

A close-up photograph of a robotic arm assembly. The arm features a black and white cylindrical joint, a silver-colored metal bracket, and a black motor housing at the base. Bright orange cables are connected to the assembly. In the background, a black cable management tray with multiple orange cables is visible. A semi-transparent blue rectangular box is overlaid on the upper portion of the image, containing white text.

Foreword

ISARC is the premiere global conference in the domain of automation and robotics in construction. Specifically, ISARC 2021 is situated in an extremely interesting and important time in history: interest in digitising, automating, and robotising construction is rising in an unprecedented scale on a global level and cross all actors. This manifests itself in an increase in academic research activity, joint industry-academia collaboration projects, the emergence of strong start-ups, and a strong and growing interest of large, established organisations (contractors, machine/robot builders, governments etc.).

To prepare ISARC for the future, this year a first attempt was made to restructure IAARC's topic framework. The technical areas summarize the paper topic areas of interest, which represents all the research themes that are relevant to ISARC/IAARC. This is an important mechanism for the technical committee to consolidate the knowledge accumulated from each year's conference while allowing for the smooth incorporation of new research topics and trends in the community.

We hope that ISARC 2021 and the proceedings serves the audience and readers and all actors interested in automation and robotics in construction as a navigation and reference system for the domain and its most recent outputs and innovations.

Table of Content

KP Keynote and plenary talks

<u>Collaborative Welding and Joint Sealing Robots with Haptic Feedback</u>	1
Cynthia Brosque, Elena Galbally, Yuxiao Chen, Ruta Joshi, Oussama Khatib and Martin Fischer	
<u>Fabrication Information Modeling: Closing the Gap Between Building Information Modeling and Digital Fabrication</u>	9
Martin Slepicka, Simon Vilgertshofer and André Borrmann	
<u>A Methodology for BIM-enabled Automated Reality Capture in Construction Inspection with Quadruped Robots</u>	17
Srijeet Halder, Kereshmeh Afsari, John Serdakowski and Stephen DeVito	
<u>iHRC: An AR-based Interface for Intuitive, Interactive and Coordinated Task Sharing Between Humans and Robots in Building Construction</u>	25
Felix Amtsberg, Xiliu Yang, Lior Skoury, Hans-Jakob Wagner and Achim Menges	
<u>A Web-Based GIS Tool for Progress Monitoring of Linear Construction Projects</u>	33
Vineela Thellakula, Varun Kumar Reja and Koshy Varghese	
<u>Towards a Distributed Intelligent Home Based on Smart Furniture for China's Aging Population: A Survey</u>	41
Rongbo Hu, Thomas Linner, Suting Wang, Wenting Cheng, Xiaolong Liu, Jörg Güttler, Charlie Zhao, Yuan Lu and Thomas Bock	
<u>Vision-based Excavator Activity Analysis and Safety Monitoring System</u>	49
Sibo Zhang and Liangjun Zhang	
<u>Semantic Optimal Robot Navigation Using Building Information on Construction Sites</u>	57
Sina Karimi, Rafael Gomes Braga, Ivanka Iordanova and David St-Onge	
<u>CIM-enabled Quantitative View Assessment in Architectural Design and Space Planning</u>	65
Vikrom Laovisutthichai, Maosu Li, Fan Xue, Weisheng Lu, K.L. Tam and Anthony G.O. Yeh	

A Sensing systems & data infrastructures

<u>A Generalizability Analysis of a Data-driven Method for the Urban Heat Island Phenomenon Assessment</u>	73
Monica Pena Acosta, Faridaddin Vahdatikhaki, Joao Oliveira dos Santos, Amin Hammad and Andre Doree	
<u>A Conceptual Framework for Secure BIM-based Design: Using Blockchain and Asymmetric Encryption</u>	81
Xingyu Tao, Moumita Das, Yuhao Liu, Peter Wong Kok Yiu, Keyu Chen and Jack C. P. Cheng	
<u>A Digital Twin Framework for Enhancing Predictive Maintenance of Pumps in Wastewater Treatment Plants</u>	88
Seyed Mostafa Hallaji, Yihai Fang and Brandon Winfrey	

<u>The BIMERR Interoperability Framework: Towards BIM Enabled Interoperability in the Construction Sector</u>	94
Nefeli Bountouni, Fenareti Lampathaki, Spiros Kousouris, Anastasios Tsitsanis, Georgios Vafeiadis and Danai Vergeti	
<u>Use of BIM in the Analysis of Concrete Damage Structures: A Systematic Review of the Literature</u>	102
Marcella de Sena Barbosa, Francisca Ires Vieira de Melo and Josyanne Pinto Giesta	
<u>Towards a Construction Site Control System – Task Management in Construction Operations and Intralogistics</u>	107
Maximilian Schöberl, Daniel Bartmann, Stephan Kessler and Johannes Fottner	
<u>Blockchain-based E-tendering Evaluation Framework</u>	115
Xingbo Gong, Xingyu Tao, Moumita Das, Yuhua Liu and Jack Cheng	
<u>The Needs and Trends of Urban Simulation Platforms- A Review</u>	122
Yun-Tsui Chang, Aritra Pal, Jürgen Hackl and Shang-Hsien Hsieh	
<u>Towards an Integrated Building Information Modeling (BIM) and Geographic Information System (GIS) Platform for Infrastructure</u>	129
Ashtarout Ammar and Gabriel Dadi	
<u>Realizing, Twinning, and Applying IFC-based 4D Construction Management Information Model of Prefabricated Buildings</u>	137
Miaosi Dong, Bin Yang, Boda Liu, Zhichen Wang and Binghan Zhang	
<u>Enabling Operational Autonomy in Earth-moving with Real-time3D Environment Modelling</u>	145
Ross Walker, Simon Smith and Frédéric Bosché	
<u>Automated Model Preprocessing for Structural Analysis</u>	153
Goran Sibenik, Iva Kovacic and Valentinas Petrinis	
<u>Bridge Inspection Field Support and Inspection Method by Heat Map Using 3D Point Cloud Data in Japan</u>	161
Kazuhiko Seki, Aika Yamaguchi and Satoshi Kubota	
<u>Developing a knowledge-based system for semantic enrichment and automatic BIM-based quantity take-off</u>	169
Hao Liu, Jack Cheng and Vincent Gan	
<u>A BIM Integrated Hazardous Zone Registration Using Image Stitching</u>	176
Si Tran, Truong Linh Nguyen and Chansik Park	
<u>Integration of Building Material Databases for IFC-based Building Performance Analysis</u> ...	182
Stefan Fenz, Julia Bergmayr, Nico Plattner, Serge Chávez-Feria, María Poveda-Villalón and Giorgos Giannakis	
<u>Dam Sustainability Assessment and Flood Volume Estimation Using Remote Sensing and GIS</u>	190
Saeid Kalantari, Mohammad Ahmadi, Khalegh Barati and Shokoufeh Khojeh	
<u>Vision-based Precast Concrete Management Plan in Off-Site Construction Site: Using PC Member Quality Grades</u>	197
Ziqing Zhu, Yik Pong Yong, Sejoon Lee, Younghee Chang and Soonwook Kwon	
<u>An Integrated Scan-to-BIM Approach for Buildings Energy Performance Evaluation and Retrofitting</u>	204

Abstract -

Due to their unstructured and dynamic nature, construction sites present many challenges for robotic automation of tasks. Integrating human-robot collaboration (HRC) is critical for task success and implementation feasibility. This is particularly important for contact-rich tasks and other complex scenarios which require a level of reasoning that cannot be accomplished by a fully autonomous robot. Currently, many solutions rely on precise teleoperation that requires one operator per robot. Alternatively, one operator may oversee several semi-autonomous robots. However, the operators do not have the sensory feedback needed to adequately leverage their expertise and craftsmanship. Haptic interfaces allow for intuitive human-robot collaboration by providing rich contact feedback. This paper presents two human-robot collaboration solutions for welding and joint sealing through the use of a haptic device. Our approach allows for seamless transitions between autonomous robot capabilities and human intervention with rich contact feedback. Additionally, this work opens the door to intuitive programming of new tasks through haptic human demonstration.

Keywords -

Robotics; Construction; Haptics; Human-Robot Collaboration; Robotic Manipulation; Tactile Feedback.

1 Introduction

In recent years, progress in mobility, manipulation skills, and AI reasoning have started to enable the use of robots in space, underwater, homes, agriculture, and construction [1]. A particularly important area of interest is the automation of dangerous, strenuous, and labor-intensive tasks [2].

Construction sites are especially challenging environments for autonomous robots because of their highly unpredictable and unstructured nature [3, 4]. Hence, fully autonomous robots that replace human labor are not the most feasible or ideal solution. The majority of current approaches rely on a human operator that oversees a single-task autonomous robot. The operator receives only visual feedback and is limited in the type of input and recovery from failure he can provide due to the lack of an intuitive interface to do so. [4] attributed this lack in technical

Figure 1: Robotic solution to a welding task combining robot autonomy and haptic human intervention. Video of task execution: [video](#). Source code can be found here: [Project GitHub](#).

flexibility of construction robots to the fact that early construction solutions imitated systems initially developed for industrial fabrication [5].

Some tasks are structured enough to be autonomously performed by a robot with little human input, but many require a more flexible approach that incorporates a higher degree of human reasoning and intuition [6]. Given this reality, a method to design construction robots should be flexible enough to allow varying levels of human-robot collaboration depending on the task.

Haptic devices (Fig.1) provide an effective interface for collaboration by allowing the human to (1) feel the contact forces between the robot's end-effector and the environment [7], and (2) easily intervene and control the robot motion in scenarios that the autonomous behaviors are not able to handle successfully [8]. Additionally, data from these haptic interventions can be collected and used to learn new autonomous skills. Remote robot control using a haptic interface has been tested in fields such as surgery [9] and underwater exploration [1], but has not yet been

widely implemented in construction.

In previous work, the authors explored human-robot collaboration solutions to five hazardous and repetitive construction tasks: installing drywall, painting, bolting, welding, and sealing precast concrete slab joints [10]. Our industry partner, Goldbeck, was interested in automating these assembly and finishing tasks that require on-site, repetitive manual effort, ergonomically challenging positions, and working from dangerous heights. [10] outlines a method for designing collaborative robotic solutions with haptic feedback and to assess their feasibility in simulation.

In this paper, we focus on two of the previously explored tasks (steel welding and sealing precast concrete joints) and apply the aforementioned method to design more flexible collaborative solutions. Different from [10], we propose relying primarily on the robot's functional autonomy and using haptics as an effective and intuitive way to intervene in unexplored or failure scenarios. Force data from the recovery strategy employed by the operator can be recorded and used to learn from demonstration and augment the robot's autonomy. Over time, the robot will require less human intervention. This higher degree of autonomy could allow a single operator to supervise many robots at once, overcoming the problems of teleoperation in which one operator per robot is needed.

2 Related Work

While factories have typically separated workers from robots due to safety concerns, human-robot collaboration cannot be overlooked in construction, as robots and humans share one workspace [2]. This requires devising solutions that allow us to effectively combine the workers' expertise with the robots' autonomous skills.

Construction literature has studied the use of teleoperation devices [11, 12, 7], particularly focusing on construction machinery, such as excavators. These solutions often involve cameras for visual feedback and GPS sensors for navigation, which can be sufficient to accomplish low dexterity tasks with increased operator safety. However, [7] states that complex tasks involving contact greatly benefit from additional sensory feedback such as tactile information. Furthermore, teleoperation solutions rely heavily on the operator's guidance and do not fully exploit the autonomous capabilities of the robot.

A different set of collaborative solutions currently used onsite have semi-autonomous robots with a human supervisor that oversees the tasks such as drywall installation, concrete drilling, and layout [13]. The supervisor can provide simple inputs to the robot, such as when to start or stop the operation, while the robot handles the rest of the task. This approach makes better use of modern robotics capabilities and allows a single operator to manage several robots. However, the interfaces used to provide inputs to

the robot are often too simplistic to allow recovery from failure.

In the event of a robot failure during task execution, joysticks and control pendants do not always provide enough feedback for the operator to intervene in an effective way that enables timely task completion. Additionally, there is currently no streamlined way to learn from the operator's intervention and use this data to improve the robot's autonomous capabilities.

By allowing the operator to feel the contact between the robot and its environment, haptic devices increase the range of scenarios in which the operator can aid in failure recovery [14]. Additionally, we can easily record both force and position data during the operator's intervention. These human demonstrations of recovery strategies can allow the robot to learn new skills [15] and augment its functional autonomy.

Haptic devices have been used by the construction industry in combination with virtual reality for task training purposes [16]. The technology has allowed workers to train in a safe environment with realistic task conditions. However, haptics are still a novel technology in construction applications and field use has not been reported.

Current algorithms for haptic control of robots [17] can handle large communication delays, making them effective interfaces for remote intervention at long distances. In [1] an operator haptically controls an underwater ocean exploration robot from a distance of 100m.

Finally, [18] provides an example that integrates two modalities of robot control: autonomous robot behavior and expert human-guided motion interactions. In this study, a group of mobile robot arms successfully installed drywall boards in simulation with flexible human intervention.

This body of prior work illustrates how keeping the human in the loop with adequate feedback can facilitate successful task automation in complex, unstructured environments. Moreover, it highlights the value of haptics as a way to provide a flexible and effective interface for human-robot collaboration as well as teaching robots new autonomous skills.

3 Methods

This section explains how we designed our collaborative solutions as well as the framework used to implement the haptic controls. Additionally, we tackle the issue of reduced workspaces, which is often challenge when using a portable haptic device.

3.1 Four-Step HRC Design Method

In order to develop the HRC welding and concrete sealing solutions presented in this paper, we built on a method

previously developed for designing collaborative robotic solutions with haptic feedback [10].

Figure 2: Perimeter welding on anchor plates four-step method: (1) collect data, (2) generate simulation environment (3) simulate autonomous behaviors, (4) allow for haptic intervention.

In this paper we focus on using autonomous behaviors whenever possible and using haptics only for failure recovery or demonstrating new skills. In summary, the improved method involves: (1) collecting production data of the manual approach onsite, (2) generating a realistic simulation based on the Building Information Model (BIM) data provided by the industry partner at Level of Development 300, (3) generating autonomous behaviors that allow the robot to interact with the environment in simulation, (4) establishing a flexible control framework that allows for seamless haptic intervention when needed.

For step three we used SAI, an open-source simulator developed by the Stanford Robotics Lab in collaboration with Google [19] to control robots in physically realistic virtual environments. Its modules include a control library with the Operational Space formulation and a dynamics engine that can simulate multiple contacts between robot bodies and the environment [20].

Figure 3: Concrete joint sealing four-step method: (1) collect data, (2) generate simulation environment (3) simulate autonomous behaviors, (4) allow for haptic intervention.

3.2 Haptic Simulation and Controls

We implemented a flexible state machine that enables switching between an autonomous mode where the robot executes the required behaviors to complete the task without human intervention, and a haptic mode where an operator can take over and intuitively control the robot end-effector pose while feeling its interaction with the environment. The haptic mode records contact and position data from the operator demonstration, which can then be used to learn new autonomous behaviors.

SAI allowed us to quickly incorporate industry feedback in simulation and iterate through multiple robot designs before converging to a final solution. The simulations considered factors such as friction, object collisions, and system non-linearities. This functionality allowed for a realistic consideration of the construction environment and its constraints.

In order to generate autonomous behaviors, we used the operational space formulation [18] which allows us to describe the equations of motion of a robot at a desired control point. Let the robot have a task to fulfill, described by the task Jacobian J_t , the task coordinates x_t , and the associated task velocity \dot{x}_t , such that $\dot{x}_t = J_t \dot{q}$, where q represents the robot generalized coordinates and \dot{q} represents the robot generalized velocities. The equation of motion of the robot in free space is:

$$M(q)\ddot{q} + b(q, \dot{q}) + g(q) = \Gamma \quad (1)$$

where $M(q)$ is the robot mass matrix, $b(q, \dot{q})$ represents the Coriolis and centrifugal forces, $g(q)$ is the robot gravity vector, and Γ is the motor torques. In the following, we will drop the dependencies in q and \dot{q} for better readability.

After multiplying eq.(1) by the dynamically consistent generalized inverse of the Jacobian, \bar{J}_t , we get the operational space equation of motion:

$$\Lambda_t \ddot{x}_t + \mu_t + p_t = F_t \quad (2)$$

where $\mu_t = \bar{J}_t^T b - \dot{J}_t \dot{q}$ is the task space Coriolis and centrifugal, and $p_t = \bar{J}_t^T g$ is the gravity projected onto the task space. The task control torques will then be $\Gamma_t = J_t^T F_t$.

Section 3.3 explains how we implemented the haptic controller for our Falcon Haptic device which has a very limited workspace using the operational space formulation.

3.3 Haptic Workspace Extension

Exploring a large virtual environment using a haptic device with limited workspace capability is challenging. The user will easily reach the physical limits of the haptic device's workspace. Similar to the approach proposed by

[21], we use a lock mechanism to hold the robot position while the human adjusts the haptic device joystick [22]. The red dashed box represents the original workspace before the lock mechanism and the green box represents the new explorable workspace of the robot after the lock mechanism. The new explorable workspace is based on an offset defined by the distance from the new haptic device position to the held end-effector position (Fig. 4).

Figure 4: Work space extension: the robot position is held constant while the operator adjusts the haptic device to continue exploring the robot workspace.

Therefore, the desired position in cartesian space is given by:

$$x_t = x_{hold} + \eta x_{haptics} \quad (3)$$

where x_{hold} is the position of the end-effector before entering the haptics state, $x_{haptics}$ is the raw value read from the haptic device, η is a scaling hyperparameter, x_t is the desired end-effector position in equation 2, which is then used to compute the required joint torques.

4 Task Descriptions

The task data for welding and joint sealing was collected from a six-level prefabricated parking structure in Germany (Fig. 5). This section describes the traditional process to complete both tasks in the field and identifies specific requirements for automation with field robots.

4.1 Welding

Each parking structure requires welding 144 anchor plates to the foundation. These anchor plates are the support of the structural steel columns that span all six levels. Given the structural importance of the joint between the columns and the foundations, field welding is a sensitive

task that requires high expertise and slow, repetitive manual work. The task consists of three key steps: placing the anchor on the foundation, welding two opposite corner points to fix the anchor position, and welding the perimeter of the anchor (Table 1).

Table 1: Welding production performance

Welding	Prod. (min/u)	Total (h)	Prep./day (h)	Workers
Place	0.5	1.2	0	1
Fix	15	36	2	1
Weld	45	108	0.2	1

Automating this welding task requires mobility and a robotic arm with a welding torch end-effector. In this paper, we developed a simulation using a 7-DOF Panda arm with a welding torch on a mobile platform (Fig. 2). The simulation allows for haptic intervention, which is particularly useful during the initial exploration of the plate geometry and in case of failure.

4.2 Sealing Concrete Precast Joints

In the same 6-level parking structure, workers must seal 6000m of concrete joints between the prefabricated concrete slabs (Table 2). This multi-step process involves three different crews that perform: pouring concrete, shot blasting, and coating to water-proof the joint. During the first step, cement is poured using a pump with a hose. Shot blasting uses a Contec Modul 300 machine, and the waterproof coating is applied manually by a crew of 4 to 5 people.

Automating the concrete joint sealing task requires a robot similar to the Contec Modul machine carried manually today. The robot solution should autonomously control the flow rate of cement and other sealant materials, safely navigate the environment, keep track of progress,

Figure 5: Six-level prefabricated parking structure involving welding and joint sealing. Built by our partner Goldbeck.

Table 2: Sealing concrete precast joints performance

Concrete joints	Prod. (sec/m)	Total (h)	Prep./day (h)	Workers
Pouring	20-30	41.7	2	2
Shotblasting	10-15	20.8	1	1
3-layer coating	115	191.7	3	4-5

and identify the joints and corner points. In this paper, we use a pump and hose mechanism mounted on an omnidirectional base (Fig. 9) with a pressure sensor that allows the system to detect corners and control pouring height within the joint. The haptic interface allows an operator to reposition the robot and to feel the joint or obstacle in case of obstructions.

5 Experiments

This section summarizes the experiments for welding and sealing concrete joints. We propose an approach in which humans and robots can collaborate in challenging construction tasks. Both solutions deploy BIM at LOD 300 provided by the industry partner and the simulation and control environment SAI to incorporating haptic control in task space.

5.1 HRC Welding

The welding solution consists of a mobile platform equipped with a Panda Franka 7-DOF robot arm and welding end-effector, capable of moving autonomously along the concrete foundation until finding an anchor plate. The platform is tall enough to roll over the anchor plate once the welding is done and is also narrow enough to operate along the 60cm foundation width.

The robot is controlled in two modes: autonomous navigation in joint space signaled with a cyan sphere, and haptic control in operational space signaled with a green sphere (see Fig. 6).

In the autonomous navigation mode, the robot autonomously locates the plate position of the anchor plate from the BIM's approximate coordinates. Upon reaching the desired plate, the expert welder can take over the task using the haptic interface. This allows the welder to select the torch position and explore the plate geometry. Once the haptic welding is done, the operator can raise the end-effector to signal the robot to transition back to the autonomous navigation mode and move to the next welding plate.

To provide real-time force feedback to the welder, the simulation includes simplified collision meshes of the environment. The anchor plate is simplified to a rectangular mesh of the same size, while the welding tool utilized a cylindrical collision mesh (Fig. 7). This speeds up collision computation while providing sufficiently accurate force feedback.

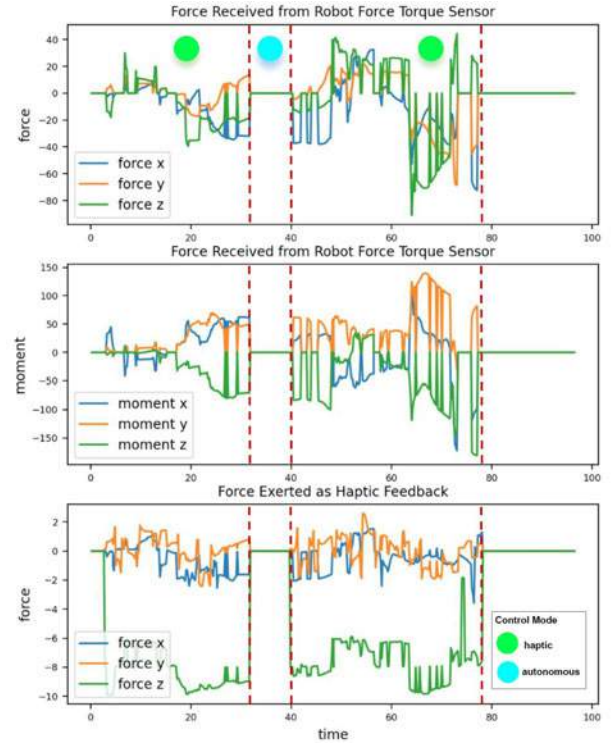

Figure 6: Haptic simulation and force feedback plot.

To determine contact between the welding gun and the concrete, we calculate the end-effector sensed force in the direction of motion. If F_{proj} is greater than threshold 0.5N, contact is "true", providing damped force and moment feedback to the user.

An added attraction force between the welding perimeter and the robot's end-effector helps the operator maintain the welding path. The real-time plot, including sensed forces and moments from the end-effector (Fig. 6), shows that with the addition of the attractive force, the user feels clamped to the surface so it is easier to follow the welding trajectory. The accumulated force exerted on the haptic feedback is the sum of the sensed force plus the attractive force.

Figure 7: Collision meshes for contact resolution in simulation.

The attraction force applied to the user is given by

$$F_{attraction} = \frac{1}{2}\eta\left(\frac{1}{x_{current}} - \frac{1}{x_0}\right)^2 \quad (4)$$

where $x_{current}$ is the global position of the end-effector, x_0 is global the position of the edge of the polls.

The haptic feedback for the user is given by

$$F_{feedback} = F_{sensed} + F_{attraction} \quad (5)$$

where F_{sensor} is the force sensed by the robot's force torque sensor.

A position limit is added to the robot end-effector to prevent it from completing motions inside of the plate and to maintain safe contact during the welding operation.

Future work will learn a strategy to complete the weld based on the human demonstration of the task, extracting key parameters such as distance between the end-effector and the plate, as well as speed and orientation during welding execution.

5.2 HRC Sealing Concrete Precast Joints

The second experiment focused on the task of sealing concrete precast joints. The process involves joint identification, edge detection and tracking, and material pouring

Figure 8: Concrete joints task schematics showing the concrete pouring sequence in six steps.

following a particular sequence to ensure structural soundness (Fig. 8).

The concrete slab dimensions were obtained from the BIM. Additionally, the simulation includes collision meshes for each individual concrete slab and joint.

The autonomous controller uses the BIM coordinates to locate each joint. Upon reaching a joint, the nozzle is lowered, and pouring begins. During pouring, the height of the nozzle is controlled using a pressure sensor. When the joint is completely sealed, the nozzle is retracted, and pouring stops so that the holonomic base can move to the next joint.

An operational space haptic controller, that collects information about the sensed forces, allows an operator to assist the robot at critical points of the task such as corner points to confirm that the nozzle is aligned and the flap is rotated before continuing to the following joint.

Figure 9: Close up of the joint sealing task in simulation.

6 Conclusions and Future Work

The experiments presented in this paper demonstrate synergistic collaboration between robots and human operators while performing two construction tasks - welding and joint sealing. The key elements that enabled this successful collaboration were: the use of a haptic device that facilitates operator intervention by allowing him/her to feel the environment, and a flexible control framework that allows for smooth transitions between autonomous robot skills and operator haptic control.

We expect this approach will provide the necessary support for tasks that are too complex for full automation. Additionally, data recorded during the operator's intervention can be used to teach the robot new skills and augment its autonomous capabilities. Overall, haptic interfaces provide an effective means for accomplishing challenging manipulation tasks in unstructured construction environments.

Future work will test these solutions on hardware using

7-DOF Franka Panda manipulators. The hardware prototypes will also allow us to collect operator feedback and gather task execution data such as accuracy and duration.

Abstract -

Additive manufacturing (AM) is no longer a new technology and is already being used profitably in many sectors of the economy. AM is also becoming increasingly popular in the construction industry, and more and more research is focused on unlocking new building materials for AM. As a digital fabrication method, AM provides many new opportunities for the design of innovative and complex architecture and also has the potential to increase the productivity of the construction industry. However, the planning effort can increase accordingly and only experts in this field are able to apply this technology to construction projects. A methodology to improve planning efficiency has already been developed for the construction industry in the form of Building Information Modeling. In BIM, however, only conventional manufacturing processes have been taken into account so far, meaning that computer-aided manufacturing processes such as AM are still considered separately. Even more importantly, the granularity of product and process information is normally not sufficient for automated manufacturing. For this reason, this study proposes a framework, Fabrication Information Modeling, which can be used to generate BIM-supported fabrication information for the use of AM in the context of construction projects. Additionally to an expected reduction in planning effort, FIM would also provide the means of realizing an end-to-end digital chain from the first draft to the production of a construction project.

Keywords -

Building Information Modeling (BIM); Fabrication Information Modeling (FIM); Additive Manufacturing (AM); Automated Construction.

1 Introduction

The construction industry plays a key role worldwide, as it has a far-reaching impact on almost all other sectors of the economy and generally on everyone's quality of life. However, if we look at the technological development of the construction industry in recent decades, we see that it has lagged behind the progress of comparable industries (e.g. mechanical engineering) in certain areas. Modern methods and more efficient materials are used only to a

limited extent, so productivity in the construction industry has been stagnant for years [1].

However, digital manufacturing methods, such as Additive Manufacturing (AM), have been enjoying increasing interest in the construction industry in recent times and their advantages have been recognized more and more. Using these technologies significantly more complex geometries or internal structures as well as variable material compositions for functionally activated components can be realized. But as products and construction projects become more and more complex, the corresponding planning and production effort also continues to increase, so that measures must be taken to compensate for this additional effort [2].

In order to better handle the ever-increasing planning complexity in the construction industry, the BIM methodology has been developed and is becoming more and more established for conventional construction. With this approach, all activities in the planning, construction and maintenance of buildings can be digitally represented and efficiently executed. Among other things, it is possible to model conventional construction processes beforehand on the basis of the digital building model. The granularity of the process description, however, typically remains on a rather coarse level, not going beyond complete tasks as 'place formwork' or 'pour concrete'. For digital manufacturing methods, such as AM, however, no such mechanisms have yet been implemented in BIM. For taking full advantage of a closed digital chain from design to fabrication, a much more precise or complete process description is necessary. Whereas in conventional construction, the predominantly manual work processes are described on a comparatively coarse level, as this information is typically interpreted by human workers, automated fabrication processes must include every detail and to be executable by the corresponding machines.

To realize a closed digital chain between digital design and digital manufacturing, this paper brings the concept of Fabrication Information Modeling (FIM), introduced by [3], into the context of civil engineering. Similar to BIM itself, FIM represents a planning cycle of its own in which manufacturing information is generated iteratively on the basis of BIM data and can then be represented dig-

itally and executed in reality. Within this iterative design process not only the creation of fabrication information for a given BIM model will be possible but also interfaces for as-designed and as-built simulations will allow for optimization of the fabrication information and pre-built planning of post-processing information.

2 Background

As already mentioned in the previous section, the majority of manufacturing in the construction industry today is manual work. A continuous digital chain from design to manufacturing is thus not given even when BIM is applied. A fact that can be changed by integrating Digital Manufacturing (DM) methods into the BIM process. However, this turns out to be very difficult, even though both BIM-based design and DM are based on similar computer-aided methods and tools. BIM and DM each have a different focus, require different levels of detail, and provide constraints to each other. For similar reasons, Computer Aided Design (CAD) and Computer Aided Manufacturing (CAM) have long been handled separately in the mechanical engineering industry and only recently have been more closely connected in the wake of "Industry 4.0" concepts [4]. In the construction industry, automated manufacturing has been limited by, among other things, scaling problems and the lack of useful, processable materials, but attempts are now being made to develop comparable concepts to "Industry 4.0" [5].

However, research on this topic has so far mainly focused on the identification of manufacturing parameters, data exchange scenarios for such planning processes and a (semi-)automatic derivation of DM parameter sets and machine control code [6, 7]. A holistic system that can deal with different processing mechanisms and different framework conditions does not yet exist. The first question to be answered, though, is what exactly DM is. Zhou et al. define DM as a computer aided manufacturing process that combines handling of product, process and resource information, implementation of product design, function simulation and rapid prototyping as well as performing rapid production and quality control [8]. According to this definition, Fabrication Information Modeling (FIM) itself is a DM method but focused on the needs of the construction industry. In this paper, the concept is applied on Additive Manufacturing (AM) techniques, as they allow for a very high degree of automation. Accordingly, FIM is designed as a framework and underlying data structure for the generation and application of fabrication information to automate and digitize construction processes that can be executed using AM. Although AM methods are to be considered predominantly (cf. section 2.1), formative manufacturing, e.g., bending of rebars, and subtractive manufacturing, e.g., for removal of excess material in post-

processing steps, must also be considered (cf. section 2.4).

The following sections provide a brief overview of the techniques and tools involved.

2.1 Additive Manufacturing (AM)

Additive Manufacturing (AM) is an overarching term for all methods in which components are created by the computer-controlled addition of material, usually layer by layer. For the manufacturing process, a AM print head is continuously moved into positions which describe the component geometry, and material is applied there accordingly. Objects printed in this way are characterized by a very high degree of geometric freedom [9].

AM methods that are particularly of interest for use in the construction industry are those that can process concrete or steel. Most of these methods – if classified according to the material distribution method – can be divided into the group of particle bed methods or extrusion methods. These two methods each come with their own advantages and disadvantages, as described below.

Particle bed methods: In particle bed processes, a flat layer of non-self-setting material (liquid or powder) is always first applied to the substrate (ground or previous layer) and then allowed to set only at desired points, either with a binder, chemical or physical selective activation. These steps are then repeated layer by layer until the print is ready. In a final step the excess material that has not been activated or bound is removed.

An important advantage of this technique is that the particle bed already provides a support structure and thus offers a very high degree of geometrical freedom and can produce objects with a very high surface resolution [10]. In some cases, however, it is problematic to remove particle bed residues from the finished printed component, e.g. if closed structures are to be created. Because of the particle bed, the possible construction space is limited in these processes and must be stabilized by outer walls.

Extrusion methods: Extrusion methods are those in which material is deposited in layers according to the specified geometry in a computer-controlled manner, usually by extrusion through a profiled opening [9]. However, the depositing process can take very different forms, depending on the specific variant and the material used.

An advantage of this method is that the desired object can be printed at high speed as well as in a particularly material-saving manner [10]. In addition, depending on the path guidance system, in-situ printing can be performed at building scale or printing can be performed in the existing building [11]. However, with this method, the material is not supported during printing and may have to

be stabilized by extra support structures or the geometrical freedom is significantly limited.

2.2 Transport mechanisms

Depending on the material, different transport systems, including mechanical screw conveyors or pneumatic pumping systems, can be used, which is why the material supply must also be planned for each AM application. If liquid or pasty material is used (as is the case with concrete), pumping systems via pipes and hoses are usually used [12]. In such a case, it must be planned for that the concrete must have a certain composition so that it is both **pumpable**, and subsequently **extrudable** and **constructible** [13]. For solids, they can be fed in the form of a wire or filament mechanically via a spindle, or as a powder mechanically by screw conveyors or pneumatically in a gas stream. For AM, therefore, not only must the material quantity be planned correctly, but volume flows must also be coordinated and controlled as a function of the print head movement. In the case of particle bed methods, using solids as the feedstock for material supply also adds a distribution mechanism that can be used to create a flat particle bed. For this purpose, a roller or a rake is often used, with which a particle heap applied at the edge is distributed over the entire installation space.

2.3 Machinery

Depending on the AM method, it is additionally possible to exchange the motion apparatus. This mainly concerns the extrusion methods, since in the particle bed processes

only horizontal travel is necessary due to the particle bed and the installation space is limited. In particle bed processes, therefore, only gantry robots are used to move the print nozzle. However, there are different print head systems here, e.g. with a single nozzle or a multi-nozzle system, which must be controlled differently accordingly.

In the case of extrusion methods, the tool path can be made much more complex than in the case of particle bed methods, since the material is applied directly during the extrusion process and can thus be moved in all spatial directions — limited, of course, by material properties and the effect of gravity. For the extrusion method the selection of the machine for end effector positioning is decisive for how complex and spacious the print path for the production of an object may be. Various machine systems with different degrees of freedom of movement are available for the end effector positioning. Among them, gantry robots, single-axis mobile portal cranes, mobile concrete pumps, and industrial robots as well as a combination of these systems can be considered (cf. fig. 1), each with the corresponding advantages and disadvantages [12].

2.4 Subtractive and Formative Manufacturing

In the context of this paper, the FIM concept is applied on AM methods. In various cases, however, a combination of AM with other techniques can be very useful. These include subtractive manufacturing methods, which remove material inversely to AM, e.g. by drilling, milling, turning or grinding tools. Furthermore, formative manufacturing methods should be mentioned, in which material is worked into a new shape by various tools, e.g. by bending.

Hack and Kloft have shown in a real-scale demonstrator how all three techniques can be used together to produce a steel-reinforced free-form wall [14]. For this purpose, the concrete core is manufactured with an AM process and provided with bent reinforcing steel (formative). Subsequently, the reinforcement is again covered with the same AM method and finally, in a finishing step, the surface is smoothed subtractively.

2.5 Machine control

Depending on the AM-method to be used, a certain movement pattern (toolpath) must be programmed into the corresponding machine and the associated material flows must be coordinated with this movement. In this context, the term machine control describes a sequence of instructions for machine tools or industrial robots, with which digital numerical information is converted into real axis movements [2]. For Digital Manufacturing Methods, these instructions are in general derived from geometric representations of the object that is to be manufactured, e.g. from the geometric information of a BIM model. This

Figure 1. Selection of possible manipulators for use in additive manufacturing [12]

derivation involves two processes, a slicing operation that cuts a 3D geometric representation into 2D Slices (layers) and a path planning operation that generates a continuous pathway (toolpath) onto these layers based on how the inner structure of the object to be manufactured should look like. For both processes several algorithms already exist and may be chosen for typical hardware configurations and manufacturing methods.

A toolpath then has to be translated into machine specific control code. While some machines (predominantly CNC-machines) are able to interpret the Standard DIN 66025/ISO 6983, commonly known as G-Code, others are controlled with code written in a vendor specific programming language (most industrial robots). Another possibility to realize machine control is via “robot frameworks”, like e.g. Player, YARP, Orocos, CARMEN, Orca, MOOS, the Microsoft Robotics Studio and Robot Operating System (ROS). All of these frameworks provide a collection of software tools, libraries, and conventions that can be used to control specific robots.

However, the processes described above (slicing, toolpath planning and machine control) cannot be carried out in just any way. Depending on the AM method, material and machine system used, the approaches can differ greatly and have different requirements for the component design, so that these steps can usually only be carried out by specially trained personnel. If a common platform or database is not used to support design and manufacturing, the two areas will inevitably be separated. In a holistic planning process, such as that promised by FIM, manufacturing problems can be addressed as early as the design stage by means of information feedback, thus reducing planning and communication efforts.

3 Fabrication Information Modeling

As described above, the gap between digital design and digital manufacturing is one of the obstacles preventing the wider use of AM methods. As a BIM-based DM methodology, FIM provides a common interface between these two disciplines and creates a shared planning and data basis. Figure 2 shows that FIM is positioned between BIM modeling and digital manufacturing. It is also shown that FIM is already linked to the early design phase of BIM via a so-called Design Decision Support System (DDSS) [15]. Fabrication Information Modeling (FIM) therefore describes, analogously to BIM, a methodology for the fabrication aware integrated design, construction and management of components in the context of an overall building using digital methods.

Even if the detailing in FIM takes place at component level, components that are related to each other in BIM must still be detailed in a linked way. Only through common boundary conditions for individual FIM modelings

Figure 2. Positioning of FIM between digital design and digital manufacturing.

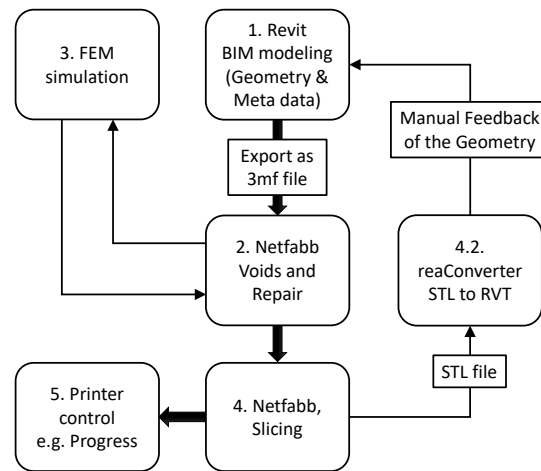

Figure 3. Data exchange Example: Separate software solutions for CAD and AM [16]

cross-component functional areas and a seamless assembly of the individual parts can be realized. At the component level, BIM data is used to model the parameters and processes involved in a fabrication aware manner and to detail the geometry to represent the material distribution as accurately as possible. For this purpose, we focus on formalizing all the information that has been summarized in section 2 to enable FIM to automate many of the detailing processes described above and to provide as much information as possible for the early design phase.

Without FIM, the presented conversion processes are tedious and involve different software solutions that are based on diverging data structures. Accordingly, a lot of file format conversions must be performed and by doing this, data gets lost on the way. In a study by Kruse, several scenarios of using BIM data to generate toolpaths and the corresponding machine control code were examined [16]. One of the respective data exchange scenarios is depicted in fig. 3, other examples only differ in certain details. In this particular example, first a BIM model was created (1) and the geometrical data was then exported to a 3MF-file

to be processed further (semantic data is already lost in this step). Then the inner structure is generated (2), the resulting geometry sliced and the toolpath is planned according to the specified AM-Method (4) using a software which is specialized in preparing CAD models for 3D printing, in this case Autodesk Netfabb. If sophisticated simulations and optimizations are needed, the model can be exported for a detailed FEM analysis (3). After another export, the generated toolpath is finally translated into machine specific control code (5) which controls the machine movement for the printing process.

As can be seen quite clearly, this process consists of various individual steps and requires file conversions during which data gets lost. FIM is intended to improve this situation by creating a data basis that is made available to all operations involved in the planning process via appropriate interfaces. Through a carefully considered choice of the data structure and additional extensions, further operations are also made possible, such as the inclusion of as-built data for subsequent processing steps. If, for example, the fabricated object is captured directly during manufacturing process and the obtained as-built data is fed back into the FIM model, a digital twin (DT) can be realized. Usually, for the collection of Digital Twin data, the object is measured precisely with the help of sensors after manufacturing. Measuring the object during the manufacturing process and storing the data in the FIM thus provides a more precise and more correct digital replica than in many other interpretations of the term "digital twin".

Figure 4 shows the proposed process structure on the basis of the data just described. It is worth mentioning that data exchange does not necessarily have to be file-based. The data structure of FIM can also be defined in the form of a database (such as a graph database or a triple store) that can be accessed via web services.

Due to the fact that FIM is supposed to incorporate diverse AM methods, which can be very different in their complexity, the underlying data structure must be flexible enough to be able to incorporate different parameter sets. It may also be necessary to be able to switch between different parameter sets or to have the option of storing multiple sets if the suitability of different AM systems is being investigated during the design phase or if multiple methods are being used to manufacture a component.

These parameters that are to be modeled can be divided into three categories, the material parameters, process parameters and machine parameters. **Material parameters** describe the material composition and the expected properties of the material in the finished state. It should be noted that several materials can be used (e.g. concrete and steel) or one material can be graded in different ways (e.g. by changing the concrete mix ratio). **Process parameters** describe all adjustable values involved in the

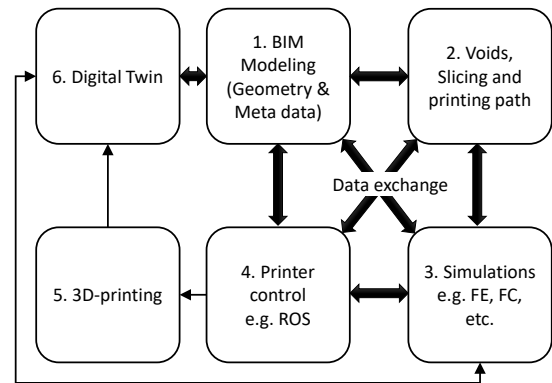

Figure 4. Data exchange scenario based on FIM.

Figure 5. Detailing Example: BIM Model of a Curved Wall (left), generated printing path (middle) and generated 3D-Geometry representing the as-designed material distribution (right).

manufacturing process (possibly multiple parameters for several AM methods), such as speeds or tool dimensions. These parameters have to be coordinated during the design process. Last but not least, the **machine parameters** have to be considered. These simply describe the machine system to be used and thus define limit values for the process parameters.

For detailing via the generation of a printing path, we created a prototype that can be used to create an interior structure in different variants for a BIM component controlled by a set of parameters fig. 5. The path planning tool was created in the Dynamo graphical programming interface for the BIM modeling software Revit. In addition, an exporter was implemented to add the path geometry to the existing IFC file for data exchange (see section 4). Furthermore, an algorithm was developed that can convert the generated printing path into a solid model via a sweep

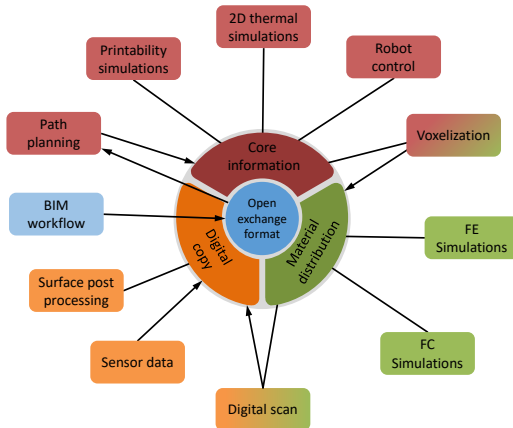

Figure 6. FIM data structure using an open interoperability standard.

operation, for the representation of the material distribution. In fig. 5, these levels of detail are lined up side by side.

A very well suited basis for the description of FIM data are open interoperability standards, such as STEP [17] or IFC [18]. The IFC standard is of particular interest in this context, as the most widespread and established format for open BIM data exchange [19] and corresponding importers and exporters exist for most BIM-capable software. In the following section, the IFC standard is used as an example to illustrate the underlying data structure of FIM. Similarly, the STEP standard would be a suitable choice, especially due to the fact that some implementations for AM have been studied already [20]. But due to the better availability of export/import tools and further reasons explained in section 4, we prioritize the IFC standard for our studies. However, this does not exclude subsequent investigations of the STEP standard.

4 FIM data structure

In principle, FIM can be implemented in any data model that can represent the parameters and geometries mentioned in section 3 (cf. fig. 6). However, since one of the objectives of the FIM methodology is a better integration of AM methods into BIM, it makes sense to consider an IFC representation of the involved data. For this, however, the question arises whether the IFC standard can represent all necessary manufacturing information, or whether an extension is necessary.

Comparing an AM process with a road construction project, many parallels can be discovered. The toolpath of AM is comparable to the Alignment along which a road is planned. Comparable to road construction, a lot of parameters must be referenced to the alignment (in case

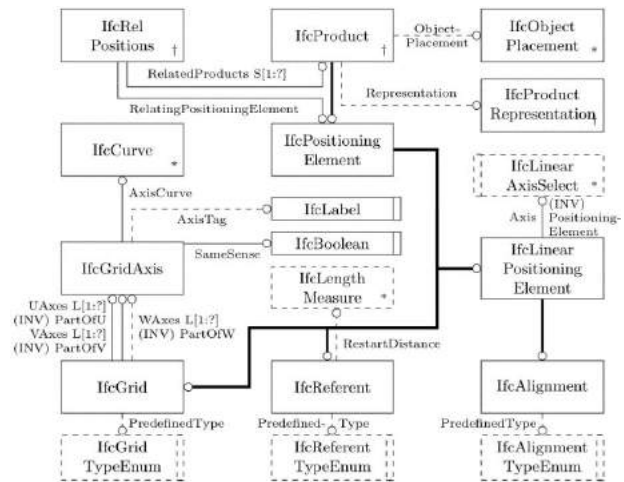

Figure 7. EXPRESS-G diagram of positioning entities from IFC4x3_RC1 that are relevant for FIM [21].

Figure 8. Visual Representation of an alignment curve and partial tree view of the corresponding IFC-file (same example as fig. 5).

of AM the toolpath) and exactly for this purpose several Classes have been defined in the latest version of the IFC standard (IFC 4.3, cf. fig. 7).

A description of the printing process along the printing path can therefore be defined in the IFC format without definition of additional classes figs. 7 and 8. The printing path itself can be represented as `IfcAlignment`, a derived class of `IfcLinearPositioningElement`, which can be used to linearly position other objects to its axis. The axis is in turn described by the toolpath geometry (in this case via the class `IfcCompositeCurve`, the IFC version of a polycurve). Non-constant, lin-

early referenceable parameters that can change during the printing process, such as the material composition, the printing speed or the extrusion rate, can be linearly referenced along the `IfcAlignment` as common in road or railway design, e.g. via `IfcReferent` or via `IfcOffsetCurvesByDistance`. With `IfcReferent` its attribute `RestartDistance`, a parametric length measure, can be used along the corresponding alignment to, among other things, reassign a parameter value e.g. by means of a property set, or to append additional information at a specific position. Similarly, a list of distance values (offset) along the alignment can be specified with `IfcOffsetCurvesByDistance`. These distance values to the alignment can also be “misused” for AM purposes, e.g. to describe a changing parameter value. All constant parameters, such as machine parameters (machine type, arm length of the robot, etc.), can be represented as Property Set and the material parameters via `IfcMaterial` on the `IfcProduct` level.

Additionally to the information necessary for the AM process itself (toolpath and referenced parameters), the aforementioned information can be used to generate the more detailed geometrical description of the object that is to be manufactured, in the sense of as-designed geometry. To perform this detailing, the expected filament cross-section can be drawn along the tool path via a sweeping operation. This results in a three-dimensional geometry which very accurately represents the material distribution of the planned AM component and can be used for simulation purposes (e.g. for component optimization). In the IFC standard, such a geometry can be represented e.g. implicitly via an `IfcSweptSolid` instance, or, if this is implemented as part of the `IfcTunnel` extensions, as a Voxel model via the potential future extension in the form of the `IfcVoxelData` class.

Similarly to the “as-designed” material distribution model, “as built” information can be stored by scanning the object during the manufacturing process to capture the interior of the built object and referencing the data to the 3D representation of the object (preferably as voxel information). Using this data, already planned post-processing steps can be adapted to the exact geometry and further performance simulations can be executed.

The resulting data structure can be described as follows (cf. fig. 6). First, the data structure resulting from the BIM modeling is adopted (e.g. in the IFC standard) and the information necessary for applying the corresponding AM method (core information, shown here in red) is derived from the corresponding data and incorporated into the existing data structure. Based on the core information, a more detailed 3D model, the planned material distribution (shown here in green), is generated and integrated into the existing data structure for possible simulation purposes.

This data set is optimized until it is ready for production and is finally expanded during printing to include the scan data, i.e. a digital copy (shown here in orange). The diagram also shows various interfaces to other operations.

5 Conclusion

AM represents an excellent method of producing prototypes quickly and inexpensively. Considering that a building is in most cases unique due to the individual conditions of its location and the decisions made during design, it is therefore only natural that 3D printing also represents a forward-looking technology for the construction industry. With significantly increased design freedom, there is the possibility that the appearance and function of modern buildings and their components will be fundamentally altered. However, the resulting additional expense is a major obstacle to increased use of additive manufacturing methods. Especially the combination of AM and BIM methods, as discussed in section 2, can remove this obstacle and bring many advantages analogous to the “Industry 4.0” concept. If FIM is implemented as described in sections 3 and 4, the planning effort, which is currently only manageable by planners with the appropriate expertise, would be significantly reduced. This could make AM technology much more attractive for the construction industry.

Abstract –

Construction inspection is an important part of the construction management process to ensure that the project is compliant with the requirements, regulations, and standards. Due to time and cost constraints, inspectors representing owners, as well as architects, designers, and other stakeholders might not be able to visit and inspect the project site in person as often as needed. Inspections performed by mobile robots can allow more frequent inspections and can help communicate project status with all stakeholders more regularly. This study explains the development of a methodology to capture the site reality with an autonomous quadruped robot through integrated visualization in a BIM-enabled 3D virtual environment. The proposed methodology can potentially facilitate construction inspectors to perform their day-to-day inspection tasks more efficiently. The proposed methodology consists of a 3D virtual environment integrated with the robot control. The methodology is further implemented in Unity Engine with a software application to visualize the space being inspected and control the robot simultaneously. The application captures 360° images of the space autonomously and visualizes the images in the virtual environment as discrete points of reality. This study can be useful to construction managers and inspectors to potentially reduce manpower in inspections of construction projects. The findings of the study can help develop more solutions to facilitate remote construction inspection using autonomous mobile robots.

Keywords –

legged robot, construction inspection, virtual environment, reality capture

1. Introduction

Construction projects are full of uncertainties. Regular and frequent inspection is indispensable for reducing uncertainties in projects [1]. Multiple people

take part in the inspection of construction projects. It involves them traveling to the site, walking around the site, observing the as-built state of the project, and comparing the as-built status with the documented as-planned requirements of the project. Traveling to the site and walking around the site consumes a lot of time [1] that becomes non-trivial when multiplied by the number of people involved in the inspection process.

Currently, many contractors, project owners, and owner representatives use digital jobsite documentation tools such as Cupix, StructionSite, and Holobuilder [2]. These tools link 360° spherical images to 2D floor plans for spatial visualization of as-built conditions. This approach provides a significant advantage over regular unorganized 2D images by providing a platform for communication and collaboration through annotations and organized as-built documentation [3]. The current challenge is that these 2D floor plans are limited to representing a single discipline (e.g. architectural floor plan). It is difficult to show various construction disciplines, such as architecture, structural, mechanical, electrical, etc. in one floor plan without making it too cluttered and difficult to read. We propose to extend this approach to visualize the as-built conditions on a 3D model of the building enabled by the Building Information Model (BIM) to be used in the reality capture process. 3D visualization is more intuitive and can allow visualization of models of multiple disciplines in one view along with the reality capture.

Automated inspection of construction status has been studied before [1], [4], [5]. However, the data collection part in these previous studies has been predominantly manual, which is time-consuming, costly [6], and inaccurate. This study proposes an automated data capturing and visualization process for site inspection using quadruped robots. The process of data collection in reality capture for construction inspection is a repetitive and tedious task [7] that requires human inspectors to persistently and accurately walkthrough inherently risky construction environments.

Robots can play an important role in automating the inspection process [6]. Robots can be programmed to

autonomously navigate through the construction site and take regular images at points of interest, thus can save productive hours for humans that can be utilized for intelligent and high-level decision-making [6].

The main contribution of this paper is the introduction of a methodology for automated reality capture integrated with BIM-enabled 3D visualization and robot control using a quadruped robot. The proposed methodology does not rely on heavy post-processing of reality capture data and provides a rapid and frequent update of project status to all stakeholders in near-real-time within an improved visualization.

2. Background

Previous studies investigated automating construction inspection [6], [8], [9]. These studies aimed to increase the frequency and accuracy of inspection by capturing visual data using semi-autonomous or autonomous systems [6]. These studies either focused primarily on the data capture alone [6], [8], [10] and not on presenting the information in a way that is intuitive for inspection, or used heavy post-processing that requires skilled personnel with specialized training [9], [11]. Another challenge with heavy post-processing of inspection data (i.e. as-built reality capture) is the delay in the availability of inspection data. By the time the reality capture is available to inspectors and project stakeholders, the construction work might have progressed further, and either the identified construction issues might be resolved already or new issues might have arisen. Our study aims to automate the process of reality capture and its visualization process to make key decision-making information available in near-real-time to remote stakeholders.

Capturing 360° images of construction status is a recent trend in reality capture because it makes the capturing process faster [12], by replacing multiple pictures with one 360° spherical image. They are easy-to-use construction inspection tools with low computation costs [12], [13]. They are proven to be effective for general inspection when accuracy and precision are not as important as ease of availability and faster processing [12]. 360° images provide a “sense of presence” [13], which is absent in 2D images. 360° images are also used as a reality backdrop which is augmented with a 3D model on top of them [12]. The proposed methodology in this paper uses a 360° camera to capture visual data of the jobsite. This study automates the process of capturing 360° images through using quadruped robots. Previous studies on automation of construction inspection use either manual data capturing or heavy post-processing [3], [11], [12]. Automated as-built data capturing has been performed before, using Unmanned Aerial Vehicles (UAVs) [14]. BIM was used

as a preloaded map for path planning of the UAV [14]. However, UAVs have many inherent restrictions. First and foremost, legal restrictions prevent UAVs or drones from being used out of sight of the pilot and in populated areas [15], which defeats the purpose of automation. UAVs also need large clearance and are too noisy to be used in indoor spaces [10]. They also have short flight times [10]. Cables, ladders, and scaffoldings add more challenges.

The use of autonomous robots has been studied for construction progress monitoring and inspection applications [6], [7], [16]–[18]. Our previous research [16] studied the fundamentals of quadruped robot applications in construction monitoring and inspection. Additionally, our prior study [19] indicated that existing quadruped robots can potentially enhance the accuracy and speed of reality capture compared to the manual and human-based process. To make robots more autonomous, various path-finding algorithms are developed to enable mobile robots to navigate the job site and reach a target from a specific starting point. A* search is one of such algorithms [20]. Other algorithms are modified A* search, genetic algorithm, potential field algorithm, and roadmap algorithm [20].

