions. In sub-section 3.2.1 an approach that is general enough while being capable of integrating optimization algorithms will be presented. Then, in sub-section 3.2.2 the multi-objective optimization algorithm that we used in this research work will be detailed.

3.2.1 The Architecture of the Holonic Execution System

The holons mentioned in sub-section 3.1 are expected to interact and share data with each other. Three basic types of interaction can be recognized [7]:

- Product-order interaction: the order holons interact with their corresponding product holon on how to correctly execute their task by using certain resources. In other words, the product holon provides the order holon with all possible next operations, and the order holon keeps track of the task being executed.
- Product-resource interaction: the product holon provides the resource holon with technological aspect to correctly process an order, e.g. the necessary process parameters to perform an operation.
- Resource-order interaction: resource and order holons mainly interact to commit operations to the resources. To this purpose, the resource holons provide the order holons with the results of virtually executed operations and reserve capacity when requested. Once a task is executed, the resource holon informs the order holon about the execution result and progress. Hence the desired coordination and control emerges in a self-organizing way from the interaction between the various holons.

In order for the above mentioned interactions to be effective, order holons must be able to reserve resource so as to optimize the overall schedule. In other words, holons must interact while seeking global optimization. Research manufacturing, found out that the behaviour of food-foraging ants, called stigmergy, is the best approach because it is capable of incorporating nonlocal information while employing only local reality-mirroring components [7]. To sum up, the following steps are performed in a stigmergic approach:

- In absence of any signs in the environment, ants perform a randomized search for food;
- When an ant discovers a food source, it drops a smelling substance, called pheromone, on its way back to the nest while carrying some of the food. The pheromone trail evaporates if no other ant deposits fresh pheromone;
- When an ant senses a pheromone trail, it will be urged by its instinct to follow this trail to the food source and will deposit pheromone itself on its way back to the nest.