Construction inspection is an important process and there is a need for fast and frequent access to project information for better inspection of the project and avoid deviations from the planned project requirements. 360° images have been an effective tool for construction inspection, automating the capturing process of these 360° images can improve the efficiency of the inspection process. Therefore, in this study, we used an autonomous robot to capture as-built site information and present it to construction inspectors rapidly through an integrated 3D virtual environment that contains 3D as-planned project data.

3. Proposed Methodology for Automated Robotic Reality Capture and Visualization

This section introduces the proposed methodology for automated reality capture and visualization. The methodology relies on the availability of the BIM model for the building. It also uses marker-based localization. We used AprilTag fiducials for this purpose as explained in Section 4. The methodology is applicable to buildings. Inspection of infrastructure projects like dams, bridges, etc. is out of the scope of the current study.

As shown in Figure 1, the BIM model is used to create a 3D virtual environment. The 3D virtual environment serves two purposes. First, it works as a map for the robot by providing geometric data of the space as well as “walkable” surfaces (explained in section 4.2) for the robot’s navigation. Second, it provides the users a 3D

virtual environment to conduct a virtual walkthrough of the building and observe the model as well as the reality capture of the actual job site alongside each other. This allows the inspectors to switch between the model view and reality capture conveniently and compare the two to better identify discrepancies. Traditionally, this process is done by looking at the 2D images or personally visiting the site and comparing the visuals with the site drawings. In more recent solutions, this process is done by using 2D floor plans of one discipline (e.g. architectural floor plan) with marked 360° images.

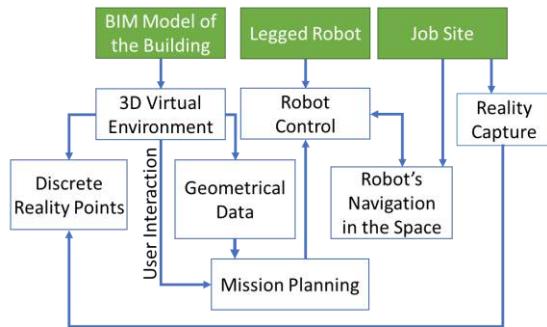

Figure 1 Conceptual overview of the proposed methodology

The proposed methodology in this study is based on a 3-step process – Robot’s Mission Planning, Reality Capture, and Visualization that are integrated into one platform. In the first step, the user creates Goalpoints in the virtual environment. We define Goalpoints as the locations in the space where the robot will navigate autonomously and capture a 360° image for inspection purposes. These Goalpoints and the geometrical data of the space are used to create autonomous missions for the robot. A mission, as we define it, consists of Goalpoints and Waypoints. Waypoints are intermediate locations that the robot will navigate through to reach the Goalpoints while avoiding obstacles. This process is explained in more detail in Section 4.2.

In the second step, i.e. Reality Capture, the robot’s mission information generated in the first step is used by the application to navigate the robot to the Goalpoints by walking on the planned path. Once reached the Goalpoint, the robot triggers the 360° camera to capture a spherical image.

In the third step, the 360° images are captured and transferred from the camera and visualized in the 3D virtual environment. The images are spatially linked to the 3D virtual space. The user or the inspector can perform a virtual walkthrough in the 3D virtual environment and compare the captured images with the 3D model for regular inspection.

4. Implementation

The proposed methodology is implemented using the Unity engine. Unity’s 3D visualization and scripting capabilities have been used previously by researchers for inspection and monitoring of buildings [21], [22].

The hardware used in this study included Spot, an autonomous quadruped robot by Boston Dynamics, and a Ricoh Theta V 360° camera mounted to the top of the robot. Spot’s Python SDK provides many high-level functions to control the movement of the robot and its navigation through the space and it has been used in this study. However, Unity uses C# programming language as its default scripting language. To enable data exchange between the two languages, the two programs use transfer control protocol (TCP) socket programming, similar to [23]. Robot Operating System (ROS) can be an alternative to TCP in future implementation.

The following subsections explain the implementation process of the proposed methodology in more detail.

4.1. Overall Workflow

Figure 2 shows the overall workflow of the proposed methodology. As discussed in Section 3, this study uses a 3D model of the building for both visualizing the site images and navigating the robot. The 3D model is extracted from the BIM model as an FBX file using the TwinMotion plugin in Revit. The FBX file also contains some of the component properties including the materials and textures of the building elements in the model.

Figure 2 Workflow of the proposed methodology

The first step in the process is Mission Planning. Once the Goalpoints are created by the user where the images should be captured, the optimum path for the robot is calculated in Unity. This process is explained in more detail in Section 4.2. The mission information generated in the first step is used to control and navigate the robot. The robot walks to each Goalpoint on the planned path and captures 360° images. This is explained in more detail in Section 4.3. Finally, the captured images are downloaded from the camera using the camera’s SDK and visualized inside the 3D virtual environment. The user can then, do a virtual walkthrough in the 3D virtual

environment integrated with 360° images and observe the space in both as-built and as-planned conditions. This step is explained further below in Section 4.4.

4.2. Mission planning

Mission planning starts with localizing Spot's initial position in the 3D virtual environment. This study uses fiducial-based localization [24]. Spot has the built-in capability to detect AprilTag fiducials, an example of which is shown in Figure 3. The application maintains a list of all fiducials observed through the robot's cameras in the memory along with their position relative to the robot. At any point in the space, the relative position of the robot with respect to the fiducials is read from the robot using the robot's SDK.

Figure 3 AprilTag fiducials in the job site (left), and on the corresponding location in the 3D model (right)

This study uses Unity's built-in NavMesh module, which in turn uses the A* heuristic algorithm to find the best path [25]. Once the robot is localized in the space, the application iterates over the predefined Goalpoints and finds the optimum path covering all the points. This operation is done by calling Unity's "NavMeshAgent.CalculatePath" function. The Goalpoints are traversed in the order they are created by default and the application does not try to minimize the travel distance. However, the points can be reordered by the user before starting the mission.

The Unity NavMesh requires the "walkable" and "non-walkable" spaces to be explicitly defined in the application using the 3D model of the space. All the elements from the floor and door families in the BIM model are set as walkable, while everything else is non-walkable. The safe distance from the non-walkable surfaces is set to 0.3m, which is slightly more than half of the width of the robot. After setting the parameters, Unity creates a mesh of walkable points in a process called 'baking'. Figure 4 shows the final baked NavMesh. The light blue areas on the floor shown in the figure are the walkable areas.

Figure 4 Walkable spaces defined in Unity

The application packages the mission data into a JavaScript Object Notation (JSON) string to be sent to the Python application for further processing. The mission data consists of the coordinates of the points on the path. The points on the path are either Goalpoints or Waypoints as explained in Section 3. The images are captured only at the Goalpoints, and the Waypoints only help with navigating the robot around the obstacles, such as walls. Waypoints are created by Unity at each location where the direction of the path changes. The number of Waypoints depends on the obstacles between the starting point of the robot and the following Goalpoints. Figure 5 shows a snippet of a sample JSON string representing a mission. The value 'isGoal' for the points states whether it is a Goalpoint or not.

```
{
  "mission": {
    "fiducials": [
      {
        "id": "285",
        "points": [
          {
            "x": -0.11544030994769898,
            "y": 0.3089998662471771,
            "z": 2.905001163482666,
            "isGoal": false
          },
          {
            "x": -0.11544030994769898,
            "y": -10.651000022888184,
            "z": 2.905001163482666,
            "isGoal": false
          }
        ]
      }
    ]
  }
}
```

Figure 5 Sample mission JSON data

4.3. Execution and Reality capture

The mission data in the form of JSON string is received in Python for further processing. First, the fiducials are identified from the JSON data. The robot's internal system is queried to find all the fiducials that are detected by the robot's perception system. As soon as a fiducial is observed by the robot, its location is stored in a list called 'known_fiducials'. During the initiation of the mission, there must be at least one fiducial in the 'known_fiducials', otherwise, the mission fails with an error. The closest fiducial from the robot's current

location is identified by finding the magnitude of the position vector of the fiducial. Then, the coordinates of the next point are read from the mission data. The coordinates are transformed to the robot's body frame of reference. The application uses the Spot's SDK to control the robot and iteratively checking its new position until the robot reaches the next Goalpoint or Waypoint. Spot's SDK abstracts lower-level controls of the limbs. Only the vector representing the target coordinates from the robot's current position are required to move the robot. Robot's built-in obstacle avoidance system prevents collision with any dynamic or static obstacles that are not represented in the model. However, the robot cannot re-route itself if the intended path is completely blocked. This is currently the limitation of the project and will be addressed in the future.

A radial tolerance of 0.5m is allowed in the application. This means the robot will start moving to the next Goalpoint (or Waypoint) as soon as it reaches within 0.5m of the current Goalpoint (or Waypoint). If the current point is a Goalpoint, the robot will stop and trigger the 360° camera. The camera must be connected to the robot's internal Wi-Fi network. The program waits for the camera to process the image by reading the camera's state using the camera's SDK. Once the image is processed and stored, the robot continues its mission. Figure 6 shows the robot executing its mission and presents its real-time virtual representation in the 3D virtual environment.

Figure 6 The robot in the job site (top), and the 3D virtual environment (bottom) visualized in real-time simultaneously

4.4. Visualization

Once the whole mission is complete, i.e., the robot

reaches the last point in its path, all captured images are downloaded from the camera. The images are applied as a texture to spheres in the 3D virtual environment representing the Goalpoints. These spheres represent bubbles as Goalpoints that contain the reality capture data. The user can then use the 3D virtual environment and navigate through the building model virtually to enter any of the bubbles/Goalpoints to view the 360° reality images from that location. When the user moves out of the Goalpoint in the 3D virtual environment, the 3D building model (i.e. as-planned BIM data) will be visible.

Figure 7 shows the interface of the application developed in Unity. The spheres in the 3D virtual environment shown in Figure 7 are each a 360° spherical image captured by the robot from the corresponding location inside the job site. The 360° images captured through the robot's autonomous mission are available to inspectors and project stakeholders on the developed platform in real-time after the robot's mission is complete.

Figure 7 Visualizing reality capture integrated with the 3D virtual environment. On top: 3D virtual environment developed in Unity using the BIM model, on the bottom: a snapshot of the captured 360° image of the reality on site

5. Validation and Results

To test the validity and feasibility of the proposed methodology, the developed application is tested in Bishop-Favrao Hall (BFH) on Virginia Tech's campus in Blacksburg, VA. A test mission was executed that involved walking through a space of approximately 4,841 sqf. in size including two classrooms and the entrance lobby and captured 360° images at six Goalpoints as shown in Figure 8. The total length of the robot's path was 42.4m. The robot successfully executed the mission within 3 minutes and 50 seconds with the moving speed set to 0.4m/s. The robot captured and sent back six 360° images for visualization in the 3D virtual environment.

Figure 8 shows the 2D floor plan of BFH with the Goalpoints and the path of the test mission in the experiment.

Figure 8 Robot's mission path and Goalpoints on the 2D Floor Plan of BFH

In this experiment, installing the fiducials at the site true to their corresponding position in the 3D model was found challenging. Small residual errors in the orientation of the fiducials created large deviations in the navigation of the robot as it moved farther from the fiducials. Installing more fiducials helped to keep the deviations small. The required number of fiducials depends on the length of the path. Spot's perception has a range of about 4m. Therefore, installing a fiducial every 8m on the robot's path ensures that at least one fiducial is always visible to the robot. For that reason, five fiducials were installed for the whole path at an average interval of 8m.

During the test mission, passing through the doors was found to be challenging. Due to the narrow clearance, the path occasionally overlapped with the walls due to the errors in placement of the fiducials as well as the localization error arising from the motion of the robot. Placing a fiducial near the doors improved the robot's navigation through the doorways.

6. Discussion and Conclusion

Regular construction inspection is crucial for project success. However, construction inspection involves many repetitive tasks that are better suited for robots. Delegating repetitive and mundane tasks to robots can potentially make the process of inspection and monitoring more effective and can allow humans to focus on more high-level tasks. For example, legged robots can traverse and scan the jobsite more frequently than humans while humans can undertake more intelligent planning and decision making tasks.

This paper is built upon the authors' previous studies on the use of quadruped robots for construction inspection [16], [19] that presented the potential and

challenges of autonomous quadruped robots in construction inspection. This paper presents the development of an autonomous data capturing and visualization method for construction inspection using a quadruped robot. This study uses the BIM model of the building for (a) mission planning of the robot, and (b) for visualizing both the building and the reality capture in a 3D virtual environment. Robot navigation through the BIM model is the key to reliable autonomous robotic construction site documentation to ensure completing the robot's mission in dynamically changing construction environments.

The contribution of this study is the introduction of a methodology for automated capturing and visualization of the as-built images of a building integrated with a 3D virtual environment of the space enabled by BIM. The study aims to provide a virtual platform to construction management personnel, owners, and their representatives for frequent and remote inspections.

This study uses quadruped robots because they are versatile and can navigate construction sites with more flexibility than wheeled robots. A software solution is developed on Unity Game Engine and Python. The integration of the 3D visualization and robot control was implemented seamlessly in Unity which allowed the development of remote autonomous mission planning. For hardware, the Spot robot from Boston Dynamics was used along with a Ricoh Theta V 360° camera. Spot's SDK provides high-level control functions for the robot that allowed the research team to focus more on mission planning and visualization instead of developing the control system for the robot.

The proposed methodology was validated by running autonomous test missions in Bishop-Favreau Hall on the Virginia Tech campus in Blacksburg, VA. Some of the challenges faced in the initial runs (as explained in Section 5) were addressed in the later revisions of the application and iterative experimental investigations. In this methodology, the only input provided by the user is the location of the Goalpoints where the inspection images are captured on the 3D virtual environment. Future studies will evaluate the developed methodology in multiple scenarios on construction sites with dynamic obstacles. The developed methodology can be further augmented by a more data-rich BIM model of the building to be utilized for creating immersive Virtual Reality (VR) environments to help with inspection tasks in comparing and analyzing the as-built vs. as-planned project data.

6.1. Limitations and future studies

The major limitation of the study is that it requires an accurate and exact model of the building for navigation. Additional furniture or closed doors can cause the robot to fail its mission. Our ongoing research is identifying

ways to cater to the additional obstacles encountered by the robot in real-time (e.g., closed doors) and re-routing the mission when required. This feature will make the autonomous missions more robust and capable of handling the highly dynamic nature of construction sites.

Future studies may investigate extending this approach with immersive virtual reality and augmented reality solutions to provide an immersive experience to construction managers and owners of the construction project.

Another limitation of the current study was that the developed application and the robot were connected to the same network. Future studies may separate the user interface and the robot across the internet to allow fully remote inspection. Executing the mission remotely across the internet will not require any complex changes in the developed application but only an additional communication layer running on a cloud server to relay the commands from the controller machine to the robot.

Future studies might also evaluate the usability of the proposed approach in hands-on experiments with inspectors, construction experts, and owners to study the adoption and acceptance of the proposed technology.

Abstract

The research presented in this paper introduces a novel method for Augmented Reality informed human-machine collaboration in the context of timber prefabrication. The concept is based on the craftsman controlled instructive interaction between a High Level of Automation (robotic) fabrication setup and a human co-worker. It argues that by enabling the craftsmen to coordinate or take over specific process parts, a significant increase in flexibility and robustness of automated workflows becomes feasible. This is highly relevant within the project-based construction industry where efficient and flexible production of one-off components is predominant.

A novel approach to integrate human and robotic co-workers in a joint fabrication setup that we call “Instructive Human Robot Collaboration” is introduced. With Vizor, a computational framework was developed for this purpose. It provides an intuitive interface between human and robotic fabrication units via a mixed reality head-mounted display (HMD).

Finally, the proposed method is tested with an initial case study in which a 14-Axis fabrication setup is connected with human craft. The HMD gives a craftsman without any knowledge in robot programming direct control over the fabrication setup and extends its individual skill set. Fabrication tasks can be shared freely and between human and robotic units, enabling a dynamically adaptive workflow.

Augmented reality; instructive Human-robot collaboration; Digital Twin; project-based, Task-Skill comparison

1 State of the Art

1.1 Requests in building industry

In recent years, the building industry and here especially the timber-based manufacturers are investing in prefabrication lines with a high Level of Automation (LoA) for a higher accuracy and process reliability. Bespoke fabrication lines are installed to produce slab and especially wall elements [1] within predefined constraints of the product portfolio. Recent developments introduce industrial robots to replace human craftsmen for another step, the wall assembly process of frame and plate elements [2]. This trend even suggests a shift to a fully automated human free prefabrication environment [3] and new specialized High LoA concepts introduce new machines to carry out tasks, which previously relied on the execution of human labor or extend the possibilities and qualities of fabrication through integrative computational design and robotic fabrication [4].

In industry, this approach is often related to a conceptual understanding of the building as a product rather than a unique project. This is motivated by the goal of standardization of building components [5] and results in a restriction of the architectural freedom. Hence, such solutions are often not sufficient to solve the demand for the housing market, especially in the inner cities, where solutions adaptive to the various onsite conditions are requested, to fill the vacant spaces or extend the building vertically by adding new stories on the existing ones. Compared to the whole market only 13 % of the upcoming projects fall under the concept of modular building solutions [6]. To address this challenge, more flexible automation approaches are necessary to be investigated [7].

In addition, the recent results of fully automated “lights-out factories” in the high batch size production of the car industry (TESLA 3) showed a lower overall production speed [8], demonstrating the need for better

integration of manual processes and automated systems. For the small and medium sized enterprises in the building industry with their request for an efficient short-term production of bespoke building elements, the human co-worker remains an essential part not just for the execution but the planning of the fabrication as well.

1.2 AR in AEC research

Augmented Reality-Technology (AR) was presented more than five decades ago [9] and introduced to the aircraft industry three decades ago [10]. As robust and affordable AR headsets became more accessible in the last decade, this technology is gaining focus within the Architecture, Engineering and Construction (AEC) field. The concept of complementing the real world with digital representation of otherwise not visible data has opened a new path for a great variety of applications in AEC.

While there is a clear and obvious use case for shared model visualization to enhance design communication and collaboration [11] and another use case in visualizing hidden parts like water or electric conduits in facility management [12,13], first efforts are undertaken to implement AR-devices in the environment of prefabrication and on the construction site to improve and extend the skillset of craftsmen via the precisely located delivery of information on-time. Here two different major directions can be observed.

1.3 AR-enhanced craft

Research in the field of AR-enhanced craft investigates how human augmentation enables the construction of geometrically complex structures by craftsmen, a task previously reserved to computer numerically controlled technology (e.g. industrial robots). This approach was presented in visually guided pick and place procedures of bricks for the assembly of uniquely shaped brick walls [14], the manual bending of structural elements (i.e. steel tubes) to erect one-off structures and their quality check [15]. The system informs the human about the next step in an instructive one-directional information flow. Potentials for AR -enhancement of craft for assembly sequences have been further investigated in relation to the replacement of instruction manuals to enable the assembly of complex structures by untrained or unskilled persons [10, 16, 17]. Investigations in other fields focus on the introduction of alternative feedback concepts like acoustic [18] and haptic feedback or the combination of several feedback systems [19], which could be used to explore their potential of training the craftsmen due to the provision of a more intuitive feedback. And the integration of sensors and additional motors has been used to actively readjust hand steered toolpaths, compensating for human imprecisions, and enabling sub-millimeter accuracy thus CNC-comparable

results with hand-held tools (I.E. Shaper) [20].

1.4 AR-based human-machine collaboration

Research in the field of AR-based HRC shows high potential to integrate human labor and industrial robots to join their forces for smarter, more flexible, intuitive fabrication sequences, combining their individual strength and extending the setup's skill sets.

In many fields of production this potential is discussed to explore novel and more flexible automation processes [21]. In car industry for example, the level of collaboration is deeply discussed to identify potential scenarios [22] based on the proximity of collaboration and the related safety issues. The International Federation of Robotics defines 4 levels of collaboration: The coexistence, sequential collaboration, cooperation, and responsive collaboration [23].

High efforts are undertaken to bring human and robot closer together, such as precise scanning systems and sensitive sleeves for the robot [24]. The level of collaboration is defined by the mode in which the robots run if the human and machine share the same workspace or if there are physical barriers [21].

Recent work in architectural research focuses on novel human robot collaboration in experimental fabrication processes, instead of functionally driven implementations in the industrial environment.

For the contextualization of this paper, we propose a differentiation of existing modes of HRC in AEC and research along 3 scenarios:

1.4.1 Humans and robots as separate units

In this scenario, humans and robots work alongside each other as separate units executing pre-determined tasks. Various examples can be found where the precision of industrial robots for pick and place or holding in space is used, while the human screws [25] or welds [26] to fix the workpiece.

Even though this sequential task sharing demonstrates the benefit of a collaborative workflow already, studies mainly have been focusing on the robotic processes, using human labor to execute tasks, which are either hard to be executed by industrial robots or out of scope of the research. Interaction or even just organized and automated communication between human and robot fabrication units is usually not considered. This applies also to processes in which human and robot do not share the same workspace, i.e. material supply, workpiece unloading [4].

1.4.2 Human as an instructor, robot as an augmenting tool

A deeper collaboration between human and robot has been introduced via the integration of sensors and emitters. Humans instruct the robot through gestural

instructions. Sensors are used to identify and localize the human intervention and special programs convert these instructions to physical actions executed by the machine.

For example a Kinect RGB-D camera attached to the end effector of an industrial robot was used for the project “Iterative clay forming” to localize the finger position of the craftsman and to deform a piece of clay based on its position [27], a combination of motion capture markers, a pressure sensor and an external camera system enabled a direct and more intuitive description of shaping a sheet of plastic using the concept of thermoforming [28] and third research uses the torque sensors of a KUKA iiwa to readjust the robot arm manually during the fabrication process if requested [29]. Concepts like these require a direct and distinct communication between human instructor and the machine. If well designed the robot becomes a tool directly attached to the craftsmen and intuitively usable, which extends their skill set significantly, without any knowledge in coding or communication design.

1.4.3 Human and robot as collaborative units

Just recently HRC is becoming a focal point in AEC research. The implementation of sensors in High LoA fabrication setups in combination with novel interfaces and communication strategies support the collaboration between robots and humans in achieving the same fabrication goal within a dynamic process.

Being an important research topic in car industry for many years, sensitive small-scale low payload industrial robots (e.g KUKA iiwa, Universal Robots) have been developed as tools for low-risk hand in hand collaboration between human and robot. These machines were adopted to establish a collaborative prefabrication setup and experiment new concepts of HRC [30, 31]. The project “CROW” [31] successfully established a collaborative task sharing of robot and craftsman enabling the cooperative fabrication of bespoke timber structures.

2 Instructive Human robot collaboration and Multi-Unit Task Sharing

Despite these developments, true human robot collaboration in the building industry has significant room for further investigation. Typically, AR technology is envisioned for the construction site predominately, while prefabrication aims for full automation. The roles of the human and machine fabrication units in prefabrication typically are seen as separate, static and not interchangeable, once the workflow is planned. This often results in an over-defined digital system, that leaves the worker unable to intuitively interact with the automation workflow. Current State of the Art lacks

adaptive, fabrication concepts, suitable for the flexible project-based demands in the building industry.

This research presents a novel method for the integration of humans and High LoA technology in a collaborative fabrication setup, combining their individual strengths to extend its skill set.

2.1 From Task-skill analysis to Multi-Unit Task-sharing

Multi-unit Task-sharing is a method which derives from the conceptual approach, of Task-Skill based fabrication planning [4]. In this concept a set of Tasks which must be executed to produce a building system is formulated. These requests are compared with the skill sets of adaptive and modular and therefor flexible fabrication setups. Such fabrication setup can consist of several fabrication units, which can be industrial robots and other automated machines, but also human workers. Accuracy, payload, and tools among others define the skill set of each unit individually and/or in collaboration with others. If the tasks required and skills provided match, the fabrication setup is suitable for the fabrication of this specific building system (Fig. 1). The fabrication tasks are distributed, based on the individual skill set of these units. If the skill set required by a task is satisfied by more than one unit, the task can be flexibly redistributed among these units depending on other criteria such as availability. If it can only be satisfied with a combination of multiple units, it can be distributed among these units for collective execution.

Figure 1. The building system leads to a set of requested tasks for its fabrication, which is aligned with the skill set of the different units of the fabrication setup

2.2 Instructive Human Robot Collaboration

With instructive Human Robot Collaboration (iHRC) this paper introduces an additional layer to the existing levels of collaboration. An intuitive communication interface, which provides the human worker with

essential process and task- relevant data from the digital model as well as the possibility to control and interact with the robotic workflow is established.

This extends the concept of sequential collaboration, enabling the craftsmen to instruct the automated fabrication units e.g. industrial robots. With the tools described in the following chapter a communication protocol is proposed, which connects the machine controllers with the human craftsmen via AR-technology. The developed Hololens interface “Vizor” is used as the central facilitator and doesn’t request any programming skills from its user. Providing a digital twin of the work piece, it further extends the users skill in terms of positioning accuracy. This enables a craftsman-controlled fabrication process, breaking free from the constraints of a linear predefined workflow (Fig. 2). Tasks can be taken over, corrected or reassigned, depending on various conditions, such as the unit’s skill set (tool, reach, payload, etc.), resulting in a dynamically adaptive fabrication process and an extremely flexible fabrication system.

Figure 2. Human wearing an HMD controls the robotic fabrication setup

3 Setup

A communication strategy and an interface for the HMD were developed, to connect the human being with the robotic fabrication setup.

3.1 Communication Strategy

A communication system is implemented through a server that can read the tasks and communicate the fabrication data to the units for execution. Furthermore, the server also allows the units to share the fabrication data and the task's progress with each other (Fig. 3).

Three elements support implementing this case study of human-robot collaborative workflow: a server that dispatches tasks, two KUKA robot controllers connected to the server by KukaVarProxy via TCP/IP connection, and a Hololens Version 1 HMD connected to the server by rosbridge via a WebSocket connection.

Figure 3. Communication strategy

3.1.1 Robotic fabrication unit

Each one of the robots is defined as a ‘Kuka-Robot’ unit in the server. The server is communicating with the robots using the Python KukaVarProxy library [32]. When starting a fabrication process, the server initiates the communication channel to each of the robot units and will keep it open through the process. According to the specific task, the server knows which data it needs to send for the task execution. For the robot to know what to do with the received information, a unique KRL code is used. In this KRL some global variables are defined at the beginning of the program. Then an infinite loop is triggered, and according to the received data, it causes a switch case to execute the desired task. Using the KukaVarProxy also allows the robot to send some data such as robot position and tool activation while running the task and informing the other units in the system on the progress. When the entire fabrication process is done, a particular signal is sent from the server to stop the loop and the communication.

3.1.2 Human fabrication unit

Information to the human unit is communicated through messages, and rendered via a Hololens app. This Hololens application is developed to work in sync with the Vizor plugin in grasshopper but can also communicate more generally with servers using the roslibpy library [33]. The information related to each task, namely description, deadline, and geometric information is sent to the human worker as the server dispatches them. At the event of a task reassignment action through Hololens, the server registers the change upon receipt of the user message and modifies the unit to which the task is dispatched.

3.1.3 Workflow and Human control

When initiating the fabrication process, setup functions for robot controllers and Hololens run to ensure all units are connected to the system. The server then broadcasts a task list, rendered on Hololens display for the operator to review. In the case of our proof-of-

concept workflow, this is a list of pick, place, nail, and screw tasks that lead to the assembly of a spiral structure composed of timber slats.

When the robot is executing a task, the human sees the target frame for the robot in the current motion, a timer documenting the duration of task, and the name of the task being executed. When the human chooses to execute such a task, the display shows specific action instructions, highlighted geometry, as well as a deadline for the task being executed.

As the process unfolds, the human may step in at any time and modify the designated unit to complete a given task. This introduces flexibility of human intervention during a high level of automation process. In the proof-of-concept workflow, this flexibility allows quick resolution of issues in robot paths (e.g. collisions) or contingent events such as material inconsistencies (e.g. knots in the wood that could prevent nails from being inserted).

3.2 AR Interface Vizor

Second corner stone is the developed application “Vizor “. Vizor facilitates bi-directional communication between multiple fabrication units. The Grasshopper plugin allows users to prototype workflows directly using GH components. The companion HoloLens application is built using Unity (Fig. 4). It includes a digital twin of the TIM setup as well as modular user interface components that let a user interact with tasks, markers, model geometry and system status. The information is provided and visually presented in four components on the Head Mounted Display, in this case a HoloLens (Fig.5).

Figure 4. Platform representation in Unity

3.2.1 Display of the Digital Twins

A digital twin of the fabrication setup is built within Grasshopper using the plugin Virtual Robot and the plugin developed within this research Vizor to support simulation of the fabrication process (Fig. 6).

Figure 5. HoloLens-Visualized forecast of the fabrication sequence and gesture-based instruction of the robotic fabrication platform

Digital twin (work object): The digital twin shows the virtual representation of the model. It shows where to place the timber slat for the robot to pick it and its final position, if the placing is executed manually. Color coding is used to show, if the task was executed by the robot (blue) or the craftsman (red). It also contains the information if a screw or nail was used, a crucial factor for disassembly and recycling. The successful use of this information relies on a precise localization in the work environment, to provide accurately projected information in-situ to the craftsmen. Therefore, accuracy required by the task must match the accuracy of augmentation from the AR device. This is an important consideration when selecting which fabrication steps will benefit from this approach.

Digital twin (robot): The digital twin builds the virtual representation of the High LoA system. It shows the execution of a specific task. It also keeps the craftsman informed of the robot's next movement. For an operator unfamiliar with pre-programmed robot paths, this allows them to be better aware of fabrication contexts and easily intervene in case problems arise.

Figure 6. Visualization of the task window (red) and task list (blue) and the digital twins of the robots (yellow) and the work object (green)

3.2.2 Display and control of Tasks

Starting with a digital design model, the fabrication process is broken down into the different tasks, which are then assigned to each unit according to its tools and a generic task assignment logic (in this case a ping-pong scenario). The CAD design information is deconstructed into general fabrication data, which can then be tailored to each unit to facilitate robotic and manual tasks.

Task window: The Task window provides information on the fabrication process. The “Current Task” shows which task is currently executed or if the system is paused for the craftsman to execute. A clock shows the runtime of the current job. This timer is especially useful for time sensitive operations e.g. gluing to prevent the exceedance of its pot life. Additional messages can be sent to inform about successful fabrication steps, or issues, which must be corrected.

Task list: The Task list gives the human control over the upcoming task and their executing unit. By default, this task will be executed as defined in the script. Whenever the human decides to take over a specific task, they can interfere and change the fabrication sequence and assign a specific task to themselves. The script will be updated, and the workflow continues seamlessly.

4 Case Study

The case study chosen for this research is based on a pervious project which was produced with the TIM-Platform [4]. The building system was represented by a trade show stand which consists of a geometrically complex, but simple arrangement of 36 Clusters of prefabricated 22-50 timber (in total 1860) slats (Fig. 7).

Figure 7. Trade show stand surrounding the robotic fabrication platform which fabricated it

4.1 Specific task description

The requests were defined as followed:

- **Execution**
 - Pic and place of timber slats
 - Timber slat fixation.

- **Physics**

- Positioning accuracy: $< \pm 5.0\text{mm}$
- Weight handle ($< 1\text{kg} + \text{End effector}$)
- Workspace ($\sim 2700 \times 2000 \times 1000\text{ mm}$)

- **Speed**

- Not specified

This collaborative process exposed two potential sources of failures:

1. The wooden nails cannot penetrate the timber if the nailing spot is at a knot hole, resulting loose connections.
2. Several programmed positions cause singularities between pic and place of a slat, requesting a stop and potential reprogramming of the toolpath.

4.2 Specific setup description

In this case study, four fabrication units share the workload of the fabrication: The robotic fabrication platform TIM is a 14-Axis fabrication setup, which consist of 2 KUKA KR-500 industrial robots and a tilt-turn table [4].

The industrial robots used in this case study have a reach of 2830 mm (+ End effector), payload (500 kg – End effector) and a position accuracy (pose repeatability of $\pm 0.08\text{ mm}$). There are 3 end effectors each (PINP: mechanical gripper, pneumatic gripper, 3D-Camera and GNM: Nail gun, spindle and Glue gun) to define their skill set. In this case study the PINP robot uses the mechanical gripper to pick and place the slat and hold it in place, while the GNM robot uses the nail gun to fix it in place. The tilt-turn table extends the reach of the individual robots via repositioning of the work pieces (Fig. 8).

Figure 8. Pick and Place procedure executed by an industrial robot and slat fixation by nailing

The human craftsman skillset is partially defined by the labor law of the individual country. For example, the load a human is allowed to carry. Other skills depend on the individual physical (i.e. reach) and training (usage of tools) and additional tools available. The weight of the individual pieces with 1 kg is within these constraints and every spot of the prefab clusters is in reach. The positioning accuracy is ensured through an Augmented Reality head-mounted display. The craftsman is equipped with a Hololens, enabling a manual positioning

accuracy within the requested ± 5 mm. An electric screwdriver is used, to fix the slats with 4 x 60 mm screw, while the craftsman holds the slat in place (Fig. 9).

Figure 9. Same tasks executed with a different skill set by a Hololens-equipped human (slat fixation by screwing)

4.3 Evaluation of the fabrication sequence

The interface and communication strategy developed in this research successfully transfers the supervision and direct control of a heavy-payload 14-Axis fabrication setup to the human co-worker. The coordination works fully Hand gesture-based and requires no understanding in robot coding. Additional information like digital twins of the model augment the human skill set.

As a result, in this particular scenario, every task can be executed by one human, or the industrial robots collaboratively. The human can take over every part of the fabrication sequence and replace each industrial robot. The combination of the different skill sets for the same task provides an opportunity for changing fabrication strategy on the fly. Toolpaths which would result in singularities can be avoided, nails which failed to join the slats can be replaced with screws.

5 Discussion and Outlook

With instructive Human Robot Collaboration, the developed setup introduced a first step into a new level of HRC. It is currently restricted to the coordination of whole linear task sequences which means only one task happens in one point of time. Next steps aim for in depth control within the sequence for higher adaptivity. This will allow the human to pause a running sequence, intervene in the process (e.g. update target position, correct errors), and then continue fabrication. Such granular control will require further software development. The development of a generalizable ontology will be necessary to enable skill set descriptions of more complex fabrication setups and of humans for the coordination of several human and robotic units for fabrication sequences with higher complexity.

The developed interface can be applied to tasks requiring hybrid human and robotic labour to execute, though it has certain limitations at the current stage. First, the interface needs user studies with untrained labour

for validation and improvement. Second, the holograms have limited positional accuracy, for which combined outside-in tracking can be useful. Third, interface cues rely on programmed triggers, and object recognition can be integrated in the future to render it context-aware.

The AR-device Hololens 1 is suitable for applications in the controlled research environment, but still shows limits to be operational in the environment of construction halls and sites due to its heavy weight and the presence of view blocking holographic projections. Alternative strategies for human augmentation (e.g. or haptic devices) can be used for a partial implementation until further developments.

Abstract -

Efficient project monitoring is a key to a project's success. Linear construction projects span across large distances and require similar activities to be carried out repeatedly over multiple small segments for project completion. Thus, monitoring their progress becomes challenging. This is a matter of concern since proper progress monitoring can aid in efficient utilization and distribution of project resources. Existing methods of monitoring are either time-consuming, expensive, or require significant human efforts. GIS has been used for monitoring linear projects, but the use has been limited. Therefore, this study aims to explore the potential of using GIS for collecting and visualizing data for enhanced progress monitoring of linear projects. For this purpose, this study proposes a process incorporating GIS and various open-source platforms in the form of a figure. The open-source platforms used are Open Data Kit (ODK) tools, PostgreSQL (and its PostGIS extension), and different JavaScript libraries. The development and illustration of a Web-based GIS tool for progress monitoring of linear projects are the main objectives of the study. Visualization and quantification of project progress using this tool would result in time and cost savings due to reduction in manual efforts expended, manual errors in processing data, and time taken for the process. The developed tool would make progress monitoring easier, faster, and more efficient since site data can be recorded even in the absence of the internet and processed later.

1 Introduction

Proper management of construction projects can facilitate the timely completion of projects adhering to the required quality, cost, and sustainability [1].

Methods currently available for monitoring the progress of construction projects include manual recording, RFID tags or QR codes, satellite imagery, photogrammetry, Light Detection and Ranging (LiDAR), Global Navigation Satellite System (GNSS), Building Information Modelling (BIM), and Geographic Information System (GIS) [2,3].

However, the management of linear construction projects, for example, road projects, pipeline networks, or cable laying projects, requires a carefully designed progress monitoring process in place and associated control steps to be taken. Monitoring such projects is challenging due to variable workplaces, remote locations, multiple work-sites required to be monitored at once, and repetitive resources being used [4]. Therefore, only some of the methods mentioned above can be efficiently used for linear projects since the other methods either become too expensive, time-consuming or need significant efforts.

The current technologies widely used for monitoring linear construction projects include satellite remote sensing [5], Unmanned Aerial Systems (UAS), BIM, GIS, and a combination of satellite imagery and ArcGIS [6]. However, the progress monitoring cycle of linear projects could be improved by automating the complete process, which is currently being implemented only for structural components in buildings [3].

The use of GIS in linear project monitoring has been limited compared to its use in monitoring other types of construction projects. 4D GIS was used only to consider the effect of surroundings on the project in many cases and for the concept of time and schedules in the monitoring process along with 3D data [7].

Therefore, the potential of using GIS for collecting data related to the work done in linear projects and visualization of their progress should be explored. A study showed the potential of using Web-based GIS as a powerful visualization tool for utility management [8].

Hence, the current study explores the option of utilizing a web-based approach for monitoring linear projects. The primary objectives of this study are

1. To propose a process involving a Web-based GIS-enabled monitoring tool to visualize and quantify progress for monitoring linear construction projects.

2. To develop the tool and to illustrate its utility for monitoring a linear construction project.

In terms of structure, this paper is broadly divided into seven sections. Section 2 briefly describes the methods currently used for monitoring linear construction projects. The proposed process for incorporating a Web-based GIS tool for monitoring linear projects is presented in Section 3. Section 4 elaborates the design and development of this tool. The various open-source resources used for developing the tool are described in this section. Section 5 and 6 discuss the results of a case study, and the advantages and limitations of the developed tool, respectively. Finally, the study is concluded in Section 7, with the future scope of work.

2 State-of-art in Linear Construction Projects Monitoring

Previously, researchers have explored various methods for progress monitoring of linear construction projects involving combinations of several technologies. This section provides a brief review of these methods and studies.

Automated data acquisition technologies were studied, which included the description of a centralized database holding all the data required for project monitoring. This database was capable of hosting data from all possible methods of data collection – RFID, Bar codes, pen-based records, LiDAR, or Photogrammetry, and stored data regarding manpower, material usage, machinery, and images [2]. Efficient management of project data, tracking and control, and construction claims could be facilitated through this database.

Omar et al. studied IT technologies, geospatial technologies, 3D imaging, and augmented reality with respect to various criteria like initial costs, training required for use, and automation level [9]. They concluded that the most suitable technology had to be chosen based on the level of automation, accuracy required, project size, and the specific progress tracking objectives of the project.

Specific studies describing the use of varied technologies for progress monitoring of linear projects have been briefed in the following sub-sections.

2.1 UAS, UAV, and Satellite Imagery

Satellite imagery and ArcGIS were used to monitor the progress of a metro rail project in India using United States Geological Survey (USGS) images corresponding to the initial and final points over the period. These images were subjected to change detection after processing and georeferencing in ArcGIS software [6]. It was concluded that using such visualization techniques

would provide construction data quickly, and project monitoring would become faster.

Using a combination of satellite remote sensing for collecting site images and Location Based Management System for planning for progress monitoring was also demonstrated [5]. A web-based platform was developed to provide the monitoring team with progress charts, location-based progress maps, and line-of-balance diagrams. It worked as an effective supporting visualization method at the macro-monitoring level by displaying the tasks behind and ahead of schedule.

2.2 Combined use of BIM and GIS

Highway Information Modelling (HIM) technology – a combination of BIM and GIS, was adopted for managing a highway project in Malaysia [10]. Data capture was done using ground survey data, LiDAR, satellite imagery, UAV imagery, and Underground Detection Mapping (UDM). The collected data was stored in numerous GIS layers to create a database for information for the design. HIM combines the features of both BIM: physical representation and functional characteristics of the facility and GIS: the associated geolocation, along with time information. Integration was carried out by first converting CAD and BIM data to ArcGIS by converting individual BIM elements to GIS features. Then, WebGIS was used to view the integrated model.

The effectiveness of the technologies and tangible benefits of using BIM+GIS in many methodologies or processes were examined. It was concluded that technology provides optimum benefits only when deployed through a proper and efficient process, modified to suit the project requirements [11].

The integrated use of BIM and GIS, specifically considering the spatiotemporal characteristics, was reviewed. The result of this study was the potential use of BIM+GIS to provide more accurate and dynamic data for decision making and analysis throughout the lifecycle of AEC projects. It had several benefits like improved communication, coordination, significant time and cost savings, and improvement in quality levels and Health, Safety and Environment (HSE) performance [12].

2.3 GIS

Integrating spatial data related to the project with other project information and using an improved system compared to Management Information System (MIS) was considered necessary. A web-based GIS tool was developed for utility management, using open source technologies [8]. This model could help in data management, spatial planning, mapping all the utilities for visualization, and other GIS-related operations.

4D GIS concept for storage and representation of complete project data (drawings, specifications,

resources, and schedules) in a single environment was proposed to visualize progress of construction projects in which Primavera was integrated with GIS, and a 4D model developed [13,14]. As a result, logical errors in schedules, time-space conflicts, and working place restrictions could be identified, and thus cost control could also be achieved. However, the focus was only on the visualization of major structural activities in buildings. Also, automating the maintenance of schedules and drawings is necessary for constructability review and project planning, and this can be achieved by integrating CAD and other available data [1].

Having an open-source GIS environment can ensure that all data can be utilized by all parties involved in the project in the construction industry [1]. Also, incorporating GIS into progress monitoring brings in the effects of the surroundings on the project scheduling related to repetitive projects [7].

2.4 Miscellaneous Techniques

The combination of Product Lifecycle Management (PLM) and BIM for linear infrastructure construction projects was also proposed for its effective lifecycle management. A digital twin was employed in the process to automate the data transfer between the digital and physical models [15]. This combination would improve the information flow and monitoring quality by establishing digital continuity throughout the value chain.

Monitoring techniques were classified into four broad categories: i) non-spatial progress monitoring, ii) spatial monitoring, iii) indirect methods, and iv) specific studies for transportation and earthwork studies [3]. The study concluded that the existing methods either required too much time, did not have the required accuracy, or were expensive.

The potential use of GIS has not been utilized suitably for progress monitoring of linear construction projects.

Thus, the need to explore and develop a web-based GIS tool specifically for monitoring linear construction projects is the aim of the current study. This tool should be easier and simpler to use, and less expensive. The process for adopting this tool for progress monitoring is explored in the next section.

3 Proposed Process for Progress Monitoring

This section presents a process for monitoring the progress of linear projects incorporating GIS on a web platform, thus creating a Web-based GIS tool, which is proposed in this study. This process requires several tasks to be carried out by three major stakeholders, namely i) the project management team, ii) the project monitoring team, and iii) the project execution team on site. Figure 1 outlines these responsibilities and the order in which the tasks are to be carried out.

The key responsibilities of the monitoring team, as presented in Figure 1, include discussions with the top management to set the project progress goals and to define the monitoring requirements based on these goals. The team then creates a proper medium to enable the people at the site to fill the data, creates a medium for data storage, creates a method to visualize this data and, analyzes and interprets the data. They can also provide suggestions to the top management to improve the rate of execution on site. The execution team at the site should have access to these mediums to update project data as per the predetermined monitoring requirements of the project. Proper coordination and communication between all these teams would facilitate the tool development, its usage and decision-making based on the results from this tool.

The flow of data in this system consists of three main stages, namely data collection, data storage and analysis, and data visualization, as shown in Figure 2.

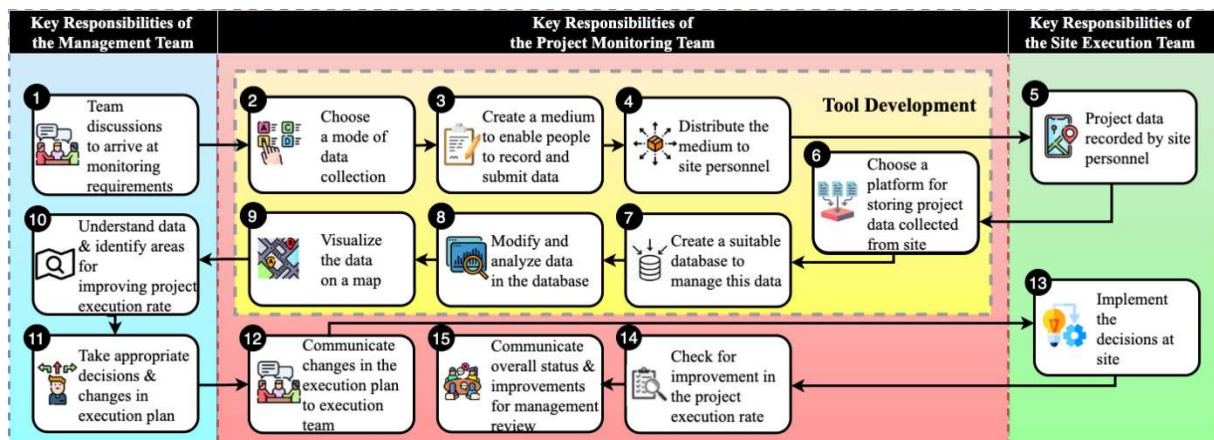

Figure 1. Proposed Process Flow for Progress Monitoring of Projects

First, the monitoring requirements of the management are translated into data entries collectable in a form. This form is then circulated among the people assigned with the responsibility of executing the work at site. As they carry out the project work at site, they can update the related location data in the forms and submit it to the server. The team at the office responsible for monitoring can then access this data and create a database. The Web-based GIS tool for monitoring is then created using the data from this database. This tool creates the visual form of the recorded data along with its numeric form. The use of different open-source resources, as illustrated in Figure 2, is explained in the following sections.

4 Design and Development of the Web-based GIS monitoring tool

After identifying the technical requirements of the process proposed in Figure 1, various open-source resources employed for data collection, data storage and analysis, and data visualization functions of the proposed tool are described in this section.

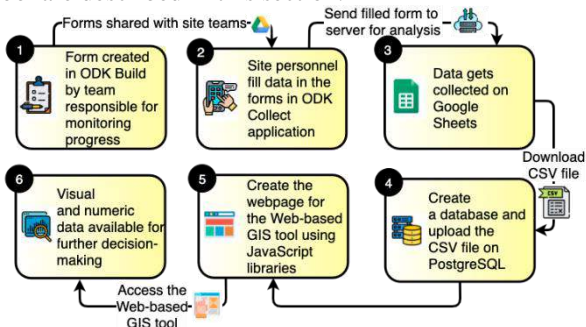

Figure 2. Flow of Data in the Proposed Monitoring System

4.1 Data Acquisition through Open Data Kit (ODK) Tools

Open Data Kit, an open-source platform that can be used to collect data in remote areas, was chosen for collecting data from the site. The data can be stored on the mobile device till the need for submitting the data to the server arises and can be submitted in the presence of internet connectivity. ODK is a collection of tools that can be used for collecting and storing data.

ODK Build was used for creating the forms for data collection. Forms can be made for text, numeric, location (geospatial points, paths, and shapes using GPS location of the device or manual selection from the map), time, and date inputs. In addition, different media, including images, videos, audios, and signatures, can be sought from the user filling the forms. These forms on ODK Collect application enable the people at site to record data like the route name and length, GPS data for points, operational stage, date of data entry, and other comments.

Once the user submits this form to the server, all the data entered by the users gets collected in the designated Google Sheet chosen while creating the form on ODK Build. For further analysis of the data, this Google Sheet was downloaded in a comma-separated value (CSV) format and saved on the computer or the local hard drive, where the Web-based monitoring tool is to be built.

4.2 Database Creation and Management on PostgreSQL and PostGIS

All the data stored in the Google Sheet must be entered in a proper database management system capable of defining, manipulating, handling, and managing all the data stored.

PostgreSQL is an open-source database management system that can manage data collected from various kinds of applications. PostGIS is its spatial extension to enable the storage and spatial querying of geographic data.

A database was created in PostgreSQL, and a table was then created in this database. Using the several data types available in PostgreSQL, different types of data collected from the site can be stored in this table. The data downloaded as a CSV file was then imported into this table. The PostGIS extension enabled the creation of geometry like points and linestrings from the location data and querying on this data represented spatially on the map.

4.3 Data Visualization using JavaScript Libraries (NodeJS and Leaflet Library)

Various JavaScript libraries were used to render the Web-based GIS tool utilizing the data stored on the PostgreSQL database. NodeJS environment, an open-source JavaScript environment, was used to set up maps on a webpage using the data delivered dynamically based on the queries generated using PostgreSQL. The base map in the webpage, which displays the required data related to the routes, was rendered using Leaflet library, a mapping application in JavaScript.

The Web-based GIS platform connects to the PostgreSQL database, queries it using PostGIS, and returns the results in a GeoJSON format, an open standard geospatial data interchange format. These results can then be passed to the client to be viewed in a map rendered by Leaflet. Data in GeoJSON format can be used to represent geographic features with their non-spatial attributes (properties).

The 'Leaflet Routing Machine' library available in Leaflet enables the identification of routes between the recorded points, calculates the distance between the points, and allows color-coding of routes based on the route properties.

Pug template engine was used for creating the view of the map. Code was written to create filters that work based on the properties of the data in the database.

A table was designed to display all the required information from the database on the tool interface. The columns of this table were chosen from those in the table created on the database. Code was written in Pug for creating this table, and the GeoJSON data fetched after querying enables the table to be filled with appropriate data. The working of the developed Web-based GIS tool is presented in the next section.

5 Experimental Work and Results

This Web-based tool is capable of displaying the progress of two types of projects:

1. Projects like transmission line projects, where the shortest distance between the points is considered as the route length (referred to as Type I projects)
2. Projects like cable laying, road laying, and pipeline projects, where the distance between the points along specific routes is considered the route length (referred to as Type II projects).

Each project stage can be represented in different colors as shown in Figure 3 – where red, blue and, green colors indicate routes along which work has not yet started, work is in progress, and work has been completed, respectively or as shown in Figure 4 – where black, and blue routes indicate planned work and completed work along that route, respectively. The placemarks indicate the intermediate points as per the collected data.

The main activities in the execution of a typical cable laying project include A1: transportation of cables to the site, A2: site clearing, A3: trench excavation or road cutting for laying the cables, A4: laying of a sand bed, A5: cable laying, A6: covering the trench with cover tiles, A7: installation of warning tape, A8: backfilling the trench or road restoration works, A9: repair of damaged underground utility (if any), and A10: shifting of excess soil and installation of related electrical equipment. Figure 5 shows the images representing some of the stages indicated above. Each of these stages can be represented in a different color on the Web-based tool.

Using the ODK Tools, data related to the work executed in a project (as mentioned in Section 4.1) was collected in Google Sheets. This sheet was then downloaded in CSV format and uploaded to the PostgreSQL database. Using NodeJS and Leaflet, a webpage that functions as the proposed web-based GIS monitoring tool was developed. The resulting webpage, shown in Figure 6, has features to display progress on a map and its tabular representation. This table has been designed to display the route's name, starting and ending points, the status of work execution, the planned and the actual executed length along these routes, and the percentage of work completed along these routes.

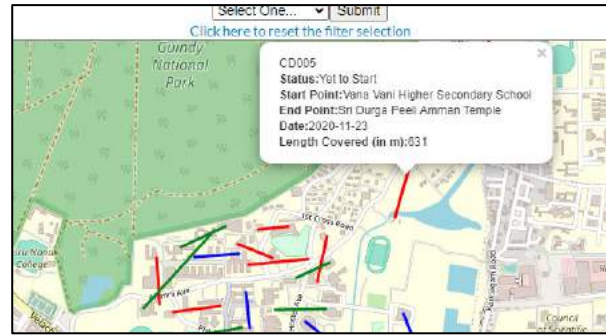

Figure 3. Web-Based GIS Tool for Type I Project

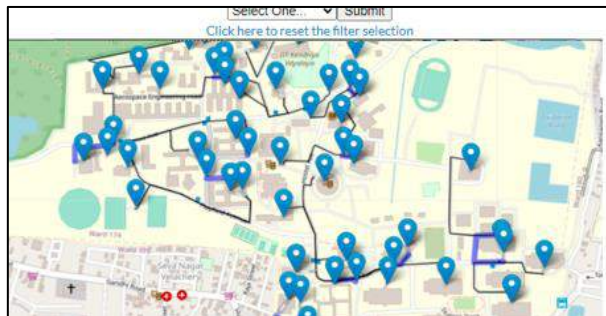

Figure 4. Web-Based GIS Tool for Type II Project

The filters at the top of the page allow the user to choose routes based on any predetermined criteria. For example, filters were created in this study to enable users to select routes based on their execution status or name.

The code can be modified to create as many filters as required to suit the project monitoring requirements (E.g., based on the reason for delay). The filters used in this study have been shown in Figure 7 and Figure 8. Here the cable drum number indicates the name of the routes in the project. On selecting the status as 'Yet to Start' in the first filter, the result is as shown in Figure 7. Only black lines displayed indicate that no work has started yet. Figure 9 also shows the result of choosing 'CD016' in the route name filter. The black path is the planned route, and the blue path (along with the marker) indicates the completed work. On clicking on any placemark, the corresponding route details are displayed in a pop-up. In this study, the pop-up has the route name, execution status, the name of the start and endpoints, and the date on which the route was last modified. The details for the routes CD016 can be seen by clicking on the placemarks on the route.

Along with the representation of the route data on a map, the progress is quantified as well. The progress in the percentage of work complete for the selection using filters or for all the routes is presented in the table below the map as illustrated and highlighted in Figure 6. The percentage of work done along each route is calculated using Equation 1.

$$\text{Percentage completion along each route} = \frac{\text{Work completed along the specific route}}{\text{Total work planned along the same route}} \times 100 \quad (1)$$

Similarly, the overall percentage of work done along all routes is calculated using Equation 2.

$$\text{Project level percentage completion of work} = \frac{\text{Work completed along all the routes}}{\text{Total work planned along all the routes}} \times 100 \quad (2)$$

This calculation enables the user to understand the level of work completed at the project level and identify the pace of execution.

The Web-based GIS monitoring tool, thus developed, provides information to enable the project managers or monitoring team to make several kinds of decisions, as elaborated in the following section. The link to the repository for demo version of this tool is <https://github.com/varunreja/Web-Based-GIS-Tool-For-Progress-Monitoring>.

6 Discussion

This section of the paper deals with the functions and evaluation of the developed tool. The tool has been designed to display information to cater to various monitoring requirements of any linear project.

6.1 The Web-based GIS Tool as a Decision Support System

The possible decisions that can be taken based on the visual and the tabular representation of site data on the

tool, followed by related communication with execution and planning teams from the site, can be regarding management of (i) materials, (ii) manpower, (iii) machinery, (iv) project budget, (v) schedules, and (vi) project scope.

Appropriate interpretation of data on the tool can facilitate better material handling. For example, in areas where delays are due to shortage or where there are excess materials, the team can direct more materials for work completion or redistribute them to other areas to avoid wastage, respectively.

Identification of the areas requiring immediate action has been facilitated on the tool using filters based on the status of work execution. The monitoring team can focus on these areas to determine the exact reason for the delay and take necessary actions to expedite the project execution.

Also, based on the actual progress, updated cost estimates can be prepared to indicate the need for any changes in budget allocation of project resources for successful completion.

Manpower and machinery can also be reallocated based on the current requirements at the site, from the routes along which work is completed to other routes depending on the requirements, i.e., strategic placement of resources is enabled.

Updated schedules can be prepared, and the revised deadlines can be decided based on the responses from the site to ensure that project milestones are met on time.

Figure 5. Stages in the Execution of a Typical Cable Laying Project

Figure 6. Visual Representation along with the Numeric Representation of Work Progress for a Type II Project

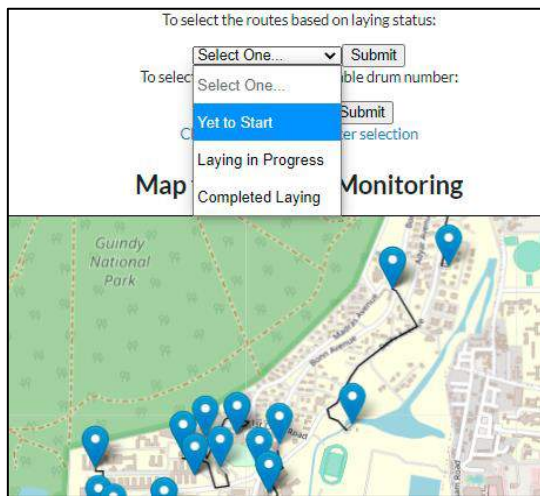

Figure 7. Results for Choosing 'Yet to Start' in the First Filter

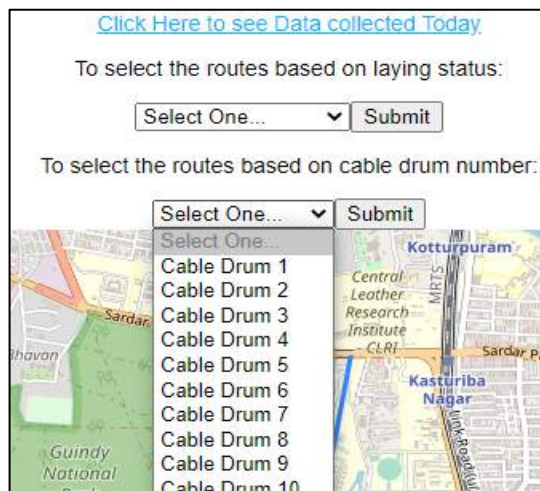

Figure 8. Filter based on Route Name

Figure 9. Results for Choosing 'CD016' in the Second Filter

Scope management is facilitated since any deviations in executed routes can be identified from the map and checked immediately to ensure that the work executed aligns with the project scope. If these deviations are not as agreed, the site personnel can be instructed immediately to undertake the route corrections required to meet the project scope.

Hence, the Web-based GIS monitoring tool provides information about various project management aspects.

6.2 Advantages and challenges of using the tool over conventional methods

- The tool and open-source applications are easy to use, and users can quickly be trained to use the tool.
- Data for progress monitoring can be recorded by the site personnel on the application, even in the absence of Wi-Fi or mobile data, making data collection robust.
- Progress can be seen both in visual and numeric forms and at route level and overall project level on a single interface.
- Due to the inclusion of the spatial aspect in the management tool, all the project participants can have the same interpretation of the work done.

The tool, hence, increases the reliability and robustness of the progress monitoring process.

The developed tool, at the current stage of development, has few limitations as well. Currently, the data is manually downloaded from Google Sheets and imported into the PostgreSQL database to visualize and analyze it. This process can be automated in the future. Further for calculating the percentage of progress, the location details of the start and end points of all routes should be available. These details can be collected during the initial route survey.

Thus, this tool would serve as a quick guide to the project management teams to monitor the project progress. Its functions provide the possibility of overcoming the existing shortcomings with the current techniques of progress monitoring.

7 Conclusion

Since proper progress monitoring of projects would aid effective utilization and distribution of project resources, it is essential for construction projects. So, this study focussed on developing a process involving the management, monitoring team, and site personnel to improve progress monitoring, specifically for linear construction projects.

The potential of GIS for monitoring was explored, and a web-based GIS tool for progress monitoring of linear construction projects was designed and developed.

The potential uses and outcomes of the tool have been explored by providing an illustration of the tool.

The key finding of this study is that by integrating existing technologies like Web-based interface and GIS, progress, of linear projects in particular, can be monitored in a systematic manner. A realistic perspective of the executed work is provided by the tool, along with support for decision-making by providing accurate information. Various open-source resources have made the development of this tool possible.

An inexpensive, fast, and accurate tool that can serve as an information system for decision-making has been developed. This information system can assist project managers in making the required decisions regarding supply chain management, resource allocation, cost analysis, schedule analysis, and scope management.

Consolidated project data for all the projects undertaken by a contractor can be maintained at a single interface using the tool. The data related to each project can be accessed using a filter indicating the project they belong to. Monitoring at the project level and the organization level would, thus, be facilitated.

In the future, the study aims to make the tool completely automated to increase the tool's efficiency for progress monitoring of linear projects. In addition, the integration of data collected from the site and data from management teams at the office, such as reports for resource planning and allocation, would enable the transformation of this information system into a decision support system.

Abstract –

Population aging is one of the major challenges facing the world. In particular, the advent of China's aging society caused by various factors will be a major threat to its future development. Therefore, serious measures need to be taken to achieve its demographic sustainability. Smart furniture can be considered as a novel subcategory of gerontechnology. One of the main outcomes of the EU-funded REACH project was a variety of smart furniture named Personalized Intelligent Interior Units (PI²Us) which served as the key component of a distributed intelligent home to promote the health and activity level of older adults. This outcome can potentially be a solution to mitigate the consequences caused by population aging. In order to understand the attitudes and opinions of Chinese older adults towards the relevant technologies, the authors conducted an opinion survey using the PI²Us as an example, which sampled more than 380 older adults in 26 out of 34 provincial-level administrative divisions of China. The survey showed that Chinese older adults in general have a highly positive attitude towards smart furniture and smart home technologies. Several other insights also can be revealed from the survey. Based on further analyses, the paper summarized why the elderly-oriented smart furniture and distributed intelligent home has the potential to thrive in China's market soon. Finally, a three-year project action plan for implementing localized solutions in cooperation with a large Chinese furniture manufacturer was presented.

Keywords –

Chinese older adults; Distributed intelligent home; Gerontechnology; Population aging; Smart furniture; Survey

1 Introduction

Population aging is one of the major challenges not only facing the developed countries, but also threatening many emerging economies. China's upcoming aging society caused by various factors will pose an imminent threat to its future development. Specifically, by the end of 2020, Chinese older adults aged 60 or over reached 264 million. Thus, innovative measures must be taken to achieve its demographic sustainability.

Gerontechnology (e.g., elderly-oriented smart home, wearables, smart furniture) is a cross-disciplinary research and development (R&D) field combining gerontology and technology that has gained substantial attention over the past decade, demonstrating its potential in the fields of aging in place and home care for older adults. However, gerontechnology research in China is still lagging behind compared to developed countries such as USA, Germany, and Japan. According to a study in 2015, China was still considered as an academic laggard in gerontechnology compared to leaders such as USA and UK, although it began to catch up in most recent years [1]. For the same reason, there is also a lack of research on the acceptance and adoption of gerontechnology among Chinese older adults.

Therefore, it would be valuable to investigate Chinese older adults' adoption, attitudes, and preferences for gerontechnology products including smart home and elderly-oriented smart furniture to guide the future implementation of these technologies in China. In the following sections, the opinion survey using elderly-oriented smart furniture as an example will be described in detail, and its results and implications will be analyzed. Finally, a project action plan for implementing localized distributed intelligent home in China will be proposed.

2 Methods

In this section, a distributed intelligent home solution based on smart furniture developed in the EU-funded research project REACH for the purpose of increasing the activity and independence level of older adults is introduced. Furthermore, based on the proposed solution, the opinion survey to investigate the attitudes of Chinese older adults towards using smart furniture technologies is detailed.

2.1 Smart furniture in context

The smart furniture devices exemplified in the context of this paper were developed in the REACH project, a large European interdisciplinary research project aiming at developing customized healthcare systems to promote older adults' activity level and independence. In REACH, a special type of modular smart furniture named Personalized Intelligent Interior Unit (PI²U) was developed, which seamlessly integrated various functions (e.g., unobtrusive sensing and monitoring, training/gaming, nutrition, AI assistant, etc.) into the different living environments. The PI²Us include but are not limited to SilverArc, MiniArc, SilverBed, and ActivLife (see Figure 1) [2].

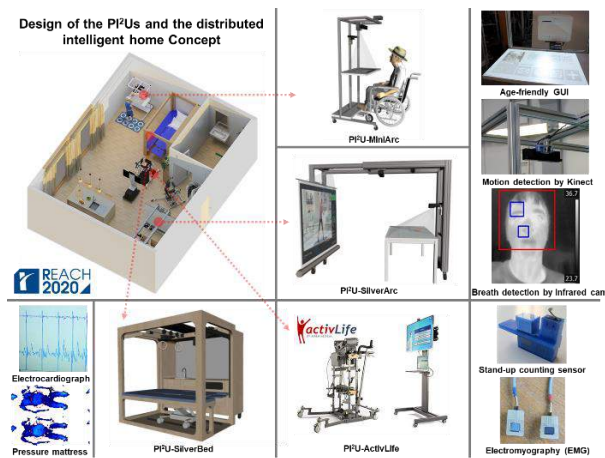

Figure 1. PI²Us with various sensors and the distributed intelligent home concept

The SilverArc is a multifunctional device developed for the use in a large kitchen or dining space (e.g., a community kitchen). The dimensions can be easily adapted due to the telescopic design. It offers an interactive projection area in the kitchen, where recipes and training programs can be displayed. It also has a foldaway projection area where an elderly-friendly graphical user interface (GUI) can be displayed.

The MiniArc can be considered as a flexible and smaller variant of the SilverArc, which is meant to assist in the training and moving of older adults who are

hospitalized or reside in smaller apartments. This prototype was fitted with wheels and is thus mobile. The philosophy of inclusive design was also considered so that a user in wheelchair can easily push the wheelchair in between the wheels (i.e., 895mm). An ultrashort projector can project the GUI on its foldaway table or on a separate table as needed. Meanwhile, a motion-sensing camera (i.e., Microsoft Kinect) is integrated to detect the user's gestures, enabling the interactive gesture control and gaming function. The major features of the GUI for both SilverArc and MiniArc include calendar, weather, appointment reminder, email, game center, and photo gallery (see Figure 2). In addition, an infrared camera can detect user's respiratory rate using machine learning.

Figure 2. Elderly-friendly home screen and sub-screens of the SilverArc and MiniArc

The SilverBed is a carpentry-based modular bed incorporating a Sara Combilizer that assists older adults to move autonomously to a sitting, standing, or supine position in a comfortable and safe manner [3]. Physical exercise is offered in combination with entertainment, motivating its users to become more active. More importantly, health functions can be also integrated such as vital signs and skin pressure monitoring.

The ActivLife is equipped with a mechanism to assist the user to stand up and to perform motor exercises of the ankles, knees, and hip joints. It also allows the user to maintain a safe, upright standing position and perform physical-mental serious gaming and balance exercises through the motion-sensing TV component.

Furthermore, based on the PI²Us, a modularized smart home solution, namely the distributed intelligent home, was proposed, integrating the PI²Us and key technologies in REACH to create a complete interior living and care environment (also known as the smart infill system in open building) for older adults in different living environments such as home, hospital, and community in a flexible and adaptable manner (see Figure 1) [2].

Thereafter, all the data collected via a variety of

sensors integrated into the PI²Us (e.g., electrocardiography, thermal camera for breath detection, body pressure mapping system, stand-up counter, etc.) will be transferred, exchanged, and stored securely via the CARP platform, which is a set of open-source software components and frameworks developed by project partner Technical University of Denmark (DTU). The platform enables the design and development of mobile health applications for digital phenotyping research (<https://carp.cachet.dk/>, see Figure 3). The PI²Us, the distributed intelligent home concept, and the CARP platform were tested and validated in several exhibitions and tests across Europe later on.

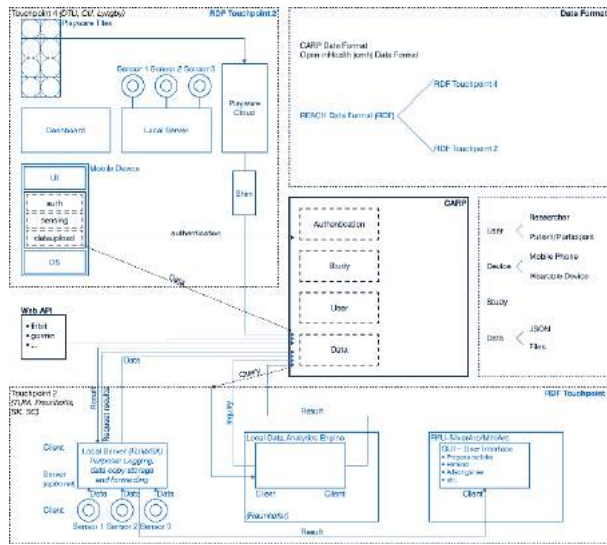

Figure 3. CARP's communication in REACH

2.2 Opinion survey

Based on the outcomes of the REACH project, a survey was conducted via two channels (e.g., mainly digitally via WeChat app and email, and in-person questionnaires as a supplement for users who do not use any smartphones or tablets). With over one billion active users only in China, WeChat provided a brilliant platform to distribute the questionnaires. The survey consisted of 11 close-ended questions that can only be answered by selecting from a limited number of options in order to investigate the current situation of the participants and their opinion towards the smart home technology for older adults (see Table 1). In particular, photos of older adults using various PI²Us were shown as an example of smart furniture to give the survey participants an intuitive impression of the appearance and functions of smart furniture. The questions were designed with principles of simple language, common concepts, manageable tasks, and widespread information [4].

Table 1. List of survey questions

No.	Question
01	What year were you born?
02	What is your gender?
03	What area are you currently living?
04	What is your highest level of education?
05	Where is your main place of residence?
06	Which of the following smart digital products have you used?
07	Which of the following smart home devices have you used?
08	What do you think is the ease of use of current technology products for older adults?
09	How interested are you in using smart furniture with health functions? (Examples from the REACH project are given.)
10	How important are the following attributes to you for using smart furniture?
11	What do you think of the prospects of China's elderly-oriented smart furniture market?

Powered by Tencent Questionnaire (<https://wj.qq.com/>), the survey is designed in a user-friendly manner in order to appeal to older adults - the main audience of this survey. The survey was kept short as much as possible, which can be easily finished by older adults in 3-5 minutes. The survey was pre-tested with several older adults before formally sending out in order to optimize the understandability and order of the questions.

3 Results

The survey lasted for 45 days from January 7th, 2021 till February 20th, 2021. In total, 1313 questionnaires were sent out and 403 responses were collected, of which 384 were valid, leading to an effective return rate of 29.2%. 19 responses were removed due to reasons such as incomplete data. The average completion time for each participant was 4 minutes and 17 seconds, which well met the expectation for the questionnaire design. The vast majority of the survey participants completed the survey without issues. Necessary guidance or explanation were provided to the participants if needed. The results of the survey are revealed in detail as follows, including the general analysis and cross analysis.

3.1 General analysis

As mentioned above, 384 older adults from 26 out of the total 34 provincial-level administrative divisions of China provided valid questionnaires during the survey. As of the beginning of 2021, there are approximately 260 million Chinese older adults aged 60 and over [5]. Therefore, it can be calculated that the survey can

represent the Chinese older population with a margin of error of $\pm 5\%$, which is acceptable for categorical data in social research [6].

There are many ways to categorize older adults by age. One study differentiated them as the young old (60-69), the middle old (70-79), and the very old (80+) [7], which is suitable for this study, because the current retirement age in China is 60 for male employees and 55 for female employees. The average age of the survey participants was 68.64 years old. Among these participants, 39.1% were male and 60.9% were female. Figure 4 shows the age (top) and gender (bottom) distribution of the survey participants.

Figure 4. Demographics of survey participants (top: age distribution; bottom: gender distribution)

In general, the education level of the survey participants was relatively balanced, among which 49.5% had college degree or above (e.g., junior college, bachelor's, and master's degree) and 50.5% had high school education or below (e.g., primary school, junior high school, high school/secondary vocational school) (see Figure 5 top).

Regarding the places of residence, 75.2% of the participants lived either alone or with spouse, and 20.8% of them lived with their children. Only 0.8% of them were living in retirement homes or nursing homes (see Figure 5 bottom). This phenomenon is likely because 1)

over 90% of Chinese citizens own their homes [8], and 2) in Chinese culture, aging in place (i.e., aging in home and community) is a common practice, and older adults tend to rely on family members for primary care in later life due to the cultural norm of filial piety [9], although living in retirement homes has started to pick up momentum in recent years.

Figure 5. Education level (top) and main place of residence (bottom) of survey participants

Regarding the user adoption rate of personal smart devices (e.g., smartphones, tablets, PCs/laptops, wearables), 93.5% of the participants used smart phones. On the contrary, only 8.9% of them used wearables (e.g., Mi Band, Fitbit, Apple Watch, Samsung Galaxy Fit), see Figure 6. A possible explanation could be the inadequate functionality and frequent need for charging for current wearables. For example, one older adult from the survey complained that “the functions of the smart band are very limited, but it requires charging the battery every now and then. Therefore, it is a burden to use, so I abandoned it.” This phenomenon also suggests that the ambient sensing solution integrated in smart furniture could provide a good alternative to wearables. In this survey, 5.5% of the participants did not use any of these devices. Although admittedly, it is likely that older adults who did not use personal smart devices were under-sampled because the majority of the questionnaires were

completed via WeChat app with a few exceptions of guided questionnaires, it is fair to say the adoption rate of personal smart devices among Chinese older adults is satisfactory.

Figure 6. Adoption rate of personal smart devices

In the next question of user adoption of smart home devices (e.g., smart speaker, smart TV, robot vacuum, pet robot, smart door lock, smart appliance, smart furniture, etc.), three quarters of the participants had experience with at least one of them, with smart TV having the highest adoption rate of 49.5%. On the contrary, smart furniture had the second lowest user adoption rate of 3.1% (only higher than companion robots, see Figure 7). This is mainly because smart furniture is relatively a new field without many mature applications on the market. On the other hand, however, it also indicates a substantial market potential.

Figure 7. Adoption rate of smart home devices

Regarding the usability of current technology products for older adults, only 45.3% of the participants thought that they were easy or very easy to use (see Figure 8). Therefore, improving the usability for older

adults is highly important for developing new or improving current technology products.

Figure 8. Usability of current technology products for older adults

When the survey participants' interest in using elderly-oriented smart furniture was asked, examples of four PI²U prototypes from the REACH project were given. As a result, 60.9% of the participants were interested or very interested in using elderly-oriented smart furniture (i.e., PI²Us). This indicates substantial interest and market opportunities for smart furniture among Chinese older adults (see Figure 9).

Figure 9. Interest in using elderly-oriented smart furniture

In terms of the importance of various attributes in smart furniture, the survey participants valued the safety of the products the most (i.e., 85.4% of the participants find it important or highly important), followed by usability (i.e., ease of use, 77.8%), quality (75.5%), privacy protection (73.4%), affordability (70.6%), multifunctionality (50%), and the aesthetics the least (48.2%). This result indicates that when developing elderly-oriented smart furniture products for Chinese older adults, more attention shall be paid to aspects such

as safety, ease of use, quality, privacy protection, and affordability respectively, while aesthetics and multifunctionality are relatively of less importance. See Figure 10 for specific statistics.

Figure 10. Importance of attributes for smart furniture

Regarding the final question of market potential, a vast majority (i.e., 73.7%) of the survey participants thought that there could be a substantial market potential for elderly-oriented smart furniture in China, which further verifies the hypothesis of this paper (Figure 11).

Figure 11. Market potential of elderly-oriented smart furniture in China

3.2 Cross analysis

This section focuses on analyzing the simple correlation between participants' demographics (e.g., age, gender, education level) and attitude towards smart home and smart furniture technology.

3.2.1 Age and adoption rate, difficulty, interest, and expectations

As shown in Figure 12, there is a sharp decline in smart home technology adoption rate when the

participants are older. In the “young old” group, 84.0% of the participants had experience in at least one smart home product, while in the “very old” group, only 35.6% had experience in using any smart home technology.

Regarding the correlation between age and difficulty in using technology products, only around 15% of the older adults in the “young old” and “middle old” groups found it difficult or very difficult to use technology products. However, the percentage more than doubled in the “very old” group.

Regarding the correlation between age and interest in using elderly-oriented smart furniture, more than 60% of older adults in the “young old” and “middle old” groups were interested or very interested in using the smart furniture developed in the REACH project. The percentage dropped slightly to 46.67% in the “very old” group, but still was close to half of that group. Therefore, the overall interest in using smart furniture is strong among Chinese older adults.

Regarding the correlation between age and expectations in elderly-oriented smart furniture technology, all three groups of older adults expressed high expectations for its future market potential. The differences between three groups are not statistically significant.

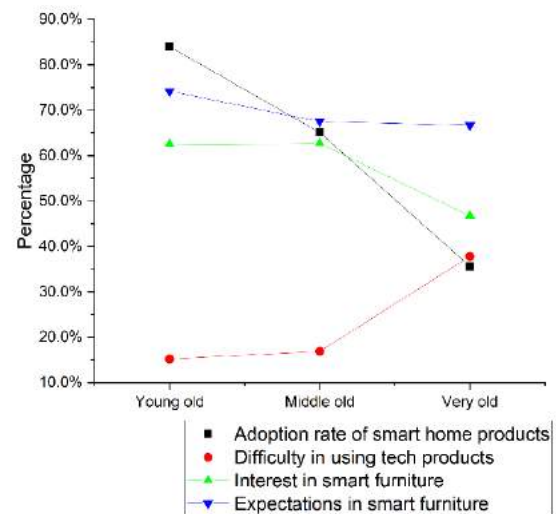

Figure 12. Correlation between age and adoption rate, difficulty, interest, and expectations

3.2.2 Gender and adoption, difficulty, interest, and expectations

As shown in Figure 13, it is impossible to observe significant differences in the adoption rate of smart home technology, interest as well as expectation in elderly-oriented smart furniture between different genders, although male participants seem to have slightly more difficulty in using technology products.

Figure 13. Correlation between gender and smart home technology adoption rate

3.2.3 Education level and adoption rate, difficulty, interest, and expectations

As indicated in Figure 14, older adults with higher education level tend to have a better adoption rate of smart home technology as well as higher expectations in elderly-oriented smart furniture. Participants with education level lower than high school seem to have more difficulty in using technology products. Meanwhile, participants' interest in using elderly-oriented smart furniture peaks among those with a junior college degree.

Figure 14. Correlation between education level and adoption rate, difficulty, interest, and expectations

4 Discussion

In this section, the limitations and implications of this survey are discussed. Furthermore, a three-year action plan for a project to implement smart furniture

technology in China is proposed.

4.1 Limitations of the survey

Like other surveys, this survey has certain limitations, although the overall conclusions are not affected. The main limitations are discussed as follows.

- The survey was conducted mainly in 26 out of 34 provincial-level administrative divisions in China. Several provinces were not covered by the survey. Furthermore, the number of older adults surveyed in each province was not proportional to the population of that province.
- The female to male ratio of the survey participants was around 6:4. According to the United Nations, as of 2019 the life expectancy of Chinese citizens was 76.9. However, the life expectancy of female citizens was 79.2, and that of male was 74.8, which led to a considerable gender gap of 4.4 years of age [10]. This phenomenon likely contributed to the gender imbalance of the survey participants.
- The vast majority of respondents answered the questionnaire via the WeChat app on smartphones. Older adults who were not able to use smartphones were likely under surveyed. In order to better reflect the opinions of older adults who do not use a smartphone, more on-site surveying after the COVID-19 pandemic will be preferred.

4.2 Implications and future work

Overall, there is a substantial amount of interest and optimism towards elderly-oriented smart furniture among Chinese older adults. Although living in retirement homes and nursing homes has started to gain popularity, the initial focused application scenario for developing smart furniture in China shall be home and community due to cultural considerations. In the process of developing localized elderly-oriented smart furniture products for China, aspects such as safety, ease of use, quality, privacy protection, and affordability shall be prioritized. The digital literacy among Chinese older adults is satisfactory but there is a clear digital gap among older adults aged 80 or over and with lower education level. As a result, it is important to close the digital gap especially for those over 80 years old and with lower education level by using measures such as improving safety, increasing ease of use, improving quality, ensuring privacy protection, and bringing down the costs. Furthermore, the method of this survey is highly adaptable and scalable, and thus can be easily adopted by researchers to other regions.

In conclusion, due to the promising survey results and other factors such as accelerated population aging process, growing middle class [8], unique culture of filial

piety [11], impact of the three-decade long “one-child policy” [12], decent digital literacy among older adults [13], state policy support [14], and catalyst of the COVID-19 pandemic, the smart furniture-based distributed intelligent home for aging society has the potential to thrive in China within the next few years.

The knowledge gained in the survey indicates that it is both necessary and promising to conduct further projects to implement elderly-oriented distributed intelligent home in China. Currently, several large Chinese furniture manufacturers showed interest and one already agreed to cooperate with the research team to promote the localization of the proposed technologies, which further proved the conclusion of the survey. Figure 15 shows the two-phase project action plan based on the Deming Cycle for developing localized elderly-oriented smart furniture technology in China. The results of the follow-up projects will be revealed in future publications.

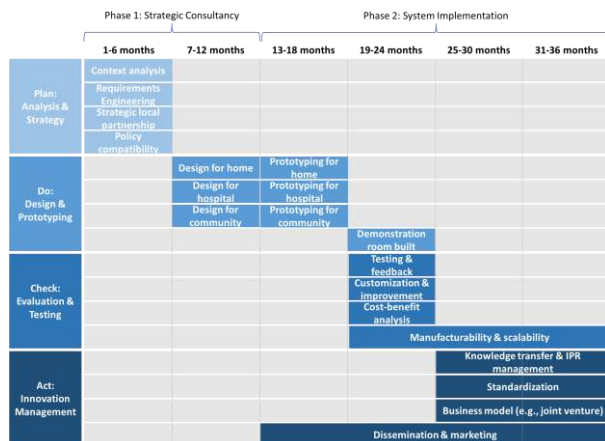

Figure 15. Three-year project action plan for developing localized smart furniture in China

Vision-based Excavator Activity Analysis and Safety Monitoring System

Sibo Zhang¹ and Liangjun Zhang¹

¹ Baidu Research, USA

sibozhang1@gmail.com, liangjunzhang@baidu.com

Abstract -

In this paper, we propose an excavator activity analysis and safety monitoring system, leveraging recent advancements in deep learning and computer vision. Our proposed system detects the surrounding environment and the excavators while estimating the poses and actions of the excavators. Compared to previous systems, our method achieves higher accuracy in object detection, pose estimation, and action recognition tasks. In addition, we build an excavator dataset using the Autonomous Excavator System (AES) on the waste disposal recycle scene to demonstrate the effectiveness of our system. We also evaluate our method on a benchmark construction dataset. The experimental results show that the proposed action recognition approach outperforms the state-of-the-art approaches on top-1 accuracy by about 5.18%.

Keywords -

Computer Vision; Deep Learning; Object Detection; Pose Estimation; Action Recognition; Safety Monitor; Activity Analysis

1 Introduction

Operating excavators in a real-world environment can be challenging due to extreme conditions, such as multiple fatalities and injuries occur each year during excavations. Safety is one of the main requirements on construction sites. With the advance of deep learning and computer vision technology, Autonomous Excavator System (AES) has made solid progress [1]. In AES system, the excavator is assigned to load the waste disposal material into a designated area. While the system is capable of operating a whole 24-hour day without any human intervention, in this paper, we mainly address the issue of safety, where the excavator could potentially collide with the environment or other construction machines. We propose a camera-based safety monitoring system that detects the excavator poses, the surrounding environment, and other construction machines, and warns of any potential collisions. In addition, based on action recognition algorithm on human activity, we successfully extend the algorithm to excavator actions and use it to develop an excavator productivity analysis system to analyze activities of the excavator. We note that although developed for AES, this system can also be generally applied to manned excavators.

To build an excavator safety monitor system, we first need to build a perception system for the surrounding

environment. The perception system includes detection, pose estimation, and activity recognition of construction machines. Detecting the excavator pose in real-time is a key requirement to inform the workers and to enable autonomous operation. Vision-based (marker-less, marker-based) and sensor-based (IMU, UWB) are two of the main methods for estimating robot pose. The marker-based and sensor-based methods require some additional pre-installed sensors or markers, whereas the marker-less method only requires an on-site camera system, which is common on modern construction sites. Therefore, we adopt a marker-less approach and develop the system solely from camera video input, leveraging state-of-the-art deep learning methods.

In this paper, we propose a deep learning-based excavator activity analysis and safety monitor system which can detect the surrounding environment, estimate poses, and recognize actions of excavators. The main contributions of this paper are summarized as follows:

- 1) We collect an excavator dataset from our Autonomous Excavator System (AES) in Waste Disposal Recycle scene with ground truth annotations.
- 2) We develop a deep learning-based perception system for multi-class object detection, pose estimation, and action recognition of construction machinery on construction sites. Then we showed our network get SOTA results on the AES dataset and a benchmark construction dataset.
- 3) We propose a novel excavator safety monitor and productivity analysis system based on the aforementioned perception system.

2 Related Works

Previous studies related to safety and productivity analysis are reviewed here. We start with some of the most basic tasks in computer vision that are essential to activity analysis and safety monitoring system, including object detection, image segmentation, pose estimation and action recognition. Then, we review vision-based activity analysis and safety monitoring system.

Object Detection. The first category is object detection. More recently, Wang et al. [2] used a region-based CNN framework named Faster R-CNN [3] to detect work-

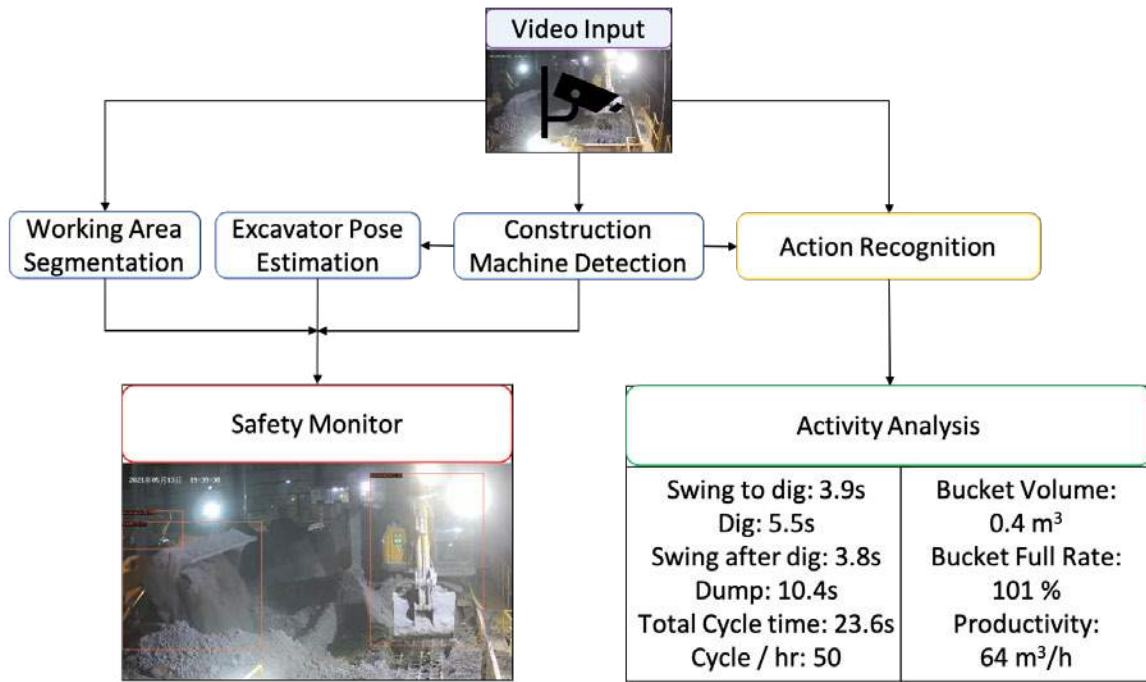

Figure 1. Autonomous Excavator System (AES) activity analysis and safety monitoring system pipeline.

ers standing on scaffolds. A deep CNN then classified whether workers are wearing safety belts. Those without safety belts appropriately harnessed were identified to prevent any fall from height.

Image Segmentation. Raoofi et al. [4] used Mask R-CNN to detect construction machinery on Job sites. More importantly, a segmentation network like Mask R-CNN can be used to decide areas like digging and dumping.

Pose Estimation. The second group of technology is skeleton pose estimation. Pose estimation has been studied [5] based on human pose estimation network like OpenPose. Soltani et al. [6] proposed skeleton parts estimation of excavators.

Action Recognition. Learning-based action recognition methods. Feichtenhofer et al. [7] proposed a SlowFast network for video recognition. The model involves a low pathway that operating at a low frame rate, to capture spatial semantics, and a Fast pathway that operating at a high frame rate, to capture motion at fine temporal resolution. Bertasius et al. [8] presented a convolution-free approach to video classification built exclusively on self-attention over space and time.

Activity Analysis and Safety Monitoring. Here we review recent vision based activity analysis and safety monitoring methods in the construction area. For example, Ding et al. [9] combined CNN with Long-Short-Term-Memory (LSTM) to identify unsafe actions of workers, such as climbing ladders with hand-carry objects, backward-facing, or reaching far. While safety hazards

of workers were effectively identified, their method only captured a single worker, and multi-object analysis was not considered. On the other hand, Soltani et al. [6] used background subtraction to estimate the posture of an excavator by individually detecting each of its three skeleton parts including the excavator dipper, boom, and body. Although knowing the operating state of construction equipment would allow safety monitoring nearby, the influence of the equipment on the surrounding objects was not studied. Chen et al. [10] propose a framework to automatically recognize activities and analyze the productivity of multiple excavators. Wang et al. [2] proposed a methodology to monitor and analyze the interaction between workers and equipment by detecting their locations and trajectories and identifying the danger zones using computer vision and deep learning techniques. However, the excavator state is not considered in their model. Roberts et al. [11] proposed a benchmark dataset. However, their action recognition model accuracy is low compared to our deep learning-based model.

Overall, in terms of activity analysis and safety monitoring with computer vision techniques, previous studies focused on different parts separately, such as identifying the working status of construction equipment or pose estimation of the excavator. Our method combine the advantages of SOTA deep learning models from detection, pose estimation, and action recognition tasks.

3 Proposed Framework

The framework for construction machine activity recognition, safety monitor, and productivity analysis is shown in Fig. 1. The framework contains six main modules: construction machine detection, excavator pose estimation, working area segmentation, activity recognition, safety monitor and productivity analysis. The input to our system is surveillance camera video. First, working areas are being segmented into digging and dumping areas. Then, the detection method is used to identify all construction machines in video frames with equipment type. Second, the excavator is identified through pose estimation and detection-based tracking. Then, the action state of the tracked excavators is recognized with pose estimation and working area segmentation. Finally, construction site safety is monitored based on detection and activity recognition results. Besides, the productivity of the excavator is calculated by the activity recognition results. The details about each module in the framework are provided in the following sub-sections.

3.1 Construction Machine Detection

The detection of construction equipment is realized based on Faster R-CNN [3]. The architecture of Faster R-CNN includes (1) backbone network to extract image features; (2) region proposal generate (RPN) network for generating region of interest (ROI), and (3) classification network for producing class scores and bounding boxes for objects. To remove duplicate bounding box, we applied Soft-NMS [12] to limit max bounding box per object to 1.

3.2 Excavator Pose Estimation

The pose estimation is based on the output bounding box from detection. We use [13] for pose estimation, which backbone is ResNet. We design a labeling method for the fixed crawler excavator as 10 keypoints. Those keypoints of excavator parts annotated are shown in Fig. 2. These 10 keypoints including 2 bucket end keypoints (bucket end1, bucket end2), bucket joint, arm joint, boom cylinder, boom base, and 4 body keypoints (body1, body2, body3, body4). Unlike other pose label methods [5] to label bucket/ excavator body as the middle point, we label corner point to improve accuracy.

3.3 Working Area Segmentation

We use image segmentation to decide digging and dumping areas as shown in Fig. 3.

The segmentation network is based on ResNet [14]. A digging area is defined as the waste recycling area which including various toxic materials. A dumping area is a designated area to dump waste.

Figure 2. Excavator and corresponding pose labels. We labeled 10 parts of excavators including 2 bucket end keypoints (bucket end1, bucket end2), bucket joint, arm joint, boom cylinder, boom base and 4 body keypoints (body1, body2, body3, body4).

Figure 3. Area segmentation. The pink color area is dumping area and the blue color area is digging area.

3.4 Excavator Action Recognition

We define three actions for excavator: 1. Digging 2. Swinging 3. Dumping. Specifically, we define four states of our autonomous excavator: 1. Digging state 2. Swinging after digging state 3. Dumping state 4. Swinging for digging state. More precisely, Digging indicates loading the excavator bucket with target material; Swinging after digging indicates swinging the excavator bucket to the dumping area; Dumping means unloading the material from the bucket to the dumping area, and Swinging for digging means swinging the bucket to the working area. Besides, there is an optional idle state when the excavator is in manned mode or malfunction status.

To determine the excavator action state, we first determine excavator position based on keypoints from pose estimation and image segmentation results. Then we use continuous frames of pose keypoints of body 1-4 to decide whether the excavator is in the swing state. We set a threshold for keypoints movement: if the mean of pose keypoints of body 1-4 movements is smaller than a set value, then we think the excavator body is still. Otherwise, we think the excavator body is not still. This rule-based module is used in our safety monitor system. Our excavator action states are defined as follows:

1. Digging state: buckets/ arm joint in digging area and body 1-4 is fixed points (excavator body is stilled).
2. Swinging state: buckets/ arm joint in working area and body 1-4 is not fixed points (excavator body is not stilled). Then we can decide whether it is Swing for digging state or Swing after digging state by the previous state. If the previous state is a Dumping state then it will be Swing for digging state. Otherwise, it will be Swing after digging state.
3. Dumping state: buckets/ arm joint in dumping area and body 1-4 is fixed points (excavator body is stilled).
4. Idle state: buckets/ arm joint in dumping area and buckets/ arm joint/ body 1-4 is fixed points (excavator arm and body are both stilled).

Then, we implement a more general deep learning-based action recognition method based on SlowFast [7]. The model involves (i) a Slow pathway, operating at a low frame rate, to capture spatial semantics, and (ii) a Fast pathway, operating at a high frame rate, to capture motion at fine temporal resolution. The Fast pathway can be made very lightweight by reducing its channel capacity, yet can learn useful temporal information for video recognition. This deep learning action recognition model is used in the productivity analysis module.

3.5 Safety Monitor

Detect Potential Construction Machine Collision. The autonomous excavator and the loader may have poten-

Figure 4. The autonomous excavator and loader potential collision scene when loader tries to load in digging area. The danger signal is sent when the autonomous excavator and the loader machines are both detected in the digging area.

tial collision as Fig. 4 shows. So it is important to detect potential collision since the loader is hard to know which state excavator is currently at from his view. If more than one machine is detected within the same region (digging or working area), then an alert may be indicated to the user, and the autonomous vehicles may pause until the issue is cleared.

3.6 Productivity Analysis

The productivity of the excavator is based on the activity recognition results. In the solid waste recycle scene, excavators usually work with other equipment, such as loaders. For example, an excavator digs the waste and dumps it into a dumping area. When waste is empty in the digging area, the loader will load and dump waste in the digging area. The excavator's productivity can be calculated with the cycle time, the bucket payload and the average bucket full rate, as shown in Equation 1. Since the bucket payload is given by the manufacturer, the target of the productivity calculation becomes to determine the cycle time of the excavator and the bucket full rate. To simplify the procedure, the two types of swinging (swinging after digging and swinging for digging) are not distinguished in this paper.

$$Productivity(m^3/hr) = \frac{Cycles}{hr} \times BucketVolume(m^3) \times BucketFullRate \quad (1)$$

The time for each cycle is measured by the workflow showing in Fig. 5. Our action recognition module labels each video frame of the excavator with an action label. Next, the action labels of two consecutive frames are com-

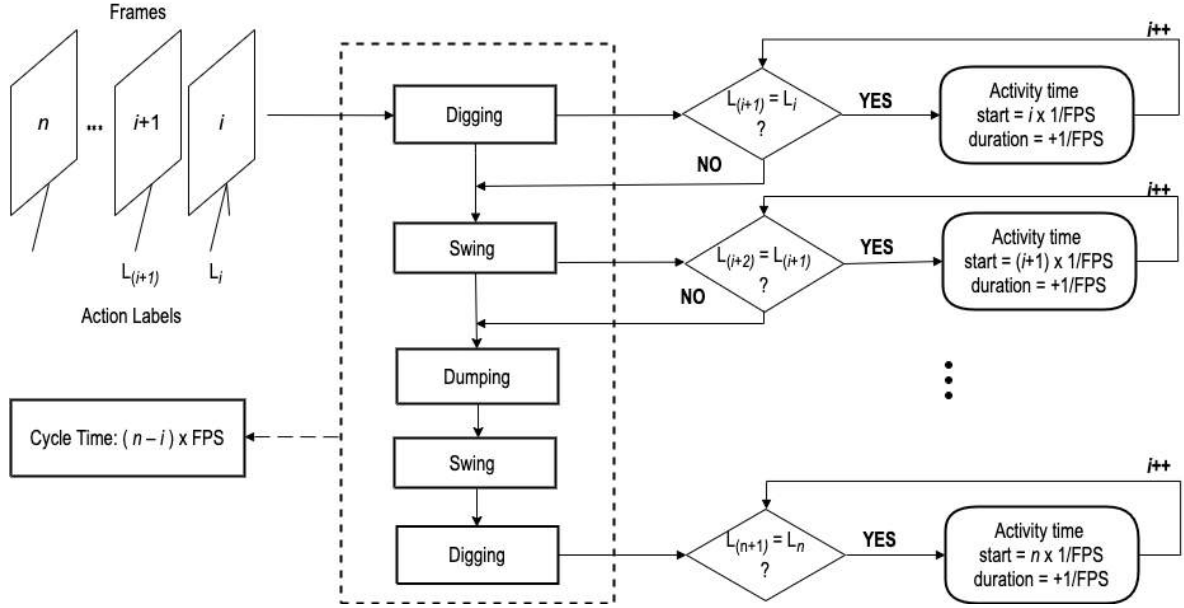

Figure 5. Excavator cycle time calculation method.

pared. If they are the same, it means that the action remains same. Thus, the cumulative time for the current action is increased by 1/FPS (frame per second). If the labels are different, it means that a new action has started, and the time of the newly recognized activity will increase by 1/FPS. We define the total time of one cycle as the difference between the start times of two neighboring digging actions.

4 Experiments

4.1 Dataset

We collect an excavator dataset from our Autonomous Excavator System (AES) from the waste disposal recycle scene [1]. The dataset including 1 hour of videos containing 2 types of construction equipment (i.e. excavators, loaders). To demonstrate the effectiveness of our dataset, we labeled 601 images with object detection bounding boxes, excavator poses, and background segmentation. 80% of the images are used for model training while 20% are for model validation and testing. Besides, we labeled 102 clips of excavator videos with 3 actions (digging, dumping, swinging). The videos were captured at 1920*1080 and filmed at 25 frames per second.

We also test our method based on the benchmark construction dataset [11] which including 479 action videos of interacting pairs of excavators and dump trucks performing earth-moving operations, accompanied with annotations for object detection, object tracking, and actions. The videos were captured at 480*720 and filmed at 25 frames

per second.

4.2 Evaluation

4.2.1 Object Detection Evaluation

The detection evaluation metrics are based on the Microsoft COCO dataset [15]. The network's performance is evaluated using Average precision (AP). Precision measures how many of the predictions that the model made were correct and recall measures how well the model finds all the positives. For a specific value of Intersection over Union (IoU), the AP measures the precision/recall curve at recall values (r1, r2, etc.) when the maximum precision value drops. The AP is then computed as the area under the curve by numerical integration. The mean average precision is the average of AP in each object class. More precisely, AP is defined as:

$$AP = \frac{1}{11} \sum_{r \in \{0.0, 0.1, \dots, 1\}} AP_r, \quad (2)$$

4.2.2 Pose Estimation Evaluation

The pose estimation matrix is based on The COCO evaluation, which defines the object keypoint similarity (OKS). It uses the mean average precision (AP) over the number of classes for OKS thresholds as main competition metric. The OKS is calculated from the distance between predicted points and ground truth points of the construction machine.

Figure 6. Excavators and loader detection result. Our system is capable detecting multi-class construction machines in real-time.

Table 1. Accuracy of construction machine detection

Network	Backbone	mAP (%)
Faster R-CNN	Resnet-50-FPN	90.1
Faster R-CNN	Resnet-152-FPN	92.3
YOLOv3	DarkNet-53	73.2

4.2.3 Action Recognition Evaluation

The performance metric is the mean Average Precision (mAP) over each object class, using a frame-level IoU threshold of 0.5.

4.3 Accuracy

4.3.1 Accuracy of the detection model

We implement experiments on the Faster R-CNN model with a backbone network of Resnet-50-FPN and Resnet-152-FPN. The model achieved high detection accuracy for construction equipment. The Average Precision (AP) values of the excavator achieved 93.0% and the loader achieved 85.2%. With an mAP of 90.1%, the model is demonstrated to be promising for detecting multi-class construction equipment accurately on the construction site.

We also compared the result with Yolo V3 [16]. YOLOv3 is a one-stage state-of-art detector with extremely fast speed. In this study, the image input size is 416x416 and this algorithm can process 20 images in one second. Compared with some two-stage detectors, the performance of YOLOv3 is slightly low, but the speed is much faster and that is important for real-time applications. The construction detection dataset from the previous step is used for training YOLOv3, which takes 12 hours for the training process. The mAP of YOLOv3 on our testing set is 73.2% from an overall view, where the AP is 80.2% in the excavator category and 60.2% in the loader category. The detailed comparison result is shown in Table 1. The

Figure 7. Excavator pose estimation result.

Table 2. Accuracy of the pose estimation model.

Network	Backbone	Input size	AP (%)
SimpleBaseline	Resnet-50	256*192	91.79
SimpleBaseline	Resnet-50	384*288	94.19
SimpleBaseline	Resnet-152	384*288	96.50

result is shown in Fig. 6.

4.3.2 Accuracy of the Pose Estimation

We apply SimpleBaseline [13] to our pose estimation model and get the following result. Experiments have been conducted on different Backbone networks including Resnet-50 and Resnet-152. Besides, experiments on different image input sizes have been implemented. The detailed comparison result is shown in Table 2. The result is shown in Fig. 7.

4.3.3 Accuracy of the Action Recognition

We applied Slow-Fast [7] to our action recognition model and get the following result. Experiments have been conducted on the different networks including SlowFast-101 and SlowFast-152. Besides, experiments on different

Figure 8. Excavators long video action detection result.

Figure 9. Long video demos of action recognition result on different scenes of the construction dataset. Prediction with the highest possibility is showing in the first line.

Table 3. Accuracy of the action recognition model on our AES dataset and UIUC dataset from [11].

Dataset	Network	Backbone	Top1 Acc. (%)
AES	SlowFast-50	ResNet3d	89.70
	SlowFast-152	ResNet3d	91.44
UIUC	Roberts[11]	N/A	86.8
	SlowFast-50	ResNet3d	91.9
	SlowFast-152	ResNet3d	93.3

clip lengths have been implemented. The detailed comparison result is shown in Table 3. The result of top 3 action prediction is showing in the Fig. 8. We input a excavator video and the system can predict action result in almost real-time. Prediction with the highest possibility is showing in the first line. Here the system predict the action as digging with 54% confidence.

Comparing our result with Roberts [11] on their UIUC dataset, our proposed action recognition approach outperforms their accuracy by about 5.18%. The action recognition video demo result of the construction dataset is showing in Fig. 9. The result shows the advantage of using deep learning model on action recognition task over their Hidden Markov Model (HMM) + Gaussian Mixture Model (GMM) + Support Vector Machine (SVM) method.

4.4 Productivity Analysis

The proposed framework was tested to estimate the productivity of excavators on a long video sequence, which contains 15 min of excavator's operation. In our video, the XCMG 7.5-ton compact excavator (bucket volume of $0.4 m^3$) completed 40 working cycles in 15 minutes and

the average bucket full rate is 101%. So the excavation productivity is $64.64 m^3/h$ according to Equation 1. Our system detects 39 working cycles in the video which the accuracy of productivity calculation is 97.5%. The test results showed the feasibility of using our pipeline to analyze real construction projects and to monitor the operation of excavators.

4.5 Implementation Details

We implement our detection module based on MMDetection, segmentation module based on MMSegmentation, pose estimation module based on MMPose, and action recognition module based on MMAction2 toolbox [17, 18, 19, 20]. We use NVIDIA M40 24GB GPUs to train and test the network.

It takes 6 hours to train detection, pose estimation, and action recognition module. The inference time of detection, pose estimation, and action recognition are 5, 2, and 1 frames per second.

5 Conclusion

In this study, we collect a benchmark dataset from Autonomous Excavator System (AES). Besides, we proposed a safety monitor and productivity system pipeline based on computer vision and deep learning techniques. We integrate detection, pose estimation, activity recognition modules into our system. We also evaluate our method on a general construction dataset and achieve SOTA results. However, our current system may have some limitations. Our dataset is relatively small due to the relatively simple waste disposal recycle scene captured from AES system.

Abstract -

With the growth in automated data collection of construction projects, the need for semantic navigation of mobile robots is increasing. In this paper, we propose an infrastructure to leverage building-related information for smarter, safer and more precise robot navigation during construction phase. Our use of Building Information Models (BIM) in robot navigation is twofold: (1) the intuitive semantic information enables non-experts to deploy robots and (2) the semantic data exposed to the navigation system allows optimal path planing (not necessarily the shortest one). Our Building Information Robotic System (BIRS) uses Industry Foundation Classes (IFC) as the interoperable data format between BIM and the Robotic Operating System (ROS). BIRS generates topological and metric maps from BIM for ROS usage. An optimal path planer, integrating critical components for construction assessment is proposed using a cascade strategy (global versus local). The results are validated through series of experiments in construction sites.

Keywords -

BIM/IFC, Semantic Navigation, Autonomous Robot, Path Planning

1 Introduction

Conventional methods of data collection for the purpose of progress monitoring rely on periodic observations, manual data collection (which is mostly textual data and a limited number of photos), and personal interpretation of the project progress [1]. These aforementioned conventions are error-prone, time-consuming and cost-ineffective since they are subjective processes [2]. Manual data acquisition by individuals would result in decentralized data; coming from different sources in different formats, thereby making it somewhat challenging to manage and analyze them. Automation of monotonous and repetitive construction processes would significantly enhance construction efficiency [3]. Hence, there is a growing need in the construction industry to automate data collection task. In addition, the applications of data collection using an Unmanned Ground Vehicle (UGV) can provide new kinds of

information and applications such as equipment tracking and 3D reconstruction which would ultimately have positive impacts on quality control, safety and sustainability of the construction projects.

With tremendous progress in mobile robots capabilities, the interest in adopting mobile robots for data collection on construction sites is increasing. Rugged platforms with high manoeuvrability are commercialized for this usage [4] and several works are enhancing their autonomy for navigating these challenging environments [5]. A handful of fundamental steps still need to be addressed for the deployment of robots on construction sites, such as their usage by non-experts (untrained) operators and the automatic integration of the diverse requirements related to construction management in their mission planing. Our solution leverages BIM semantics extracted in an interoperable data schema, IFC, and translated for robot indoor navigation. This semantic information, intertwined with the robot navigation and mission, help the operator manage the robotic system as they share conceptual knowledge of their environment.

This paper proposes a novel method for semantic robot navigation with an optimal path planning algorithm using building knowledge on construction sites. The optimal path is extracted from user inputs using BIM/IFC which provide digital representation of the construction project [6]. The resulting path (which is not necessarily the shortest path) can be altered with the weights of several criteria such as robot and workers safety, BIM new information requirement and sensors sensitivity to environmental features. In this step, the building semantics play an essential role on defining the start, the end and the transitional coordinates with which the robotic system plans the path. Furthermore, all along the mission, the local paths are computed based on the relevant complementary information for the low-level navigation extracted from IFC. This is essential to cope with limitations of the robot. For instance, a path planer should avoid trajectory near glass walls: they are hard to detect by many sensors. Luckily, information about wall materials can be retrieved from BIM. Among the conventional methods on path planning

[7], we use topological map representation in order to store the building semantics in nodes and graphs. The current paper contributions are as follows:

- An optimal high-level path planner integrated with the low-level navigation (cascade navigation stack);
- Semantic teleoperation and navigation for autonomous UGV during the construction process;
- Practical implementation of the proposed system deployed on an autonomous mobile robot navigating a construction site.

2 Related Work

Conventional methods of indoor path planning often refer to optimal path as the shortest path calculated by various algorithms such as A* and Dijkstra's [8]. To enhance the performance of these planners, many studies suggested ways to leverage BIM/IFC for indoor path planning. Wang et al. [9] develop a framework for converting the BIM digital environment to a cell-based infrastructure to support indoor path planning. In this work, they emphasize on the "*BIM voxelization*" process rather than the path planning problem. In another study, a BIM-based path planning strategy is used for equipment travel on construction sites [10]. The authors extract the start and end points from BIM and then generate the shortest sequence of rooms for the operator, but does not support robot path planning. Ibrahim et al. [11] propose a path planning strategy based on BIM for an Unmanned Aerial Vehicle (UAV) on construction sites which uses a camera for data capturing. They use BIM geometries to define a path for outdoor environments but do not address indoor semantic robot path planning. In this direction, Follini et al. [12] utilize BIM geometries for path planning of an UGV supporting construction logistics application. Their proposed system uses a human-assisted approach in a controlled environment and is yet to thoroughly leverage BIM/IFC semantics in a construction site. In [13], the optimal route for a data collection mission using an UAV is proposed. They utilize 4D BIM to identify which building spaces are expected to change during the construction phase (implemented in a simulated environment) so that the flight path navigate through those areas and collect data.

Delbrügger et al. [14] developed a framework supporting humans and autonomous robots navigation which mostly uses building geometries in a simulated environment. In [15], the indoor localization of an UAV is assessed using AprilTags with their known location in a BIM-generated map. They present this work as a proof-of-concept for the use of AprilTags in indoor environment. However, due to inaccuracy of localization in their work, they improve their previous work by using Extended

Kalman Filter (EKF) in their localization framework [16]. Another study examined the use of BIM in robot localization in which the proposed system uses a hierarchical reasoning for path planning [17]. BIM was also demonstrated to be powerful for the identification of different paths from which a hierarchical refinement process can find the shortest path [18]. That work provides only high-level path (rooms sequence) with respect to BIM geometries and the integration with ROS is not studied. An approach using hypergraphs generated from IFC files was also developed in which a modified A* algorithm is able to detect the optimal path among nodes in the graph [8].

In these inspiring works three aspects of the BIM potential for indoor robot path planning are yet to be thoroughly studied: (1) considering the full potential of the BIM/IFC semantic rather than only the geometry (2) integrating the high-level (rooms sequence) with the low-level sensor-based information in a full navigation stack (3) the field validation of strategy using BIM/IFC for both global and local path planning. In this paper, we cover these gaps by integrating Building Information Robotic System (BIRS) into a navigation system in ROS in order to determine the optimal path and then navigate autonomously.

3 Topological building maps created from BIM/IFC

IFC data schema provides construction stakeholders with semantic information of buildings containing attributes and relationships between different entities [19]. This information can be extracted in graph database [20]. However, the use of that information for reasoning is complex since the IFC files encompass large amounts of data. In order to cope with this, we first identify the required data for robot navigation on construction sites, then, we extract and store the data in an XML database. The conceptual semantic relation between BIM/IFC and robot navigation is covered in a previous paper on BIRS [21]. We extend the hypergraphs of Palacz et al. [8] with the semantic and geometric information of IFC files. All the semantic information required to the global and local planners retrieved from IFC is in the form of a topological map.

As IEEE 1873-2015 [22] defines, nodes and edges are the components of topological maps and we fill them with the following information:

- Nodes contain the rooms information namely: room's name, room's unique ID, room center, room area, walls' unique IDs, wall material, last scan date, construction activity (hazard for the robot)
- Edges contain the doors information namely: door's unique ID, door's location, doors opening direction

In the hypergraph, one node is created per *IfcSpace* and

Figure 1. A directed hypergraph of $S = (V, E)$ where $V = \{V_1, V_2, \dots, V_n\}$ is a set of nodes and $E = \{E_1, E_2, \dots, E_m\}$ is a set of hyperedges. Each node (V_i) is an *IfcSpace* containing its relationships and each hyperedge (E_j) is an *IfcDoor* with its attributes extracted by BIRS [21].

for each *IfcSpace*, the bounding *IfcWall* and *IfcCurtain-Wall* elements are identified. With the above-mentioned information, a graph is generated as illustrated in fig. 1. Then, the edges need to be attributed with the cost (weight) of passing over each (from a room to another). In this direction, $W = (W_V, W_E)$ is a pair of weights where W_V and W_E are the node and hyperedge weights respectively. W_{V_i} is the i node total weight obtained from:

$$W_V = w_m + w_a + w_s + w_h \quad (1)$$

where w_m depends on the walls material, w_a , on the room area, w_s , on the room scan-age, and w_h , on the room hazards. W_{E_j} is the j hyperedge weight obtained from:

$$W_E = w_d \quad (2)$$

where w_d depends on the door opening direction. For passing from one node to the other, there might be several paths the robot can use. The overall weight of a path (from start to end node) is as follows:

$$W = \sum_{i=1}^n W_{V_i} + \sum_{j=1}^m W_{E_j} \quad (3)$$

One challenge for the robot is to be able to detect obstacles. To help the robot predict and avoid potential failures, the material properties of the walls are extracted through *IfcMaterial* and its super-type *IfcProduct*. The weight of each curtain wall, i.e. walls that are *invisible* by design, in each node is $w_m = 12$, while all others are $w_m = 4$ since they can be easily detected. The time required to go through a transition node is also taken into account, i.e. bigger rooms take more time for the robot to cross. Accordingly, the weight for the rooms less than $50m^2$, between $50m^2$ to $100m^2$ and more than $100m^2$ are $w_a = 2$, $w_a = 8$ and $w_a = 12$ respectively. Since one of the core purpose of deploying robots on construction sites is to collect data, the scanning age of all rooms is incorporated. The progress monitoring needs up-to-date data and when the robot is collecting data it can optimise its path to visit more rooms

and collect more data. The scanning periods are selected according to industry needs, therefore, we assign $w_s = 10$, $w_s = 6$, $w_s = 0$ for the scanning period of less than 1 week, between 1 week and 2 weeks, and more than 2 weeks respectively. Since the construction projects evolve constantly, the safety aspects of robot navigation are essential. In this direction, the data collection for the spaces with ongoing construction activities should be postponed to a safer moment for the robot to navigate those rooms. If the hazardous space is one of the transition nodes, an alternative route needs to be automatically planned so we assign $w_h = 500$ for the weight of passing through such spaces. In this case, another path will be selected by the algorithm if there is any. If there is not an alternative safe path for the robot, the algorithms provides a warning for high-weight paths so that the supervisor of the robotic deployment is warned. The hypergraph representing building topological map enables the robotic system to find the optimal path by running an algorithm. In this paper, we use directed hypergraph (with directed hyperedges) allowing us to assign cost for door opening directions. *IfcDoor* as a sub-class of *IfcBuildingElement* provides the center coordinates of the doors creating hyperedges (with their coordinates) in the hypergraph. *IfcDoor* also stores the opening direction through y-axis of *ObjectPlacement* parameter. For pushing and pulling the door, we assign $w_d = 2$ and $w_d = 6$ to the hyperedge's weight respectively. This is due to difficulty for pushing and pulling the doors respectively. Ultimately, the total weight of passing one to the other is the sum of nodes weights and edges.

4 Finding The Optimal Indoor Path

As Gallo et al. [23] define, directed hypergraphs are divided into two categories according to their hyperedges namely: forward hypergraph (F-hypergraph) and backward hypergraph (B-hypergraph). The former is a directed hypergraph in which one node diverges to several nodes and the latter is the one in which several nodes converge to one node. As an example of applications, F-hypergraphs are employed for time analysis on transportation networks [24]. Also, B-hypergraphs are used to perform deductive analysis to find the optimal path in a hypergraph. The combination of B-hypergraph and F-hypergraph is a BF-hypergraph having both divergent and convergent nodes [23]. In topological building layouts, we deal with BF-hypergraphs since we have spaces which connect several spaces to other spaces (an example of such nodes is corridors). In addition, we intend to find the optimal path (a "*deductive database analysis*" from several possible paths) based on several criteria which are represented as weights in the hypergraph, therefore, we use the "*Shortest Sum B-Tree*" algorithm which finds a hypertree (subhypergraph) of the nodes as explained in [23]. We also use *additive*

```

Inputs:
  layout_graph : hypergraph
  tail_room, head_room : node
  door : hyperedge
  path_weight : hyperedge_total_weight
Outputs:
  semantic_path : list<node, hyperedge>
  x_y_path : list<nodes_coordinates,
  hyperedges_coordinates>
  hyperedge_total_weight : number

```

Figure 2. Data structure for IFC-based semantic optimal path planner algorithm

weighting function to calculate the cumulative weight of each possible route and then we choose the lighter route which is the optimal path for the robot.

In order to create the hypergraph, we first retrieve all the relevant IFC information. The process is done with a Dynamo script (a visual programming tool) to extract the IFC parameters in order to export the IFC information in a XML database. A Python script is developed to parse the XML data in order to translate meaningful data to ROS (for example, the rooms center coordinates are retrieved as strings so they need to be parsed to be integrated with the robotic system). With an hypergraph of the whole building, the user defines the start and end nodes (rooms), and let the algorithm find the optimal path. Since we are implementing BF-hypergraph, each pair of nodes is connected with two directed hyperedges together, thereby making a comprehensive B-hypergraph within the BF-hypergraph. This practice allows considering forward and backward direction in a path so that the door opening direction is considered. "*Shortest Sum B-Tree*" algorithm provides the possible hyperedges from a start node to other nodes [23]. Then, the retrieved information is used to create a sub-hypergraph from the start node to all other nodes representing all the possible paths. By giving the destination node to the sub-hypergraph, the possible paths from start to end node are identified and finally the lowest cumulative weight of the paths is retrieved. Having a set of nodes and hyperedges from the optimal path, the building information is extracted to enable semantic navigation. Each node is represented by the name of the corresponding space and the center coordinates of that room. As illustrated in fig. 2, the optimal path outputs a set room names, their coordinates and a set of door coordinates in the sequence of node location and hyperedge (door) location. The room names enable semantic navigation and the 2-D coordinates provides destinations one after the other.

5 Semantic Graphical User Interface

A Graphical User Interface (GUI) was developed based on BIM semantics to allow users to intuitively operate the robot and configure the path planner. The GUI connects to the ROS running in the robot and presents semantic information of the building and data from the robot in real time. The integrated high-level and low-level navigation system moves the robot to the destination. The GUI allows the non-expert users to work with their domain knowledge, thereby making robot deployment more intuitive and simpler. Figure 3 illustrates the interface window. The GUI is developed in Python notebooks, allowing for easy integration of visualization widgets and customization.

The GUI provides the building's rooms in a drop-down list, from which the user selects a destination and then launch the path planner to find the optimal path. The center area of the GUI shows a map of the building, with the robot's pose being updated in real time, along with the paths objectives. The left panel shows the selected room's (end node) attributes. The right panel allows the user to alter the weights of each parameters of the path planner. After changing and saving the new weights, the user can generate the path again and see the results on the map. Finally, the user can click on the *Move Robot* button to trigger the robot to start moving.

6 Field deployment

Our approach was validated from simulation to the field with an experimental case study. The goal was to drive a mobile robot through the corridors of one of the buildings at the École de technologie supérieure, for which an as-planned BIM was available, and collect data. The semantic path planner was used to generate a set of waypoints from the user inputs, then a low level A* path planner aided by a collision detection stack navigates the robot.

Our robotic platform, shown in fig. 4, is built from a four-wheeled UGV (Clearpath Jackal) equipped with wheel encoders, an internal IMU and an onboard NVidia Xavier computer. The Jackal is delivered with ROS nodes for control, odometry estimation (from encoders and IMU) as well as diagnostics tools provided by ROS.

The sensing system, which was envisioned for point cloud collection in construction sites, contains two Li-DARs, five depth cameras and one tracking camera. The sensors are positioned in different directions to cover as much as possible of the robot's surroundings. While all sensors collect and record data of the environment, most of them are also used by the navigation stack for localization and collision avoidance. Below we present a detailed description of each sensor or group of sensors:

- **Front facing cameras:** One Intel Realsense D435i depth camera and one Intel Realsense T265 tracking

Figure 3. Semantic GUI for the intuitive operation of the robot navigation on construction sites. The controls in the header allow selecting a destination and generating the path. The panel to the left shows the attributes of the selected room. The center contains a map of the environment, with the robot's pose in real time represented by the purple arrow. The center points of the rooms and doors in the path are represented in the map by the yellow circles. The right panel allows the user to reconfigure the different weights applied to the path generation.

Figure 4. Mobile robot platform equipped with various sensors

camera are mounted in front of the robot. The T265 software estimates the camera's pose and integrates data from the base odometry (wheel encoders and IMU), providing accurate odometry that is fed to the localization algorithm. The D435i provides depth images that are used to detect obstacles immediately in front of the robot, triggering an emergency stop;

- **Velodyne Puck 32MR LiDAR:** Mounted horizontally on top of the robot, it captures laser scan data from all around the robot. This information is used by the localization algorithm to estimate the robot's global position on the building map;
- **Depth cameras:** Three Intel Realsense D435i depth cameras are mounted pointing to the top and left and right sides of the robot. Their purpose is to collect RGB images and depth images from the walls around the robot and from the ceiling;
- **Ouster OS1 LiDAR:** The last sensor, an Ouster OS1 LiDAR is mounted in the back of the robot, inclined

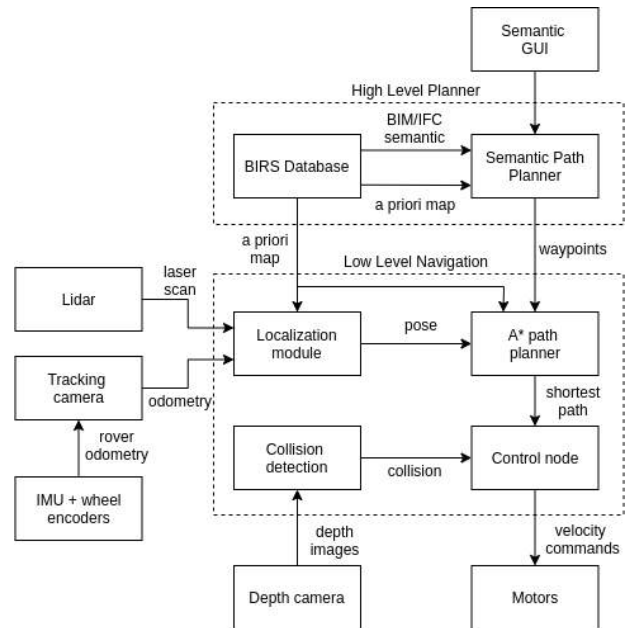

Figure 5. System Overview: A high level planner that process BIM/IFC information and user inputs is integrated to a low level navigation stack in a cascade design. The low-level module takes care of the localization, local path planning and collision avoidance tasks, while the high-level planner generates paths based on BIM/IFC semantics.

by an angle of 45 degrees in order to capture point clouds of the ceiling. Since this sensor has a large 90° field of view, it is also able to cover the walls and part of the back of the robot.

Figure 5 gives an overview of the system. The robot pose in the map is obtained through the use of a ROS

Figure 6. View of the simulated environment used to test the BIM/IFC optimal path planning approach. The building 3D model was built with geometry information extracted from the BIM. The robot model simulates the sensors and possesses the same characteristics as the real robot.

implementation of the Adaptive Monte Carlo localization algorithm[25][26]. Before deploying the robot, wall geometry is extracted from BIM to generate an occupancy grid of the building. During the robot navigation, this map, the odometry, and the laser scan data from the horizontally mounted Velodyne LiDAR are fed to the localization algorithm, which then estimates the robot's current pose in that map. When a destination room is selected, the semantic path planner outputs the preferred path to that room as a list of waypoints, containing the center points of each room, door and corridor in the path. An A* path planner[27] then calculates the shortest path from the robot's current position to the next waypoint in the list. Velocity commands are generated from the A* path and sent to the robot's internal controller to drive it through that path.

The simulation was performed using the Gazebo Simulator. The building information is exported to create a 3D model, a digital twin. Clearpath, Gazebo and the ROS community provide all the required software packages required to generate an accurate simulation of our robotic platform. Figure 6 shows the simulated robot and its environment with different wall textures and transparency.

7 Results

The experiment had two main objectives:

1. Test the effectiveness of the semantic path planner in generating the optimal path to reach the destination, given the building information obtained from BIM/IFC.
2. Test how changes in the building information affect the final path that is generated.

In our case study, the robot starts in a corridor (CORRIDOR OUEST) on the west side of the building and must reach an open area (CORRIDIR EST) on the eastern part

of the building. Figure 7 shows the building map, and the path in red line generated by applying the A* algorithm from start to end. This is the shortest possible path between the two points, taking into consideration only the building geometry and a small safety collision radius around the robot. When the Semantic Path Planner is applied to the same scenario, a similar result is obtained as expected, represented by the blue path in fig. 7. Since there are no doors, undesirable materials or hazards in the path, the algorithm outputs a list of rooms that must be visited by the robot that represent the shortest distance from start to end. The semantic path planner provided the order of rooms' names from the start to the end as it shows in the GUI in fig. 3. Therefore, the user operating the robot can intuitively track the path from the data collected. In this direction, the as-built data can be directly compared to the as-planned since the path is recorded semantically. Also, the waypoints of rooms' center coordinates and doors' center coordinates are provided by the semantic path planner. If there is a door made of materials invisible to sensors (such as glass), the complementary door coordinates helps for safer, smarter, precise data collection. Following this, the A* algorithm finds the shortest path between the waypoints.

In a second run, the building information was altered to include a construction operation carried out in the area highlighted with a dashed box in fig. 7 (not visible in the GUI). Since the construction activity represents a hazard with a high cost for the Semantic Path Planner, a different path passing through another corridor is automatically selected, as illustrated by the orange path. Nevertheless, the high cost of the shortest path triggered a warning in the system indicating a hazard to the user through the semantic GUI. Therefore, the user can understand the risks associated with navigation through an active construction area and decide whether to scan the environment or postpone it to a safer time. The orange path was automatically generated, although it is not the shortest path, as the optimal path from the default parameters mentioned in section 4. This path passes along a large curtain wall invisible to the robot's sensors. The additional semantic information provided by the BIRS is given to the robot as well as the BIM occupancy grid so it contributes to collision avoidance with the wall. The GUI provides the user with the scan aging of the rooms so the user can decide which rooms to select as the destination for data collection. This allows the users to run multiple data collection mission with the robot which increases the efficiency of robot deployment on construction sites. As illustrated in fig. 7, the integrated BIM-ROS information provides a cascade navigation system on construction sites enabling autonomous and accurate data collection of the spaces scanned.

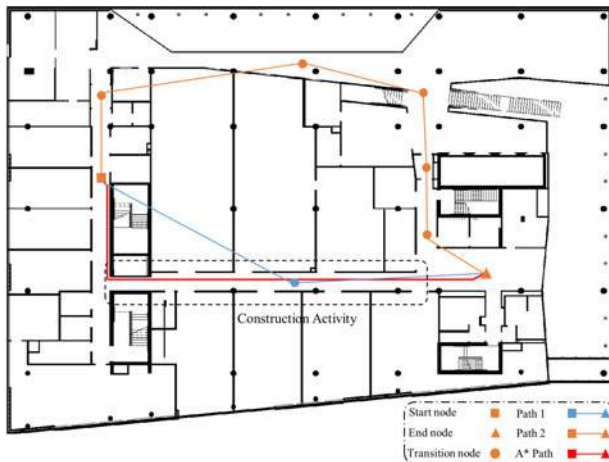

Figure 7. High-level and low-level paths: A* generates the shortest path possible between start and end, not taking advantage of the BIM/IFC semantics. Path 1 has the lowest total weight among other alternatives. Path 2 is automatically generated when there is a hazard to the robot in path 1.

8 Conclusion

This paper presented a semantic path planner that uses building information from IFC data schema to generate optimal paths for safe and efficient navigation of autonomous robots on job sites during the construction phase. We used the BIRS for extracting building information from IFC represented in a hypergraph structure. Path planning algorithms can then be used to calculate optimal paths in this graph given the building information. Weights are designated to each connection in the path to represent how different conditions can affect the robot's navigation and to prioritize paths with more desired characteristics. The optimal semantic path is then integrated with low-level navigation system and A* algorithm is used to calculate the shortest path within the optimal path. The effectiveness of the path planning to generate different paths given different conditions was shown in a simulated and real life case study.

This algorithm can be extended in the future to include Mechanical, Electrical and Plumbing (MEP) semantics for data collection. Different locations can be added based on the kind of information needed at a specific time of construction through the GUI in order to give to the robot more destinations for data collection. In this case, the high-level path planning algorithm would provide semantic navigation, as well as a more efficient route for data collection. A future study will be conducted to assess the usability of the semantic navigation approach by studying the user scenarios and they leverage the construction progress monitoring workflows.

Acknowledgment

The authors are grateful to the Natural Sciences and Engineering Research Council of Canada for the financial support, to Mitacs for the support of this field study as well as to Pomerleau; the industrial partner of the ÉTS Industrial Chair, for providing the terrain for data collection.

Abstract

A view is among the critical criteria in an architectural design process. Presently, it is assessed by conventional site observation, labour-intensive data collection, and manual data analysis before designing a building mass, plan, façade, openings, and interior space. City Information Model (CIM), with its capabilities to store, visualize, and analyze a wealth of site-related information, has a great potential to support an automated view assessment. However, its realization is nascent, and it has not integrated with architectural space planning in either research or practice. This research, therefore, aims to develop a model through which CIM can be extended to assist view assessment in architectural space planning. By literature review, brainstorming, prototyping, and case study, this research corroborates that by harnessing the power of CIM, the conventional view evaluation can be transformed from qualitative to mix-used. It helps practitioners assess a view and design a space in a more precise and rapid manner. This research also provides the integrated model for view evaluation in architectural space planning with three stages to support the real-world practice. Future studies are recommended to develop the proposed model and integrate it with multiple criteria to advance the generative design.

Keywords –

Architectural design; Generative design; Space planning; View assessment; City information model; Deep learning.

1 Introduction

The characteristics of the view outside a window considerably influence the occupants' well-being (e.g., stress recovery), building comfort (e.g., sleeping quality),

as well as working productivity [1-4]. In healthcare architecture, the preferred view, including green, water, and other natural scenes, can improve patients' satisfaction, shorten a hospitalization period, and ultimately enhance recovery after medical treatments [5]. Because of these significances, the building orientation, shape, form, envelope, space, openings, fixture, furniture, and decoration are usually designed to capture a great view and maximize its benefits to a project. In some building types, including hospitality and wellness architecture, a view is highly prioritized during design to achieve higher star ratings and improve clients' satisfaction. The gorgeous view must be well reserved for important spaces, e.g., bedroom, living, dining, and working areas, while service spaces, e.g., storage and mechanical rooms, are located in a place with a less impressive view or without a view. In Hong Kong, for example, the triangular bay window is used for the hotel space planning and façade design to capture the breathtaking view of the Victoria harbour (see Figure 1).

Figure 1. The architectural space planning and façade design to capture a preferred view [6]

In the current architectural design practice, the view is assessed manually before conceptual design, mass development, and space planning. The common ways include visiting a site, exploring surroundings, and using a camera or drone to capture photos in every level and direction (see Figure 2) [7-9]. Then, all photos are reviewed and analyzed manually by a design team using criteria, such as view types, content, distance, quality, and surroundings' future development [10]. Apparently, this view evaluation method is time-consuming, labour-intensive, and costly. The process highly depends on the designers' perception and perspective without automatic tools to help the determination process, while other design criteria, including climate and energy consumption, already have advanced computational tools to simulate and facilitate precise and rapid decision making. Furthermore, additional site visits or drone flights are sometimes required when vital information is not collected in the previous visit [7]. Therefore, this process urgently needs an effective tool for supporting view evaluation in architectural design practice.

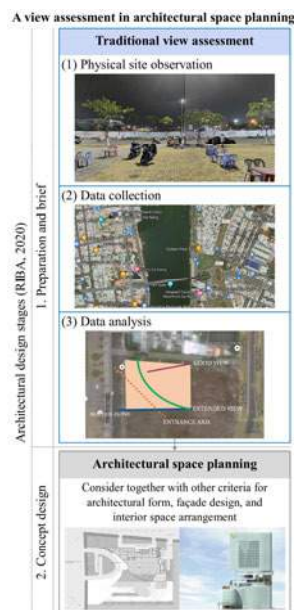

Figure 2. View assessment in architectural design

With the advancement of 3D reconstruction and remote sensing technology, the emerging city information modelling process has started to develop the City Information Model (CIM) and serve urban computing, simulation, analysis, and design [11]. CIM has been widely used in various intelligent applications due to its well-preserved geometry and digital reflection of the real world. The related location-based application covers a broad spectrum of fields such as navigations in transportation [12], disaster simulation in emergency response [13], utility and facility management in smart

city construction [14], site design in urban planning and development [15], and big data analysis in urban computing [16]. Harnessing the power of CIM, studies in the field of architectural design have also presented numerous new findings, involving window design [17], solar estimation [18], and ventilation analysis [19].

Recently, an automated and accurate window view assessment has been further validated on CIM for urban-scale view evaluation [20]. CIM-based view assessment is also expected to help the architectural space planning and interior arrangement. However, this potential approach is rarely discussed in the previous literature. Moreover, the implementation process in real-world practice remains unclear. What is urgently needed is not only the program development but also the integration of CIM into the current design practice.

This research, therefore, aims to develop CIM to assist view assessment in architectural space planning. It is achieved by adopting a 5-step research method: empathizing the view evaluation in architectural design, defining the practice challenge, brainstorming the potential solution, developing a CIM-enabled quantitative view assessment model, and finally validating through the case study in Hong Kong.

2 Literature review

2.1 Architectural design

Architectural design is generally a highly creative and dynamic process to manage available resources, resolve difficulties in the built environment, and finally establish the environmental conditions for activities [21]. This process can be regarded as a Multi-Criteria Decision Making, since it copes with various factors in the complex social realms, such as users' requirements, site conditions, laws and regulations, functionality, feasibility, technologies, and aesthetics [22-24]. It has been demanded to mitigate more difficulties in the Architecture, Engineering, and Construction (AEC) industry, including manufacturing and assembly processes [25], sustainable building life cycle [26], and construction waste minimization [27]. According to the real-world case study, it is currently an arduous task, if not entirely impossible, for practitioners to understand, scrutinize, and reinterpret all factors before locating them into one design [28]. Assistive tools, such as CIM, Computer-aided design, Building Information Model, virtual reality, and design management software, are indeed required to help this intricate process [21, 28-29].

2.2 A view

In architecture, a view is a visual connection with the outside world, allowing occupants to keep in touch with

ongoing activities, time, and seasonal changes [30]. It can be regarded as one of the basic human needs, since the view provides humans information about the environment for their feeling of safety [31-32]. The view is separated into three main layers with different purposes [30]. Firstly, the sky is a source of natural light and weather information. Secondly, the city or landscape part provides information related to the environmental condition and surroundings. Lastly, the ground is to observe or recognize ongoing activities outside.

Due to the significance of view in architecture, several view assessment measures have been proposed (see Table 1). The measures include, for example, the categories of view or information content received from exterior view [30]. Many studies agree that the view of nature, garden, and the well-landscaped area tends to be more preferred by occupants than the urban environment [2-3]. This view type can positively change the emotional state and increase occupants' satisfaction [1]. The content and composition of sky, land, ground, building, and city, also affect the view attractiveness. A wide view, containing more information, is more interesting than a close and narrow one [38]. Furthermore, the quality of view outside is influenced by the density of both internal space and surroundings [2]. Sometimes, the openings and outside world can also affect occupants negatively [30]. For instance, the window facing directly to other buildings or service facilities may be harmful to privacy.

Table 1. Examples of view assessment criteria

No	Criteria	References
1.	View type	[2-5, 30]
2.	View composition	[30]
3.	Density	[2]
4.	Distance and privacy	[2, 30, 33, 38]

The perception of beauty and satisfaction of view depends on not only the view itself but also how we design the frame to capture it [33]. The quality and impact of view also associate with the architectural mass and form, façade, interior space arrangement, and windows' type, size, and mullion [10]. Architecture must be well designed and crafted carefully to capture the best view outside. However, in reality, the view evaluation criteria must be balanced and weighed with other factors, e.g., functionality, feasibility, and laws and regulations. Each criterion requires a large amount of information to be collected and pondered together. It is still a herculean task for practitioners to handle this wealth of information from every design aspect at one time.

2.3 Simulation-based view assessment

The simulation method as a convenient and effective tool has been widely adopted in the architectural design field. For the simulation-based view assessment,

previously, some methods were developed through projection [34], raytracing on hand-made models [35-36], or a fish-eye lens [34, 37]. However, they tend to rely on manual work and thus are time-consuming. Recently, a new technological window of opportunity opens for this study, consisting of high-quality 3D photo-realistic CIMs, mature 3D view capture APIs, and robust online computer vision tools. Utilization of existing 3D photo-realistic CIMs brings users effortless scenes of buildings and their neighbourhood environment, while making full use of the 3D view capture techniques and computer vision tools can help visualize and quantify the view photos with high automation and accuracy.

For instance, Li and Samuelson [18] effectively integrated the outside view assessment into the window frame design by using textured CIMs from Google Earth Studio. The simulated views were assessed by the criteria including window direction, openings' geometry, and human preference. Li et al. [20] classified the window views into two groups, natural and urban, for a city-scale view disparity assessment. Harnessing the power of deep transfer learning, the window views of nature were distilled automatically. Both studies show that the view photos generated from photo-realistic CIMs are similar to the ground truth photos in the real world, and the assessment results of views are accurate for decision-making. However, there exists a gap and method in connecting the automated view assessment method with the architectural space planning for more comprehensive judgment. Space planning concerning a view assessment may gain more momentum from these new technological breakthroughs in terms of efficiency and accuracy.

3 Research methods

This research comprises five stages to both constitute knowledge contributions and resolve real-world challenges (see Figure 3). It began with a comprehensive literature review to gain a holistic view of the current architectural design practice, view evaluation method, and CIM performance. Secondly, all information was analyzed, redefined, and discussed with practitioners to highlight critical challenges in the view assessment. It was followed by brainstorming to explore the potential solution in the third stage. This stage was to fabricate innovation in complex social conditions and bridge the gap between theoretical knowledge and design practice. In this research, the solutions were to identify view evaluation criteria for architectural design and develop a CIM-enabled view assessment model. The fourth stage was mainly about developing CIM as an assistive tool for assessing, visualizing, and facilitating the architectural design process, and aligning with the current practice. Finally, the proposed model was validated and improved through a case study implementation in Hong Kong SAR.

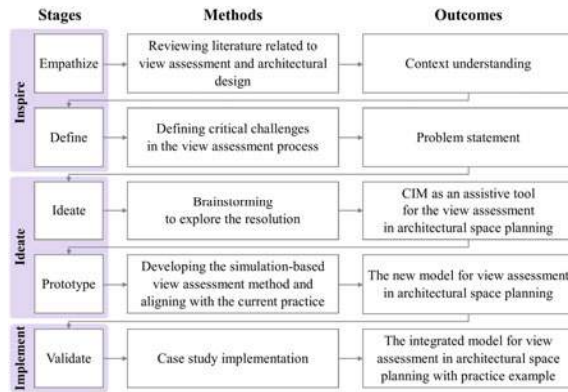

Figure 3. Research methods

4 The integrated model for view assessment

After reviewing the literature, redefining the real-world challenges, and brainstorming the potential solutions, the new view assessment model is generated (see Figure 4). It is the consolidation of simulation-based view assessment and traditional site observation and evaluation.

Figure 4. The integrated model for view assessment in architectural space planning

4.1 Traditional view assessment

At the beginning of the architectural design process, the design team visits a construction site to observe site-related factors. The collected qualitative data include, for example, surroundings, site terrain, wind direction, existing features or structures, traffic and transportation, noise, and view quality. Moreover, alternative data are also gathered for further analysis, discussion, and decision-making, such as maps, drawings, and pictures. In this stage, the team uses multiple tools to collect data of the site and surroundings, including a camera, drone, laser distance meter, surveying instruments, etc. The data is then analyzed manually by several methods, e.g., sketches and diagrams.

4.2 Simulation-based view assessment

Apart from physical site observation, the CIM and computational technology advancement can support the simulation-based view assessment and strengthen the design. Its realization comprises three main stages (see Figure 5).

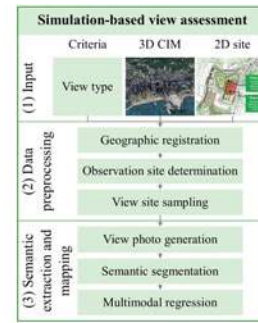

Figure 5. Workflow of simulation-based view assessment

4.2.1 Input

The process initiates with a 3D photo-realistic CIM and 2D site preparation, and critical criteria selection. The criteria should be well selected and prioritized depending on specific project conditions, such as users' requirements, building function, site location, and surroundings. This study searched through the scientific database and generated a list of view assessment criteria for practitioners to choose from (see Table 1).

4.2.2 Data processing

The data processing consists of three key steps: geographic registration, observation site determination, and view site sampling (see Figure 5). First, the 2D site and 3D photo-realistic CIM are registered on the 3D WGS-84 globes to identify the development area. Thereafter, considering the site settings such as shape and neighbourhood environmental characteristics, the users can determine the representative observation site. Then, to examine the view disparity quantitatively, the view site at eight directions from 0° to 360° are evenly sampled from different altitudes. A sample interval h ($h=5m$) is set here to simulate the view situation of different floors.

4.2.3 Semantic extraction and mapping

As the nature view is more preferred within the cityscape, view types, including nature and urban, are set as the judgment criterion to demonstrate the semantic extraction and mapping process. In this study, we extend Li's method [39] to visualize and quantify the nature view index. Firstly, by mounting the virtual camera at the sample view sites of the 3D photo-realistic CIM, the view photos are captured in batch. Thereafter, one of the best

pre-trained deep learning models on Cityscapes, *Deeplab v3*, is transferred to segment the view photos into 19 classes of features automatically. Furthermore, a connected layer is constructed to map the view features into the two target groups through a multimodal regression. In the end, the predicted nature indices of view photos are collected for space planning.

4.3 Architectural space planning considering the view assessment

Finally, the quantitative result from the last stage is used together with traditional site observation and qualitative view assessment. The result is then weighed and balanced with other criteria in the built environment, e.g., users' requirements, site conditions, climate, laws and regulations, and construction method, to draft a preliminary design, justify building mass and orientation, develop details, and generate construction documents.

5 A Case Study

To validate the feasibility of the integrated approach, the Pokfield campus, the University of Hong Kong, Hong Kong SAR, was selected to be a case study. This area would be redeveloped into new office and education buildings. The experimental process workflow began with the physical site observation (see Figure 6). Researchers faced several challenges in this stage. Firstly, due to the complicated site terrain and surroundings, the team could not capture the view from every direction and level without assistive tools, e.g., a drone. Furthermore, some photos could be taken only by entering surrounded buildings. It was indeed tedious and time-consuming for practitioners to observe and collect all necessary data. All data, including photos, maps, and drawings, were then used for the traditional analysis (see Figure 7). It reveals that the visibility to natural elements such as mountains, sea, and vegetation, is blocked by high-rise high-density constructions in many directions and levels. However, what remains unclear is the exact level or angle to improve the detailed design of planning, interior space arrangement, openings, and façade design.

Apart from the traditional method, the simulation-based view assessment was implemented. The curation of the datasets included 2D site design data and 3D photo-realistic CIMs in this study. The 2D design of the case site, collected from HKU Estate Office [40], measured the site geometry accurately, from which the key view site can be determined by designers. The sketch map is shown in Figure 8a. The 3D photo-realistic CIMs were collected from the Planning Department [41], Hong Kong SAR, for surrounding environment expression, and one of the buildings was highlighted for method validation (see Figure 8b).

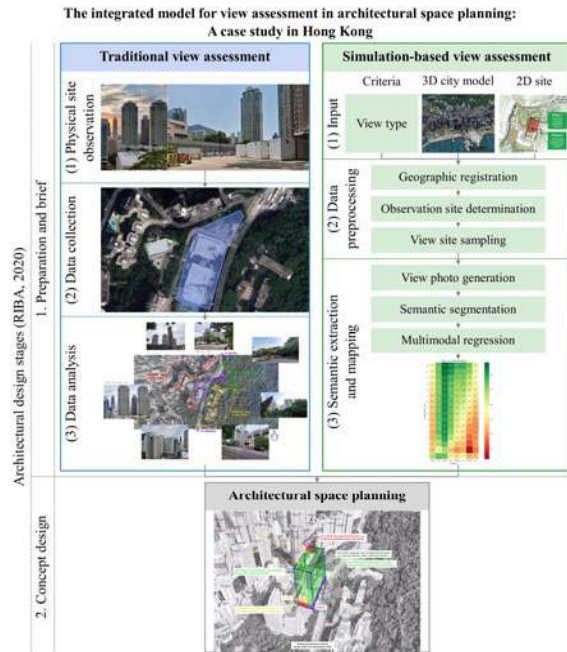

Figure 6. The implementation of proposed model in the case study

Figure 7. Traditional view analysis

Figure 8. Data preparation of the case planned building site. (a) 2D site design, and (b) target building site and its environment.

Cesium (version 1.73) as an open-source 3D visualization platform was used in this study to load 3D photo-realistic CIMs and generate the view photos through computer programs. The *Deeplab v3* model within the *Tensorflow (version 2.4.1)* framework was to segment the view photos. Then the multimodal regression was finally implemented in the data mining platform *Orange3 (version 3.26.0)*. The whole process experimented in a workstation with an Intel i7-10700 CPU (2.90GHz, 16 cores), 128 GB memory, an 8G Nvidia GeForce RTX 2070 SUPER GPU, and Ubuntu 20.04 64-bit operating system. By implementing the view assessment workflow (see Figure 5), each direction of the building site has a portfolio of nature view indices. The heat map representing view index distribution around the case planned site was visualized from 0 m to 80 m (see Figure 9). The nature view index ranges from 0 to 1, from which 0 indicates 'poor' and 1 stands for 'excellent'.

Figure 9. The simulation-based view assessment result

The simulation result reveals a huge different possession of natural resources in different directions and levels, further reflecting the design. For instance, the lower part tends to have lower proportional nature views, such as the area ranging from 180° and 315° horizontally, and from ground level (0 m) to 15 m vertically. On the other hand, the upper-level part has a more favourable

view, especially in the area ranging from 45° and 235°. In some specific directions, the nature views are obviously scarce, such as the direction ranging from 315° (Northwest) to 0° (North). In some directions, the nature views are of significant variation from the vertical dimension, i.e. the direction from 135° to 315°.

The design team can use this detailed result for architectural space planning and design in three main stages. In the initial concept design, the building's mass, form, and zoning are decided. The important space should be placed on the higher level with the best view in a site, while the podium area can be used for the back of the house or service zone, which are not required a good view, such as circulations, storage, and mechanical, electrical, and plumbing systems (see Figure 10). The vertical circulations or building systems may be placed in the northwest part. Then, this conceptual model is developed and detailed. The architectural plan, functions, rooms, circulations, and building envelope are designed with the consideration of view assessment results, site surroundings, and other factors. The important functions such as a lobby, living, and dining, are allocated on the tower part to enjoy the preferred view of green space and harbourfront area. Lastly, in interior design, the view evaluation result can also be used for space and furniture arrangement. The position and location of all features, e.g., working table and bed, should be well located to make occupants enjoy the excellent view outside the openings. It can be seen that the design team can refer to the view evaluation results throughout the entire design process.

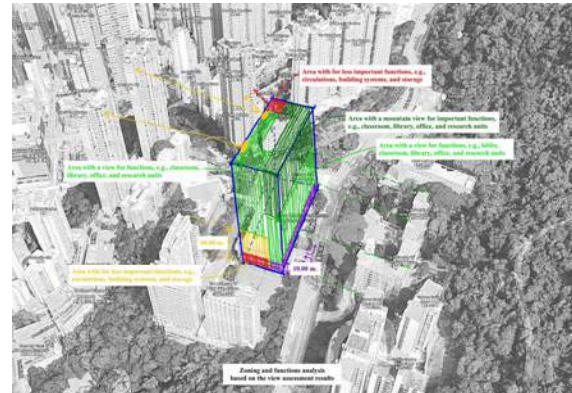

Figure 10. The application of simulation-based view assessment for architectural space planning

6 Discussion

This empirical research firstly reveals difficulties in the conventional site observation, which support the promising approach of using computational technologies

to aid this process. Then, the implementation in the real-world context affirms that CIM, with its capability to manage and analyze a large amount of information, can be a less expensive virtual platform supporting view assessment in architectural design and space planning. CIM can be used through three main stages: input, data preprocessing, and semantic extraction and mapping. Its outcome can confirm the qualitative result from physical site observation and add more details to facilitate precise and rapid decision-making throughout the entire architectural design process. Furthermore, its integration with the conventional assessment approach transforms the process from qualitative to mixed methods: combining qualitative and quantitative data. These findings also support the current thought of generative design, where computational intelligence can automatically generate floor plans from project conditions. It has a high potential to integrate with other tools to achieve various criteria simultaneously and revitalize a labour-intensive task in design.

Despite its advantages, the practice of CIM-enabled view assessment also faces several challenges. For instance, it requires a huge effort to collect related information and build a digital model before simulation and automatic evaluation. The proposed model is thus efficient to be utilized for a site with high density and complicated surroundings like Hong Kong. Moreover, in reality, a view is merely one of the numerous design criteria. The view analysis results have to be weighed and balanced with other factors, e.g., users' requirements, site conditions, laws and regulations, feasibility, and aesthetics, before involvement in a project.

This research also has several limitations. As this study is grounded on the archival study and one case study in Hong Kong, additional cases from different contexts are necessary for generalization and model improvement. In addition, there is no "one size fits all" solution for every project. The view assessment criteria and CIM model development may be varied depending on particular conditions.

7 Conclusion

Architectural design is presently stipulated to prevent many difficulties by considering various criteria in the AEC industry. This trend makes the process more sophisticated and time-consuming, so generative design tools are urgently required. This research fulfils this demand by developing CIM to be an assistive tool for quantitative view evaluation in architectural design and space planning. The case study affirms CIM's capabilities to revitalize a conventional labour-intensive process and facilitate precise and rapid design decision-making. Besides, this study highlights both prospects and core challenges of CIM-enabled view assessment. For

practitioners, it also offers the integrated model for view assessment in architectural space planning with practice examples.

However, this is merely the beginning of simulation-based quantitative view assessment for architectural design. It still requires additional case studies in other sociocultural conditions to validate and develop this potential further. Future research is also recommended to integrate the proposed model with other criteria and computational tools to advance the computer-aided generative design.

Abstract –

Cities worldwide are experiencing increasing temperatures due to the urban heat island (UHI) phenomenon. UHI is caused by the replacement of natural land surfaces with man-made dark surfaces. Among others, it causes a number of public health problems associated with heat events, particularly in the construction sector, where construction workers are more likely to die from heat-related illnesses compared to other industries. To address the negative effects of this phenomenon, researchers around the world have proposed different alternatives for studying the effects of UHI. Among these methods, data-driven approaches are becoming increasingly popular. However, as with all data-driven models, there is always the question of the extent to which they are generalizable. To answer this question, this research work applies the data-driven UHI assessment framework previously proposed by the authors to the cities of Montreal, Canada, and Apeldoorn, the Netherlands, in five different scenarios. The results showed that while the data-driven models have good prediction capabilities within the scope of the training data set, they do not demonstrate good generalizability on the testing data from a different context. Also, the results of this research highlighted that as cities continue to grow, there is an urgent need to standardize the understanding and assessment of the UHI at a pedestrian level. The intrinsic differences in how UHIs are assessed and tackled worldwide can create confusion about the phenomenon, and limits the applicability and generalizability of data-driven approaches.

Keywords –

Data-driven methods; decision trees; generalizability; urban heat maps; mitigation policies.

1 Introduction

The Urban Heat Island (UHI) phenomenon refers to the temperature difference between the outskirts and the inner city caused by the replacement of natural land surfaces with dark man-made surfaces [1]. As a result of these changes, cities are more prone to store solar radiation causing a series of public health problems associated with heat events [2]. The construction sector is no stranger to the harmful effects of this phenomenon. Construction workers, who often have to cope with high temperatures as part of their daily operations, are more likely to die from heat-related illness compared with other industries [3]. To further exacerbate the situation, there have been thirty-eight heat waves in Europe in the last century, seventeen of them in the last decade. The heat wave of 2003 caused 70,000 excess deaths over four months in Central and Western Europe [4]. Yet, cities are only projected to continue expanding. By 2050, cities are expected to shelter 68% of the world's population [5].

To counteract the negative effects of this phenomenon, researchers around the world have proposed different alternatives for the study of UHI effects. For example, physics-based simulation models try to mimic the thermal exchanges between urban surfaces and air temperatures. Yet, generating accurate and detailed simulations requires databases with three-dimensional representations of the built environment, resulting in very expensive simulations in terms of both computing power and time. Additionally, the complex interplay between the morphological characteristics of inner cities, socio-economic factors and UHI makes it difficult to develop an accurate and comprehensive physics-based model. Finally, the physics-based models are commonly too complex to be used by regular urban planners, making it difficult to incorporate UHI concerns into design and planning of cities.

In recent years, data-driven methods have gained popularity in solving complex multi-dimensional

problems. For example, Sutjaritvorakul et al. [6] developed a data-driven approach to detect workers from cameras installed on cranes. Similarly, Langroodi et al. [7] presented a data-driven approach to monitor the activities of construction equipment. Nutkiewicz et al. [8] developed a methodology to characterize and model the energy performance of buildings at multiple spatial and temporal scales. Regarding the domain of urban climates, a handful of machine-learning approaches have been developed in order to predict temperatures in specific urban settings [9-13]. For instance, Vulova et al. [10] developed a deep learning approach to discover hot spots in Berlin, Germany. The authors of this paper have also proposed a data-driven framework for the development of a user-friendly decision-support tool for UHI-sensitive urban planning that uses publicly available datasets [14]. Although this framework and similar ones developed by other researchers are shown to be effective and very promising, there is always the question of how generalizable these models are. This common question to all data-driven models is relevant because data-driven models are often trained and tested on the data collected from a limited geographical scope. Whether or not the intrinsic correlations and patterns discovered in the data are generalizable to other contexts is a question seldom addressed. Therefore, the aim of this paper is to assess the extent to which data-driven UHI assessment models can be generalized for different urban contexts. To do so, the data-driven UHI assessment framework previously proposed the authors [14], which relies exclusively on publicly available data, is applied to two different cities in five different scenarios. The studied cities are Montreal in Canada, and the Apeldoorn in the Netherlands. Apeldoorn is a medium-sized city, the 11th largest municipality in the Netherlands, with 150,000 inhabitants (2020). Located in the middle the country and the nature reserve De Hoge Veluwe, it presents a unique combination of greenery and built environment. In terms of infrastructure, the city center is densely built, having buildings with an average height ranging from 10 to 15 m. The construction materials of the building facades are homogeneous, varying from the dark to the light colors of traditional Dutch bricks. The city of Montreal, located in the southeast of Canada, is considered a metropolitan city, with a wide-ranging urban geometry. It covers an area of approximately 499 km², with a population density of 3.9 inhabitants/km².

Montreal and Apeldoorn constitute a good comparative basis because they are located in different climatic regions, have different scales in terms of size and population, and have distinctive urban morphologies and socio-economic characteristics. The remainder of the paper is structured as follows. First, in the interest of completeness, the data driven framework proposed by the authors is explained briefly. Then, the two case studies

are briefly explained. This is followed by the presentation of the results of the comparison of different scenarios. Finally, the conclusions and future work are presented.

2 Data-driven UHI assessment framework

As shown in Figure 1, the methodology consists of three main steps, namely: (1) data collection, (2) data preparation, and (3) model development. For the completeness of this research, the three steps are explained briefly in this section.

Figure 1: Overall framework [adapted from 14]

2.1 Data collection

The factors affecting UHI at a micro level (i.e., street level) can be categorized in three groups: (1) environmental factors, which have been described in the literature as uncontrollable factors [15], (2) socio-economic factors, and (3) urban morphology factors. Given that socio-economic and morphology factors have the greatest potential to be influenced by policies and urban planning decisions, they are the main target of the data collection strategy.

Table 2 presents the types of public data that are used for the development of the data-driven model. These data are used as the features (i.e., independent variables) of the data-driven model to assess the UHI effect at the street level. The sources from which these data were collected for the case of Apeldoorn are also presented in Table 2. In turn, the temperature variations in the city are used as labels (i.e., dependent variable) in the data-driven model and can be represented either in terms of the Physical Equivalent Temperature (PET) or Land Surface Temperature (LST). In the Netherlands, PET maps are widely used by the local authorities as a metric for the assessment of the heat stress.

2.2 Data preparation

Once the required data are collected, they first need to be processed to prepare them for the model development. To mine the urban features presented in Table 2, all features must be reduced to the street level. This requires the street jurisdiction to be determined first. This is the area surrounding the street segment from which all the urban features affecting the UHI can be assembled (e.g., building height, population, width of the

street, percentage of greenery, etc.). As shown in Figure 3, the street jurisdiction was based on the average width of the streets plus the minimum distance between the fence of each building and the adjacent street. For example, in the case of Apeldoorn, the street jurisdiction is defined by a buffer size of 15 m (the blue area in Figure 3 represents the buffer size).

Table 2. Primary features

Category	Primary features	Source
Socio-economic factors	Land use	pdok, land use [16]
	Building materials	Manual collection
	Population density	WorldPop Data, 2020 [17]
	Transportation (i.e., traffic flow)	Not available
Urban morphology	Building geometry	pdok, 3D building [18]
	Average building height to street width ratio (H/W)	NWB Wegen, pdok [19]
	Built-up density	Computation based on street jurisdiction
	Water bodies/cool sinks	
	Vegetation/green spaces	

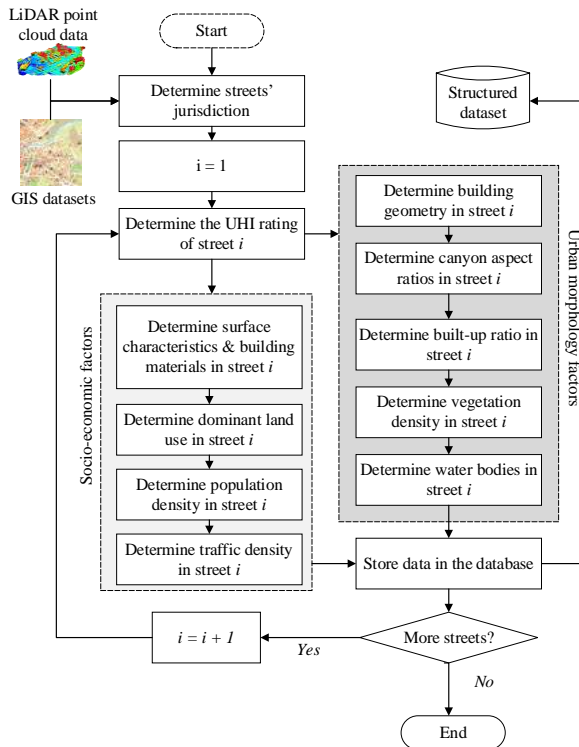

Figure 2. Overview of the data preparation process [adapted from 14]

Figure 2 presents an overview of the data preparation

process. In a nutshell, all the socio-economic and urban morphology features were computed as follows: building, water, and vegetation density are calculated by taking the average overlapping area of each feature with the area of the corresponding street jurisdiction. Likewise, the population density and land distribution are calculated by projecting the administrative unit-based census data into geospatial gridded cell datasets and computing the average per street jurisdiction.

Regarding the data preparation of building materials, this is done by manually assigning a material type of each building in the city. This process can be conducted via Google Earth.

Figure 3. Average street section [images adapted from 20]

2.3 Model Development

In the model development, which is shown in Figure 4, the datasets are firstly split into training and testing sets to train the regressors. For this study, Decision Tree (DT) is used as the principle regressor. The hyperparameters of the DT model are set by default. This is followed by an optimization process in which the minimum number of levels of the tree (max-depth) is selected randomly, while minimizing the number of features that can successfully boost the learning process. Once the performance threshold is reached, the most important features, with the minimum max-depth, from the best performing models are selected.

3 Case studies

As mentioned earlier, the cities of Montreal and Apeldoorn were selected for the study that aims to assess the generalizability of data-driven models. The details of Montreal data were explained elaborately in the previous work of the authors [14]. For the case of Apeldoorn, the labels for this case study was retrieved from the work of Koopmans et al. [21].

It should be highlighted that label data of Montreal

was available in the form prescribed by the Jenks Natural Breaks Classification method [22]. In order to compare the two cities, PET temperature data of Apeldoorn were also classified using the Jenks Natural Classification Method. In a nutshell, this method splits the data in such a way that the mean standard deviation of data points in each category is minimized, while the standard deviation of distances of each data point to the means of the other categories is maximized. Figure 5 shows the classification of 2,768,169 data points into nine categories of PET temperatures.

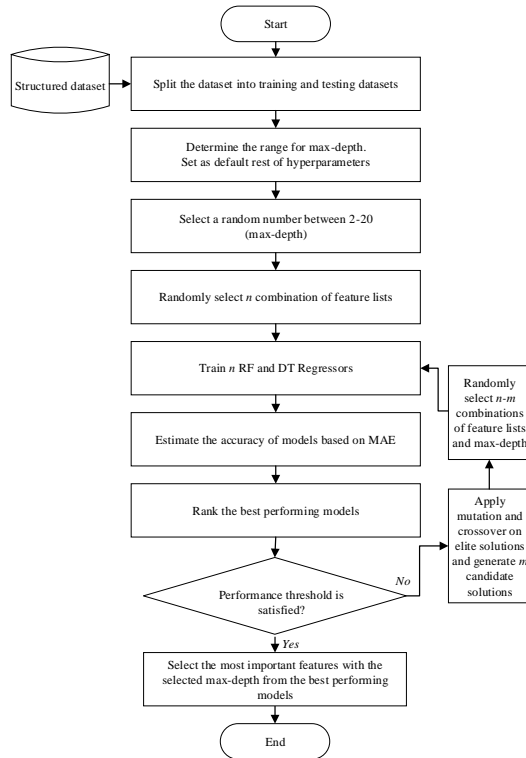

Figure 4. Overview of the model development [14]

Given the importance of the interpretability of the data-driven model in the context of urban climates [14], a DT regressor with a max-depth of 7 was implemented for all scenarios (to allow for the interpretability of each level of the DT). The other hyperparameters were initialized with the default configuration. The main primary features common to the two datasets were used to train the models and, subsequently, to compare their performance. These features are the following: building

façade materials, predominant land use per street jurisdiction, population count, average building height, vegetation, and building densities. Each dataset was divided into training (75%) and testing datasets (25%). Overall, 7,986 vector data instances were collected, of which 5,578 belong to Montreal and 2,408 belong to Apeldoorn.

Figure 5. PET map of Apeldoorn

3.1 Comparison of the Models

Five different models are developed to analyse the scenarios presented in Table 1.

Table 1. Scenarios studied in this research

Dataset	Scenarios				
	1	2	3	4	5
Training	Montreal	Apeldoorn	Montreal	Apeldoorn	Combined
Testing	Montreal	Apeldoorn	Apeldoorn	Montreal	Combined

In scenario one, the dataset consisted of 5,578 data instances distributed in 4,183 feature vectors for training, and 1,395 feature vectors for testing. The model performs with a Mean Absolute Percentage Error (MAPE) of 0.07, and an R-squared (R^2) of 0.61 for the testing data sets. Figure 5(a) presents the overall dispersion of the predictions in terms of the predicted temperatures.

(a) Scenario 1

(b) Scenario 2

(c) Scenario 3

(d) Scenario 4

(d) Scenario 5

Figure 5. Model performances for different scenarios scenario 5

In scenario two, the training and testing datasets consist of 1806 and 602 instances, respectively. The model performs with a MAPE of 0.07 and a R^2 of 0.20 for the testing data samples. Figure 5(b) shows the accuracy in terms of the predicted temperatures. The models show a higher dispersion, not fitting very well the predicted values vs. the actual temperature values. On the other hand, for scenario three, the already trained model from scenario one (i.e., the Montreal model) was tested with the dataset from Apeldoorn. Figure 5(c) shows the performance of the model, with a MAPE of 0.11 and an R-squared of -0.75, for the testing data set. Similarly, in scenario four, the trained model from Apeldoorn, is tested with data from Montreal. Here the MAPE is 0.12 and the R-squared is -0.22. Figure 5(d) shows the performance of the model. In the last scenario, the two data sets (i.e., Apeldoorn and Montreal) are used together to train the model. The dataset consists of 7,986 instances. A total of 5,989 data instances were used to train the model (75% of the total dataset). To test the accuracy of the model, a sample of 1,395 data instances from Montreal and 602 from Apeldoorn were selected. The model performs with a MAPE of 0.07, and a R-squared of 0.60 for the testing data samples, showing better generalizability and improved performance compared to scenarios two through four. Figure 5(e) shows the dispersion of the model.

4 Discussion

From the results provided by the scenarios evaluated in this research, two main discussion points can be derived.

(1) As presented in Table 2, scenarios one and five performed the best, with a MAPE of 0.07 for both models, and an R-squared of 0.61 and 0.60, respectively. This highlights the importance of diversity in the datasets. In the particular case of scenario one, given the very nature of the city of Montreal as a metropolitan city with much wider variety in urban morphology and socio-economic characteristics, the model is based on a more diverse dataset. Therefore, it is justified that the model performs better than when compared to models trained with smaller datasets, as in the case of scenario two. The same can be observed in scenario five, where the model has data samples from both cities, and therefore learns from different contexts with a good performance.

However, when the models are faced with the challenge of predicting data from different urban environments and outside the context of the training data (i.e., scenarios three and four), both models perform poorly. In the case of the model from Montreal when tested on the data from Apeldoorn (i.e., scenario 3), while

the MAPE is comparatively good (as highlighted in Figure 6, most of the data are in the range of 0 to 14 % error range); however R^2 is very low. Negative R^2 in Scenarios 3 and 4 suggests that the models perform worse than taking the mean temperature class value. Nevertheless, R^2 is not always a good indicator of fitness, depending on the characteristics of the data [23, 24]. According to these studies, the performance of the model needs to be evaluated in the context of how well the predictions are made on unseen datasets, (a.k.a., the predictive capacity of the model) and not only in goodness of fit. Whether or not this is the case in this research, still needs to be investigated. The same can be said for scenario four, where the estimated error is 12 %.

Table 2. Results from scenarios studied in this research

Performance Metric	Scenarios				
	1	2	3	4	5
MAPE	0.07	0.07	0.11	0.12	0.07
R-squared	0.61	0.20	-0.75	-0.22	0.60

(2) A very recurrent problem during this research has been the inconsistency of what is understood by UHI in different urban contexts. For instance, in the case of Montreal, a tailored thermal classification of hot and cold islands was generated. This was done by using a statistical model with geospatial variables generated from a Landsat 8 satellite image. Variables such as: (1) normalized difference vegetation index (NDVI), (2) the impermeability index, (3) the average air temperature on the day and in the 72 hours prior to the acquisition of the LST images, and (4) the average wind speed on the day the images were acquired for the classification [25]. In the case of Apeldoorn, the assessment is based on PET-model, where it is implemented for a standardized person (male, 35 years old, 1.75 m tall and weighing 75 kg) for 10 typical Dutch street configurations. In this case, the vegetation index (NDVI) was also included, in addition to the land use, Sky View Factor (SVF), and daily air temperatures [21].

Although the two heat maps assist different governments and urban planners in designing their mitigation strategies, and ways to deal with UHI in their own contexts, the two heat maps are not comparable, and thus, create a different understanding of the UHI phenomenon, and corresponding mitigation strategies in the two countries.

The current trend in urban planning is gravitating towards the use of digital twins and data-driven methods. These technological advances provide cities with a unique opportunity to evaluate UHI in a systematic and consistent manner worldwide, at both local and global

scales, and therefore feeding knowledge and innovation from one context to another. Yet, the heterogeneous and inconsistent manner in which local governments and municipalities assess UHI hampers the application of data-driven methods. This is because the training dataset per se can have different meanings across urban environments.

Figure 6. Percentage error in scenario 3, where the majority of the data points have 0- 15% error.

5 Conclusion and future work

This study evaluated the extent to which data-driven UHI assessment models can be generalized to different urban contexts by applying the previously data-driven UHI assessment framework proposed by the authors to the cities of Montreal, Canada, and Apeldoorn, the Netherlands, in five different scenarios.

The results of the five scenarios show the potential of data-driven models to predict UHI categories with a fair accuracy. However, it was also highlighted that while each model has good prediction capabilities within the scope of its specific training data set, these models do not demonstrate good generalizability on the testing data from a different context (i.e., city).

It should be mentioned that the temperature datasets were centered mainly in categories 5 to 8, with small samples from lower, and higher categories. This has created an imbalanced dataset. In the future, efforts are required to sample wider data points from all categories.

An interesting future research would be to investigate the causes of variability in the behavior of UHI of different urban contexts. The previous work of the authors have considered this for the single case of Montreal [14]; but it is hypothesized that the important features that govern the behavior of UHI heavily depends on the urban context. In the future, the authors would like to expand the scope of this investigation and study the most dominant causes of UHI variability between different cities.

Moreover, as cities continue to grow, so does the need

for a standardized understanding of UHI at a pedestrian level. The presented research highlights the need to develop standardized methods for definition and measurement of UHI. The intrinsic differences in the way UHI is evaluated and dealt with can potentially create confusion about the phenomenon across the world, and constraint the applicability and generalizability of data-driven approaches.

Abstract –

Blockchain is a disruptive technology that has great potential in securing BIM data immutability and traceability. However, integrating BIM management with blockchain still faces a risk of sensitive information leaking because blockchain is such a transparent network that BIM data are disclosed to every member. Therefore, this paper proposes a blockchain-encryption integrated (BEI) framework to protect the access of sensitive BIM data when collaborating in a blockchain. The proposed framework contains two parts. Firstly, a “greatest common zone” (GCZ) method is developed to decompose BIM models for data segregation. Besides, an asymmetric encryption-based method is designed as the access control approach. In this way, sensitive BIM data would be encrypted and then shared in the blockchain ledger, which are maintained by all project members. Only authorized members can decipher the confidential information using a private key. The feasibility of the conceptual framework is validated through an illustrative example, showing that the BEI framework is a promising solution in securing the BIM-based design process.

Keywords –

BIM-based design; Blockchain; Asymmetric encryption; Greatest common zone (GCZ) method; IPFS

1 Introduction

Building Information Modelling (BIM), a game-changing technology that has been mainstreamed across the global construction industry, plays a significant role in design collaboration, in which BIM serves as the digital representation and shared knowledge resource of a physical building [1]. Designers can define and modify any design attributes in BIM and share them with the whole project team digitally, rather than working in

isolation. Therefore, various BIM-based collaboration platforms have been developed to enable real-time and smooth communication, reduce the risk of rework, coordinate design changes, and federate models [2]. However, these existing platforms have a centralized system architecture, suffering a high cybersecurity risk of data manipulation [3]. For example, malicious insiders with authorized access have the motivation and opportunity to unwittingly modify design records or BIM models to run away from responsibilities. As a result, the project team cannot secure data integrity, traceability, and accountability.

Blockchain is a promising solution in keeping data security by integrating technologies including peer-to-peer (P2P) networks, decentralized data storage, and consensus mechanism [4]. Information shared in a blockchain network would be synchronized to every peers' local database (i.e., blockchain ledger) to avoid unilateral data manipulation [5]. Recent research efforts presented the feasibility and benefits of integrating blockchain into construction processes to accelerate collaboration. Initial explorations in construction interim payment [6], supply chain management [7], and on-site quality management [8] highlighted that blockchain could address some key concerns hindering collaboration. The Winfield-Rock report [9] indicated that blockchain could provide a secure and collaborative environment for BIM processes by emphasizing network security and data traceability.

Very few studies have investigated methods to facilitate access control methods in blockchain-based BIM design collaboration. Blockchain is a transparent network, and every member could access design data in his local blockchain ledger without any limitation, leading to data breaches and compromising intellectual property and commercial secrets. The latest ISO 19650-5: 2020 [10] standards have pointed out that controlling unauthorized access to information that can be confidential or sensitive is one of the primary tasks in

BIM-based collaboration. Traditional access control approaches like log in control or table lock for centralized databases are not suitable for blockchain due to its special chained data structure and distributed data storage manner. In a blockchain ledger, data are placed in different blocks, preventing setting access control to every block, because there would be thousands of blocks in a ledger and not each block contains sensitive data. Besides, distributed data storage makes synchronously managing access control to multiple peers' repositories difficult [11].

Thus, this paper proposes a conceptual blockchain-encryption integrated (BEI) framework to protect sensitive BIM data access. In this framework, a "greatest common zone" (GCZ) method is designed to decompose BIM models into sensitive and non-sensitive components for data segregation. Besides, an asymmetric encryption-based method is designed in the BEI framework to enable sensitive data access control. In this way, the proposed BEI framework ensures design data integrity using blockchain, while keeping sensitive data confidentiality using asymmetric encryption. Finally, the conceptual BEI framework is deployed in an illustrative design example to validate its feasibility.

2 Blockchain in Construction

Blockchain, known as a distributed ledger technology (DLT), is the underlying technology of Bitcoin [11]. Figure 1 shows the blockchain structure. Blockchain is a peer-to-peer network where no central servers control the network. Every peer in blockchain network maintains an identical copy of data (i.e., blockchain ledger). Each block is chained with the previous one via a hash, an irreversible value based on the content of the previous block. Any slight modification on block data would dramatically change the hash value of block, leading to invalidation of the entire chain [12].

Figure 1. Blockchain structure

Blockchain is a disruptive technology to create a trusted and secure environment in the construction industry. Li et al. [13] reviewed potential blockchain applications in the built environment, revealing its potential to promote efficiencies and drive digital transformation in construction. Nawari and Ravindran [14] proposed a blockchain-based framework and applied it in post-disaster recovery. Wang et al. [7] introduced

blockchain in construction supply chain management, within which a blockchain framework and a smart contract algorithm were developed to ensure data traceability. Sheng et al. [8] investigated blockchain employment in on-site construction quality management. Das et al. [6] designed a blockchain-based interim payment system to protect payment records and execute payment automatically. However, very few studies have developed methods to facilitate sensitive BIM data access control in the blockchain environment.

Blockchain is inherently unsuitable for storing large-sized files like BIM models, which may cause high latency and network congestion. Thus, an interplanetary file system (IPFS) [15] is integrated with blockchain to solve such problems. IPFS is a peer-to-peer, decentralized data storage system where every peer connecting to IPFS is a "file server". When a file is uploaded to IPFS, a cryptographic hash value named content identifier (CID) is generated based on the file content. This value is authenticity proof and a "hyperlink" of the file. It should be noted that the files are still stored in providers' local database, and only people who have corresponding CIDs could access files. Thus, several studies have designed an integrated method that large-sized data are placed in the IPFS, while CIDs are distributed in the blockchain to enable data traceability [16]. However, very few studies have developed methods to facilitate sensitive BIM data access control in the blockchain environment, posing a high risk of sensitive data leaking.

3 Conceptual BEI Framework

This paper proposes a conceptual blockchain-encryption integrated (BEI) framework (Figure 2), whose scientific contribution lies on two parts: (1) proposing a "greatest common zone" (GCZ) to decompose BIM model for data segregation and (2) developing an asymmetric encryption-based method for sensitive BIM data access control. Section 3.1 introduces the GCZ method, and the development of access control method is in Section 3.2.

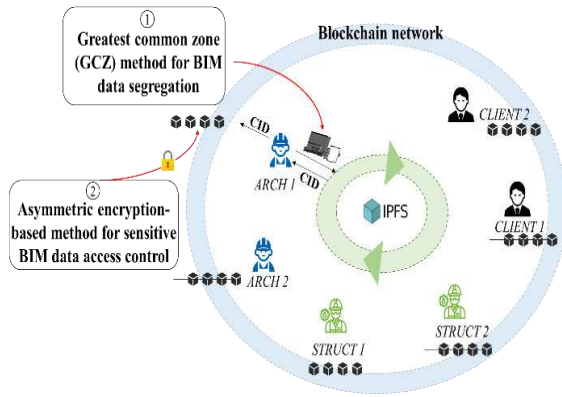

Figure 2. Conceptual BEI framework

3.1 GCZ Method for BIM Model Decomposing

A GCZ method is designed to decompose BIM models into sensitive and non-sensitive (public) BIM components to facilitate data segregation. The basic idea of GCZ is to remove sensitive zones (e.g., the layout of zones) in a BIM model and pass the remaining non-sensitive components to members who have no rights to access sensitive zones. Components contain sensitive zones are only shared with authorized members. The decomposing process involves two steps. Firstly, for each zone in each component, members who can access the zone are selected. Then, GCZ reserves the common zones that they all can access in this component.

For example, Figure 3 shows a BIM model example containing multiple sensitive zones (i.e., zone 1, 2, 3) and a non-sensitive zone (i.e., zone 4). Table 1 displays the zone access metric where ARCH 1 (design leader in architecture team), STRUCT 1 (design leader in structure team), and CLIENT 1 (leader client) can access all zones, ARCH 2 (an architecture design helper) can only access zone 2 and 4, STRUCT 2 (a structure design helper) can only access zone 4, and Client 2 can only access zone 1, 2 and 4. Figure 4 shows the model decomposing process using the proposed GCZ method. Project members who can access zone 1 can also access zone 2 and 4. Thus, in BIM component 1, zone 3 is removed while zone 1, zone 2, and zone 4 are kept. Similarly, people who can access zone model 2 can also access zone 4. So, component 2 contains both zone 2 and zone 4. It should be noted that component 1 model is only used for zone 1 coordination, and so as the remaining component models. For example, when there are design changes in zone 1, design team would update component 1 and share it with other disciplines.

Figure 5 shows the results of decomposing BIM models, including a root BIM model and BIM components. Three benefits are summarized as: (1) GCZ facilitates BIM data segregation, (2) GCZ is practical, efficient, and easy to handle, and (3) GCZ helps to reduce

unnecessary work of removing zones (e.g., we don't need to remove zone 2 and 4 in zone model 1).

3.2 Asymmetric Encryption-based Method for Access Control

As every peer could see any shared transaction in the blockchain network; thus, this paper integrates asymmetric encryption protocol with blockchain to facilitate sensitive BIM data access control. Asymmetric encryption is a cryptographic protocol that encrypts and decrypts data using two separate keys: a public key and a

private key. The public key is known to others, while the private key is kept secretly. Any person can encrypt a message using the receiver's public key, and that encrypted message can only be decrypted with the receiver's private key.

Figure 6 shows the access control method. In Figure 6, designers would store BIM components in the IPFS network in Step 1. Before sharing CIDs to blockchain network, the designer would first check if this is a CID for a sensitive component. If no, the CID would be directly distributed to other disciplines in the blockchain network through proposing a transaction (Step 2). Otherwise, the CID would be encrypted using public keys of authorized receivers (Step 3) and then shared in blockchain (Step 4). In Step 5, design information (e.g., CID or encrypted CID) would be synchronized to every member's local blockchain ledger as a design record. Subsequently, any member who wants to access a BIM component for design coordination could download it using CID he receives (Step 6). As for the encrypted CID, he could decipher it (Step 7) using a private key and download the component from IPFS (Step 8) if he is an authorized member of this component.

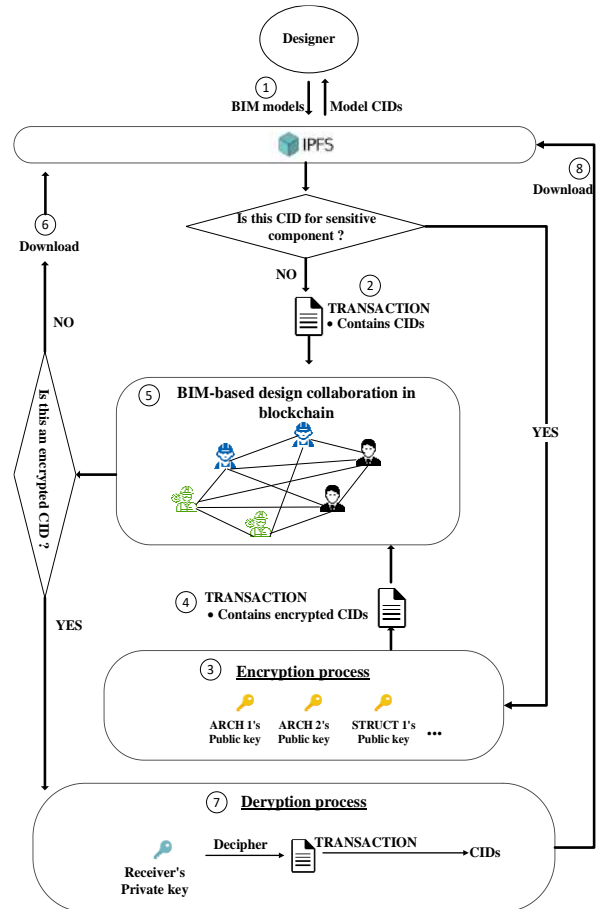

Figure 6. Asymmetric encryption-based method

for access control in blockchain

4 Illustrative Example

4.1 Prerequisites

A private blockchain platform, Hyperledger Fabric [17], is configured with three organizations (i.e., architecture team, structure team, and client). Besides, an IPFS desktop is set up for storing BIM components. The RSA (Rivest–Shamir–Adleman) [18], an asymmetric encryption protocol that is widely used for secure data transmission, is selected in this example.

4.2 Validation Process

Step 1: decomposing BIM model. As mentioned in previous sections, it is the very first step to partition BIM data into sensitive and non-sensitive part. The illustrative example utilizes the components and access requirements that are defined in Section 3.1. Figure 7 shows the BIM models and components. A root BIM model with three sensitive zones is decomposed into four BIM components. Components 1, 2 and 3 are sensitive for they contain sensitive zones. The remaining component 4 is non-sensitive. Figure 8 shows the blockchain configuration and BIM data storage in the IPFS.

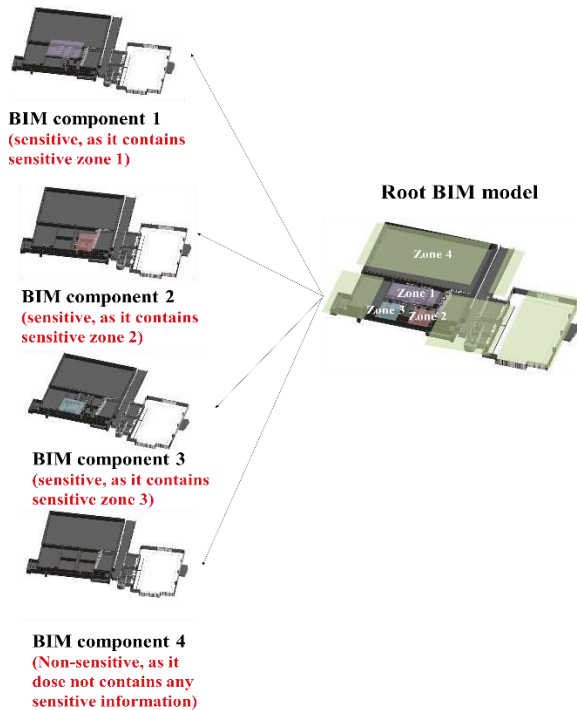

Figure 7. BIM model decomposing process in illustrative example

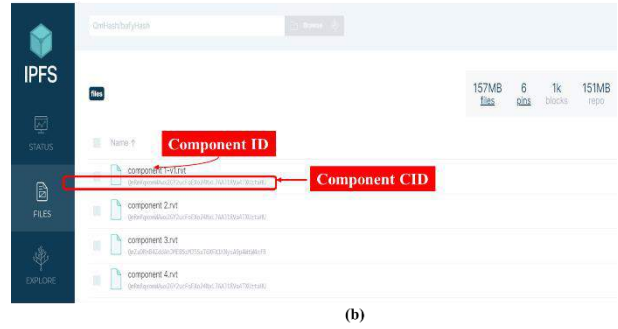

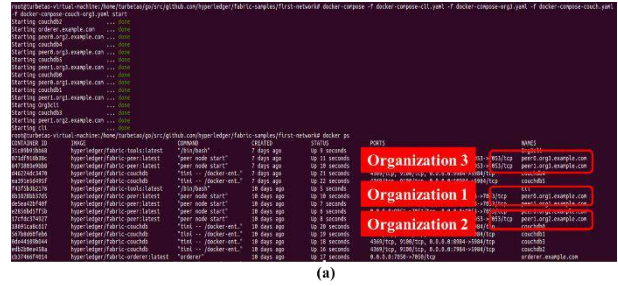

Figure 8. Blockchain configuration and IPFS data storage

Step 2: collaborating on a non-sensitive component.

ARCH 1 uploads component 4 (non-sensitive component) to IPFS and gets its CID. This is followed by proposing a transaction (Figure 9 (a)) in blockchain to share component CID. As this component is non-sensitive, there is no encrypted CID (ECID) in the transaction. Figure 9 (b) shows that the transaction has been successfully shared. Figure 9 (c) shows that a block has been generated in the blockchain network.

Step 3: collaborating on a sensitive component. To share a sensitive model (e.g., component 3), ARCH 1 would encrypt its CID using authorized receivers' public keys and proposes a new transaction. Thus, in Figure 10 (a), the CID is encrypted to two ECID for CLIENT 1 and STRUCT 1, respectively. Figure 10 (b) shows that the transaction has been successfully shared in blockchain network. Everyone can check the encrypted CID of component 3 in their blockchain ledger. However, only the right receivers can decipher the encrypted CID and download component 3. Figure 10 (c) shows a new block has been generated and chained to the previous one.

5 Conclusion

This study proposes a blockchain-encrypted integrated conceptual framework for a secure BIM-based design process. The main scientific contributions are summarized as this study developed a GCZ decomposing method to enable BIM data segregation. Besides, a blockchain-encryption integrated solution is designed to protect BIM data immutability and data confidentiality. The illustrative example section validates the feasibility BEI framework. However, this framework is an initial exploration of blockchain application in the construction industry. Potential future work includes (1) integrating technologies such as machine learning to automatically decompose BIM models and (2) implementing the framework in an actual project to evaluate its performance on network latency and throughput.

A Digital Twin Framework for Enhancing Predictive Maintenance of Pumps in Wastewater Treatment Plants

Seyed Mostafa Hallaji ^a, Yihai Fang ^a and Brandon K. Winfrey ^a

^a Department of Civil Engineering, Monash University, Australia.

E-mail: Mostafa.Hallaji@monash.edu; Yihai.Fang@monash.edu; Brandon.Winfrey@monash.edu

Abstract

Wastewater treatment plants (WWTPs) are a type of critical civil infrastructure that play an integral role in maintaining the standard of living and protecting the environment. The sustainable operation of WWTPs requires maintaining the optimal performance of their critical assets (e.g., pumps) at minimum cost. Effective maintenance of critical assets in WWTPs is essential to ensure efficient and uninterrupted treatment services, while ineffective maintenance strategies can incur high costs and catastrophic incidents. Predictive maintenance (PdM) is an emerging facility maintenance technique that predicts the performance of critical equipment based on condition monitoring data and thus estimates when maintenance should be performed. PdM has been proven effective in optimising the maintenance of individual equipment, but its potential in predicting system-level maintenance demands is yet to be explored. This study proposes a digital twin framework to extend the scope of PdM by leveraging Building Information Modelling and Deep Learning.

Keywords

Digital twin, Building information modelling, Deep learning, Predictive maintenance, Wastewater treatment plants

1 Introduction

Wastewater treatment plants (WWTPs) are a critical civil infrastructure, which plays an important role in protecting the environment and public health by reducing wastewater pollutant loads discharged into waterways [1]. However, the successful operation of WWTPs relies on the effective maintenance of critical assets to ensure efficient and uninterrupted treatment [2]. Among the critical assets in WWTPs, pumping facilities account for 25% of total energy consumption and 10% of total operating costs [3]. In addition to WWTPs, pumps are integral assets in many other industries, such as the petrochemical [4], [5], mining [6] and building sectors [7].

Operating nearly continuously in WWTPs, pumps are subjected to severe degradation. Adopting effective

maintenance approaches can ensure their performance quality [8], energy efficiency [9], and reliability [10]. Predictive maintenance (PdM) is regarded as a promising method to address these issues through continuous monitoring of the asset's condition. PdM assesses the asset performance and predicts the asset's future variations in performance and failures. PdM has started to gain significant attention in research and industry recently due to the advances in the Internet of Things (IoT) and machine learning. PdM offers the opportunity to reduce the energy consumption of poor-performing pumps and the cost of maintenance in WWTPs, where this approach has not been applied. Despite successful and wide applications of PdM in the manufacturing and oil and gas industries, PdM practices are yet to be leveraged in the building and civil infrastructure sector [11]. Furthermore, the current PdM of pumping assets still requires extensive expert knowledge, which not only is a barrier to automating the PdM process but may also lead to human errors stemming from operators' subjective influence. This study critically reviews emerging technologies under the Digital Twin (DT) paradigm and investigates their potentials and challenges in integrating with the current PdM practices of pumps in civil infrastructure. The remainder of this paper is organised as follows: Section 2 reviews the literature in Building Information Modelling (BIM) and Deep Learning (DL) in the context of asset maintenance with a focus on pumping facilities. Section 3 analyses the findings from the review and propose a DL-enabled PdM framework, followed by the conclusion in Section 4.

2 Literature review

2.1 DT frameworks for pumps maintenance

A digital twin is a virtual representation of real-world entities and processes, synchronised at a specified frequency and fidelity [12]. Collecting data from the physical system, a DT aims to replicate the behaviour of the system to offer insights into the condition and performance of the system. A DT generally consists of five components: 1) the physical asset, which refers to the facilities whose behaviour is planned to be modelled

based on the data collected; 2) IoT to communicate the generated data from the physical asset; 3) Aggregation of data, which refers to data management and storage in a data repository; 4) Analytics, which conducts data analysis and generates information for enhancing the decision-making process; and 5) Actuators, which return the modified decisions to the physical object to reflect the latest strategy of the system.

A DT promises to predict system behaviour using real-time condition monitoring [13]. Fault diagnosis is transformed from a data analysis practice to an immersive and context-relevant platform. A DT is capable of enhancing the PdM of pumping facilities by adding context-awareness to the predictions, which allows automated and accurate decisions. Despite the extended application of DT in recent years, only a few studies were found relevant to the application of DTs in PdM of pumping facilities. For example, Cheng et al. proposed a DT for predicting the condition of mechanical, electrical, and plumbing (MEP) components [11]. The proposed DT consisted of 1) BIM for integrating the facility maintenance information and IoT data, 2) Machine learning for analysing the information and predicting the asset condition. It should be noted that although the term DT was not explicitly used in their research, their framework's components complied with the framework of a DT. Lu et al. proposed a DT framework to facilitate anomaly detection of pumping facilities using machine learning methods [14]. They extended industrial foundation classes (IFC) entities and attributes to accommodate the datasets from different sources, such as asset management systems, space management systems, and building management systems. The data were further analysed for anomaly detection using machine learning methods. These studies demonstrated the use cases of a DT for pumping facilities. It should be noted that the proposed DT in these studies was only limited to anomaly detection of asset conditions and did not include more sophisticated fault diagnosis, such as severity classification.

2.2 BIM for pumping facilities maintenance

BIM is used for the management, integration, exchange and visualisation of data with the intent of facilitating effective collaboration of different stakeholders during different phases of a construction project [15]. In the BIM environment, data interoperability plays an important role in managing and exchanging data in complex projects. To address this issue, IFC and Construction Operation Building information exchange (COBie) were employed to enhance data exchange and interoperability in asset management applications [16]. IFC is a non-proprietary exchange format of building information between architecture, engineering & construction software [17].

COBie captures and delivers the required information in a BIM model to facility management systems [18].

Although BIM is well-established in the building sector, its application to facility maintenance and civil infrastructure is still developing [19]. Chen et al. proposed a BIM-based facility maintenance framework for data integration and automatic scheduling of facility maintenance work orders [20]. In their proposed framework, they leveraged the BIM capability to visualise building facility components and employed IFC to map the data between BIM and facility management systems. Furthermore, BIM is expected to be a comprehensive database, capturing essential information of all building components, which can be efficiently retrieved in a BIM environment. Cheng et al. employed this feature of BIM for managing condition monitoring data of the MEP system in an academic building [11]. They showed that, in addition to interoperability enhancement, BIM could visualise real-time sensor data and analysis result. Finally, they used the proposed framework for evaluating the condition of the facilities at present and in the future, whereby the work orders were rescheduled dynamically.

2.3 DL for pumping facilities maintenance

Significant advances in IoT and Information and Communication Technology (ICT) have enhanced the quantity and quality of data collection. This has been an essential step towards using machine learning models in PdM of pumping facilities [21]. However, traditional machine learning methods are not fully capable of analysing big data (i.e., large volume, velocity, variety, and veracity) due to shallow architecture, which is a barrier to learn complex data scenarios [22]. On the other hand, contemporary methods such as DL are capable of accommodating and analysing big data scenarios. DL algorithms are constructed by deep hierarchical architectures of neural networks, which are able to incorporate feature selection and feature extraction in neural network classifiers [21]. This approach eliminates the need for separate pre-processing, reduces operators' subjective influence and experience requirement.

Applications of DL methods in pumping facilities are discussed in this section. According to our literature review, the use of DL in PdM of pumping facilities is in the primary stage of development, which dates back to 2015, when Zhu et al. employed the Stacked AutoEncoders (SAE) method for diagnosing faults in the cylinder, valve plate, ball bearings, and piston of an axial piston pump [23]. They showed that even in small data scenario problems, DL outperformed traditional methods such as support vector machine (SVM) and backpropagation neural networks (BPNNs). Another DL method that has been employed for fault diagnosis of pumping facilities is Convolutional Neural Networks

(CNNs). CNN focuses on shifts in different properties of data sets, which can accelerate the convergence rate and reduces overfitting in training and validation stages [21]. CNN is a promising method for image and it has been recently shown that it performs robustly in processing time-series data as well. Wen et al. illustrated that this method outperformed SAE, SVM, and BPNNs in processing time-series data when the data is converted to 2-dimensional images [22]. They employed the CNN method for diagnosing six types of fault in an axial piston pump and a self-priming centrifugal pump, using vibration signals with a 10 kHz sampling frequency.

3 A DT framework for PdM of pumps in WWTPs

With recent advances in machine learning and information modelling technologies, it becomes possible to enhance the PdM and sustainability of critical facilities in civil infrastructures. Based on the literature review of the applications of DL and BIM in DT, this section presents the challenges and opportunities in a DT framework that incorporates BIM and DL for improving the PdM of pumping facilities.

3.1 Data management

An effective DT system is expected to facilitate context-aware decision-making in the pumping facilities of complex infrastructure such as WWTPs. However, designing and deploying a DT system for such complex infrastructure is not straightforward, as the unique operation and maintenance requirements need to be incorporated. Data management is a critical step in a DT system, particularly with the recent development of IoT and ICT, which significantly increased the quality and quantity of data that describes the performance and condition of assets. BIM is a promising data management technology, having a high potential for managing big data and being integrated with the DT framework [24]. BIM has been mainly employed in the architecture, engineering and construction (AEC) industry to integrate the data and formulate parallel offline and online simulations for structural integrity, energy, safety, human comfort and well-being [25]. However, the BIM application in WWTPs is expected to be with the intent of integrating sensor data, maintenance management data and wastewater treatment process data for the corresponding simulations and optimisations in WWTPs. In order to employ BIM in WWTPs successfully, the IoT network data and the computerised maintenance management systems (CMMS) data must be integrated

within the BIM environment. The IFC schema facilitates the integration of IoT data with the BIM environment, whereby BIM would be able to visualise the corresponding entities and attributes of WWTPs' facilities, particularly pumps.

3.2 Simulation and optimisation

Simulation and optimisation are critical components of a DT in different applications such as the AEC industry [26], smart cities [27] and manufacturing [28]. Similar to the AEC industry, the WWTP's applications of DT are expected to incorporate simulation and optimisation as critical components. However, the simulation methods and optimisation aims of these components differ significantly in WWTPs. For example, in the application of DT in infrastructure such as bridges [26], finite-element analyses are the core of the simulations to investigate the structural integrity of the infrastructure. Nevertheless, in WWTPs applications, it is expected that a DT supports multiple simulations such as facilities performance simulation and wastewater treatment process simulation. Furthermore, the optimisation in WWTPs focuses on environmental aspects such as carbon emission, energy conservation and water quality. Aggregation and integration of the results obtained from the multiple simulations in WWTPs for automating the system-level decision-making can be regarded as one of the prospective challenges in this field.

3.3 System architecture

Integrating BIM and DL in the DT framework can potentially provide significant opportunities in the PdM of critical pumping facilities in complex environments such as WWTPs. To guide future research works in this direction, this study presents a DT framework that incorporates BIM and DL with the intent of implementing PdM practices of pumping facilities in WWTPs. As shown in Figure 1, the proposed framework consists of three major components, namely physical asset, digital twin, and decision making. In this framework, the pumping system acts as a physical asset. Sensors act as IoT for conveying real-time condition monitoring data. The DT comprises the data/model integration layer and analytics layer. The data/model layer collects the pumping facilities data from the IoT system and CMMS database, then integrates the collected data in the BIM environment via IFC and COBie. In the next step, the data is employed to conduct the data analytics, with the intent of providing an insight into current and prospective conditions of pumping facilities.

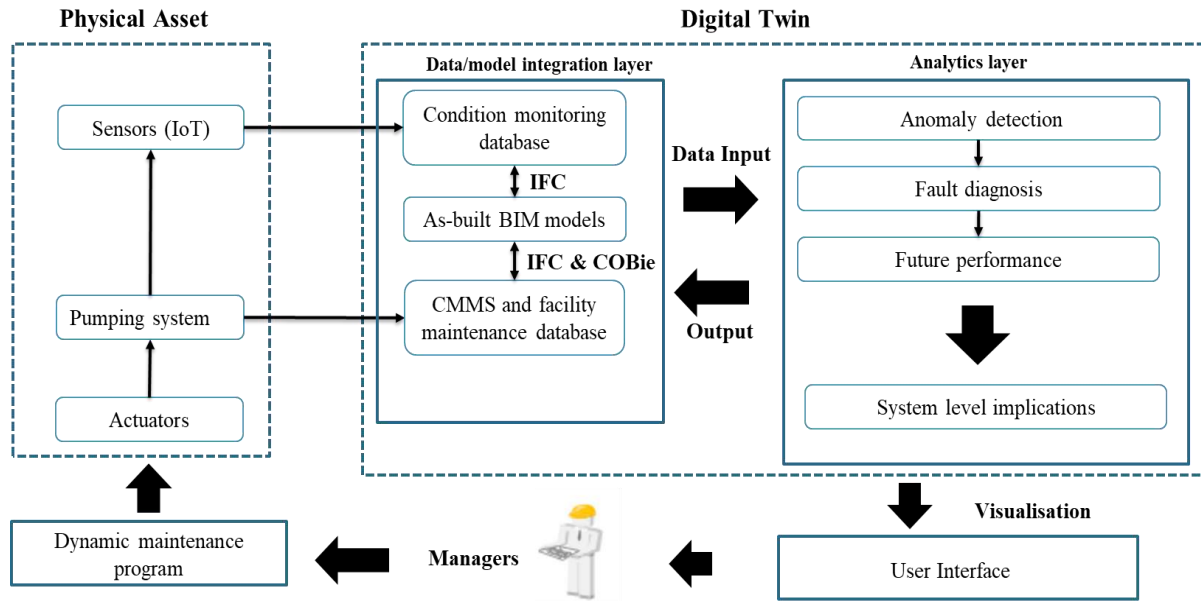

Figure 1. Proposed DT-enabled pumps maintenance framework in WWTPs

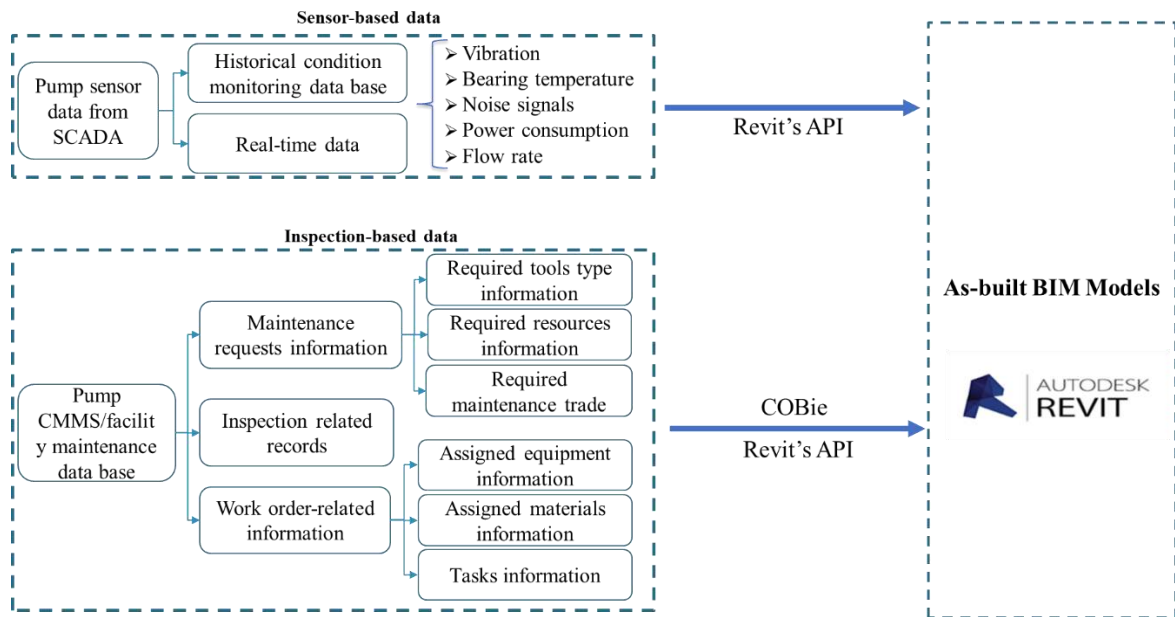

Figure 2. Illustration of data/model integration layer for big data management

Figure 2 illustrates how pump condition data and maintenance information are acquired and integrated into a BIM model using IFC, COBie and Revit's Application Programming Interface (API). Pump condition data can be collected by sensors in real-time or by querying a database, while pump maintenance information, including maintenance requests, inspection records, and work orders can be retrieved from the CMMS. In the proposed framework, sensor data are integrated into the BIM model, by developing corresponding IFC entities.

The CMMS data was mapped into the BIM model by leveraging COBie. In this architecture, DL serves a functional role in the analytics layer, where the integrated data from the BIM model are employed to detect faults and predict the future performance of pumping facilities. Next, leveraging the high visualisation capabilities of BIM, the results of the simulations above are delivered to managers to make context-aware decisions for ongoing and future maintenance of pumping facilities.

This proposed framework is expected to address the

technical challenges in the current PdM of pumping assets in WWTPs. However, the following potential issues should also be noted in the implementation of such a framework:

- WWTPs are operated by multiple teams from different backgrounds, such as mechanical engineers, process engineers, and chemical engineers, who utilise different software for their analyses. Teaching staff how to maximise collaboration via using the developed BIM and DL-based applications under the paradigm of DT can be challenging. Leveraging augmented reality can be helpful to address this challenge since WWTPs are a very critical infrastructure, and trial and error strategies on real-world plants can compromise the efficiency of the plant.
- The vast majority of WWTPs have already been constructed decades ago and deploying multiple sensors to the constructed facilities might be time-consuming, cost-intensive and technically difficult. To address these challenges, it is essential to develop DL methods performing well with the sensors available in WWTPs.
- Moving toward automation of asset maintenance and treatment processes in WWTPs, cyber security might be raised as another challenge. Therefore, relevant risk assessments should be carried out before the implementation of the DT framework to construct proper risk mitigation strategies.

4 Conclusions and Future Work

This paper presents a review of emerging technologies including Building Information Modelling (BIM) and Deep Learning (DL) under the Digital Twin (DT) paradigm for their potentials and challenges in strengthening PdM practices of pumps in civil infrastructure. Based on the review, this Hoppe study envisions a digital twin framework with the aim to extend the effectiveness of PdM in WWTPs. It was shown that in order to enhance data interoperability and collaboration in WWTPs, it is indispensable to expand the data schemas (e.g., IFC and COBie) that link different operation databases and platforms. It was also shown that DL could offer significant opportunities, such as enhancement of automation and precision in PdM of pumping assets. Implementing such a framework has the potential to improve sustainability and facilitate informed decision making in the operation and maintenance of WWTPs.

Abstract

Interoperability is an ever-present challenge for the construction industry despite the intensive research and standardisation efforts, including Building Information Modelling (BIM), and Common Data Environments (CDEs). This paper presents the BIMERR Interoperability Framework (BIF), a cloud-based platform aiming to facilitate seamless data integration, leveraging flexible ontology and data model management capabilities combined with flexible querying and retrieval mechanisms, to allow secure collaboration of legacy systems and cutting-edge applications in construction projects. The design principles of the BIF and interactions of any construction tech application with the BIF are elaborated while the perspectives opened up through the demonstration activities in the construction sector summarize this work.

Keywords –

BIM; Semantic Interoperability; Data Integration; CDE; Construction Tech; BIMERR; BIF

1 Introduction

From the collaboration between relatives from the same family towards a common goal in the stone age [1], up to the cooperation of highly specialised teams in the construction field that reaches the modern era, communication, trust and information act as core enablers that would allow the production of material goods, services and infrastructure as a sum of collective intelligence and the division of labour [2]. Contemporary digital technology however, replaced the old school, and heavily human-dependent tools of information capturing, such as drawing boards and paper documentation, with powerful software products featuring automation capabilities, that in contrast to their predecessors, were found to be unable to converse

in a mutually comprehensible language, thus resulting in data fragmentation [3] and creating the so-called “islands of information” [4].

In general, interoperability can be defined as the “ability of two or more systems or components to exchange information and to use the information that has been exchanged” [5]. Interoperability aims to bridge these isolated islands and has been widely studied in the field of construction within the previous 30 years with ever-evolving shifts in the point of view that led to the emergence of the research-intense topic of Building Information Modelling (BIM) and the conception of new paradigms for the construction of the future [6]. However, the industry still struggles with the adoption of BIM and the efficient management of the resulting information overload by organisations that are rendered in a state described as ‘drowning in data’ [7].

In this context, this paper aims to present the BIMERR Interoperability Framework (BIF), a cloud-based platform developed within the EU-funded project BIMERR [8]. The BIF is built on the principles of interoperability and standardisation, aiming to lay at the core of IT systems that integrate a multitude of construction tech tools requiring the communication of heterogeneous data for optimal collaboration, and embracing the centralised data exchange paradigm proposed by Common Data Environments (CDEs) [9], by actively supporting extensible semantic modelling, mapping and linking capabilities accompanied by flexible querying and reasoning functionalities. In Chapter 2, the paper studies interoperability in the AEC sector through a brief literature overview of three core concepts: BIM, Standardisation and CDEs. This study acts as the basis to extract the principles that underlie the design of BIF and are presented in Chapter 3. Following, Chapter 4 outlines the interactions foreseen in the context of BIF in the form of use cases, highlighting the envisioned flow of actions and the added value brought by BIF to the every-day data exchanges that take place among stakeholders and

applications in AEC projects. Finally, the paper concludes in Chapter 5 with a summary of the presented BIF framework and the upcoming demonstration activities for the validation and testing of the proposed solution in real-life conditions.

2 Literature Review

2.1 BIM

Building Information Modeling (BIM) is an information-based representation of a built asset for effective data management throughout its entire lifecycle, that is supported by a set of processes, roles, policies and technologies [10]. As per [11], BIM is the “use of a shared digital representation of a built asset to facilitate design, construction and operation processes to form a reliable basis for decisions”, thus spanning over several phases of the project, from conception and design, up to the maintenance and demolition of the built asset and facilitating collaboration and decision-making by diverse teams. To allow for informed decisions, BIM is not limited to the physical construction or to the inclusion of the temporal factor, but shall encapsulate other aspects such as safety, costs, resources, graphs etc. The multi-dimensional BIM paradigm (nD BIM) [12] has emerged to encompass the various modeling dimensions, without however having reached a clear consensus on the succession of dimension spaces and the individual dimensions per se [6]. According to the BIM dictionary [13], 3D BIM corresponds to the geometrical representation of the built asset, 4D BIM extends the geometrical representation with the addition of time, and the dimensions go up to the 5D BIM that also incorporates the cost parameter. The inclusion of additional parameters to the building modeling, has expanded the application areas of BIM in construction, with use cases in scheduling, construction simulation, construction logistics, site monitoring, clash detection, safety management, visual communication, cost estimation, quality control and more [6]. At the same time, Construction Tech systems that incorporate BIM can be categorized under the following four types: Design and construction management tools, BIM-to-field (i.e., tools realizing designs in the actual field), Robotic applications, field-to-BIM tools (i.e. tools capturing data from the fields and updating the BIM) [14]. The exponential growth of construction project data, resulting from the adoption of BIM - voluntarily to achieve better collaboration or a market edge, or after governmental [15] - and spawning for the multitude of available BIM solutions, is not by default beneficial, as it has led organisations to a state of ‘drowning in data’[7], while the fragmentation of the data models

used in the various project phases and by the various software lead to generic, incomplete 3D BIM representations, with little value for the post-construction phases [6]. Whereas BIM has been recognized as the most efficient concept in the AEC towards effective information management [16], it needs to adapt to the changing landscape of construction IT that calls for intersection with the domains of IoT and AI, that is now not possible due to incompatibility of legacy formats with the semantic web. A proposed solution towards this end is the Digital Twin paradigm [6].

One of the challenges that emerge from the variety of BIM-related software is that not all participants within a project use the same BIM solutions. ClosedBIM environments dictate the use of the same software (or even the exact same software version) by all key stakeholders. Such environments can be restrictive, as they require familiarity with specific tools and vendors, and hinder true interoperability. On the contrary, the approach of OpenBIM platforms is based on non-proprietary, neutral file formats, and the use of open standards, to allow seamless exchange of information regardless of the selected authoring solutions [17].

2.2 Standardisation

Integration of construction IT with emerging digital technologies such as the semantic web, cloud computing and IoT open new technical means of collaboration [16], while at the same time emphasizes the inefficiency of traditional import/export functionalities to serve the data exchange requirements between an overwhelming number of Construction Tech tools and platforms aimed at different stages of a project’s lifecycle [6]. Standardization of data exchange is a core feature towards supporting semantic and technical interoperability and has been extensively studied as an enabler against data silos and fragmentation.

The first standardization attempts for the construction industry can be traced back to the late 1980s with the conception of the ISO STEP standards for the integration of computer-aided design (CAD) and computer-aided engineering (CAE) software [18] defining specific information exchange mechanisms and EXPRESS as the common descriptive language and establishing a standard implementation method with the STEP format [16]. Efforts for the further development of the ISO-STEP standardization have been shifted in the early 2000s towards the specification of the open, object-oriented and industry-led Industry Foundation Classes (IFC) for building assets and infrastructure representation [19]. Since the first registration of the IFC with ISO in 2013, it continues evolving to cover needs raising from practice and to incorporate the latest

advancements in the IT and constructions. Standard Model View Definitions (MVD) are subsets of the complete IFC schema, developed to narrow down the otherwise large and complex IFC schema for specific applications of interest, using the Information Delivery Manual (IDM) [20] as a standardized method for specifications definition. More recently, the integration of linked data and ontologies is seen as a possible way to address the rather static nature of classic IFC that does not allow dynamic model modifications [6], resulting in developments such as the ifc-OWL [21][22], an ontology representation that offers a more flexible basis for interoperability [23]. Construction Operations Building Information Exchange (COBie) is a non-proprietary data format standard for the collaborative collection of a construction project's information in defined project stages, allowing communication among teams and the handover of complete documentation by the project's end to the client [24]. It is oriented towards capturing asset data without their geometrical characteristics and is the designated format for non-geometric information exchanges in open data formats according to the UK National Annex within [25]. Other ontologies in the domain include the BIM Shared Ontology (BIMSO), CBim, cityGML, SEMANCO, SAREF, DogOnt, ThinkHome, SEAS, IC-PRO-Onto [26].

Despite the wide adoption by OpenBIM solutions, of the IFC standard for built asset representation, and COBie for BIM information exchange and management [27], true interoperability is a challenge that can be viewed under the 'interoperability aims' (access data, re-use data, check data, retrieve data, link data, combine data, combine data hubs) that should be served through the communication of systems.

2.3 CDEs

Common Data Environments are technology solutions that enable collaborative working in the AEC sector [9]. The term CDE was initially conceived in the code of practice BS1192-2007 for collaborative information production and management in the AEC and was part of the PAS 1192-2 specification [28], that were later both superseded by BS EN ISO 19650 [11], and refers to systems that serve as a single source of information, responsible for the collection, management and dissemination of documentation, graphical models and non-graphical data (i.e. including both BIM and conventional data) among teams involved in a project to avoid duplications, erroneous data and unavailability of the latest information.

Towards this end, CDEs deliver a mix of services to their users, with core features including: file publication, document management, data security, search capability, reporting/dashboarding, information viewing, mobile

and field support, integration potential [9]. From the perspective of technical interoperability, CDEs fulfill what they promise through cloud and web-based technologies, as for example with the implementation of REST APIs in place of traditional direct file-based exchange [29], while from a semantic scope the adoption of open data formats and federated data models is key for the seamless collection and reuse of data authored in different tools and formats. Except for semantic and technical interoperability, CDEs need to address key challenges touching upon legal and organizational aspects. More specifically, a CDE shall handle issues concerning among others, data security [30], data ownership and copyright [31], data sovereignty [32], data privacy [33] and more.

In correspondence to the closed versus open BIM approach, CDEs have evolved in a similar way. This has led either to the development of closedCDE solutions offering high levels of interoperability between tools of the same suite, based on proprietary formats and specifications, while excluding competitive or open solutions, or to openCDE tools that follow the openBIM guidelines for vendor-neutral interoperability. Ongoing efforts are also directed towards the specification of openCDE APIs aiming to further improve interoperability within the AEC software ecosystem through closely-knit, domain-specific APIs. Going beyond the level of information exchange between tools within a single CDE, to cover interoperability requirements introduced by concepts as the construction digital twins, [17] suggest a paradigm that considers multi-dimensional interoperability among CDEs. According to this paradigm, interoperability can take place between tools within one CDE (one-dimensional CDE), between CDEs within a project or company (two-dimensional CDE) or among collaborative and digital twin platforms (three-dimensional CDE). With the addition of dimensions, comes inevitably an increase in complexity for handling a wider range of data formats, and environments, that could be addressed with the assistance of semantic web and linked data technologies [34].

3 BIF Design Principles

Interoperability in the AEC sector remains a challenge. Construction Tech solutions with high specialization operate in a siloed manner as they use their own internal representations and perform any required data exchanges with other tools in a bilateral manner. In the meantime, the industry is still in the progress of efficiently adopting Level 2 BIM that focuses on full collaboration, whereas the latest developments in construction IT (e.g., digital twins, AI, field-to-BIM solutions etc.) call for full integration

through truly interoperable data – what is known as Level 3 BIM maturity.

The BIMERR Interoperability Framework (BIF) aims to remediate this gap in the BIM chain by providing a technological enabler for achieving holistic interoperability between the various tools and stakeholders in AEC projects. Through the BIF, applications involved in the same building construction or renovation project, no longer need to exchange data in a direct bilateral way. On the contrary, BIF will act as the mediator, incorporating the required data models, functionalities and access-control mechanisms that allow the collaborating tools and actors provide and consume data in a centralized manner.

Semantic interoperability is supported by the underlying ontologies and common data models [35] developed from the in-depth analysis and enrichment of existing AEC-related data models and ontologies, to cover the semantic linking and data model population needs of the interoperating tools. Each data model corresponds to a different dimension of a renovation project; tangible objects (i.e., the building assets, materials), sensor data, analytics data and results (i.e., occupants' comfort profiling and prediction, renovation scenarios), processes and time (process modeling, workflows and schedules), communication (e.g., annotations by occupants or workers, health and safety issues). The distinction of the data models per domain allows easy exploration and identification of concepts suited to each user (application or human actor). However, the case of multi-domain data residing within the same data asset is common among construction tools, thus requiring the support of data model linking and cross-domain reuse of common concepts and data fields.

Interoperability is often tightly related to standardization. Therefore, the basis for the development of the BIF common data models is comprised of open and standardized models that are widely adopted in the domain, including IFC [36], obXML [37], SenML [38], SAREF4Building, BCF. In alignment with the latest trends in construction technologies that highlight the need for dynamicity and extensibility [6], data models in BIF are implemented as living entities supporting versioning, continuous evolution and backwards data compatibility. Existing data models can be managed throughout their entire lifecycle, to cover newly identified modeling needs and allow integration of information coming from new tools and platforms, while the overall data model collection can be expanded in a continuous manner to cover new domains of interest and allow even more construction applications enter the BIF framework, thus expanding the scope of interoperability in various phases of a build asset's lifecycle.

From the perspective of data, their compliance to

standardization is a natural outcome of the mapping to the common data models that follow greatly the existing standards. For further alignment with the ISO 19650 specifications for CDEs, BIF provides versioning, status and category metadata options. Finally, as BIF follows an openCDE approach, the utilization of open data sources is possible through the available data collection and mapping mechanisms.

The design of the appropriate technological means for data exchange facilitates interoperability at a technical level. Driven by flexibility [29], BIF provides REST-based data collection methods, using APIs provided either by the interoperating applications or exposed by BIF, while also providing the option for direct file upload as a secondary method. Users can utilise the APIs to send plain text data or accompanied by binary files, such as audio, video, photos, ifc files and more. Further customization of data collection aspects, such as collection and processing periodicity, and the capability of data enrichment with static or dynamic parameters, allow users tailor the process to the needs of their applications. Another interoperability need that needs to be satisfied is the 'access to data' [27]. BIF integrates a search and query engine for the exploration of available data and the definition of customizable queries for data retrieval. The available filtering, sorting modules facilitate easy identification of data assets of interest and an enhanced user experience, while the integrated search functionality supported by data indexing methods allows efficient and fast keyword-based searches to be performed over field names and content. A query configuration interface provides the user with the option to fully customise the incoming results that will be fed to the requesting application, be selecting the subsets of data they need and query parameters that can be utilised upon request for filtering. The actual data retrieval mechanism is corresponding to the respective upload method, being either direct file download or API based retrieval. Various data linking challenges (such as semantic, temporal and spatial homogeneity) can be addressed through the combination of the mapping to context-related concepts inside the models and the retrieval mechanism allowing to join data from multiple datasets.

Security in BIF is addressed in a multi-dimensional approach. User authentication and authorisation is enabled through the integration with the Keycloak open identity and access management solution. Token-based API access authentication is enforced for all API requests to the BIF either for data collection or retrieval purposes. An important aspect in the exchange of data among different stakeholders and tools concerns access control. In compliance with the principles of organizational interoperability, the original owners of the data shall be able to define explicitly the applied

access policies. Elaborate research on the requirements of AEC projects and stakeholders, revealed that for data that are not intended to become publicly available, access can be decided on user-level (identity or assigned role within an organisation), application-level, project-level or even on apartment-level. Once defined by the data owners, the access policies are enforced on the data assets and the access control mechanism is activated whenever a user or application tries to gain access to data, at search or querying time, to ensure that the requesting actors gain access only to the parts of information they are eligible. Data ownership and intellectual property rights, another legal and organizational interoperability requirement, is resolved through the attachment of licensing metadata on the data asset, defining various aspects of proper data usage based on preloaded Creative Commons, Community Data License Agreement and Open Data Commons licenses for public data, or customized licenses composed from the selections of the user. The operational status of BIF is constantly monitored through a deployed application monitoring and error tracking software that offers real-time alerting, customizable error logging and performance overview features to ensure timely response and operational stability.

Although the BIF integrates AEC data models, it is a platform that can in the future be generalised and used in other domains too, by integrating the respective data models (such as the energy, cybersecurity, health and more). Opposed to other open-source solutions, it provides a flexible mechanism for data exchange and reuse by applications with different specifications and processing capabilities, based on the use of common data formats and going further from simple file exchange functionalities

4 BIF Interactions

The BIF aims to serve the collaborative working paradigm as a central cloud-based information point, ensuring the seamless and secure data exchange among the individual construction tools and applications. It has been designed and developed in the context of the H2020 project BIMERR [8], that envisions the design and development of an ICT-enabled Renovation 4.0 toolkit comprising tools for Architecture, Engineering & Construction (AEC) stakeholder support throughout the energy efficiency renovation process of existing buildings. However, the extensible and application-agnostic approach in the design and implementation of BIF will allow its adoption in AEC projects outside the renovation stage, facilitating semantic interoperability throughout all phases of the complete lifecycle of building assets and infrastructures.

Figure 1 demonstrates the internal architecture of BIF along with the typical data exchanges that take place between BIF and interoperating tools but also among the BIF subcomponents. The functionalities and implementation and deployment of the BIF subcomponents are extensively documented online [8]. Additionally, the specific data exchanges that take place in the context of the BIF interactions (Model Management, Data Upload, Data Retrieval) are depicted in three detailed sequence diagrams developed in the context of the BIMERR architecture.

4.1 Model Management

The Building Semantic Modelling subcomponent is the facilitator of semantic interoperability with the support of the underlying data models that are created, integrated and maintained within the framework by users of the BIF assigned with the role of model manager. The users can navigate and manage the models of the BIF throughout their entire lifecycle using the graphical interface of the Model Manager. During the model creation stage, the user can add the data model concepts and fields, defining their main details

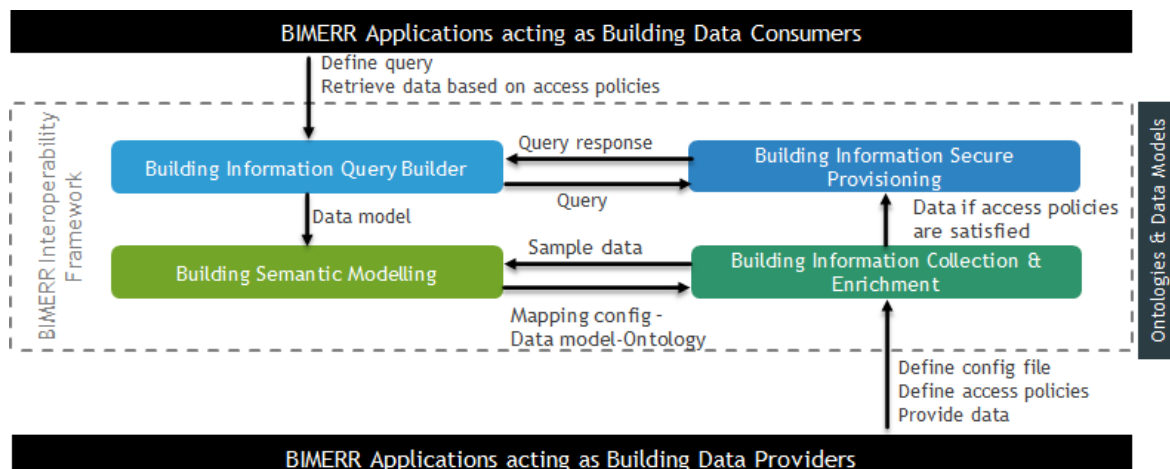

Figure 1. Overview of the BIMERR Interoperability Framework (BIF) components and interactions

and adding various metadata, such as the field type and cardinality, but also defining parameters, as for example the related terms, that will be fed to the mapping prediction engines of BIF for improved and efficient data retrieval. As a good practice in the design of the models and to ensure compatibility with industry applications, the models created for the BIF can be built upon existing semantic models directly or indirectly related to the AEC, coming from a multitude of sources, without any technical restrictions to creating totally new models being imposed by BIF. To further facilitate the linking with existing domain standards and ontologies, the user can assign to each field the corresponding standard it is associated to. Building semantic links as bridges between individual data models is an efficient way to avoid duplication of concepts that are common among different AEC domains. During the semantic linking step, the user attempts to link different data models, along their concepts in a drag-n-drop manner, thus reusing concepts that have already been modelled, saving time and ensuring the unified modelling of data representing the same type of entities. As time goes by, existing models are updated, while new ones may emerge, and individual concepts or complete models may become obsolete. Additionally, during the application of the data models, any inefficiencies and omitted concepts or misunderstandings in the initial conceptualisation of the model will be revealed. The functionalities for these dynamic adjustments and expansions can be realised following a semantic model reconciliation process through the Semantic Model Lifecycle Management tool. Any changes performed in the data models at operation time, are also applied by the data scientist to the respective ontologies through the Ontology Manager Framework.

4.2 Data Exchange

Once the underlying data models are available, the other services of BIF are launched in a distributed manner to instantiate the models and populate them with actual data. During this phase, real-time and batch data are ingested through APIs from the interoperating tools and users can start acting as data consumers and providers in a workflow that will be described in the following paragraphs. The envisioned use case follows the journey of a data asset in BIF, from the initial collection preparation steps and the actual data collection, processing, and storage up to the moment it is retrieved by another interested tool or user.

AEC professionals are participating in a construction project and want data generated from their application to become available to other teams. They first need to access the Building Information Collection & Enrichment user interface to configure the various aspects around data collection, such as method of data

collection (through their application's API, using an API generated by BIF on demand, or even with direct file upload), the periodicity of collection and data processing, as well as specify the subset of the data that shall be harvested. Afterwards, the user is prompted to the Building Semantic Modelling UI, where she can semantically map the data that will be provided by their tool to the BIF common data models, in a drag-n-drop manner. The underlying mapping prediction engine that is built on schema matching techniques, generates mapping recommendations with an assigned confidence level to speed up the overall process. If the user identifies any missing fields or concepts from the available data models, she can make ad-hoc requests that are forwarded to the Model Manager component and appropriately assessed and handled by the data model administrators in case model remediations are required. Once the mapping is completed by the user, a background validation check is performed to ensure error-free data transformations when the actual mapping service is invoked, and the user is appropriately informed of any discrepancies. To complete the data collection configuration, the user is led to the loader configuration step to define the name and description of the data asset. Once the configuration process is completed, a configuration file encapsulates all the information and is used by the underlying orchestrator for the timely invocation of background services provided by the Building Information Collection & Enrichment and Building Semantic Modelling components for the collection, mapping, enrichment, processing and finally the indexing and storage of the data asset, that is now transformed from the native format to the target format of the common data model, thus allowing other tools retrieve and re-use it for their operations. At any time, the user acting as the original data owner of the data can define and update the asset's metadata, to make them available to the other users of the BIF, specifying apart from informative details, such as related keywords, language, format, also the fine-grained access policies that shall be enforced by the Building Information Secure Provisioning tool and will regulate access provision based on various aspects thus ensuring data privacy and security.

On the other side of this journey, we find applications that want to consume data assets for their operations. To facilitate this, the developers of the application shall access the Building Information Query Builder UI and explore the available data assets – note here that they can only view assets they are eligible for based on applied access policies - utilising the filters, keyword search and sorting modules of the Search UI to easily identify the appropriate data assets. Then the user can proceed with fully customising a query for the retrieval of the selected data asset(s), by explicitly

indicating the fields she wants and defining query parameters, previewing a sample of the query results to ensure that the data asset indeed fits the needs of the consuming tool and finally utilise the retrieval API provided by BIF. Token-based authentication/authorisation prevents any illegitimate access to data. The fully configured query can be used multiple times by the consuming application to retrieve information and is stored in the Building Information Query Builder for easy access and updates by the user who created it.

5 Conclusions

Technical and semantic complexity, coupled with legal and organisational factors act as prohibitors for the adoption of truly interoperable solutions in the constructions industry. The BIF, developed in the context of the BIMERR project, aims to surpass these limitations, by providing the appropriate data management and integration functionalities and following widely adopted industry standards and design principles, that will allow any construction tech application retrieve and provide semantically coherent data for efficient collaboration. Considering the ever growing of data-intensive technologies entering the construction IT landscape, the need for the development and adoption of efficient, flexible and extensible interoperability solutions such as BIF becomes even more apparent.

The offerings of the BIF will be showcased in the context of the upcoming demonstration activities within the BIMERR project, that will validate its added value and will act as a proof-of-concept for the overall vision of BIF. Several applications involved in the overall lifecycle of a renovation project, from building information capturing and modelling up to renovation design support, planning and monitoring, will exchange data through BIF. More specifically, these will include software and hardware-enabled tools developed as part of the BIMERR Framework. The demonstration activities will take place in the upcoming period, in two real-life multi-family residential pilot sites that will undergo renovation, in Poland and in Spain.

Abstract

The application of Building Information Modeling (BIM) technology allows a digital representation of physical and functional characteristics of places, which is particularly beneficial to civil engineering. The present article proposes to evaluate the utilization of BIM technology to quantify the damage caused to concrete structures, based on a systematic review of the literature. The findings support the view of BIM as a promising path for the analysis of concrete structures, both in terms of representation and prevention of non-occurring events. It also highlights the existence of few studies exploring the topic and consequently the need for research into this area.

Keywords –

BIM; Civil engineering; Damage; Concrete structure

1 Introduction

During a building life cycle, around 20% of the expenses are associated with design and execution phases, while the remaining 80% refers to the operation and building management costs. The importance of effective communication from the initial project phase to the complete stage of construction challenges project managers to find ways to improve project efficiency since traditional methods don't meet up with operational requirements and are no longer effective [1].

The discussion about the maintenance of buildings is critical as it predicts and corrects possible problems, also optimizing service lives of systems and components. It should be noted that this must be done through actions that prevent the occurrence of disasters and/or unnecessary expenditures related to recuperation or reconstruction as result of damage. In other words, building maintenance consists on a set of activities to be carried out in order to preserve, conserve or remedy the

integrity and functional state of the building and its systems [2].

In this context, it's possible to say that designing projects through BIM software will have a direct impact on the operation and management phases. The models represented by 3D (project), 4D (planning), and 5D (budget) spheres are rich in data that can be extracted at any time, providing detailed information about the elements of construction [1].

Nonetheless, when building maintenance or adverse events that affect the building such as, fires and earthquakes are neglected, the task of identifying the source of damage in order to plan the correct action is very difficult. Therefore, as discussed by Ma et al. [3], during the subsequent phase of reconstruction and recovery, the inspectors need information about deformation and displacement that has occurred in the components of the building structure in order to properly assess damages. Thus, BIM technology provides a useful and appropriate method to collect and communicate all these data.

The role of structural engineering in the management of existing buildings consists of safety assessments and the planning of retrofit interventions, if required. The process begins with the acquisition of a set of data that forms the input when defining a structural model that represents the mechanical behavior of a construction [4].

Independent of the country, it is necessary to register defects and damages for later assessment and maintenance planning. Modeling damages within a BIM context is a pre-requisite to support the full life cycle of built infrastructure. Aiming at modeling damage information it is important to know existing damage types and related parameters [5].

Therefore, if the concept of building maintenance is already in place, then we can say that the recovery process would be facilitated since the building in question has been regularly monitored. On the other hand, the absence of important information, consequently, will make the task harder, and require procedures to detect

deterioration, monitor possible deformation and estimate post-disaster damage.

Considering the discussion above, the present work seeks to evaluate, through a systematic literature review (SLR), the different methods of quantification of damage using BIM technology. This study highlights not only different techniques used as assessment tools but, also, promotes an important discussion among scientific community embracing the insertion of multi-professionals into this field.

2 Research Method

Systematic literature review consists on secondary studies that aim to map, find, critically assess, consolidate, and aggregate findings from relevant primary studies about a specific research topic. With this in mind, it is possible to state that the SLR allows the identification of gaps in the researched topic that still need to be filled in. The term "systematic" implies that the review must be based on a method that mainly guarantees the impartiality, precision and replicability of the study [6].

This paper deals with the use of different BIM approaches to analyze structural concrete damage. To do so, we used the P.I.C.O. model, as illustrated in Table 1, to address some of the research questions i.e. Population, Intervention, Context/Comparison and Outcome.

Table 1 PICO model for research questions

P.I.C.O.	Research Questions
Population	Buildings with presence of damage
Intervention	Use of BIM methodologies in damage analysis
Comparison	Different ways to determine and quantify damage
Outcome	Check the use of BIM methodology in the calculation, quantification and simulation of damage to buildings

Databases such as Springer, Scopus, ASCE and Compendex were selected to conduct this SLR. The search string used included the use of keywords related to the theme such as: BIM, damage, concrete, structure and simulation. The boolean operator "and" was used throughout the search period, which occurred from December 2020 to February 2021. The stages of the review as followed and carried out are illustrated in

Figure 1, according to Vilela et al. [7].

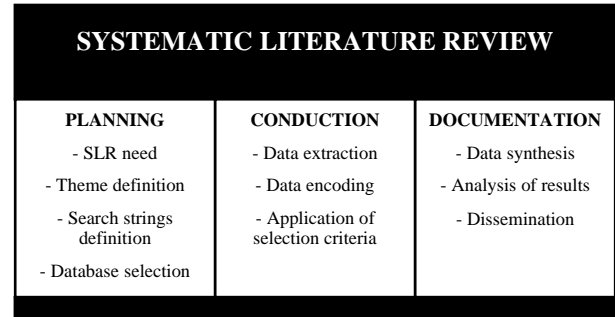

Figure 1. Stages of the Systematic Literature Review

The search strategy consisted in running the searches in the previously mentioned databases and related papers filtered out according to the following inclusion criteria: (1) publications from the last 6 years, (2) published papers in conferences and journals and, (3) open access articles. The exclusion criteria were the following: (1) papers not addressing the theme and, (2) repeated publications between databases. The selection process is illustrated on Table 2 which shows a total of 10 relevant papers to the topic in question.

Table 2 Assessment and selection of studies for the SLR

Databases	Total	Inclusion criteria			Exclusion criteria		Total per database
		(1)	(2)	(3)	(1)	(2)	
Springer	178	120	51	40	4	4	4
Scopus	7	1	1	1	1	1	1
ASCE	134	81	79	78	4	4	4
Compendex	12	6	4	4	2	1	1
TOTAL							10

The results allow us to identify geographic areas conducting research on the topic. Thus, we highlighted countries where papers have been published with more frequency (Figure 2) along with the growth of publications over the last 6 years (Figure 3).

Figure 2. Number of publications on the topic by countries

Figure 3. Number of publications on the topic over the course of 6 years

3 Results and Discussion

3.1 Damage Type

The structures in service can suffer serious durability problems, whether due to the natural aging mechanism, the lack of building maintenance or even unforeseen events, as discussed by Ghahremani et al. [8]. Therefore, it is essential to analyze the type of damage that could impose risk to the safety of the structure.

In the studies covered by the SLR, the following types of damage were investigated: seismic events, terrorist

attack, degradation and cracking as seen in Figure 4.

Figure 4. Number of publications about the type of damage studied

Vogelbacher et al. [9] used a plan-level approach to assess risk and analysis of urban neighborhoods with vulnerability to terrorist attacks in accordance with empirical risk analysis, based on the history of terrorism events. At the plan level, the urban topology becomes known, including the location and infrastructure of the buildings. However, without having information about the exact geometry and materials used, it is only possible to identify city blocks and not individual buildings.

Zakeri et al. [10] presented a review of several image processing approaches to check cracks in asphalt surfaces. In addition, they also addressed emerging and evolving technologies to automate processes, such as non-contact assessment techniques classified as Charged-Coupled Device (CCD), Ground Penetration Radar (GPR), Laser Systems (LS) and Hybrid Systems (HS).

Ghahremani et al. [8] analyzed the degradation in structures through a methodology consisting in automatic and systematic detection along with the quantification of damage in structural components. They used a high-fidelity 3D point cloud data in conjunction with a finite element analysis.

The article written by Xiong et al. [11] proposed the simulation of multiple levels of detail (LOD) considering various structural types, available data and simulation scenarios in a real application of seismic damage to urban buildings.

The research carried out by Zhen et al. [12] discussed a simulation method (5D) for post-earthquake building repair process using BIM technology; the repair activities were linked to a 3D model along with estimation of time and related costs.

Ren et al. [13] analyzed seismic events through the junction between BIM and finite element analysis. The study suggested that it is possible to identify patterns of damage from different structures using skyscraper and

community building simulations. Ma et al. [3] also supported the use of BIM technology for damaged buildings and synthetic scan generation. The authors discussed a post-earthquake reconstruction analysis with precision based on a representative database.

The research conducted by Xu et al. [14] proposed a post-earthquake fire simulation method. The seismic damage of the sprinkler systems was considered in order to assess the effects of fire damage in buildings. Lu et al. [15] addressed the simulation of an indoor post-earthquake fire rescue scenario using building information modeling (BIM) and virtual reality (VR).

Finally, Gavrilovic and Haukaas [16] completed a post-earthquake visual damage analysis along with methodology for estimating seismic losses based on the type of damage prediction, estimation of repair costs, length and working hours.

3.2 The usage of BIM

There are several types of BIM usage models. BIM Excellence (BIMe) - a tool for evaluating BIM performance - brings a classification of BIM usage models based on surveys by Succar and other international collaborators. According to the Model Uses List [17] the studies were classified in six domains as shown in Figure 5.

Modeling of concrete structures - 1050 <ul style="list-style-type: none"> • Ma et al. (2016) • Xiong et al. (2019) • Gavrilovic and Haukaas (2021) 	Finite element analysis - 4100 <ul style="list-style-type: none"> • Ghahremani et al. (2018) • Ren et al. (2019)
Structural integrity monitoring - 7050 <ul style="list-style-type: none"> • Zhen et al. (2020) 	Urban modeling - 1490 <ul style="list-style-type: none"> • Vogelbacher et al. (2016)
Simulating and quantifying fire and smoke - 4120 <ul style="list-style-type: none"> • Xu et al. (2017) 	Virtual reality simulation - 4240 <ul style="list-style-type: none"> • Lu et al. (2020)

Figure 5. Classification according to the BIM usage model

The model used that had the greatest prominence was the modeling of concrete structures on papers published by Xiong et al. [11], Ma et al. [3] and, Gavrilovic and Haukaas [16]. The papers published by Ghahremani et al. [8] and Ren et al. [13] supported two different applications of BIM; the modeling of concrete structures and finite element analysis. The usage of structural

integrity monitoring was only mentioned in the study by Zhen et al. [12]. The topic of urban modeling was discussed in Vogelbacher et al. [9], and the simulation and quantification of fire and smoke in the study by Xu et al. [14]. The paper by Lu et al. [15] also addressed two different applications of BIM usage on simulation and quantification of fire and smoke, as well as virtual reality simulation. Finally, the study conducted by Zakeri et al. [10] was not part of the review due to its classification as a systematic review of the literature itself.

3.3 Simulation Models

The analysis of the 10 selected papers on the SLR shows that the most popular simulation is the 3D dimensions. This could be explained by acknowledging that 3D is a popular type of simulation that has been utilized for a longer period of time, when compared with the five dimensional method (5D). The 5D dimension method is newer and was only observed in a study published in 2020 as seen in Figure 6.

Figure 6. Type of simulation applied over the years

There is a lack in studies that analyze advanced levels of simulations, hence narrowing access to a higher degree of accuracy and even more innovative features. The studies of Vogelbacher et al. [9], Ma et al. [3], Xu et al. [14], Ghahremani et al. [8], Xiong et al. [11], Ren et al. [13], Lu et al. [15], and Gavrilovic and Haukaas [16] reviewed the application of 3D simulation. As per articles addressing the use of 5D simulation, we refer to the studies of Zhen et al. [12] and the systematic literature review of Zakeri et al. [10].

4 Conclusions

BIM presents itself as a promising path for the analysis of concrete structures, in terms of both, representation and prevention of non-occurring events. It is also favorable to the process of reconstruction through the simulation of events that have already occurred, such as: terrorists attacks, earthquakes, etc. Simulation allows us to predict and understand the structural behavior as well as to develop appropriate plans of action. The simulation process is basically a test that is performed through the use of a digital model.

This review gave evidence to the existence of only few studies on the subject. However, this can be seen as an encouraging factor to promote the development of new research exploring a topic that will contribute to the insertion of multi-professionals into this new job market.

Towards a Construction Site Control System – Task Management in Construction Operations and Intralogistics

M. Schöberl^a, D. Bartmann^a, S. Kessler^a and J. Fottner^a

^aChair of Materials Handling, Material Flow, Logistics, Technical University of Munich, Germany
E-mail: max.schoeberl@tum.de

Abstract –

The operation of automated construction equipment and autonomous construction robots depends on contextual information regarding the job to be carried out. Therefore, robots as well as equipment require a task-based construction site control system. Such a system also provides some advantages for construction managers. However, some prerequisites must be met prior to implementation. This paper positions the construction site control system concept in the current and future task management on construction sites and compares approaches from autonomous intralogistics with those of the construction sector. The paper then examines the required functionality of a construction site control system in detail and closes with the demonstration of an exemplary construction site control system (CS²).

Keywords –

Construction Site; Control System; Task Management; Construction Robotics

1 Introduction

Standardized processes and the application of autonomous construction equipment are innovative, high-performing and versatile approaches and represent the key elements in the digitalization of the construction site. Autonomously operating equipment implies the need to efficiently assign explicit tasks to such equipment. However, task assignment on construction sites is currently hardly automated. In most cases the whole communication is verbal and informal. In order to meet the growing demand for automated task assignment, the concept of a control system can be adapted from other industries. A control system provides equipment with significant data and tasks before and during operations. The aim of such a system is to manage operations efficiently, to detect disturbance variables at an early stage and thus to realize a smooth, excellent construction process. Additionally, a control system infrastructure enables the exchange of environmental information

between autonomous equipment, which simultaneously forms a uniform data basis for cooperative operations. In addition to the necessity for increasingly automated equipment operation, there are a number of positive effects on the management of construction processes. Coordination efforts for reoccurring tasks and misunderstandings when passing on tasks between site manager, foreman and vehicle driver are eliminated with a CS². Furthermore, job results are automatically reported from the autonomous equipment to the CS², reliably documented, and made accessible to authorized users. Site managers and foremen can thus focus on managing inevitable, unforeseeable changes. In the future, the meta-data generated during the processing and reporting of tasks can be used for project control and enable process mining approaches on the construction site.

2 Research Method and Structure

Motivated by the vision above, the overarching research question of this paper is: *How does an applicable and sustainable control system concept for the automated construction site look like?*

In order to approach this research question, expert interviews with various construction stakeholders and equipment manufacturers have been carried out. They form the basis for the process analysis described below and the assessment of applicability. Subsequently, an interdisciplinary expert workshop on the understanding and functionality of a CS² was conducted as part of a research project. Additionally, literature on task management and control systems applied on construction sites was systematically reviewed to classify existing solutions. In order to sustainably address future fields of action in autonomous construction, other, more automated, sectors were also consulted. With intralogistics, a suitable industry was found in which autonomous transport systems are already integrated into the warehousing process. The comparison of task management in both industries provides structure for defining and conceptualizing a CS² and, moreover, an established template for implementation. Finally, parts of the template were implemented in a small case study, to

demonstrate practicability.

3 State of the Art

This section covers the state of the art regarding the research matter and is divided in four parts. First, some fundamental concepts are defined in this section to familiarize with the topic and create a universal understanding. Second, the current task management process and state of control systems on construction sites based on expert interviews is depicted. Subsequently, a systematic literature review depicts the current state of research regarding task management and control systems in construction. Finally, the fourth section covers an excursus to the advanced control systems of autonomous intralogistics.

3.1 Fundamentals

It is important to clarify the two fundamental concepts of task management and control systems before going into more detail.

First, task management is defined as the process of managing tasks, specifically planning, testing, tracking, and reporting, in order to accomplish a collective or individual goal [1]. Adherent to this definition, it composes an element of project and process management [2]. Second, a control system can be defined as a “system that can command, direct or regulate itself or another system to achieve a certain goal” [3]. More specifically in the ISA 95 [4] automation pyramid, industrial control systems are divided into 5 levels, from production process (Lvl. 0) to business planning and logistics (Lvl. 4). The scope of control systems regarded in this paper spans from level 2: Monitoring and Supervision to level 3: Manufacturing Operations and Management. Typical systems for these levels are Supervisory Control and Data Acquisition (SCADA) for level 2 and Manufacturing Execution System (MES) for level 3.

3.2 State of Practice

Before going deeper into the above defined theoretical concepts, the current state of task management and control systems on construction sites is reviewed. Therefore, expert interviews with various stakeholders of the construction industry have been carried out.

Task management on today’s construction site can be divided into three levels: project management, work instruction and execution. Today, the information exchange between these levels is based on direct, verbal dialogs. At the project management level, the site manager translates the general project data (e.g. timetables, plans) into concrete instructions for action and passes them on to the foreman (see Fig. 2).

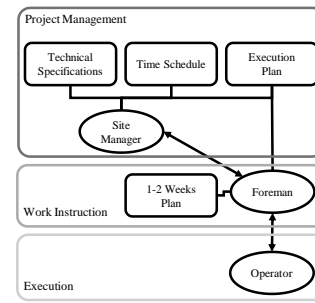

Figure 2. Task management on today’s construction sites

The foreman, in turn, uses this data to create a one-to-two-week plan and passes on the practical instructions verbally to the equipment operators. The equipment operators as well as the foreman keep monitoring the progress on the task and verbally report any deviations or task completion to the site manager. As this task management process is mainly verbal and unstructured, it depends heavily on the involved persons. Digital tools are hardly used in this context. Technical challenges are the standardized description of tasks, transparent, open interfaces and ongoing digitalization as well as automation. Introduction and training of the necessary processual and technological changes is the main non-technical challenge in this context. However, machine control vendors today offer systems to automatically transfer digital terrain models (DTM) to automated earth-moving machines [5]. These can be interpreted as early forms of control systems. More automated scenarios are still a field of research.

3.3 State of Research

In order to get an overview of current research on task management and control systems in construction, a systematic literature review has been conducted. The results have been classified according to their contributions to the topic. The search strategy for the systematic literature review is shown in Figure 3.

Figure 3: Search strategy for the literature review

The keywords were searched for in the Scopus database with aspects being combined through the Boolean “AND” operator and synonyms being differentiated by the “OR” operator. A number of 94 literature sources was initially obtained. For filtering out

relevant sources, first the titles (43 sources) and then the abstracts (22 sources) have been examined regarding their topical relevance. The identified literature either motivates the design and implementation of a CS² (3.3.1), sets requirements on such a system (3.3.2) or presents a prototype control system (3.3.3).

3.3.1 CS² Motivation

The need for a CS² is subject of two main groups of publications: construction planning and construction robotics literature.

In construction planning, better project operating systems are expected to increase productivity by controlling equipment, machinery, and processes in complex situations automatically [6]. Therefore, researchers work on integrating established task planning techniques like Building Information Modeling (BIM) and the lean construction Last Planner System (LPS). They find that “software support is not treated thoroughly” [7]. In this context Cai et al. [8] identify state of technology gaps between academic research and products, products and on-site application as well as the construction and robotics industry. In order to foster the on-site take-up of construction automation and robotics, they propose the joint development of robots and automated construction systems [8]. A CS² is a viable instance in this context.

The same need for integrating process automation efforts and robot development can be observed in construction robotics literature. Meschini et al. [9] stress the need to integrate construction planning and robot task planning platforms in order to derive robot tasks from construction information systems. Other sources, like Seo et al. [10], Ha et al. [11] and Kim et al. [12], develop single-task construction robots and thereby identify a lack of task planning systems, capable of equipping the construction robot with the necessary job information to cope with the task at hand. While, integrating the development of a task management system in the development of a single-task construction robot is state-of-the-art, Melenbrink et al. [13] envision a future system that is capable of coordinating among heterogeneous machines performing many different tasks. They find that coordinating operations between different robot systems has been largely neglected in research. Gharbia et al. [14] support this claim by stating that only a few papers propose an integrated robotized construction site, while most of the papers studied single construction tasks. Research into the design for automation is essential to create integrated systems of on-site robotics, capable of transferring the digital design data directly to operations [14]. Ha et al. [11] states similar aspects to achieve cooperative operations of unmanned platforms in earthmoving. Vahdatikhaki et al. [15] stress that such systems could help achieve potentials in collaborative

and post-mortem learning, leading to continuous improvement in construction project performance.

Above mentioned, multiple needs for a CS² motivate the conceptualization of such a system in this paper. The next section gives an overview of requirements towards the system under development.

3.3.2 Requirements on a CS²

Literature lists manifold requirements towards a CS². The main requirements are enlisted below with a short description from literature.

1. *Generate standardized tasks automatically*

A CS² should be capable of deriving standardized tasks automatically from planning data. Bock and Linner [16] emphasize that even today the construction task has to be split up in a multitude of subtasks that are complicated to coordinate. Dallasega et al. [16] also find, that a main shortcoming of current construction planning concerns, the lack of detailed modelling of the execution process in terms of workflow, dependencies or locations. Schimanski et al. [7] therefore propose the Should-can-will-did (SCWD) scheduling logic consisting of five steps with increasing level of detail. Complementary, Sacks et al. [18] see the generation of construction tasks as one functionality of BIM.

2. *Integrate machines and robots*

Ha et al. [11] require a CS² to allocate subtasks among several (automated) platforms, perform a shared task in association with other platforms, manage and prioritize events, to cooperatively handle more sophisticated tasks with higher efficiency. Melenbrink et al. [13], Gharbia et al. [14], Seo et al. [10] and Kim et al. [12] need a CS² to be capable of equipping construction robots with the necessary job information, as a basis for robot operations (e.g. trajectory planning, navigation, etc.) and handle the robot’s sensor data backflow into overarching project management and documentation systems. In this context, Part four of the ISO 15143 facilitates the exchange of site topology data between earthmoving machine control systems and proposes the exchange of job description and process data between machines, vendor integration systems and a central site control system [19]. Thereby, a machine-readable representation of the surrounding world, similar to building representations through BIM or point clouds in high-rise construction is provided [12,20].

3. *Facilitate on-site coordination and communication*

Antwi-Afari et al. [21] see critical success factors for construction projects adaptable to the CS² in “coordination and planning of construction works” and “collaboration of simultaneous access of construction work”. Akpabio et al. [22] formulate several software

requirements towards a construction management software, among them “allow for efficient communication” and “give a platform to effectively collaborate and team up to achieve stated goals”. Tezel and Aziz [23] state that a project production control system should be directed towards mobile systems and enable work units to compare what is actually planned and what is actually done. They propose virtual visual control boards, similar to Kanban boards. According to Dallasega et al. [17] a CS² should support a frequent monitoring of the work on-site and base the scheduling of the execution process on it. Oskuie et al. [24] add the monitoring of construction processes, and real-time evaluation of productivity, as BIM-related functions.

4. *Support overall project management*

The connection of the CS² to more general project management tools is subject to requirements by Akpabio et al. [22] and Dallasega et al. [17]. Sacks et al. [18] stress the online communication of product and process information towards BIM. Furthermore, Antwi-Afari et al. [21] see improved construction project performance and quality as well as integrating project documentation/bid preparation as critical success factors incorporated by a CS².

5. *Feature the supply chain*

To support construction execution control, according to Dallasega et al. [17] a CS² should not only be focused on construction work but it should also consider the supply chain. In more detail, Akpabio et al. [22] demand that materials on site should be effectively managed to reduce wastage and improve efficiency.

6. *Adapt to changes*

Rouhana et al. [25] investigate the emergence of ‘new tasks’, which should be manageable through a CS², in construction planning. They divide the inevitable causes behind the emergence of ‘new tasks’ into three categories: the realm of planning, ongoing construction, and uncertainties. Ghasemi Poor Sabet et al. [6] add “untracked planning/scheduling (poor project control)” as a potential root of poor productivity and list “updating and adjustable planning for microplans in case of overlooked requirements and troubleshooting” as a productivity fundamental.

These six requirements along with the results of the expert workshop on a CS² form the basis for the assessment of existing control system prototypes in the next section and the concept development of the CS² described in section 4.

3.3.3 **Control System Prototypes**

In the existing literature, nine control system prototypes were identified. In this section, they are

briefly introduced and assessed regarding the requirements enlisted in section 3.3.2. Akpabio et al. [22] present requirements on and the development of a web-based construction management software. It consists of a task, document, materials handling, budget and messages module. Abdelmegid et al. [26] integrate simulation modeling with the LPS. They utilize information available in the LPS, especially the phase schedule, to define activities and their relationships. An exemplary activity list for the renovation and expansion of a public stadium is demonstrated. Future research can include applying the framework on the complete operations of a construction project in realtime. Corucci et al. [27] present a three-level control system for an autonomous demolition robot. The system consists of a high-level planner identifying subtasks and robot base positions, a medium-level planner defining demolition style and contact points, as well as a low-level planner computing a collision-free trajectory. On top of the control system, they propose a convenient representation of the surrounding world, in order for the robot to be situational aware. Thereby, they solve the trade-off between a representation rich enough for reasoning but simple enough for real-time processing through down-sampling of 3D sparse point clouds and semantical identification of objects. Sriprasert et al. [28] differ between three levels of planning: project or product level, process or operation level, and assignment level. They propose a new construction planning technique called “Multi-constraint planning”. The technique is supported by an information management system: Lean Enterprise Web-based Information System for Construction (LEWIS). It derives process data from interfaces to project planning and scheduling software. Schimanski et al. [7] introduce a conceptual model for BIM-LPS integration. The original LPS model is extended by the BIM part which serves both as input and output visualization instrument. Additionally, a (digital) Kanban system is proposed, to optimize flow and improve visual management. They also stress the positive pull effect of the Kanban method, enabling higher productivity. Seo et al. [10] develop an intelligent excavation system along with an excavation task planner. Therefore, they use an earthwork design model and project management information systems. Vasilyev et al. [29] integrate QR-code exchange data technologies into a construction control system based on BIM, providing availability of data, security and mutual cooperation on a construction site. Kim et al. [20] investigate the task planning process of an autonomous excavator. They assume the availability of a digital terrain model (DTM) and its compatibility with the task planning system. Kim et al. [12] present a robot task planning system that can generate behaviors of robots based on the project information from BIM and the construction schedule. They use an IFC-SDF converter to

link BIM and ROS for a wall-painting robot. The next version of their system should incorporate a diverse list of construction tasks and mobile robots that can be simulated in the created virtual environment. Vahdatikhaki et al. [15] combine location-based guidance systems and safety management methods in a multi-agent system in order to improve equipment operations, safety and equipment management. Table 1 assesses the introduced control system prototypes regarding the requirements from section 3.3.2.

Table 1. Control system prototypes from literature assessed against requirements on a CS²

Prototype	R1	R2	R3	R4	R5	R6
Akpabio			x	x	x	x
Abdelmegid	x		x	x	x	x
Corucci	x	x				
Sriprasert	x		x	x	x	
Schimanski			x	x	x	x
Seo	x	x				
Vasilyev			x	x	x	
Kim_20	x	x			x	
Kim_21	x	x				
Vahdatikhaki	x	x	x	x		

In summary, current control system prototypes either focus on supplying a robot or automated equipment with machine-readable, standardized tasks or focus on coordination and communication on a project management level. None of the existing prototypes combine task management on the equipment level with the project management level.

3.4 State of Practice in Intralogistics

As the assessment of the control system prototypes in Table 1 has shown, very few control systems from the construction sector fulfill the multiple requirements from equipment automation and project management. In order to prepare the CS² concept development in the next section, this subsection looks into the more advanced control systems of the autonomous intralogistics sector.

Intralogistics can be analogously to current task management on construction sites (see 3.2) divided into three levels. One difference is that instead of the first level being project management, warehouse management precedes the work instruction and execution levels in intralogistics. The automated information exchange between these levels is based on digital interfaces standardized in industry standards like the VDA 5050 [30]. At the warehouse management level, a warehouse manager configures the warehouse management system, which in turn transfers data to a control system. The control system creates tasks from the data received and transmits them to the autonomous mobile robots (AMR) or automated guided vehicle (AGV). After successful

execution of the task, it is acknowledged by the AMR/AGV. In addition to task information necessary for its execution, the AMR/AGV sends and receives information about the operational environment to a shared environment model available to each robot in the network. Figure 4 summarizes the task management environment in intralogistics.

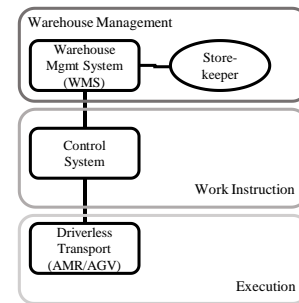

Figure 4: Task management in intralogistics

4 Construction Site Control System (CS²)

Picking up on the excursion to autonomous intralogistics, the formulated requirements and the motivation for a CS², this section proposes an applicable and sustainable control system concept for the automated construction site of the future. Therefore, the CS² is located in the task management environment of future construction sites. Subsequently, the functional concept of the CS² is examined in detail, before the subsection closes with an exemplary implementation of the CS².

The following concepts are founded on the results of an expert workshop on task management and control systems in the construction sector as part of an interdisciplinary research project on the digitalization of the construction site as well as the findings of expert interviews and the literature review presented in the previous section.

In the future, task management on the construction site can still be divided into the levels of project management, work instructions and execution. Nonetheless, the automated information exchange between the three levels is based on digital interfaces. In addition, there is a verbal information exchange between the site manager and the foreman for task management issues, like changes or emerging tasks, as well as the overall project management. Tasks are generated from the job description of the object under construction. More specifically, the information sources will be information rich building information models (e.g. 5D BIM) and project management simulation systems (e.g. Discrete Event Simulation). The CS² is responsible for task management and the digital supply of the autonomous equipment with the information required for task

execution. At the work instruction level, the foreman can interact with the CS² to manage tasks, similar to a task backlog or Kanban board. Figure 5 shows the task management environment of future construction sites with the CS².

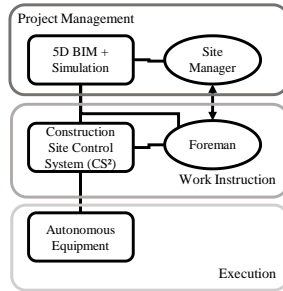

Figure 5: Task management on future construction sites

4.1 CS² - Functional Concept

The CS² connects the project management and execution levels, as shown in Figure 5. The individual functions and their interactions are broken down in Figure 6.

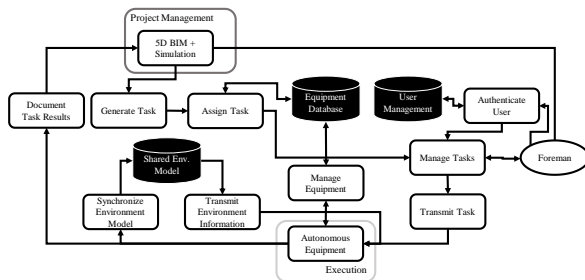

Figure 6: Functional concept of the CS²

First, a task is generated from the project data stored in building information models and project management simulation systems. The construction task is segmented into subtasks suitable for the specific piece of equipment (Generate Task), whereby the task design and the added data differ depending on the equipment. In order to facilitate a project management, an assignment to the job description and an execution period should be specified with each task. After the task has been created, it is assigned to a piece of equipment that is available in the execution period (Manage Equipment) and that matches the task requirements (Assign Task). The foreman, as the main user of the CS², can manage and manually edit the orders (Manage Tasks) after authentication (Authenticate User). The task is then transmitted to the autonomous equipment, including all the necessary data (Transmit Task). Likewise, relevant environmental information from a shared environmental model is sent with the task

to the equipment (Transmit Environment Information). The sensor data of the autonomous equipment collected during task execution synchronizes a shared environment model (Synchronize Environment Model). After successful execution of the task, the work result is documented and transferred to the project management level (Document Task Results).

Through this functional structure, the CS² covers all requirements from section 3.3.2 (see Table 2). Standardized tasks are automatically generated from BIM and other sources of planning data (R1). These tasks are broken-down and transmitted to automated equipment and robots (R2). Through a Kanban board like interface for task management, the on-site coordination and communication is supported (R3). Results of the executed tasks are fed back into overarching project management solutions, like BIM (R4). With this interface to BIM and other planning data, the supply chain can be incorporated in task generation or work results can be considered in supply chain controlling (R5). As the foreman is a crucial part of the CS² the whole system can react to changes by managing or creating tasks, fostering on-site flexibility (R6).

Table 2. CS² assessed against the requirements from section 3.3.2

Prototype	R1	R2	R3	R4	R5	R6
CS ²	x	x	x	x	x	x

4.2 Exemplary Implementation

The introduced functional concept of the CS² is partly implemented to validate the concept. Autonomous machine integration and a shared environmental model are not implemented in this case study. In this specific case study, which can only be briefly addressed here, the focus is on earthwork (e.g. digging, grading, compaction) and transport tasks (e.g. bulk material, unit loads).

The exemplary system can create tasks either through importing a standardized job description (German GAEB-xml-format) or manually through the task creation function. Attributes for specific tasks (e.g. digging or transporting) are predefined and can be automatically or manually filled with the respective information. After a task is created, the task is allocated to an equipment. Therefore, the machine database “Equipment Information System” (EIS) and a fleet management platform are connected to the web-service through APIs. In these systems, equipment can be administrated and managed. Figure 9 shows the system architecture, which is based on the client-server pattern, with the web browser taking on the role of the client. The client sends a request to the server, which then responds and transmits the desired information. At the core of the architecture is the server with the associated database. In

addition, two services (equipment information and fleet management) are currently integrated, however further services can be seamlessly integrated if necessary. During operations, the foreman can move the task through the states (backlog, in progress, on hold, in review, done) on the Kanban board (Fig. 9) or, in a more automated scenario, the robot automatically feeds back his current state of work. The foreman can always intervene and stop, review, comment or reopen tasks, staying in full control of construction.

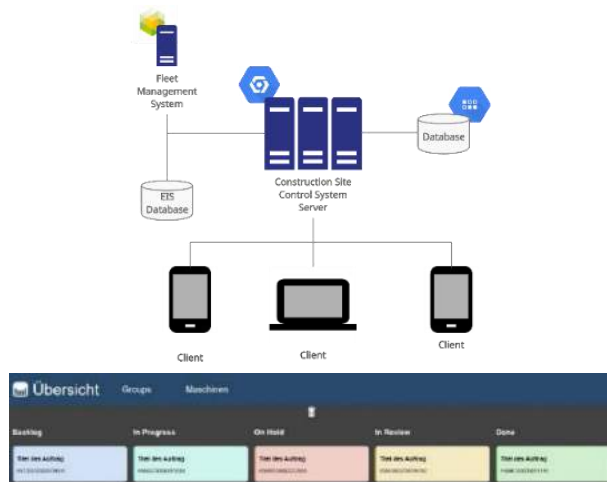

Figure 9: CS² system architecture and Kanban board with task states

5 Conclusion & Outlook

A CS² is necessary for autonomous equipment and brings numerous advantages in construction robotics as well as construction planning and management. However, some functional requirements must be met for a successful implementation. This paper classifies the CS² in the current and future management of tasks on the construction site and enhances existing approaches from a systematic literature review in construction research with those of autonomous intralogistics. The paper then goes into detail about the necessary functionality and demonstrates a partial implementation of the CS² to foster the development of a sustainable control system for the construction site and validate applicability.

This paper thus forms the basis for the implementation of a complete CS² in the near future. Under way is the complete demonstration of the CS² with the integration of autonomous equipment. Additionally, the enclosed literature review reveals a trend towards single-task construction robots. On the one hand, future research should therefore focus on coordinating mixed robot fleets in physical challenging environments with varying tasks. On the other hand, robotics should also

investigate the development of multi-functional robots that can be configured for several tasks in a general construction workflow (e.g. inner-city construction).

Abstract –

Tendering & Bidding generally involve many construction units participating in a project bidding. The purchaser selects the best bidder with a short construction period, low cost, high quality, and good reputation. There are huge economic benefits and points of concern behind it. However, tendering suffers an increased risk of data tampering due to the centralized database architecture, resulting in huge financial losses and unnecessary consumption of human resources. Blockchain technology has gained increasing attention in the construction industry because of its high transparency, information traceability, non-repudiation, and non-tampering characteristics. Initial explorations have been carried out to discuss blockchain benefits in the e-tendering process. However, existing studies are limited to conducting qualitative analysis or proposing conceptual frameworks. A workable blockchain-enabled solution that supports basic functions in the e-tendering process still lacks. Therefore, as an initial exploration, this paper presents a secure blockchain-based framework for tender evaluation. Besides, technical components such as tendering smart contracts are developed to support framework functionalities. The framework feasibility is validated in a tendering evaluation example. Results show that the proposed framework guarantees secure tender evaluation by keeping data traceability and immutability.

Keywords –

E-Tendering & Bidding; Blockchain; Smart contract; Tender transaction

1 Introduction

Tendering and bidding refer to a type of business in which many construction units participate in project bidding. By selecting the best, the project task is assigned to a company with low price, good quality, short construction period, or relevant experience. On this basis, the purchaser unit and the bidding unit will sign a contract. Digitalization (or e-Tendering) is a trend in

tendering process to solve low efficiency and unfairness problems [1]. However, most of the current e-tendering systems rely on a centralized database, suffering cybersecurity risks especially data tampering, as all data are controlled in one sector. For example, authorized personnel can modify the bidding data, which will cause the authenticity and traceability of the data to be lost in the bidding process.

Blockchain technology has the characteristics of high transparency, non-tampering, non-repudiation, and traceability. Blockchain is a shared, unchangeable ledger that facilitates recording transactions and tracking assets in a business network. From the initial cryptocurrency to the current smart contract, the application feasibility of blockchain in the construction industry has been analysed. For example, Penzes B et al. [1] proposed the determination to reduce disputes and optimize storage, as well as the retrieval analysis and framework design of key areas by Li, J et al. [2] etc. Meanwhile, the feasibility of blockchain has been verified in the AEC industry. For example, Li H et al. [3] proposed saving database overhead in the Internet of Things technology. Chang S et al. [4] applied the tracking process in the supply chain.

Some initial explorations have investigated the benefits of applying blockchain in e-tendering. For example, Ambegaonkar et al. [5] proposed a blockchain-based e-tendering system case designed to include analysing its security, and Li, et al. [6] explored the feasibility analysis of its data processing performance. However, these studies mainly focused on qualitative analysis or conceptual models' development. A solution that can be applied in practice has not been designed.

Therefore, this paper aims at designing a blockchain-based e-tendering system that can be practically applied. The objectives are: (1) to develop a blockchain-based e-tendering system framework, (2) to design technical components (transaction data model & smart contract) required by the framework, (3) to test the feasibility of the framework in an e-tendering example. In addition, this paper discusses the potential uncertainty that may arise in the actual situation.

2 Blockchain in E-Tendering

As a point-to-point distributed data structure, the blockchain records all transaction data in chronological order and stores it safely. The blockchain is essentially an encoded digital ledger, which can be stored on a computer on a public or private network [7]. The current hash in the blockhead of each block is calculated from all other information in the entire block. If the data in transaction is changed, this block's real current hash value will be changed. The previous hash value in the next block corresponds to it, as shown in the Figure 1.

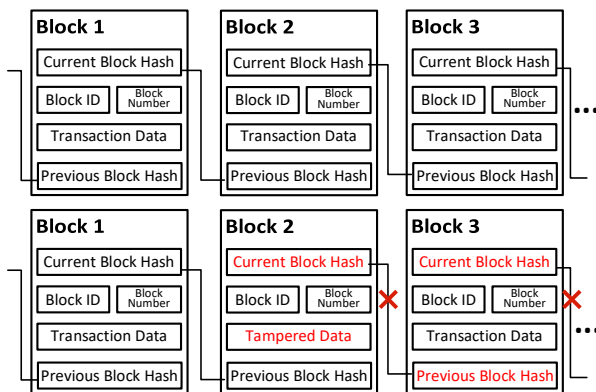

Figure 1. Blockchain Structure

In the transaction process of the blockchain system, each block needs to hash the previous block and link the newly calculated block with the previous chain. A block will contain blockhead, transaction data, timestamp, and last block hash in this process. The blockhead includes the block height (the number of the block) and the current hash of this block. The data or information stored in it has the characteristics of "unforgeable," "fill traces," "traceable," "open and transparent," and "collective maintenance" [8]. Based on these characteristics, blockchain technology has laid a solid foundation of "trust" and created a reliable "cooperation" mechanism. Because of these advantages, the application of blockchain technology in the e-tendering system is promising.

In the past research in the e-tendering system, most of the information exchange methods used were centralized databases [9][10]. Centralized databases often cause information loss or tampering because the only data storage location is attacked. Persons with authority to the central database can easily enter it. Once the information obtained by bid-base or other bidders is acquired through illegal means, it will give them an unfair advantage. According to the analysis of the bidding framework of the credible third-party model adopted in the past research, it is prone to some mistakes that lead to economic losses and bidding failures. One of the most representative is data manipulation.

The tendering system in the trusted third-party (TTP) mode is currently the most mainstream build model. Its organization provides certification for bidders and purchasers who need to access the database and determines that other people cannot access the contents of the centralized database. However, suppose a member of the bidders or purchaser unit uses illegal means to tamper with the information in the database due to economic interests. In that case, the third party cannot guarantee the security of the file.

In the application of tendering, because of the complexity and security requirements of the process itself, many scholars have carried out a blockchain-based design in this regard. Because the laws and institutions of many countries have higher requirements for confidentiality in tendering, Hardwick, Akram, & Markantonakis [11] have designed a bidding framework for government procurement. In addition, Ambegaonker et al. [5] proposed some suggestions for improvement of the Blockchain-based e-Tendering System.

In these similar studies, the consideration of the bidding process has been simplified. The main proposals are conceptual frameworks. There is no analysis for special procedural requirements; for example, verifying the submitted information in the "prequalification" link and the information exchange in the "clarification" link is omitted.

3 Blockchain-based E-tendering Evaluation Framework

3.1 Development of Framework

Because of the complexity of the tendering evaluation stage, the system framework adopts the parallel mode of blockchain system and centralized database. This type of "public service platform" is filed by the government's market supervision unit, and it is also the mainstream method of bidding for large-scale projects. Although there are many resources used to protect the security of the database, it still has the structural flaws of a centralized database.

The framework mainly consists of the following steps:

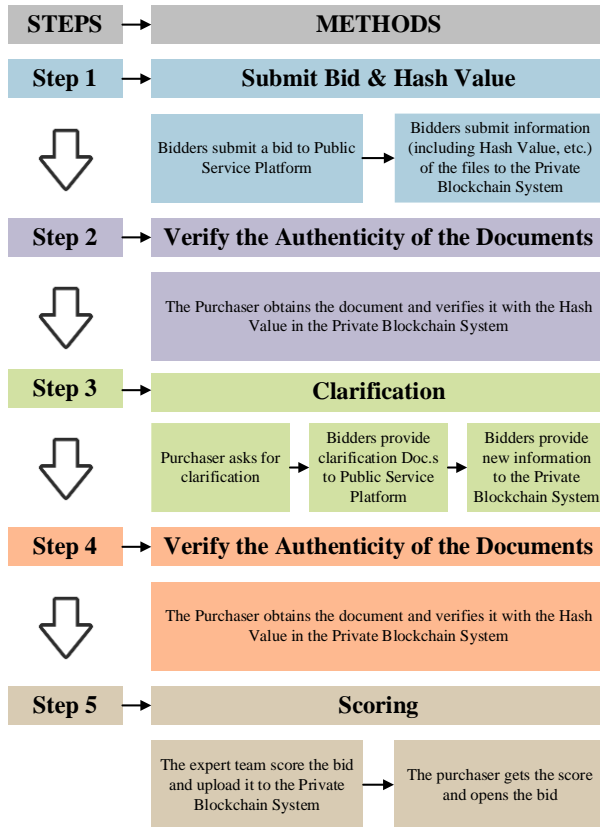

Figure 2. Framework Steps

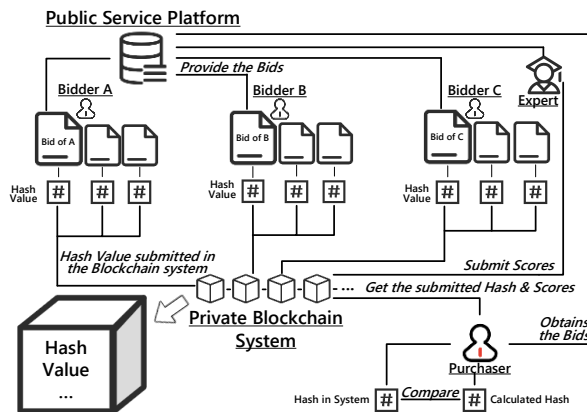

Figure 3. Blockchain-Based E-Tendering System of Tendering Evaluation

Figure 2 illustrated the framework that mainly consists the process from submitting bid to scoring. Especially for the critical "clarification" step, the framework designed in this article plans for bidder's need to update information.

For the clarification stage, in the actual project, there are often many clarifications. Each clarification may be aimed at different bid parts, such as the business part, price part, etc. During a clarification process, you may be

asked to provide information multiple times. Therefore, in the design process, the two stages of "clarification" and "verify and clarify the authenticity of the documents" will be carried out many times by the actual situation until the change step is completed.

After the "clarification" section is over, follow the process to score the bidder's files. The scoring results should be sorted according to the scores of all bidders. Choose the three (or more) with the highest scores as candidates for advertising. And after the advertising period, the final bidder is determined among them, generally the bidder with the highest score.

In this framework, the expert group needs to score documents in the private blockchain system. Therefore, the expert group should obtain all bidder documents (including bid and all clarification documents) from the "Public Service Platform" or from the purchaser.

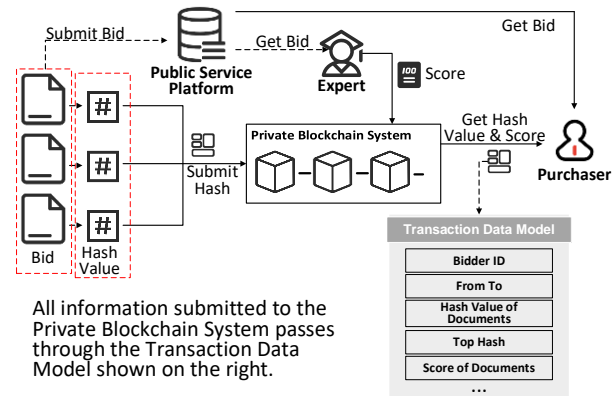

Figure 4. Framework Design of Scoring Part

Whether the bidders or an expert group are uploading information to the private blockchain system, it should be compared to the transaction data model designed for Tendering Evaluation intended in this article.

3.2 Development of Transaction Data Model

For information transmission and acquisition in smart contracts, the transaction data model should be adopted. This article is aimed at the tendering stage, and a dedicated data model is designed. This model can summarize the information that a bid should have. A qualified bid should have a business part, a price part, and a technology part among the implemented specifications. In addition, all communications between the purchaser and bidder should be added to the bid in the clarification process. There are corrections and supplements to the original information in the information required to be provided subsequently.

Each part of the bid should meet the requirements of the project. If there is a bid base, it should be checked at the bidding base. If some rigid requirements cannot be met,

the bid shall be invalidated. In addition, after the clarification is over, the purchaser should blindly select the members of the expert group. Those who have a deep understanding of the technology and the project score the documents. The expert group obtains the authority from the purchaser, accepts all the documents, and divides parts into bid scores. In this transaction data model, the score of each item is set to 100 points, and the total score is 300 points. In addition, the clarification document is a supplement to the above three parts and will not be scored. The transaction data model is represented in Table 1.

Table 1 Transaction Data Model

ATTRIBUTES	VALUES
Bidder ID	002s0001
Bidder Name	ZHANGSAN
From To	002 to 001
Hash of Business Part	bd4674b81fcd40...
Hash of Price Part	4489a0052b40f4...
Hash of Technology Part	85d56bb4cebd08...
Hash of Clarification Doc	NULL
Top Hash	fe2245a47443aa6...
Score of Business Part	NULL
Score of Price Part	NULL
Score of Technology Part	NULL
Score of Bid	NULL
Clarify Number	0
Date	04-15-2021

Because the blockchain system cannot transmit large files, the hash value of each part of the file should be calculated in advance. This design uses SHA256 to encrypt documents.

For a message of any length, SHA256 will generate a 256-bit hash value called a message digest. This summary is equivalent to an array with a length of 32 bytes, usually represented by a hexadecimal string with a length of 64. The purchaser can place large documents through the bidding service platform. Calculate its hash value after obtaining the document. In addition, for the "Top Hash" item in the model.

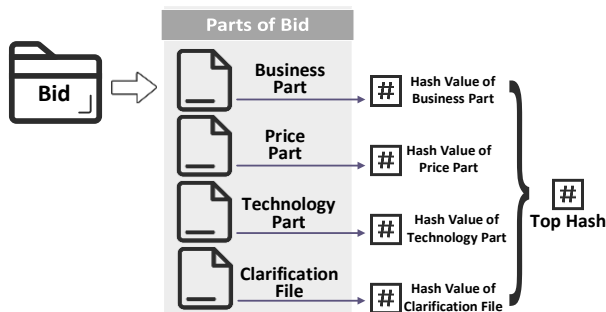

Figure 5. Top Hash

Top hash is derived from the four hash values in the document, which are calculated through SHA256 again. When users want to verify the document's authenticity, they can first verify the value of Top Hash. If the corresponding data is correct, it can be considered that the document has not been tampered with. If the data is different, you can check the four sub-items. This process can reduce the time for verification and save related costs.

As shown in Table 1, the transaction data model contains the bidder's name, bidder ID and submission date, and other related information. The purpose of bidder ID is to make it more convenient to query transaction records. The submission time is only accurate to the date because a block will have its timestamp. The timestamp will be stored in the block with a time accurate to the second, and authorized users can query the data. It is not necessary to express in the model.

For scoring items, because the ID of the expert group set in the framework is different from other users (Expert ID: 000) when querying the score, the result will not be affected by other incorrectly entered data.

Because the business part, price part, and technology part cannot be changed after the first submission (you can make changes in the clarification file), the value will not be altered in different submissions. But the top hash will vary with the data of the clarification file.

3.3 Development of Smart Contract

The designed blockchain-based tendering system framework and transaction data model develop the smart contract, as shown in the Figure 6. The smart contract is based on the Go language. The main functions are installing, instantiation, upgrade, etc., that come with Hyperledger Fabric, and three other functions are also designed.

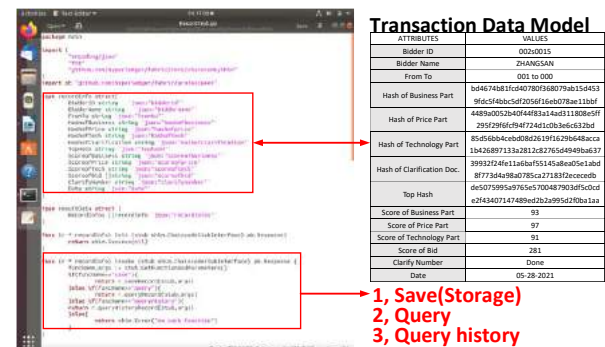

Figure 6. Smart Contract Design

As can be seen from Figure 6, Smart Contract: "RecordTest" has three main functions: (1) Save Function, (2) Query Function, and (3) History Query Function.

The two functions of save and query are important requirements in the bidding process that requires frequent communication. In the design of this article, information such as time, bidder, hash value and score of the file, etc., are all carried out through these functions.

In the survey, the actual situation of tendering evaluation, data storage is also an essential item. All documents in the bidding process (bidding documents, bids, clarification documents, confirmation letters, etc.) need to be kept appropriately for a possible eventual inspection for possible inspection. Based on this fact, the function can be designed to query all historical information submitted in the past.

4 Illustrative Example

This article designs an experiment based on the e-Tendering System in the Tender Evaluation phase and the smart contract used above. The design and experimental scenarios are as follows: one purchaser (No.001), one bidder (No.002), and one expert group (No.000).

The bidders submit bids and clarification documents according to the process. The purchaser makes queries in order. After the clarification is completed, the bid will be scored by the expert group. Finally, check the score. The function of querying historical information is also set up.

The whole process is mainly divided into four steps, omitting the repetitive steps of the intermediate process. This is to verify whether the completed e-Tendering System can work normally. The framework is based on Hyperledger Fabric 1.4. Specific information about the above three scenarios is also shown below.

4.1 Scenario I : Initial Submission of Information

Bidder submits information about the bid for the first time; the ID of the Purchaser is 001. The ID of this bidder is 002. Therefore, the query code is set to 002001. When Purchaser searches for "002001", all the latest information provided by the bidder can be obtained. The hash value calculated from the files obtained from the "public service platform for tendering and bidding" database can be compared with the information obtained from the blockchain system.

In general, the three main steps in the bid: Part of Business, Part of Price, and Part of Technology, will not be changed during the clarification process. So, the purchaser needs the bidder to submit clarification documents.

Figure 7 shows the validation results in Hyperledger Fabric, transaction data for Step 1, and the current blockchain status after Step 1 are displayed.

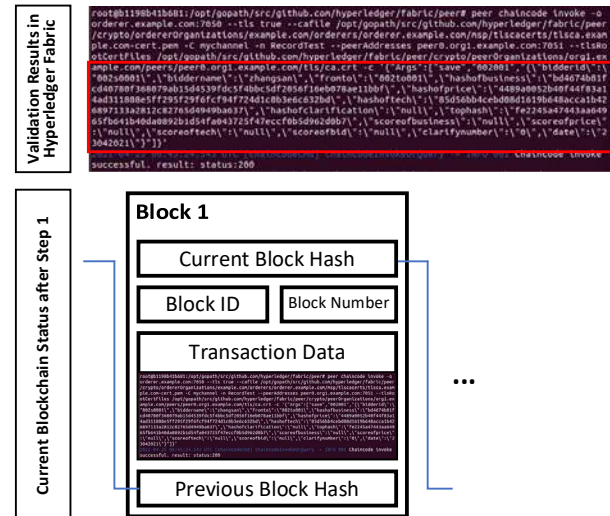

Figure 7. Scenario I : Initial Submission of Information

4.2 Scenario II : Update Submitted Data

This scenario shows two updated information of No.002 bidder, respectively, in the first clarification (second submission) and the fourth clarification (fifteenth submission). The content submitted for the fifteenth time is the final information submitted by the bidder. The two submission dates are April 23, 2021, and May 23, 2021, respectively, and the hash value and top hash of the clarification information in the content have also been updated.

Because of the complexity of the tendering and Bidding process itself, the purchaser often requires multiple clarifications. In each clarification work, the bidder will also be required to provide corrections/additional information as required. In the verification experiment, the intermediate steps were omitted as shown in Figure 8. However, in the application, there may be multiple submissions of information in each clarification. So, there will be a fourth clarification, but the number of submissions is 15, as shown in Figure 9.

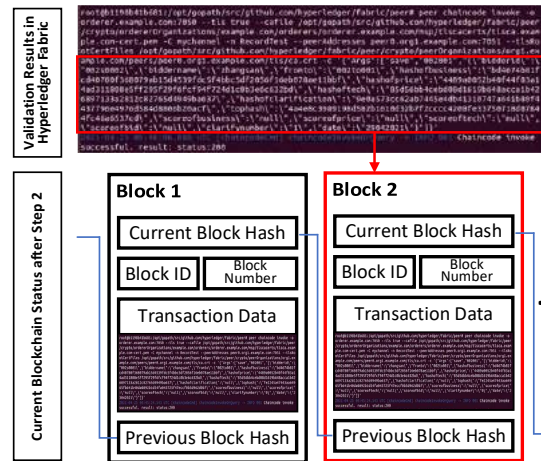

Figure 8. Bidder Submits Information for Second Time

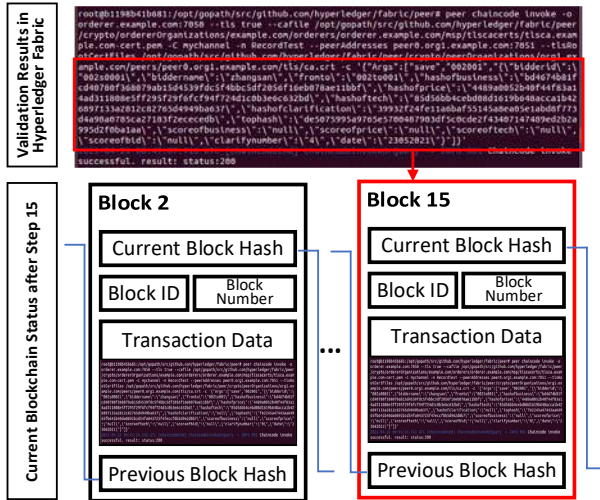

Figure 9. Bidder Submits Information for Fifteenth Time

4.3 Scenario III: Scoring Bid

After the whole clarification part is over, the expert group needs to score the bids submitted by each bidder. Scoring the business part, the price part, and technology part, respectively.

As shown in Figure 10, the scores given to the bidder are as follows. The business part score is 93, the price part score is 97, and the technical part score is 91. The total score (score of bids) is the sum of the above three items, 281 points. The total score of this scene-setting is 300 points, and the total score of each item is 100. The query result is also the score transmitted by the expert group to the system and the relevant information of the bid.

The ID of the expert group set in the experiment is 000. Therefore, in the input and query, the ID of bidder number 002 should be set to 002000. The ID (002000)

can coexist with 002001 (the ID used when the bidder enters information) in the smart contract. So, there is no need to update the chaincode.

The input data corresponds to the data obtained by the query. Since then, the blockchain-based e-Tendering System of the entire tender evaluation process has been experimentally verified and succeeded.

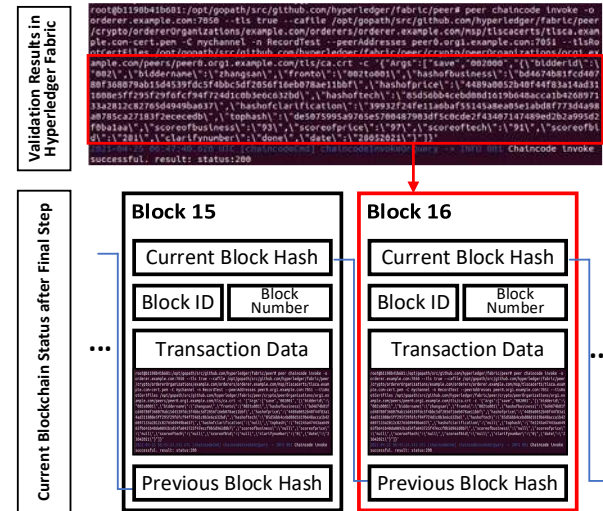

Figure 10. Scenario III: Scoring Bid of No.002 Bidder

According to the information inquired by the purchaser, the ID required for the query is 002000. The result is the latest submission. The experiment of this step is finished.

Because a large amount of data needs to be stored in tender evaluation, the documents submitted in each clarification work need to be properly held for future inspection and verification if necessary. The smart contract "RecordTest" designed in this article also has a historical query function. In the experiment, all the information submitted by bidder No. 002 was extracted, and the results are shown in Figure 11.

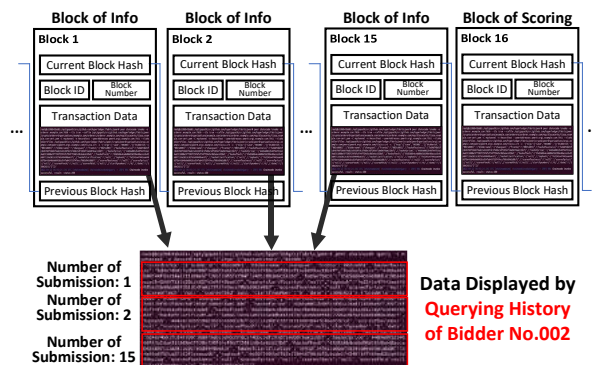

Figure 11. Query Historical Data of No.002 Bidder

Because the format of the input information used in the scoring stage is different, when querying the historical information of the bidder, the content related to the score

is not displayed in the result. As shown in in figure 11, because the verification design omits the repeated steps in the middle, only the three entered information is displayed. They are the first submission (submission of bid), the second submission (first clarification), and the fifteenth submission (fourth clarification).

5 Conclusion

This study proposes a Blockchain-based E-tendering Evaluation Framework for enhancing data security in electronic biddings. The framework proposes a transaction data model to realize the information exchange in tendering. A smart contract is proposed to complete the interaction between the transaction data and the blockchain system.

The framework has been verified in three scenarios: "Initial submission of information," "Update submitted data," and "Scoring bid." The verification results show that it can provide a more secure e-tendering collaboration.

However, there are still limitations in research: (1) The framework only tests some limited scenarios. (2) This design only considers tendering evaluation under standard conditions. Some special requirements, such as quality assessment, have not been validated.

Abstract

Half of the global population lives in cities, and it is still increasing as people are moving to cities in search of better education, job opportunities, and so on. The existing infrastructures of the cities are being stretched beyond their capacity and requirements for well-organized urban environment and efficient urban management are rising. Urban simulation platforms create opportunities to review and analyze complex urban scenarios and help authorities in effective and efficient decision-making. The recent advancement in information and communication technologies (ICT) and data-driven environments have even aggravated the use of such platforms. To understand the current trend of the developed urban simulation platforms and to investigate the needs for future platforms, this study reviews academic research papers that focus on the subject area. From the findings of the study, it is observed that most of the developed simulation platforms focus on short-term analysis and cover specific sectors. Also, there exist merely few city-level deployment cases of such platforms. To this end, this study emphasizes the needs for multi-disciplinary, scalable, expendable, open and interactive simulation platforms for the development and management of future cities.

Keywords –

Urban simulation platforms, Urban complexity, Interdisciplinary simulation

1 Introduction

Cities are large settlements that accommodate large populations and support their diverse activities [1]. They are also systems of interacting people in densely built spaces serviced by infrastructure and managed by organizations [2]. In practice, they are commonly handled as vast land-use systems to be designed and managed based upon best practices from economics and engineering [3]. This approach often defines the operational issues as simple problems and mainly describes the short-term activities, but becomes

insufficient when considering urban issues over long-term horizons and problems involved with human socioeconomic dynamics [4]. Since the nature of cities is complex, attempts to design and manage them with a few facets are risky. A more holistic understanding of cities becomes critical and is now an emerging trend of urban studies [5].

Theoretical and mathematical models have long been used to reduce complexity and produce concise understandings of urban structures [5]. Their values are to foster broad knowledge of underlying principles of urban development, but they are too simplified and abstract to support decision-making for agencies. To meet the operational needs in planning and governance decisions, computerized models were developed and used since the 1960s to simulate the dynamic processes and interactions of urban developments and components [6]. Nevertheless, these models mainly focus on one or a few disciplines and systems to provide insights for specific policies and investments in particular urban settings. They fall short to represent the relationships and complexity between different disciplines and systems within cities. With the rapidly developing ICT in recent years, researchers have started to develop urban simulation platforms which can accommodate various urban simulation models and data to provide more holistic pictures of urban dynamics [7]. However, an overall reflection on the past development of these urban simulation platforms and their needs and trends are lacking.

The objective of this study is to identify the needs and trends of developing urban simulation platforms for academia. Related academic literatures are collected and reviewed, and their developed platforms are analyzed by their related disciplines and technologies, target users, and study cases. Limitations and outlooks of current and future platforms are summarized based upon the review and analysis results. The outcome of this study provides readers the state-of-the-art knowledge of the development of urban simulation platforms and potential directions for future research.

2 Developed platforms

To understand the past development of urban simulation platforms by academia, relevant academic literature was collected using keywords including “urban/city”, “simulation” and “platform” for article titles via Scopus in mid-May 2021. 51 papers fitted the searching criteria and 14 of them were excluded because of their languages (non-English), types (book chapter), or focuses (not related to urban governance nor planning). The features of these platforms are presented as following subsections: their general profile (e.g., developed year, affiliation countries), related disciplines and technologies, target users and study cases.

2.1 General profile

To understand the research trend of urban simulation platforms, the collected literature is analyzed by their publication years, document types, and sources. The discussion on developing urban simulation platforms gained attention around 2005 and increased gradually throughout the years (as shown in Figure 1). Among the 37 collected pieces of literature, 26 of them are conference papers while the rest are journal articles. This indicates that many of the proposed platforms are still in their development process and are to be completed. As for the document sources of the collected literature, most of them are published by different sources and this might be because that the development of urban simulation platforms is related to a good variety of disciplines (e.g., cyber-physical systems, transportation engineering, etc.).

Figure 1. Year -wise number of publications

Among the collected literature, 37 urban simulation platforms are developed by 49 universities and research groups spreading across 20 countries in the world. Figure 2 shows the country-wise number of publications. China, Japan, Italy, USA, and Sweden are the top five countries in terms of the number of publications related to this field. Since Eastern Asia had experienced the most rapid urbanization, their needs for developing urban simulation platforms are higher than other regions.

Figure 2. Country-wise number of publications

2.2 Related Disciplines

The developed platforms reviewed in this study are found to be of seven broad categories: traffic [8], energy and sustainability [9], disaster management and urban security [10], urban landscape [11], water supply [12], 3D visualization, and, inter-disciplinary [13]. From the distribution of the reviewed simulation platforms in Figure 3, it is observed that 78 percent of the platforms deal with single-discipline simulations and only 22 percent focus on simulations integrating multiple disciplines. Within the single-discipline applications, simulations of traffic-related aspects in the urban context are the most studied area followed by energy, sustainability, disaster management, and urban security aspects. Social and economic urban systems are overlooked by the existing platforms.

Figure 3. Related disciplines of the reviewed simulation platforms

Table1 shows the list of platforms that integrate more than one discipline in simulation scenarios for assessing inter-disciplinary impacts. The integration mostly focused on assessing the environmental impacts

of urban mobility, holistic optimization of the city's energy system, and the impact on power supply from the incorporation of electric vehicles in the city. Recent applications such as Dong *et al.* (2021) [14] tried to simulate traffic, emission, and energy usage scenario together. Also, studies like De et al. (2019) [13] focused on integrating several disciplines within a scalable software system for large-scale simulation through an application programming interface (API). Among the reviewed platforms, although a few of them were open source [7], [14], this is the only one that was created with an open-design approach. In this platform the functionalities are delivered through API and users get the opportunity to customize the system to fit to their requirements. Because the urban environment works as a complex combination of multiple disciplines, simulation of a single discipline without considering the impact of other disciplines often leads to unrealistic outcomes.

Table 1. Simulation platforms that integrate multiple disciplines.

Name of the platform	Integrated categories	Year	Ref.
Opus (the open platform for urban simulation)	Land usage and Traffic	2006	[7]
A simulator integration platform for city simulations	Electric mobility and power supply	2011	[15]
A co-simulation platform for the analysis of the impact of electromobility	Electric mobility and power supply	2016	[16]
MobiWay (Smart City Mobility Simulation and Monitoring Platform)	Traffic, temperature, location, pollution	2017	[17]
InterSCity (A scalable smart city software platform with large-scale simulations)	Interdisciplinary scenarios (e.g., smart parking, smart grid)	2019	[13]

SureCity (Sustainable and Resource Efficient Cities platform)	Holistic optimization of the energy system including air quality, land usage, and water usage	2019	[18]
Diesel, petrol or electric vehicles: What choices to improve urban air quality	Air pollution and road traffic	2020	[19]
A smart city simulation platform with uncertainty	Traffic, emission, and energy usage	2021	[14]

2.3 Related Technologies

The advanced technology adoption in different urban simulation platforms was found for four main purposes: sensing, visualization, integrated large-scale simulation and computing. A list of technologies related to different purposes found in the reviewed literature is listed in Table 2. Sensing technologies are required for collecting data from the real-world environment. The collection of data from citizen's mobile devices through crowdsourcing is found to be effective in energy usage and carbon dioxide emission simulation [20], street lighting simulation [21], and traffic simulation [22]. The use of various wireless sensors was also found in many applications such as traffic simulation [17], urban flooding simulation [10], radiation [23] simulation, and so on. Some recent applications have also used vision-based sensing devices such as LiDAR [23], and image capturing devices [11] for simulating radiant heat and agricultural production respectively.

Visualization of simulation scenarios and outcomes through a map and/or three-dimensional representation provide end-users a better opportunity for well-informed decision making. OpenFlight was one of the early options for modeling 3D visualization systems [24], [25]. However recent simulation platforms have started using the latest 3D modeling technologies, such as building information modeling (BIM) [9] and CityGML [26], and represented them on the world map views using OpenStreetMap [27] and Geographic Information System (GIS) [11]. Software packages such as ArcGIS [11] and QGIS [26] are often used for the analysis of geospatial information. For more immersive user experiences, recent studies have represented the simulation scenarios through virtual reality models created using a 3D game engine named Unity [27]. Access to the simulation platforms through the web-

based graphical user interface is also one of the recent trends [13][18].

The integrated simulations include multiple disciplinary simulations, and often those are simulated in real-time. As these tasks are computationally heavy, performing them in a centralized system will be time-consuming and inefficient. To overcome that, early researchers used de-centralized distributed simulation platforms [8][28][16] which follow High-Level Architecture (HLA) [29][30], a distributed simulation standard published by IEEE. Most recent studies have implemented cloud computing [13][21], and edge computing technologies for performing complex simulations in real-time. Some studies have also implemented Hardware-in-the-loop (HWIL) technology for simulation through complex real-time embedded systems [31]. Uninterrupted connectivity between systems and with sensing devices through 4G/5G wireless networks is essential for the effective implementation of integrated simulation platforms [32].

Although earlier simulation platforms have relied on various simulation models for analyzing the scenarios, recent ones are more inclined to data analytics through artificial intelligence techniques such as machine learning and deep learning. Agent-based models are widely adopted simulation models for simulating the actions and interactions of autonomous agents to understand the behavior of a system [16][33]. The use of various discipline-specific models was also observed during the review. For example, Simulation of Urban Mobility (SUMO) was used as a traffic simulation model [16][8][14], CupCarbon [21], and TinyOS [34] were used for wireless sensor network simulation, and so on. The latest AI techniques were adopted by Zhou and Dai (2021) [11] for agricultural production simulation and by Aviv *et al.* (2021) [23] for simulation outdoor radiant environment.

Table 2. List of technologies used for different purposes.

Purpose	Technology
Sensing	IoT, Vehicular sensor network, Wireless sensor network, Crowdsourcing mobile data, Images, LiDAR point clouds
Visualization	GIS (e.g., Open Street Map), 3D (e.g., OpenFlight), BIM (e.g., CityGML), 3D game engine, Virtual Reality
Simulation	Mathematic models, Artificial neural networks
Computing	Parallel Computing (e.g., De-centralized Distributed Platform & HLA), Hardware-

in-loop, Cloud computing, Edge computing

2.4 Target users and study cases

Most of the developed urban simulation platforms are for city governments, infrastructure companies, and urban planners to monitor and operate existing infrastructure systems and to review and evaluate potential urban plans, which is regarded as the top-down approach [35]. However, in recent years, more developed platforms have also integrated the bottom-up approach, which emphasizes citizen engagement for urban governance and planning. The importance of model reuse and data sharing [9][13][36], crowdsourcing input [20][21][22], interactive interface [10][18], and immersive environments [25][27] is recognized by researchers to develop more public engaging urban simulation platforms, yet not addressed enough. How urban simulation platforms can interact with the public more should be investigated continually in the future.

Applying urban simulation platforms to real-life problems is valuable. Among the 37 developed platforms, less than half of them (17) was used to study real cases, while the rest were applied to virtual cases. More case studies should be fostered to validate the effectiveness and demonstrate the value of existing and future urban simulation platforms. Among the study cases mentioned in the collected literature, 6 of them are Asian cities (i.e., Tokyo, Kyoto, Beijing, Shanghai, Qingdao, Singapore), 6 are European (i.e., Dublin, Paris, Cologne, Stuttgart, Luxembourg, Judenburg), 3 are North American (i.e., Seattle, San Francisco, Philadelphia), and 2 are South American (i.e., Sao Paulo and Lima), whose sizes vary from 16,411 km² (Beijing) to 13.22 km² (Judenburg) and populations from 26 million (Shanghai) to 1 thousand people (Judenburg). How the developed urban simulation platforms can be used to study different cities with different sizes from different regions is rarely discussed in the collected literature and should be investigated in the future.

3 Limitations and outlooks of current and future platforms

The existing simulation platforms are still in early phase for city-scale urban simulation due to the following limitations and challenges. Firstly, only a few studies have tried to incorporate multiple disciplines and domains for co-simulations. Secondly, the existing platforms mainly focused on short-term analysis and covered specific sectors. The main drawback of such

platforms is the inadequacy to support collaborative features and their limited or focused set of solutions. Thirdly, the open-source approach needs to be adopted for engaging more development communities in developing integrated platforms. Lastly, flexible platforms that support the easy integration of multiple disciplines need to be in the focus.

For existing integrated platforms, challenges lie in their scalability, interoperability, maintainability, and reuse in the context of different cities. Incorporating sufficient uncertainties in simulation is needed for making it more robust. These systems need to be tested for large-scale complex city scenarios. Production instances of such platforms need to be created with city-level applications. Real case studies highlighting the challenges and best practices are still limited in the present literature. Furthermore, the use of these urban simulation platforms still needs to deal with some open challenges such as the security and privacy issues of the cyber-physical systems, the requirement of highly skilled workforces for operating them, limited involvements of citizens and governments. All these challenges should be addressed for future urban simulation platforms.

The following characteristics are summarized as essential for future urban simulation platforms in response to future cities with more complex challenges and rapidly changing environments. Firstly, they should be interdisciplinary to reflect the essence of urban governance and planning. Secondly, they should be scalable, level and tempo-wise, to integrate different disciplinary simulations. Thirdly, they should be flexible and expandable to accommodate new simulation scenarios and models. Fourthly, they should be open data and source wise to enable future reuse and further development. Lastly, they should be web-based, interactive and immersive to engage more stakeholders for more inclusive urban planning and management.

4 Conclusion and future work

Urban simulations are needed to gain a deeper understanding of potential future developments and to support sustainable decision-making. In recent years, scientists have been working on various types of simulation platforms to perform such types of analysis. In this work, 37 of these urban simulation platforms were investigated and compared. This work shows that there is a clear rise in the number of platforms available over the last few years. With the increase of available real-world data and computational resources, more and more platforms make use of novel Machine Learning and Artificial Intelligent algorithms to predict future events. The analysis of the different platforms reveals that only a few are currently designed to integrate

models from different disciplines. Furthermore, challenges in platform scalability, interoperability, maintainability, security, and privacy are identified. While the analyzed platforms build a solid foundation for urban simulations, further work is needed to enhance the simulations. An important aspect will be the capability to integrate approaches from multiple disciplines to better model real-world phenomena.

Abstract

Due to the increasing global population, the Architecture, Engineering, and Construction (AEC) industry is placed in front of a significant challenge to provide and maintain the necessary urban development and solid infrastructure systems to support this increase. Infrastructure systems must be resilient and sustainable, especially being critical to the nation's economy and progress. Creating such systems can be achieved by implementing emerging technologies and adopting efficient and cost-effective approaches to rehabilitate and expand the existing infrastructure systems and creating new ones. A major technology implemented in the horizontal construction sector is Building Information Modeling (BIM), which also has proven beneficial for the vertical construction sector. However, implementing BIM in horizontal construction is still emerging. To maximize its potential, BIM will require its integration with another technology pillar: Geographic Information System (GIS). Generally, BIM's central focus is to provide comprehensive semantic information of the construction projects, while GIS provides spatial data and details about the surrounding environment. Thus, their integration can leverage their adoption, and it becomes vital to study how BIM and GIS interact. This paper addresses the BIM-GIS integration by synthesizing the existing research corpus and provide insights into the current usage of an integrated BIM-GIS system for infrastructure. The paper's findings show that the applications mainly cover modeling and design of infrastructure assets, infrastructure construction and scheduling, monitoring and compliance check, and infrastructure facility and asset management. Furthermore, this paper investigates the requirements to optimize the adoption of integrated BIM-GIS for infrastructures.

Keywords –BIM; GIS; Infrastructure; Emerging Technologies

1 Introduction and Background

The integration of BIM and GIS in the Architecture, Engineering, and Construction (AEC) industry has been trending in recent years in both research and industry. The term integrated BIM-GIS system first appeared in literature in journals and conference publications in 2008 [1]. In 2012, the researcher's interest in the integrated BIM-GIS system increased sharply and peaked in 2016-2017, indicating an increased awareness of this integration's potentials [2]. The integration of BIM and GIS can provide a digital representation of architectural and environmental entities, manage spatial information, facilitate a transformative direction to integrate spatial data at different levels of detail, and permitting efficient, standardized, and coherent methods to plan construction development [2].

GIS technologies date back to the 1960s with the establishment of the Canada Geographic Information System (CGIS) as the first recognized GIS application [3]. Esri, an "Environmental System Research Institute" responsible for supplying GIS software and the web GIS geodatabase management applications, defines GIS as "a framework for gathering, managing, and analysing data. Rooted in the science of geography, GIS integrates many types of data. It analyses spatial location and organizes layers of information into visualizations using maps and 3D scenes. With this unique capability, GIS reveals deeper insights into data, such as patterns, relationships, and situations—helping users make smarter decisions".

BIM, on the other hand, has contradicting views about its date of origin; some researchers date BIM back to 1982 with the development of the ArchiCAD software, while others suggest that the real implementation of BIM started with the establishment of the Revit software program in 2000 [4]. Autodesk defines BIM as "a process that begins with the creation of an intelligent 3D model and enables document management, coordination and

simulation during the entire lifecycle of a project (plan, design, build, operation and maintenance)".

Although BIM and GIS provide a digital representation of buildings or environmental surroundings, their approaches are different. BIM's central focus is directed towards construction projects with its massive ability to detail geometric and semantic construction information [5]. On the other hand, GIS is specialized in covering the geospatial data of the outdoor environment surrounding the construction project but provides limited comprehensive information about the building itself [6]. Thus, the strengths and weaknesses of both pillars make them extremely compatible. For instance, BIM can benefit from GIS's spatial information to optimize the tower cranes' location on a construction site [7]. Conversely, GIS applications can benefit from the detailed design of the pipe network provided by BIM for efficient management and analysis of the pipeline network [8]. Also, information from GIS such as site selection and on-site layout materials can facilitate BIM applications, while detailed BIM models can assist GIS with better utility management [2]. Therefore, the integration between these two systems will lead to the effective management of information in all stages of the project's life cycle, a better understanding of how the projects interact with its surrounding, and the availability of heterogeneous multi sourced-data will enhance decision making [9].

Moreover, the integrated BIM-GIS system is considered a pillar for developing sustainable smart cities for its ability of data interoperability, quantitative analysis, technology applications, and urban management [10]. Since GIS is limited in providing 3D models, the best practice to leverage its scope and implement detailed spatial analysis is by using 3D models offered by using BIM software such as Revit, CAD, and SketchUp [11].

The research done by [1], summarized the benefits of an integrated BIM-GIS system compared to using BIM on different aspects of AEC's user requirements including quality management, progress and time, cost, contract, health safety and environment (HSE), information, and the coordination of various sectors. It was found that the benefits of an integrated BIM-GIS system are way more efficient compared to using only BIM and can widely benefit the AEC's industry user requirements. Knowing that the integrated BIM-GIS system has shown successful implementation in the AEC industry and has been trending in recent years, the objective of this paper is to investigate the existing research corpus and identify the applications of the integrated BIM-GIS system in the AEC industry with a focus on infrastructure systems. Also, this paper highlights the gap in the existing literature and investigates the requirements to leverage the

implementation of the integrated BIM-GIS system in the horizontal construction sector.

2 Applications of Integrated BIM-GIS System in the AEC Industry

Several researchers investigated the integration between BIM and GIS with a wide range of various applications. A comprehensive literature review of the published research on integrated BIM-GIS applications in the AEC industry was conducted. We used Google Scholar to search English language articles published since 2008 (the year when the term integrated BIM-GIS system first appeared in literature) by using "BIM/Building Information Modeling" and/or "GIS/Geographic Information System", and "AEC/Architecture, Engineering, and Construction" as key terms for the literature's topic. Since the focus of this paper is to highlight the applications of the integrated BIM-GIS system, only publications with applications of the integrated system in the AEC industry were selected by reading the abstract or the full text sometimes. As a result, 100 literature items were obtained.

The obtained literature items were then analysed and classified into three categories based on the application object: 1) integrated applications on urban districts and cities; 2) integrated applications on buildings, and 3) integrated applications for infrastructures. The distribution of the publications based on the application object is represented in Figure 1. As expected, the major applications of integrated BIM-GIS covered buildings with 57 publications, then urban districts and cities with 28 publications, and the least are infrastructures with only 15 publications.

Figure 1. Integrated BIM-GIS Application Object Distribution in the AEC Industry

2.1 Integrated Applications on Urban Districts and City

It is common to use BIM to create, manage, and share lifecycle data of buildings, while GIS provides more holistic information on the urban environment. As such, the integrated BIM-GIS system is beneficial for Smart City applications and urban representation where data of the building facilities and urban environment is required [10] [12]. It was found that the integration of BIM and GIS on urban districts and cities has been applied mainly in activities including urban data management [13] [14]; urban representation, 3D city models and urban visualization [14], 3D cadaster [15] [16]; waste management [17]; energy efficiency and management [18] [19]; urban facility management [20] [21], traffic planning [22] [23]; safety and disaster management and prevention [24] [25].

2.2 Integrated Applications on Buildings

Conversely, the application of integrated BIM-GIS for buildings can be divided into four sections based on the construction phase, i.e., planning and design, construction, operation and maintenance, and demolition.

Applications of BIM in the buildings' planning stage include building modeling, site analysis, and architectural planning. Moreover, in the design stage, BIM applications consist of program demonstration, visualization design, collaborative design, quantity statistics, building data collection, energy analysis, safety design, and sustainable design [26]. However, the applications of the integrated BIM-GIS system in the planning and design phase of building projects extend to cover the energy and climate adaptation design of buildings and to facilitate energy simulations and buildings' energy management [27] [28]. Also, it was implemented for building design [29]; building site selection [30]; space conflicts [31]; preconstruction operations, structural and post-construction analysis, and construction safety planning [32] [33], which optimizes the entire design process and improves the building's performance.

BIM has also been applied during the construction of buildings to conduct construction progress and organization simulations, digital construction, material tracking, site coordination, construction visualization, construction safety, and green construction [26]. As such, BIM can be protracted and integrated with GIS to support visualization of construction time control, supply chain management, construction process, and construction activity tracking [34] [35]. This integration supported the visualization of the construction process and improved the coordination between different stakeholders. Besides, the integrated BIM-GIS was used for urban renewal projects by conducting building retrofit projects to

support decision-making on building renovation from an economical and environmental perspective [36].

Traditionally BIM was used for designing buildings; however, the application phase of BIM is recently moving toward pulling its implementation throughout the whole building lifecycle. The application of BIM in the operation stage of buildings includes completing model delivery, develop a maintenance plan, assist in facility management, provide indoor space management, analyze building systems, and conduct disaster emergency simulations [26]. However, this implementation will face several problems such as insufficient levels of details, lack of information accuracy, and lack of information standardization. Thus, implementing BIM for the operation and maintenance phase should be pull-driven by asset owners and requires integration with other technologies [26]. As such, most of the applications of the integrated BIM-GIS system for buildings collected from literature reveal that more than half (35 out of 57) of these applications are in the operation and maintenance phase. These applications included indoor navigation and emergency response [37] [38]; heritage management and visualization [39] [40]; safety management [6] [41]; hazard identification and prevention [42]; energy consumption by buildings and transportation networks based on people's behavior [43]; and building facility management [44] [45].

Furthermore, BIM-GIS integrated system was used in the demolition phase of buildings. Data from BIM and GIS was integrated to facilitate demolition waste management by calculating the number of trucks needed to load and haul the generated waste and estimating the required travel distance between sites, storages, and landfills [46].

2.3 Integrated Applications on Infrastructures

Since it was found that the applications of the integrated BIM-GIS system in the AEC industry for infrastructures are still limited, this paper aims to highlight and elaborate on the use of the integrated BIM-GIS for infrastructure. As such, the investigated applications were clustered based on the construction phase, i.e., planning and design, construction, operation and maintenance, and facility and asset management.

2.3.1 Applications in Planning & Design

The planning and design of extensive infrastructure facilities such as tunnels, bridges, subways, and utility networks require a massive amount of detailed data and the consideration of different scales; i.e., demanding a multi-scale representation of data [47]. As such, researchers of [47] utilized BIM and geometric semantic modeling to achieve multi-scale models to support shield tunnels' design. Also, they proposed the concept of

explicit Level of Details (LOD) in tunnel design by extending and using concepts from GIS to help to detect clashes between the designed tunnel and the existing infrastructure facilities. This mapping supported the analysis and evaluation of the tunnel design based on geographical criteria. Similarly, [48] investigated BIM and GIS integration in China's tunnel engineering. They stated that this integration would simplify the modeling and analysis process of tunneling and optimize BIM technology implementation in China's tunnel engineering.

Also, researchers of [49] developed a system that integrates BIM and GIS to estimate the cost of building a national road to be applied in the feasibility stage. The cost estimation included construction costs, land acquisition costs, and operation and maintenance costs. The user-defined GIS information was imported to the CAD system, and the output data related to bridge and tunnel properties, earthwork quantities, lot numbers, and boundary lines and images were imported to a web system that was used to estimate the total project cost. In the proposed approach, the end-user can choose the best route because of the better 3D visualization, better understanding of the project, and the generated cost estimation. Also, [50] developed 3D Geotechnical Extension Model or 3D-GEM to integrate semantic information models to contain surface and subsurface objects such as subsurface geological and geotechnical objects to support the development of infrastructure projects.

Recently, [51] proposed a framework to integrate BIM and GIS for an innovative design approach for transport infrastructure. This framework aims to eliminate any possible conflict that could be faced between the infrastructure design and environmental limitations and provide an integrated technical and ecological indicator of the proposed design. The researchers tested the proposed approach on an airport infrastructure, where the information model was developed using Revit and Civil3D while the environmental model was produced using GIS. Also, [52] proposed a framework based on BIM-GIS integration to plan and design utility infrastructures to meet the needs of expanding cities in the future. The infrastructure utilities include freshwater networks, sewer networks, and electrical networks. The proposed framework emphasizes smart and sustainable cities' concept and supports decision-making for better planning and management.

2.3.2 Applications in Construction

For the construction of infrastructure projects, BIM and GIS were also integrated. [53] integrated BIM highway models with Digital Elevation Model (DEM) of the surrounding topography, and they utilized real-time on-site photos to generate highway construction

schedules for further schedule management and analysis, to monitor construction delays.

[54] utilized BIM to save data about road components in highway construction and the GIS system to import data about land boundaries and topographic data. The integrated approach aims to provide spatial data analysis needed for earthwork calculation. Infrastructure geometric information such as road shape and different geometrical elements were exported from the corresponding BIM models. Conversely, geographical reference, soil type, infrastructure data, etc., were collected from GIS, then semantic web integration between the associated BIM files and GIS files was conducted. This approach permits end-users to perform several cut and fill simulations and facilitates the generation of an optimized construction plan. Moreover, [55] utilized BIM to manage all the information and data related to subway stations' construction. Also, they installed Global Positioning System (GPS) receivers on large, heavy, and high-risk pieces of equipment used in the construction process and linked the data with GIS to establish the 3D geographic spatial location of machines to eliminate high-risk accidents. The integrated GIS-GPS-BIM system was developed to assist in risk management associated with cranes, drilling machines, excavators, loaders, and dumpers used to construct subway stations. The risks include collisions between equipment or neighboring buildings, resulting in the deformation of foundation systems and retaining walls. This approach will be able to provide early warning signals, which will support its development and implementation.

2.3.3 Applications in Operation and Maintenance

Monitoring and compliance check for roads is essential to provide a certain level of serviceability; however, roads' maintenance and rehabilitation are complicated because of the widespread road systems. [56] developed a Road Monitoring and Reporting System (RMRS), which includes a mobile app and a web-based RMRS based on the integration of location-based services (LBS) and Augmented reality technologies (AR). The developed RMRS can be used by the public or engineers to monitor defects and report their spatial coordinates to the web-based RMRS using a downloaded app on their smartphones. The defect location will be determined based on the location of the person who reported the defect. The reported information will be shown on the field road engineers' phones, and they will be able to extract the relevant data from the web-based RMRS. The AR technology in the mobile RMRS was also programmed and used by field engineers to obtain real-time reports and support in visualization and planning the maintenance and rehabilitation operations.

Moreover, [57] developed an automated utility

compliance check by integrating natural language processing (NLP) -which is an “algorithm that translates the description of spatial configuration into a computer processable spatial rules”- and spatial reasoning which logically extracts the spatial rules to a GIS system to identify its compliance. The researchers suggested that the developed method can be extended to various computing applications if implemented in the BIM platform with interoperable mapping and ontologies and integrating sensing technologies to obtain spatial data from construction sites.

2.3.4 Applications in Facility and Asset Management

Facility and asset management of buildings with the surrounding infrastructure can only be conducted using BIM and GIS integration. The building’s internal system information is extracted from BIM, and the external input of utility infrastructure can be extracted from GIS. In this context, [58] connected BIM models of the building’s mechanical electrical and plumbing (MEP) systems with the surrounding subsurface pipeline network. Revit files and GIS data were imported and integrated to support the network visualization outside the building.

Moreover, [59] investigated the potential of improving asset management by integrating BIM and GIS systems. However, the researchers faced challenges in exporting the BIM geometry of an underground railway into 3D GIS. Also, [60] proposed integrating BIM with GIS, and they developed a web-based GIS management system to assist in the management of a bridge model. The developed system contributes an advanced 2D and 3D visualization, in addition to a real-time sensor data reception to permit real-time visualization and monitoring.

2.4 BIM-GIS Platform for Infrastructures

Recently, there has been a considerable amount of studies and national efforts to encourage the use of BIM for horizontal projects on the one hand and extending the implementation of BIM to cover the operation and maintenance phases of construction projects on the other hand. Additionally, the increase in the construction projects’ complexity is associated with large amounts of challenging data that requires better approaches to store, share, and manage [61].

Moreover, researchers of [61] suggested five trends that will remodel how construction projects are conducted. The first trend that will shape the future of construction is a higher definition of surveying and geolocation, associated with the second trend of 5 dimensions of BIM, in addition to the digitization of processes and data sharing (third trend). This will be accomplished with the aid of the internet of things (IoT) (fourth trend), with intelligent asset management and

smarter decision-making and designing with materials and methods of the future (fifth trend). As emphasized by [61], better geolocation and data mapping integrated with BIM, IoT, and digitized collaboration are the pillars for an inevitable and crucial transformation in the construction industry.

Also, [62] defined BIM for infrastructures as “a system of processes for collecting, storing, and exchanging data used to plan, design, construct, operate, and maintain highway infrastructure through the entire life cycle.” The researchers considered data as a keyword that pertains to anything that could be accessed in a seamless digital environment. Data extend beyond physical transportation assets and attributes to include functional values such as financial, design, and specification information. BIM allows the extraction and data sharing among different business units and segmented stakeholders to support the department’s infrastructure’s decision-making. Conversely GIS has proven to be beneficial in providing better visualization, simplified data sharing and data accessibility, proactive asset management, and informed decision making [63].

Therefore, to leverage the implementation of BIM for infrastructures, and as emphasized by [61] and [62], BIM should integrate with GIS to ensure a geolocation mapping that will support the allocation of infrastructure assets. This integration will provide information about the asset’s condition throughout its lifecycle within the surrounding environment. To optimize this integration, sensor technology should be used to facilitate real-time mapping, data sharing, and data collection, besides IoT that will facilitate storing, sharing, and integrating data. Integrating BIM, GIS, IoT, and Sensor technology will constitute a robust framework toward leveraging the implementation of BIM for infrastructures and throughout the project life-cycle. This will create one source of data instead of data silos, facilitate seamless integration, and allow for better decision-making. The BIM-GIS platform for infrastructures is presented in Figure 2.

2.5 Conclusion and Future Recommendations

This paper conducted a comprehensive review of the applications of integrated BIM-GIS systems in the architecture engineering and construction industry. This review showed that a total of 15 publications out of 100 discussed the application of the integrated BIM-GIS system for infrastructures. Also, it was found that these applications were mainly implemented for modeling and designing infrastructure elements, construction, monitoring, and compliance checks, and facility and asset management. Therefore, there is a noticeable gap in adopting BIM and GIS integrated applications in the horizontal construction sector compared to the vertical construction sector. As such, optimizing the implementation of BIM-GIS for infrastructure and leveraging their adoption requires its integration with other technologies including the Internet of Things (IoT) and sensor technology.

Data is a contributing element throughout the project lifecycle and is a critical asset for better resource allocation and decision-making. Thus, detailed models with comprehensive information from BIM with the advanced GIS capabilities of data integration and data analytics will enhance data interoperability and will ensure the existence of reliable and high-quality data. Therefore, future research is required to investigate the potential of this integration to optimize the implementation of BIM and GIS for infrastructure and identify the requirements and standards necessary for leveraging their adoption.

Abstract –

Prefabrication is regarded as the first level of industrialization in the construction industry. A unified 4D information model with good interoperability is the key issue to realize effective project management of prefabricated buildings. This paper intends to promote prefabricated buildings' management by developing an IFC-based framework to institute a unified 4D information model and realize its interoperability in Graph Database. The framework consists of three parts. The first part is to realize a unified IFC-based 4D construction management information model of prefabricated buildings. The prefabricated building information model is extended based on the IFC schema, including the extension of schedule information, resource information, and cost information. The second part is twinning the obtained information model into a graph database via Neo4j. The third part consists of strategies to interoperate, verify, and visualize the IFC-based information model based on the graph database. A prefabricated engineering case verifies that the proposed framework's feasibility. This framework can be extended to the nD and lays the foundation of IFC-based digital twin and thus could favorably contribute to the development of prefabricated buildings.

Keywords –

IFC standard; prefabricated buildings; construction management information; graph database

1 Introduction

In recent years, prefabricated buildings have attracted more attention in civil engineering due to their characteristics of low pollution, low cost, and high industrialization [1]. However, prefabricated buildings have not rapidly developed as expected.

Researches show that information sharing among the whole participants and process is one of the most influential critical success factors required for construction management of prefabricated buildings [2,3]. The BIM platform aims to promote information sharing between stakeholders at different construction project stages to make better decisions [4]. Limited by the current barriers of information interoperation in different BIM software, the 4D construction management information of prefabricated buildings cannot be well transmitted to all disciplines, participants, and the whole construction cycle. As the primary data standard of BIM, the IFC (Industry Foundation Classes) standard developed by buildingSMART plays a significant role in the process of describing building information since it is mainly serving as a global standard for BIM data exchange[5]. Therefore, a unified construction management information model can be established using the IFC standard, thus promoting the management of prefabricated buildings.

Although the IFC standard is widely applied in various scenarios, it still has obvious shortcomings. Firstly, there is no extension of prefabricated buildings' construction management in the current IFC schema, making it challenging to share completed construction management information [6]. Secondly, most data mining techniques lack the capability to handle IFC directly[7]. Further, there is a lack of efficient strategies to use IFC as the data foundation of digital twin[8]. Therefore, this paper intends to promote prefabricated buildings' management by developing an IFC-based framework to institute a unified 4D information model and realize its interoperability in Graph Database. The framework consists of three parts. The first part is to realize a unified IFC-based 4D construction management information model of prefabricated buildings. The second part is to twin the obtained information model into a graph database via Neo4j. The third part consists of strategies to interoperate, verify and visualize the IFC-based information model based on the graph database.

This framework will be the foundation of any researches about the IFC-based information model's analysis.

2 Literature Review

2.1 4D BIM in construction management

The 4D BIM construction technology increases the dimension of time based on the 3D model[9] so that the entire construction process can be expressed dynamically and thus more intuitive. The 4D theory was first proposed by Stanford University in 1996, and the CIFE 4D-CAD system was developed on this basis[10]. Jianping Zhang's team proposed an extended 4D construction management model[11]. This model takes WBS as the core and combines construction management elements such as schedule planning and resource management to visualize the construction process. In 2012, a 4D Site Management Model (4DSMM)[12] was further proposed by this team. 4DSMM links 3D models with specific schedules to generate 4D models of site management. Additionally, De Soto[13] also used a tabu-search algorithm and 4D models to improve the construction project schedule.

Albeit using 4D BIM in the management of prefabricated buildings can benefit a lot, 4D BIM cannot be cultivated with incomplete, untimely data exchange and lacking real-time visibility[14]. Firstly, forming the 4D BIM models relies on specific BIM software, which means information cannot interoperate with other BIM software once separate from this particular software. Moreover, information from a single BIM model is insufficient to meet construction management[15]. However, there is no effective information transfer mechanism between different BIM models. In summary, the lack of information exchange between BIM software keeps the management of prefabricated buildings inefficient and locked-in to tool vendors[16]. This paper intends to adopt the standard for sharing data in the whole process of engineering projects - IFC standard - as the basis for modeling the 4D management information model of prefabricated building.

2.2 IFC Standard

The IFC standard has been widely studied and applied worldwide once it was launched. Many scholars extended the IFC standard in terms of construction management information. Jongcheol Seo[17] proposed an IFC extended model that can store plan information. Akinci[18] proposed extending the IFC framework and integrating the project model of completion and design information to achieve automatic completion conditions assessment. Nevertheless, reviewing the existing literature, there is no method to extend the IFC standard

to the construction management information of prefabricated buildings.

Meanwhile, the extension model based on IFC standards can seldom be verified on the appropriate software. The functions and characteristics of common IFC software are shown in **Table 1**. For example, common 3D BIM software such as XbimXplore can perform an excellent 3D display of IFC files, but they do not support 4D display of the construction process.

Table1. Software for parsing IFC files and their features

Functions	Software	Features
IFC files parsing	xBIM	It can generate IFC files.
	IFC-gen	It can automatically generate syntax trees.
	IfcEditor	It can parse text and generate syntax trees.
	IFC File Analyzer	It can generate xls files.
	IfcOpenShell	It supports Python to compile IFC files.
IFC models display	BIM Vision	1. Can display 3D models. 2. Support the parsing of most IFC entities, except IfcTask and IfcTaskTime.
	Solibri Anywhere	
	XbimXplore	
	IFC++	

2.3 Database Technology's Applying in the IFC Information Model's Storage

As mentioned before, IFC information model stored as pure text is hard to be applied directly. Hence, database technology is chosen to store IFC. Researches have tried to use a relational database to store IFC information models. Solihin[19] transformed BIM data into an open relational database to make the BIM data accessible for wide ranges of query capabilities. Marmo[20] mapped the IFC schema into a relational database to support performance assessment and maintenance management. However, using a relational database to store IFC requires creating extremely complex data tables and a lot of time-consuming cross-table joins to perform various complex queries. Meanwhile, other researchers verified the NoSQL database's advantages in query speed and flexibility. Beetz[21] developed an open-source BIM server based on BerkeleyDB, which provides incremental model storage, extraction, and conversion functions. Lin[22] realized IFC's storing for path planning based on MongoDB. Ma et al. [23] developed a Web-based BIM collaboration based on MongoDB. This framework will adopt a more intuitive non-relational database – graph database to store IFC information models. The detailed description of the graph database will be seen in Section 3.2.

3 Proposed Framework

This paper intends to promote prefabricated buildings' management by developing an IFC-based framework to institute a unified 4D information model and realize its interoperability in Graph Database. The

proposed framework is shown in Fig.1. The framework is divided into three parts, namely, establishing, twinning, and applying the IFC-based 4D construction management information model of prefabricated building.

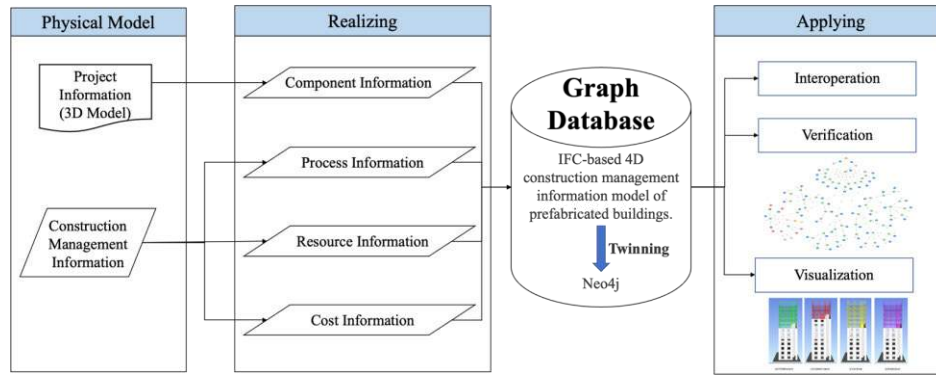

Fig.1 Proposed Framework

3.1 Establishing the IFC-based 4D construction management information model of prefabricated buildings

This framework proposed a unified method to realize an IFC-based 4D construction management information model of prefabricated buildings. The establishment of an IFC-based 4D construction management information model is divided into two steps. The first step is to extend the IFC schema by creating the template of the IFC-based 4D construction management information model. The second step is to instantiate the template one by one according to the obtained construction information.

3.1.1 Realizing process information's extension based on IFC standard

Firstly, this framework realizes process information's extension based on IFC standard. In the IFC standard, the entity *IfcProcess*, its subtypes and the corresponding relationship entities are used to describe the project's process. *IfcTask* is used to describe specific tasks in the construction process, and the entity *IfcRelSequence* is used to describe the sequence of these tasks. Furthermore, *IfcTask* can establish a hierarchical relationship with each other through the entity *IfcRelNests*.

Secondly, this framework realizes resources information's extension based on IFC standard. In the IFC standard, the entity *IfcResource* and its subtype *IfcConstructionResource* are used to describe resource information. Similarly, this framework realizes cost information's extension based on IFC standard. In the IFC standard, the entity *IfcCostItem* is used to describe the cost items. With entities *IfcRelAssociates-*

AppliedValue, *IfcAppliedValue*, *IfcCostValue*, and *IfcAppliedValueRelationship* to describe the algorithmic association between cost and value. Therefore, the cost information of the IFC information model can be formed.

Finally, this model takes the *IfcTask* as its mainline and relates with the relevant components, resource information, and cost information. Specifically, *IfcRelAssignsToProduct* associates *IfcTask* with the components related to the construction process, and the relationship entity *IfcRelAssignsToProcess* associates *IfcTask* with the resource information and cost information related to the construction process. Fig.2 illustrates the complete template of the construction information model based on the IFC standard.

3.1.2 Instantiating the IFC-based 4D construction management information model of prefabricated buildings

This part will use the xBIM Nuget package under the Visual Studio platform to instantiate the IFC-based 4D construction management information model of prefabricated buildings.

Through the instantiation of process, resource and cost information of prefabricated buildings, a complete IFC-based 4D construction management information model of prefabricated buildings is formed eventually. The prefabricated building construction process is divided into components' prefabrication, transportation, hoisting, and installation in the information model. Therefore, these four parts correspond to four summary job tasks and further subdivide these four summary job tasks according to the types of components. The summary task TaskFabricate Summary is subdivided into prefabricating slabs, walls, roofs and other components.

Then the summary tasks at this level are subdivided into tasks corresponding to specific components. The rest of the summary tasks and specific tasks can be deduced by analogy. Finally, each specific task is associated with

process information, resource information, and cost information, and forming a complete IFC-based 4D construction information model of prefabricated buildings.

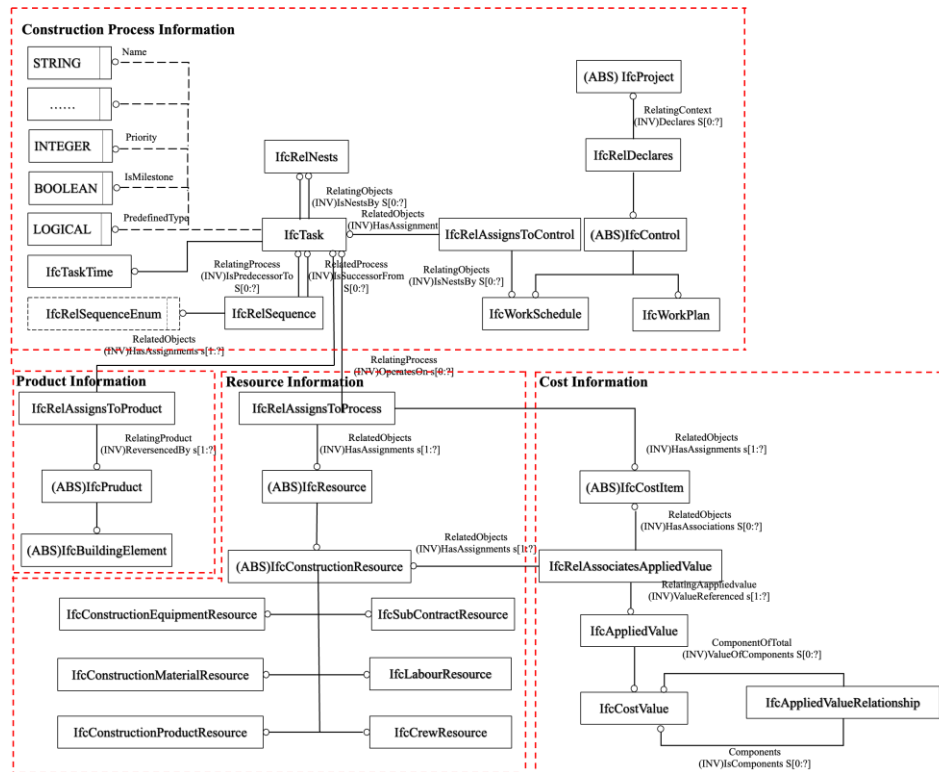

Fig.2 IFC-based construction management information model's template

3.2 Twinning the IFC-based 4D construction management information model into Neo4j

Furthermore, this framework twins the obtained IFC-based 4D construction management information model into a graph database Neo4j. One feature of the IFC Standard is that the reference relationship between the entities in the IFC-based information model is complicated, leading to the poor readability of the IFC files. Meanwhile, the IFC files obtained in the previous step are hard to modify, update, and interoperate. In sum, IFC information models are insufficient in digital interoperation. Thus, an automatic algorithm to parse and twin IFC files is necessary to reveal the IFC files' complicated inner relationships in an intuitive graph and increase data interoperability for further management requests.

The reasons to use Graph Database to store and twin the IFC-based information model are as follows. Firstly, according to the literature review, the non-relational database is more suitable than the relational database to store IFC information models. Secondly, the Graph

Database is more suitable than other non-relational databases. IFC files and Graph Database have the same graph format. The reference relationship between entities in the IFC files is analyzed and shown in **Fig.3**. These entities' relationship is very similar to the relationship between nodes in a graph database, as illustrated in **Fig.4**. A graph database can be seen as a combination of nodes and relationships. And the graph database stores data in nodes with attribute values and uses relationships to organize these nodes, which are all consistent with IFC files' characteristics. Therefore, using Graph Database to store IFC files is more intuitive than other NOSQL databases.

Fig.3 Entities reference relationship in an IFC file

Fig.4 Graph database [24]

Therefore, it is feasible and reasonable to adopt the graph database to store and twin the IFC-based information model. All the procedures are realized in Neo4j, which is a popular Java-based Graph Database. This paper will twin the IFC information model into the graph database via Java. The process is divided into the following six steps.

Step1. Using IFC Java Tool Box to parse IFC files. The IFC Java Tool Box consists of three main parts: obtaining the Java class by parsing the IFC entity type, obtaining the Java type by parsing the IFC data content, and providing the object model *IfcModel* for IFC data to access.

Step 2. Based on IFC schema, constructing a dictionary of the IFC entities and its key/value is corresponding to IFC entities' attributes;

Step 3. Specify the database path and create an *EmbeddedGraphDatabase* instance under the path;

Step 4. Generate the Node instance corresponding to the IFC entity through the designed *createNode()* method, and the information in the IFC entity is stored in the node's properties through the key-value set by the dictionary;

Step 5. Create the relationship between nodes, which is the relationship between IFC entities, through the designed *createRelationship()* method.

Step 6. Accessing the graph database using Cypher command.

Therefore, an automatic algorithm to twin the IFC-based 4D construction information model to the Neo4j graph database is realized and the database can be used as a platform for participants to interoperate the construction information.

3.3 Applying the IFC-based 4D construction management information model of prefabricated buildings in Graph Database

3.3.1 Interoperation of the IFC-based Graph Database

The ability to interoperate the construction information in real-time is the most significant advantage of twinning the IFC information model into the graph database. The process of data interoperating is simple.

Through uploading the Graph Database to the cloud, the participants in the process of prefabrication, transportation, hoisting, and installation can interoperate on-site data to the database. Further, the construction data obtained by vision-based construction process sensing[25] can also be updated into the database. This process will be much easier than interoperate with the IFC files.

3.3.2 Verification of the IFC-based Graph Database

Through this form of a graph, the users can clearly understand the inter-related relationship between entities, as well as the hierarchical relationship of the entire information model. Benefitting from the graph database's intuitive relationship, users can also get other information directly related to the construction information. For example, a user searches for a construction task and returns an *IfcTask* node, as well as the *IfcResource*, *IfcCostItem*, and *IfcProduct* nodes that are directly associated with the *IfcTask*. Accordingly, the correctness of the extension is verified. Specifically, whether the extensions of the relevant entities are completed and whether the associations between entities are correct can be visually verified.

3.3.3 4D display of the IFC-based Graph Database

As for the prefabricated buildings, what users are most concerned about is the state of the components in a prefabricated building over time, as well as information about the resources and cost associated with them. This section proposed a method to display a process model extracting from the IFC-based and graph database-based information model in 4D effect.

In this section, MS Project 2013 and Navisworks 2019 are used to visualize the information model. Project and Navisworks are the most commonly used management software in building construction, but they don't support the IFC format well. It makes the use of construction management information very inefficient and inconvenient. The specific implementation process is as follows. Initially, all the *IfcTask* entities in the created IFC-based graph database are obtained automatically through programming. Next, these *IfcTask* entities' properties are written into the Microsoft Project software. The same method is used to extract the information in *IfcCostItem* entities to obtain the cost corresponding to each *IfcTask* entity. Finally, importing the Revit building model and MS Project data into Navisworks simultaneously to achieve the 4D display of construction information management.

4 Case Study

The engineering case selected is a high-rise affordable housing project located in Shanghai, China,

with a total construction area of 32,500 square meters, and the main building has 13 floors. The simplified model is illustrated in Fig.5.

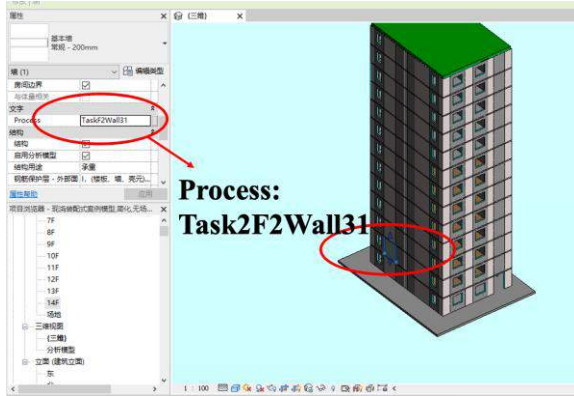

Fig.5 The simplified building's Revit model

4.1 Realization of IFC-based 4D construction management information model of engineering case's prefabricated building

According to the framework proposed in this paper, an IFC-based 4D construction management information model of this case study's prefabricated building is established.

The central part of this created IFC-based 4D construction management information model is shown in Fig.6. In this IFC model, the project (#1) has a general construction task named TaskGroundLevel(#1036), which is composed of 1-13 floor's construction tasks(#1039-#1063). Every floor's construction task includes four summary tasks: fabrication's summary task (#1065), transportation's summary task (#1091), hoisting's summary task (#1171), and installation's summary task (#1143). Furthermore, taking fabrication's summary task as an example, fabrication's summary tasks nested by slab fabrication's summary task (#1067), slab fabrication's summary task (#1072), and roof fabrication's summary task (#1085). The slab fabrication's summary task is composed of tasks corresponding to specific components (#1067). Meanwhile, for each task of a specific component, the process information, resource information, and cost information related to the task are established in the information model. Taking the fabricate task of the 1st-floor slab as an example (#1067), the process information, labor resource information (#1247), material resource information (#1248), equipment resource information (#1249), and cost information (#1253-#1255) as well as the slab (#200) corresponding to the task are associated to it.

Fig.6 Selected IFC file

4.2 Twinning the IFC-based 4D construction management information model of engineering case's prefabricated building

The IFC-based 4D construction management information model of engineering case's prefabricated building is twinning into Neo4j Graph Database. From Fig.7, we can conspicuous detect that *IfcTask* is divided into four levels. The first layer is the summary construction tasks for each floor, which are all associated with the *IfcWorkSchedule* entity representing each floor's general schedule. The second layer is the four summary tasks of prefabrication, transportation, hoisting, and installation. The third layer is the next layer's summary tasks, which means the fabricate task is divided into three summary tasks: slab fabrication, wall fabrication, and roof fabrication. The fourth layer is the specific tasks. For example, the fabrication of walls is divided into the fabrication of No. 1, No. 2, No. 3, and No. 4 walls, and the rest of the specific tasks are analogized. Therefore,

through the IFC information model's storage and analysis by the graph database, the relationship between entities in the IFC information model can be read and analyzed intuitively.

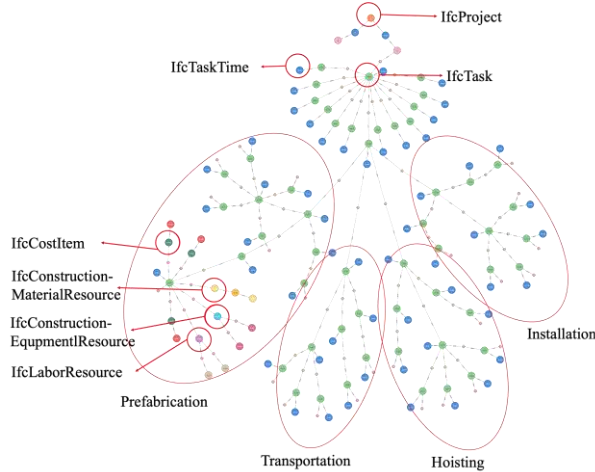

Fig.7 Information model's verification

4.3 Applying the IFC-based 4D construction management information model of prefabricated buildings in Graph Database

The interoperation of participants and Neo4j database will be performed throughout. In the stage of schedule plan, the Graph Database will be imported into a discrete event simulation model, established by using CBS(constraint based simulation) method [26], and the output schedule plan will be updated into the database. When it comes to the actual construction phase, the construction data obtained by advanced technologies such as vision-based automatic progress monitoring[27] will also be updated into the database. Therefore, the information sharing among the whole construction management stages is realized.

The correctness of the extension and entities' interrelationship can be easily verified in Fig.7.

The 4D display of IFC-based 4D construction management information model is executed as follows. First, the process model is extracted from the IFC-based and graph database-based 4D construction management information model. Fig.8 is the demonstration of this step's effect. Then, importing the Revit building model and Project data into Navisoworks simultaneously to achieve the 4D display of construction information management. The screenshot of the animation is illustrated in Fig.9. To distinguish different stages in the process of dynamic display, this paper divides the construction process of the prefabricated building into four stages: prefabrication, transportation, hoisting, and

installation. In the displayed animation, the four stages can be marked with different colors so that the entire construction process looks more intuitive and vivid.

Fig.8 Importing process information into Project

Fig.9 Screenshot of animation in Navisworks

5 Conclusion

In conclusion, the proposed framework is validated through the case study. It is illustrated that this framework successfully realizes an IFC-based 4D construction management information model of prefabricated buildings and twins it into Graph Database which can be applied to interoperate, verify, and visualize this construction management information model. Shortly, the significance of this paper is to innovatively propose an IFC-based and graph data-based information model to solve the difficulties of ineffective data interoperation in prefabricated buildings' construction management. In the future, this framework can be extended to the nD and becomes the standard process to extend the users' needed information during the construction management. Further, this framework's IFC-based Graph Database can be the digital foundation of advanced smart construction services, such as digital twin.

Enabling operational autonomy in earth-moving with real-time 3D environment modelling

Ross Walker¹, Simon Smith¹, Frédéric Bosché¹

¹School of Engineering, University of Edinburgh, UK

r.m.walker@ed.ac.uk, simon.smith@ed.ac.uk, f.bosche@ed.ac.uk

Abstract -

Digital 3D environments are already integral parts of construction and are on the critical path of end-to-end site autonomy. They currently provide human users at all levels of an organisation, access to relevant digital representations of job-critical information at various lifecycle modes, from asset design through to asset maintenance. However, existing solutions lack the real-time functionality, suitable model resolution and machine interfaces which open the door to realising operational improvements from these models. This work proposes a method and proof of concept that enables high-fidelity, real-time 3D modelling of asset construction phase operations using Photogrammetry, Terrain Deformation and Plant Telematics / IoT. This will create a digital twin to act as a platform to facilitate machine automation, which is imperative to catalyse and drive adoption of automation and autonomy in construction. Initially and specifically seeking to facilitate Connected Autonomous Plant (CAP) for earth-moving operations, the work will also give rise to other monitoring, safety, environmental and efficiency benefits, but also be extensible to other site automation tasks.

Keywords -

3D Environments; Terrain Deformation; Photogrammetry; Telematics; Connected Autonomous Plant; Digital Twin;

work is a response to the ever present demand for safer, faster, better, smarter construction project delivery at less cost, but more granularly, the recent maturity of various technologies which will be discussed and combined to facilitate a subset of autonomy and automation specifically relating to construction Plant and its application within earth-moving. Earth-moving plant presents a good candidate for automation and autonomy due to the scale and repetitive nature of work however it does present unique challenges that differentiate it from manufacturing or automotive automation and autonomy technologies which can be considered more mature [2, 3]. This is also why thus far, extensive applications of autonomous earth-moving have been limited to the mining industry, having less changeable haul routes and far less on-site personnel they are both easier and safer environments. Not only must a vehicle in construction interpret and understand its environment, it must understand and be reactive to the dynamic nature of construction sites, as well as have the facility to manipulate and alter the environment based on a given design and specification. Through the lens of Singh [4] there are three aspects to an operational autonomous machine of which regular reference will be made throughout this paper, sense, plan and execute.

1 Introduction

Enabling the autonomous future should be a priority for companies to super-charge profitability and safeguard futures. Companies are increasingly reliant on technology-based differentiators to win work, and this will only increase as the remit, quality and abstracted nature of technology solutions increases. We have seen that technology companies have a history of creating new markets and facilitate creation of entirely new business verticals due to radical innovation. Technology native businesses pose a significant risk to incumbent businesses [1] and as such, incumbents need to own differentiated solutions to overcome incumbent inertia and allow them to grow market-share whilst also defending against faster moving new entrants and competition. At a higher level, this

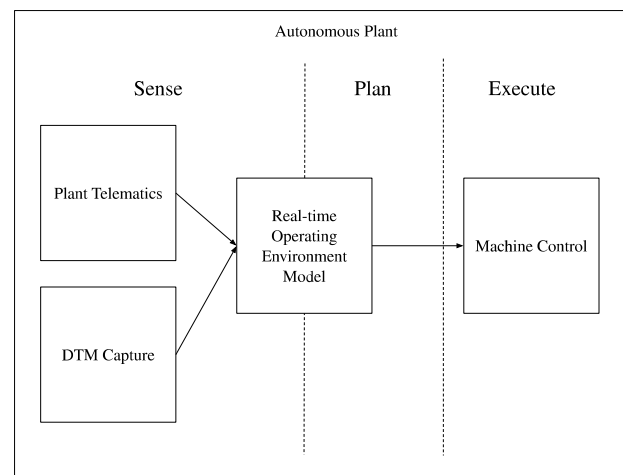

Figure 1. Method Diagram

To that end, this work contributes a method as well as a review of adjacent technologies required to enable the method, and can be seen as a early stage presentation of a much larger investigation which is notable in that the conclusion does not draw on any discrete data. As indicated in Figure 1, the higher level concept is for a telematics integrated, real-time 3D environment that deforms upon interaction by plant that can not only act as the bridge between design and as-built, communicating visually to project stakeholders, but specifically to earth-moving machines acting in semi and fully autonomous capacity too, giving autonomous machines access to detailed information about their environment, and other agents within it. This will also provide the interface to disseminate commands to machines, as well as acting as a central data platform for visualising and manipulating real-time 3D data.

2 The Contribution

BIM uses 3D to help inform decision making for stakeholders, whilst manufacturers provide machine control to assist plant operators. This work proposes that DTMs can be combined with plant telematics thus creating a bridge between the aforementioned, a digital twin or Real-time Operating Environment Model (ROEM) that can ultimately result in fleets of autonomous vehicles completing tasks efficiently. The method to be described here theorises that a digital twin can be used to facilitate autonomous plant by bolstering all three facets of Singh's [4] sense, plan, execute philosophy by creating a two-way relationship between intended design, and operational autonomy. The novelty in this method is the combination of local-sensors which are the commonly referred to environment sensing strategy from Singh [5] with non-local and pooled (drawn from multiple sources) sensing, combined with a DTM that can deform based on the interaction therein of accurately simulated plant in real-time (from telematics / IoT). Other contributions are secondary and are outlined outlined in section 3.

2.1 The purpose of digital 3D visualisations

Graphical processing and 3D environments are not trivial and present various challenges relating to implementation, so why use them, especially if the primary purpose of this work is to facilitate machine control?

3D World In order for machines to execute an activity within their environment (carry out autonomous work), they must first sense their environment and plan the activity based upon it. It follows that having an accurate digital 3D representation of an environment can enable machines to understand it, as it is in reality.

Human Control Secondly, while humans remain primary stakeholders and beneficiaries of construction, and also while they are universally accepted to be in direct control of construction (this will change), they will continue to have a vested interest in acquiring increasingly accurate information from which to generate insight for decision-making. It follows that an accessible 3D environment is a correct method communicate in construction.

3 Use Cases

3.1 Enabling Plant Autonomy

The primary focus of this work is using Digital Twin for facilitation of Autonomous Plant. The benefits and reasons to automate are not new and are widely researched within construction. Paulson [6] indicates the prerequisite technologies and the potential of borrowing from more automation-mature industries like manufacturing in 1985 with further work by Skibniewski [7] indicating progress to date, largely validating Paulson's foresight and further in Singh 1997 [4] where the slow uptake is indicated but with acceleration being identified as a result of progress in safety critical applications in Space and Nuclear outweighing the potential economic drivers in construction. Most recently, a study by National Highways indicated £200Bn in potential productivity benefits by realising effective plant autonomy by 2040 [8].

3.2 Earth-moving Optimization

Having an operational environment tracking precise movements of plant and their interactions with the environment means that we can quickly build up a significant database about the efficiency of the current operation of earth-moving vehicles, but also compare between projects, use transfer learning to incorporate existing models, and most importantly provide a more comprehensive ability to simulate and optimize earth-moving operations. There are many existing models that are useful to study in this area. However, as identified by both Moselhi and Alshibani [9] and more recently by Louis and Dunston [2], they do not support the dynamic changing nature of real-world operations, nor do they have the facility to optimize in real-time. The environment to be outlined helps facilitate this and should assist developments in Reinforcement Learning (RL) based optimisation techniques such as explored by Shitole et al. [10] where an RL agent dictates an approximately optimal policy that can be enhanced with real-world data and then disseminated to autonomous plant to execute the task.

3.3 Monitoring

A real-time 3D environment presents a useful solution to both operational and strategic leaders, showing changes

to a site as they occur and enabling time-critical decision making. An example use case for this is as-built monitoring, we should be able to automatically identify when an earth volume has been correctly graded thus saving significant manual survey time. This is explored further by Anwar et al. [11]. Additionally to this, similar to the intentions of Wang and Cho [12], real-time 3D digital twins can be used to give plant operators an additional perspective of their machine and surrounding environment.

3.4 Safety

Construction remains one of the most dangerous industries in the UK and the top priority for construction firms. Accounting for 27% of workplace fatalities in 20/21, and further, 18% of fatalities involving being struck by a moving vehicle [13]. Having a connected site enabled by, for example, wearable IoT positioning locators, integrated into a real-time 3D environment gives rise to a number of safety benefits such as automated proximity detection between machines and humans. This use case builds on design and planning phase safety improvements from 3D Environments (BIM), previously largely targeting fall from height injury and fatality by Zhang et al. [14] into more operational, real-time safety advances as seen in Teizer et al. [15]. Utilising autonomous plant as in 3.1 also further adds to the safety benefit by removing operatives from harm's way entirely.

4 DTM Capture

In this section we discuss sensors, capture methods and context relating to capturing a DTM. From first principals, the basic requirement for the foundation of this method is to create an accurate digital representation of an environment from which we can measure, manipulate and predict. These environment models have various nomenclature and are often used interchangeably however the following is generally understood from Li et Al [16], Digital Terrain Model (DTM) is the all-encompassing term for digitally representing a physical environment including surface features whereas, Digital Elevation Models (DEM) and Digital Surface Models (DSM) are a subsets indicating bare-earth. Various hardware is available for collecting 3D data at varying levels of maturity. For the purpose of this method, we are primarily considering exterior modelling across larger geographies although the techniques still apply for internal building modelling. UAV is the primary collection method with other methods identified to augment the UAV base model with delta changes and increase the real-time nature of collected data.

4.1 Sensors

4.1.1 Photogrammetry

Photogrammetry is the process of using images to generate information about objects and environments. Initially used for mapping objects, it has become more widely used to map larger objects and environments (DTMs) as collection methods have improved and computer systems have become more capable of handling large amounts of data. This is of particular note because the benefits possible from automation of earth-moving are compounded with larger work areas and as such the ability to map large areas is important for a successful outcome. Photogrammetry creates a higher resolution DTM and is also beneficial because it uses the visible light spectrum and as such, accurate color data is also captured, important for representing the environment to both humans and machines from which further context about an environment can be understood, deducing materials for example using techniques as identified by Rashidi et Al. [17] or surface terramechanics as demonstrated by Bretar et Al [18].

4.1.2 LiDAR

LiDAR (Light detection and ranging) uses lasers to directly measure distances from which DEMs can be created. LiDAR has lower absolute accuracy and by default does not enable a coloured point-cloud (although they can be coloured in post-processing by using traditional coloured digital maps). The technology can provide a better result when the survey area has moderate levels of foliage as light pulses can penetrate gaps in and around foliage, thus reaching ground-level and producing a more complete DTM. It is most commonly therefore used in a forestry setting for canopy height mapping, and is less commonly found on a construction site vs. Photogrammetry.

4.1.3 Combining LiDAR and Photogrammetry

Using a hybrid approach and merging the two techniques has been done and can attain an optimal model for certain use-cases, see [19] or [20] where two respective data sets are combined to create a single resultant DTM, although unless the site has moderately dense vegetation, the additional payload weight of suitable LiDAR scanner is not worth the reduced flight range. It is also noted that although it has been done, there is a literature gap in simultaneous capture of Photogrammetry data and LiDAR data using a dual gimbal of which the method to be described here would use.

4.1.4 Radar

Radar (Radio detection and ranging) uses radio waves in a similar strategy to LiDAR but is not to the same extent

vulnerable to poor lighting and weather conditions which makes it an attractive candidate for use on a construction site. It is currently less commonly found due to the sparse point clouds it generates due to low spatial resolution and specularly, although a recent technique by Qian et al. [21] appear to increase point-cloud density, although still far from the density and overall quality of both LiDAR and Photogrammetry.

4.2 Platforms

4.2.1 UAVs

UAVs are the primary way in which 3D Data is collected today, principally using structure-from-motion photogrammetry as described above. It is the collection of data points across a wide range of different locations at a given altitude above ground that makes it well suited. Due to recent advances in battery technology UAVs have improved greatly in the past 5 years with many consumer and more advanced commercial solutions being developed with increased range, payload capacity and control system quality which has made them the obvious choice for surveyors.

Autonomy The primary challenge of site use of UAVs through the lens of this framework is the supervised nature of their operation which is prohibitive to high-frequency operation. The process currently requires manual setup and calibration of Ground Control Points (GCPs) or Real-time kinematic (RtK) base-stations to yield the centimeter precision needed for accurate surveying, combined with the need for a pilot to be physically located on the site to fly and have visual line of sight to the aircraft and also to change the aircraft battery means that remote piloting and autonomous recharging solutions need to be in place and aligned with the regulator. Notable attempts at overcoming this are power-tethered design in [22] or ground task automation designs proposed in [23]

Sortie Frequency The frequency of airborne scans be increased to reduce delta drift in the environment, however it is noted that sorties are best conducted when site activity is minimal to reduce unwanted artifacts arising from active operations. A combination of telematics, machine learning and diffs between sorties can be considered to filter out plant and other unwanted dynamic artifacts from images and would allow continuous sorties and data capture.

4.2.2 Static

Static hardware can also be used to assist with DTM capture, for example Wang in 2015 [12] sets up a multi camera and scanner system to create a DSM augmented with live video feed give operators a external perspective of their vehicle. By mounting capture hardware statically

in this way or for example a on a high point, e.g. crane, it is possible to get a near real-time point cloud data of a specific area.

4.2.3 Vehicle Mounted

Mounting capture hardware on vehicles, specifically the plant machinery that is the focus of this study is an optimal way to capture local environment data, as is stipulated by Singh [5]. The quality of data is also higher as the roving nature of the vehicles gives a wider range of perspectives from which to interpolate.

4.3 Location considerations

Accuracy and ultimate usability of models is largely dependant on the synchronicity between the captured data and its alignment with real-world 3D vector space, as identified in [24]. The importance of accurate location information increases as we want to superimpose plant machinery on our DTM as well as use our DTM to inform plant operationally. There are three primary methods of attaining this alignment: Ground Control Points (GCPs); Real-time Kinematic (RTK); Post-processing Kinematic (PPK).

GCPs are the most commonly used method and they are often used alongside more advanced techniques. They rely on physically marked locations which are geo-referenced using traditional survey equipment, these points are then identified in post-processing to align the model. RTK and PPK use a drone based receiver with an accurately positioned base-station/s and enable highly accurate location information to be recorded directly into the 3D data by using carrier phase signals which can be thought of as a local coordinate reference. These measurements are either converted in real-time to real-world vector coordinates with RTK or in post-processing in PPK. Kinematic technologies require more specialist equipment and cost more, and of the two Kinematic methods, PPK is preferred for reliability due to reduced number of persistent reliable connections required and its compatibility with longer flights, especially beyond visual line-of-sight.

4.4 Software

Once data has been captured, it must be processed. The goal of this processing is to generate an accurately geo-referenced point cloud to form the basis of a DTM. This process varies in complexity dependant on the sensor technology used, and the specifics are outside the scope of this work. The steps are outlined here at a high-level and for this work are handled by Pix4D (7.2) and LGSVL (7.3).

Point Cloud Generation This first step in processing is to create a point cloud from the captured sensor data.

This process involves stitching together collections of photographs or distance data.

Coordinate Plane Alignment The second step is to align the point cloud with a real-world coordinate system. This process depends on the accuracy embedded location data of the captured images and is largely manual in the field, however the method in this paper will seek to make use of an server-based processing engine to create a robust and automated data pipeline that makes use of new techniques such as automated GCP identification.

5 Plant Telematics and IoT

In this section we explore the second part of our method, relating to plant telematics and IoT sensor data that can be used to accurately model and superimpose vehicles (and more) into an environment. We again look at context and important aspects for informing the ultimate system design.

5.1 Real-time Requirement

Although it is generally accepted that 30fps is the minimum frame-rate for which the human eye deems to be smooth, the definition of real-time, relating to the latency between an event taking place and being observed in a digital system is not very well defined, this is largely because any definition negates itself as in-fact any latency makes a system no longer technically real-time, however the commonality and the one that we will use for this method relates to the perception of humans to a delay which sets the requirement for latency from the event happening to it being displayed to the end-user in the low tens of milliseconds.

5.2 Data Communications Requirement

To attain sub 30ms latency, 5G technology is proposed in this work. Having superior performance and higher range than WiFi technology, 5G has as low a 1ms latency and has reached a suitable maturity to make it the obvious choice for data transfer between site-based devices in this system and cloud-based processing.

5.3 Location and positioning

In a similar way to the requirement for highly accurate location information for DTM sensor platforms, any vehicle wanting to interact as part of the environment must have accurate real-time positioning data available. In practice, this means employing RTK base-stations from which all agents interacting in the environment can operate from the same local reference frame.

5.4 Required sensor data

The sensor data we require for accurate synchrony is quite comprehensive and also dependant on the specific vehicle we want to support. Additionally, the precision of this sensor data must again be sufficient to ensure that real-world and digital environments do not diverge. The availability of plant-integrated sensor data is increasing with time, although the majority of systems currently are designed for non real-time reporting, such as idle-time monitoring. Legacy plant can be equipped with IoT sensors to allow them to participate in ROEM.

Standards There are numerous standards that outline how telematics data should be formatted and specifically the ones of interest as identified in ISO/TS 15143-3 [25]. Each plant manufacturer has slightly differing mechanisms for formatting and accessing its telematics data, despite the existence of [25]. For each plant manufacturer supported by the method, a unique feed of raw data must be secured with appropriate resolution and then cleaned and standardised.

6 Real-time Operating Environment Model (ROEM)

Telematics, IoT data and DTM are combined to create ROEM, a real-time environment containing data from multiple sources to create an interactive digital representation of a site. Given the input data from sections 4 and 5, this section identifies the required capabilities of this model in order that it maintains an accurate representation of the real-world.

6.1 Terrain Deformation

In this work, terrain deformation is the process of manipulating ground mesh and point cloud data to allow us to synchronise the built environment with ROEM by updating it based on plant sensor data from section 5. This will be achieved in real-time by mirroring the actions of real-world plant within our model to create delta changes from our base-model provided by DTM sensor data. To achieve delta deformation for model synchronicity, we use the Unity3D Vector3 API to manipulate the meshes by transforming mesh vertices through a vector based on the collisions of the digital representation of the plant machine on the environment.

6.2 Agent State Representation

In order to represent agents (Vehicles, humans etc.) correctly within ROEM, alongside telematics/IoT data, we must also have geometrically accurate 3D representations of the respective agent that we want to represent. This

is to ensure that we can accurately represent the state of an agent within the environment and ensure that machine interaction with the terrain and environment is correctly modelled, critical for correct terrain deformation.

6.3 Data smoothing

Despite intentions for low latency, high frequency data, to project data into an environment that is perhaps running in excess of 100fps, data will be smoothed using a Kalman Filter see Welch et al. [26] to facilitate gaps in data between frame renders and to ensure accurate representation of machine state.

7 System Architecture

There are two sub-systems making up the architecture of ROEM as outlined in Figure 2. The first is the data processing and facilitation system, transforming and persisting data. The second is the 3D environment itself which consumes input data, enables it's manipulation as well user interaction and monitoring, plus additional sub-modules to enable use-cases defined in Section 3. Both sub-systems will be contained within an AWS virtual private cloud environment. This section considers each ROEM input, process and output step at a high-level.

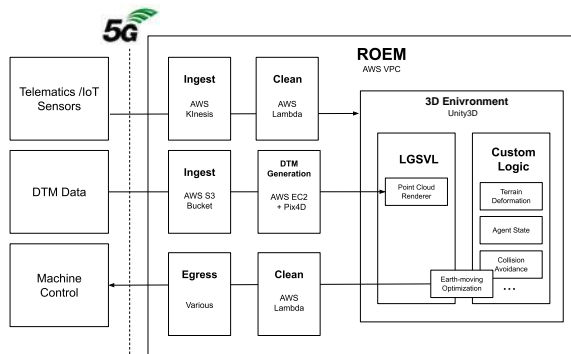

Figure 2. High-Level System Architecture

7.1 Telematics and IoT (Input)

Ingest Real-time telematics data will be ingested from various sources using AWS Kinesis, a real-time big data streaming platform.

Clean Data contained within Kinesis shards will be cleaned using an AWS lambda function and formatted to a unified format understood by ROEM before being persisted in an S3 bucket and passed directly onto Unity.

7.2 DTM Data (Input)

Ingest Raw DTM image and LiDAR data will be directly uploaded to an S3 Bucket, this will trigger an upload event on SQS (Secure Queuing Service).

DTM Generation The upload event will be detected by an SQS consumer running within an EC2 (Cloud Compute Resource) instance, also running Pix4D engine. The respective 3D data will be processed and combined to create a single LAS point cloud file. Any post-processing will be carried out (Diff generation, M/L etc.) on this file before it is persisted in an S3 bucket where it is fetched by the ROEM environment and the point cloud and associated ground-mesh reconstructed.

7.3 3D Environment (Processing)

The environment is the physics engine and 3D model that combines data to enable us to create a real-time digital twin, but also allows us to feedback sense, plan and execute information back to plant whether operating in autonomous or manual modes.

Unity3D A versatile 3D engine is required to power ROEM and to enable the user to view and interact with the environment. Unity3D is a widely used cross-platform 3D engine originally created for game-development that now has applications across industries and is seeing growing use in construction, most commonly for VR and XR purposes. It is the flexibility of this engine, which handles the complexities of an efficient 3D engine that allows the developer to focus on implementing differentiating features and makes it the suitable choice for this method.

LGSVL LGSVL [27] is an open-source project developed LG Electronics America Research and Development Lab in California. It provides a set of tools to build autonomous vehicle simulations based on Unity3D as well as containing a solution to process point clouds and create associated ground meshes. It also provides vehicle driving mechanics, important for agent state representation.

7.4 Machine Control (Output)

Once an activity has been planned within ROEM, it can be disseminated back to the plant machinery where machine control can execute the activity.

Clean ROEM output data must be cleaned and formatted to match the receiving machine control system. An AWS lambda function will be created for each receiving system.

Figure 3. Earth-moving site

Egress Different providers of machine control systems also have different methods of receiving control data. Provider specific connectors will enable support for these systems.

8 Case Study

The case study shown in Figure 3 is a proof of concept of the ROEM 3D environment whereby a 1cm precision scan of an earth-moving section of a complex real-world road-building site has been ingested, a point-cloud generated along with a ground mesh.

9 Conclusion and Future Work

In this paper we introduce the concept that Plant Telematics and IoT can be combined with Digital Terrain Models to create a Real-time Operating Environment Model that can be used to accelerate plant autonomy adoption by providing a mechanism to fulfil Singh's [4] sense, plan, execute philosophy alongside other benefits outlined in Section 3. We explore the relevant adjacent, enabling technologies and associated literature, before outlining a system architecture along-side presenting early proof of concept implementation of the architecture using data from a real-world construction project. Future work is listed below and is largely relating to validation of the concept.

- Complete the implementation of the method outlined.
- Integrate ROEM in a live site trial.

- Utilise ROEM to manage, optimize and monitor autonomous tasks.
- Gather and synthesize data from this trial and quantify findings and benefits in further papers.

E-mail: goran.sibenik@tuwien.ac.at

Abstract

Numerous modelling and structural analysis workflows reflect the heterogeneity and vague standardization in the construction industry; hence their automation is not straightforward. Procedures like redefining geometry from scratch or assigning loads one-by-one, are mostly performed manually, are time-consuming and error-prone, reflecting traditional workflows in digital BIM environments. BIM tools for structural analysis, compared to finite element method tools, aim to automate and interrelate structural design, analysis and documentation. This paper investigates the potential and obstacles for automation of structural analysis workflows. We focus on automation of model preprocessing, the procedures which interrelate structural design and analysis.

Through literature review and a practical use case analysis, automatable procedures were identified and formalized. They were further verified in the experts' panel discussion. The results indicate that defining floor levels, loads and load combinations, supports and joints are standard model preprocessing procedures. In special cases, e.g. special grounding conditions or heavy machinery, manual overriding of automatically assigned values might be required. Lack of clarity and traceability in the structural analysis of a complete building model, and the lack of confidence in background processes in BIM analysis tools, are identified as the main obstacles for automation.

Finally, we deliver a prototype of the automated procedures with structural analysis software RFEM Dlubal, which exemplifies implementation. The automation of preprocessing is especially important for design optimization and time-dependent structural analysis during construction or demolition. This research contributes with an improvement proposal of BIM-based structural analysis thus enhancing the overall digitalization level of the building design process.

Keywords –
Preprocessing; BIM; Automation; Structural analysis

1 Introduction

The use of digital tools to perform structural analysis increased in the last decades; currently the tools are present in most structural analysis practices, although some analyses are still performed manually [1]. The building information modelling (BIM) paradigm gained on popularity among structural engineers, but the finite element method (FEM) tools, which have been used for a longer time, are not clearly distinct from the ones referred to as BIM structural tools. Automatic relations between structural design, analysis and documentation is found to be the main feature of BIM software tools [2]. These relations have not yet been fully realized, and significant manual work is necessary for the design tasks leading to structural analysis [1]. It is necessary to address the technical issues which will provide structural engineers with benefits promised by BIM [3].

Preprocessing of a building model involves data management procedures of assigning new information like loads or supports to create an analysis-ready model. In this paper, the procedures are called preprocessing methods if they are automatically performed. The procedures interrelate structural design and analysis, and automating them could reduce time, errors and cost needed for structural analysis. Achieving an automated relation between the design, analysis and documentation is the way to fully enable the BIM ideas in structural analysis software tools – therefore defining the preprocessing methods is unavoidable. Besides achieving the full BIM potential, the preprocessing methods allow for real-time feedback in the form of a quick preliminary structural analysis of the interpreted and imported physical building model originating from architectural design, as the manually performed time-consuming tasks are automated and the information necessary for the analysis is promptly assigned. Automated preprocessing of building models is a research gap addressed in this research

In our preceding research we developed a software tool which interprets building models for structural engineers [4]. The model which can be used for the analysis is prepared on the non-proprietary central storage and can be imported to any structural analysis

tool which offers a way to access and manage its internal structure and data (e.g. via application programming interface (API)). A building model imported in such a way is not ready for structural analysis and assigning additional information is required. However, the information origin and the way it is defined remains in the gray area, and needs to be further investigated. Some design management literature exists which roughly indicates services provided by project stakeholders (e.g. [5]). The description of services does not reach the building element information level (such are objects and their properties); therefore the information assignment procedures within the workflow need to be investigated. Information origin provides the base for automation – focus is on the information assigned after the architectural model is interpreted and imported (analytical model with geometry and element types), and before the structural analysis takes place (analysis-ready model with supports and loads).

The next section presents a review of existing research regarding the automation of preprocessing procedures. Section 3 describes the research methodology, followed by the proposal of automation methods in section 4. Section 5 provides the example of implementation and section 6 the verification of the proposed methods via an experts' panel discussion. The results are discussed in section 7.

2 Literature review

The topic of automatic preprocessing of structural analysis models has not been widely addressed in the light of the existing design practices. Literature review performed in [6] shows how automation of structural analysis is becoming a more popular topic over the years, since the structural design automation and interoperability with other domains is of highest importance for the design process. In the academic community, new forms of design workflows are often proposed without consideration of the traditional approaches, especially in the early design phase. Reconsideration of traditional workflows is desired, however a complete paradigm shift has not received a positive feedback in practice [1]. The aim of this work is to provide a solution to automatically perform preprocessing steps existing in practice. Such tools have not been found for the developed design phase – however implementation of preprocessing in the early design phase or other domains such as tunnel engineering is addressed in the literature. The automatic preprocessing promises more design variants due to prompt structural analysis feedback, resulting with more optimal design, less errors and finally less time and money required for the whole project.

A design cycle lasts longer than a month for a single design alternative, the main limitation being unsuitable representation for analysis, whereby the engineers spend more than half of their time in managing information [7]. Automation of analysis of design alternatives is viewed as a solution to this problem. Focus of their work [7] is a multidisciplinary optimisation with numerous design variants, existing in the early design stage. Energy and structural optimisation in the early design stage is investigated in [8]. Compared to developed design, the early design lacks information for a detailed analysis, therefore tools used for performing energy and structural performance need to consider some uncertainties. Accordingly, models with varying amount of information, as required during the evolving designs, are proposed [8]. In our work, the focus is on developed design where a sufficient amount of data is usually available for structural analysis. However, a required data scope is hardly ever formalized on the level of building elements and belonging properties so it could be correspondingly validated.

Automating preprocessing steps for structural analysis is more common in infrastructural projects such as tunnel design than in the building projects. Similarly to BIM, [9] propose tunnel information modelling (TIM) which is able to unify multiple models relevant for tunnel design in an object-oriented manner. In their “BIM-to-FEM”, tunnel design information is extracted and preprocessed for the FEM analysis, whereby the boundary conditions are automatically assigned based on the design data. A framework calculating wind effects on the building is developed in [10], recognizing the need for automatic geometry interpretation and analysis for such a repetitive and error-prone task.

A workflow common for structural analysis shows how significant amount of manual work could be avoided by relating it to the architectural model [11]. They present a fairly simple case study and describe how loads like self-weight and uniform design load are manually created for the analysis. A traditional design workflow is presented in [12], describing that from schematic design through design development the architectural design is generally imported to FEM tools. They propose a workflow supporting data analysis during the design, but focus on structural design and not structural analysis. A plug-in for structural analysis tool Robot developed in [13] supports structural engineers in performing optimization of a building structure. Most of the inputs are however assigned manually in the model.

Another form of automation of structural analysis is provided as a support tool for architectural design, by introducing structural knowledge to architectural design tools. Members and connections design can be realized in such a way [14]. However, this approach can hardly replace established structural analysis practices which

rely on structural analysis software tools having a large market share. Additional tool in Matlab which helps architects in the early design stages to receive feedback for the renovation projects based on the floor plans is described in [15]. Their motivation are iterative requests on design feedback, which structural engineers usually provide only at the decided design, similarly to the developed design stage. Researchers [15] focus on the floor plans and walls as structural elements, which does not entirely correspond to the BIM approach in the developed design stage. Specialized knowledge regarding seismic performance of buildings is automated and described in [16]. They propose a platform that automates iterative steps usually performed by structural engineers to find optimal and satisfying structural design. Structural analysis practices for buildings during developed design are heterogeneous and have not been sufficiently explored. The automated preprocessing methods are not available except for methods provided by software tools which overcome software-specific problems in the form of workarounds. Research describing the structural analysis workflows and data requirements can be found, and will be considered in section 4. As the structural analysis practices differ, so do the ways to automate the model preprocessing procedures. Besides international standards, numerous project-, company- or country-specific standards exist defining the workflows leading to structural analysis. These standards have suited well the traditional practices, but leave plenty space for intuitive experience-based decision making which is not suitable for automation in such form [17]. The standards do not address objects used in the software tools.

Lack of technical solutions for structural analysis is evident from the literature review, especially for the developed design stage [3]; automated preprocessing and modelling of structural components is a research gap addressed in this research. The research question we address with this work is: “How to automatically preprocess a building model for structural analysis?”

3 Methodology

This paper is part of a larger project investigating data exchange between architectural design and structural analysis. In the preceding research, a tool interpreting an architectural building model was developed and implemented with multiple building models [4]. Building models containing geometry and information about element types created by architects are interpreted to representation suitable for structural engineers. The interpretations focused on geometric information and result with an analytical building model. This tool, although being a useful aid for structural engineers and saving significant amount of time needed for redefining

information available in another form, does not provide structural engineers with an analysis-ready model. Additional information which is not available in architectural design model is required before the structural analysis can take place. The heterogeneity of design workflows makes automation of certain procedures difficult or even impossible. Hereby, the question of automating preprocessing procedures for structural analysis is addressed through several methodological steps:

- Preprocessing methods are identified through literature review describing workflows to structural analysis on building element level and a real use case analysis of a modelling and data exchange process of a German structural engineering company. This analysis delivers information origin which is a base for formalizing preprocessing methods.
- Preprocessing methods are formalized so they could be automated with a data management tool. The preprocessing methods are derived from the previously conducted analysis. The methods are developed by comparing the initial and expected building models, and by identifying and describing processes which provide a desired result.
- Data management tool is developed as a prototype and the formalized methods are implemented. The tool maintains communication with the central data storage (realized with MongoDB) and facilitates the conversion to the particular structural engineering finite element calculation tool (RFEM Dlubal). The developed preprocessing methods are implemented and verified with a test building model originating from the above-mentioned structural engineering company.
- Finally, the feedback and evaluation of generalization-potential of implemented automation methods was assessed through practitioners’ panel discussion. Practitioners’ expertise is needed to identify optimization potentials as preprocessing rules are bound to individual or interfirm conventions.

4 Automatable procedures

The literature review and the use case analysis revealed information stemming from the architectural design as well as the information defined by structural engineers. Barely any information originates from the cooperative work between architects and structural engineers in a standard workflow, but a significant amount of information is of interest to both stakeholders. This analysis was used to propose the preprocessing methods.

Figure 1 Overview of the workflow leading to structural analysis

4.1 Information origin

The information origin investigation is necessary to determine which preprocessing procedures are performed in the existing workflows in academia and practice - which information is assigned in the preprocessing part of the workflow. The preprocessing methods are depicted within the workflow (Figure 1), which also implies the software tools which will be used for their realization.

From the literature review of workflows presented in Table 1 it can be concluded that: geometry of all building elements enclosing a space, materials of building elements with visual properties and types of building elements, is delivered by an architect to a structural engineer. Occasionally, after the consultation with structural engineers, architects define the information about the load-bearing property of building elements, foundations and raster. The information which is usually not explicitly defined by the architect are the analytical geometry of structural building elements, loads, structural properties of materials, supports and structural connections of building elements. The architectural software tools generally do not provide ways to define that information.

Table 2 Information origin according to use case analysis

Information origin	Information
Architectural model	Geometry, building element types – architectural semantics, materials with visual properties, space uses (not always defined)
Mutual consent on architectural model (structural model)	Geometry of structural system, load bearing properties
Structural analysis model	Analytical geometry, building element types – structural analysis semantics, materials with structural properties, load types and cases, supports, joints

Following the literature review, a use case analysis of the workflow leading to structural analysis has been performed. A use case analysis is performed with a German construction company, including the procedures of design, interpretation and preprocessing. It was conducted in a period of time of eight months through multiple interviews, observation of processes and continuous feedback through a team of company experts. The use case analysis delivered similar results to the literature review and they are summarized in Table 2. Analysis of processes showed that the engineers use 2,5d analysis characterized by multiple models based on slabs. They do not use a complete building model to perform the analysis, but divide the model into multiple models,

Table 1 Information origin according to literature review

	Architect	Structural engineer
[18]	Geometry, location of the members, types of materials and properties	Load types and cases, boundary conditions
[19]	Drawings, initial dimensions, section sizes	Analytical models, structural properties, loads
[12]	Geometry	Section properties, boundary conditions, loads
[20]	Appearance – art, geometrical and spatial aspect	Simplified model, loading component and joint connections
[21]; [22]	Geometric locations, member section profiles, material data, structural members that are provided by the architects as a vertical and lateral load transferring system	New structural members, load cases and their combinations, geometric boundary conditions
[13]	Geometry (option 1)	Geometry (option 2), sections, supports, load cases
[23]	Geometry (physical model)	Loads and supports
[24]	Elevation, grids, geometry	Analytical model, material properties, section properties, boundary conditions, load information
[25]	Geometry, element connectivity, cross-sectional dimensions, material mechanical properties	Geometry and support creation, material definition, load assignment

according to the floor levels. While the horizontal load-bearing elements are represented as building elements, vertical ones are represented as loads or supports. Therefore, we account 2,5d approaches in the proposal of preprocessing methods.

4.2 Preprocessing methods

Based on the literature review and the use case analysis, it was concluded that four types of information are assigned after the data from architects is interpreted and recreated. Interpretation of information coming from the architects is addressed in more detail in our previous work [4]. New information realized through preprocessing methods involve the creation of floor levels characteristic for 2,5d analysis, load and load combination assignment, definition of supports and joints between the building elements. Table 3 depicts schematically the recognized methods, which are enumerated and described in the follow-up. This additional information is assigned to the analytical model directly within the structural analysis software tool.

Table 3 Proposal of preprocessing procedures

1. Based on the performed analysis, structural engineers do not rely on the analysis of a complete 3d building model, but rather perform 2,5d analysis. 2,5d analysis means identifying floor levels and modelling only slabs as building elements. Upper vertical elements are modelled as loads, while the

lower vertical elements are modelled as supports. In our research we proceed with a 3d analysis as we consider it the future of assessing structural building performance; still, we identified the need to define floor levels in order to support the established practices. After the definition of floor levels further methods can be implemented.

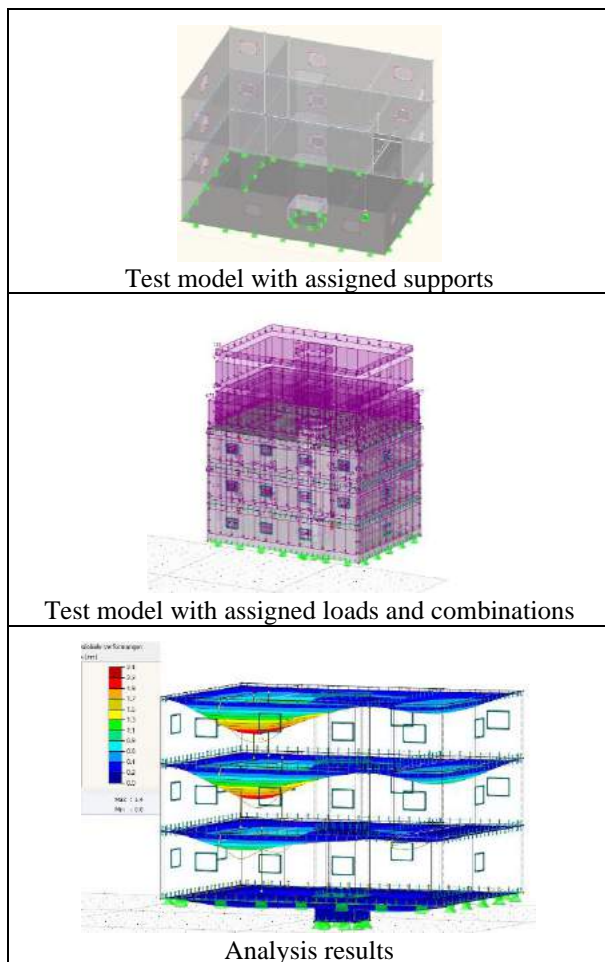

2. Loads and load combinations need to be defined for structural analysis. Four types of loads can be assigned: dead, live, impact and environmental loads. Out of these four types, only impact-loads are not standard for each structural analysis. We identified that self-weight is a requirement for each building element as a dead load. Live loads are dependent on the use of space which is sometimes provided within a model by an architect, but on other times needs to be assigned by a structural engineer. Environmental loads affect the external elements of the building and are based on the environmental conditions of the geographic location. In the case of 2,5d analysis they are assigned to the top slab. Other loads are assigned floor-wise to each slab in the model.
3. Supports can sometimes be found in architectural models, but they are usually defined by structural engineers as they do not affect a building appearance. They are placed on the bottom of building elements and can be defined as points, lines or surfaces. We assign them to the lowest floor depending on the vertical elements above the slab.
4. Detailed descriptions of the way to define joints in the developed design phase was not found in the examined literature nor in the use case analysis since they were not present in the 2,5d approach (as only slabs are represented as building elements). Vertical elements represented as supports in 2,5d analysis partly indicate the joint behaviour, since supports have similar properties. In our work, joints are defined as pin-connected, not transferring the rotation in the case of column-slab connection, and the wall-slab connection can transfer rotation in the direction of a connection line. Joint definition is a complex topic highly influencing 3d analysis which has not been sufficiently investigated for all possible cases.

5 Prototype implementation

A prototype for RFEM plug-in has been developed that is able to preprocess a test building model. The plug-in is developed with RFEM Dlubal API and .NET Framework. It uses the Open Cascade geometry kernel to handle the geometrical information. The plug-in is linked to a central storage where information is stored in a non-proprietary format, and at the same time it is linked to

RFEM Dlubal internal storage and proprietary model. The preprocessing methods are therefore specific for a proprietary software tool, unlike the model interpretations taking place on the central open storage. It was possible to realize all methods with the prototype plug-in, and to perform a satisfying structural analysis in the follow-up. Table 4 shows screenshots of a test model with the results of preprocessing methods and analysis. The methods are fully automated with default values, but allow some interventions, e.g. changing the use of space influencing the live loads, or the floor level where the environmental loads or supports are placed. These methods do not represent the exhaustive possibilities for structural analysis, however they represent most common procedures and aid structural engineers not to start from a blank model with their work. Additional enhancement are available in the further step directly within the RFEM Dlubal, these may however be integrated within the plug-in if recognized as standard for certain workflows.

Table 4 Test model after preprocessing and analysis

6 Panel discussion

The panel discussion involved structural engineers from two companies. The feedback provided by the participants in the discussion addressed general issues regarding the preprocessing automation, as well as the specific preprocessing methods. The remarks were:

- Both companies use architectural models originating from Revit and RFEM Dlubal for structural analysis
- 2,5d is preferred to 3d structural analysis primarily due to traceability and clarity of analysis, however the analyzed cross sections of building elements may be larger than in the case of 3d.
- 3d analysis delivers results which are difficult to verify due to lack of clarity of calculation in a structural analysis software tool. Traceability of analysis is demanded by inspection engineers, which is not provided in 3d analysis.
- Automation of preprocessing methods is regarded as useful and usable, but needs some adaptation.
- Practices do not significantly differ between companies.
- Structural engineers are generally part of the project before the developed design and specific information can be defined in advance.
- Significant amount of experience-based knowledge is used for identifying and analyzing the model.
- Feedback received from the participants recognizes the standardization potential in the proposed preprocessing methods.
- A similar approach is performed to identify the floor levels; however, an important point is the detection of the ground floor, which is usually placed close to $\pm 0,00$ elevation
- Foundations can be defined in two ways, based on the results of the geotechnical analysis: i) as the proposed solution, under each element separately; ii) by excluding the support capabilities of a ground plate due to bad ground characteristics.
- Loads are highly dependent on the building use and special building requirements. The proposed loads can be regarded as standard input. It is necessary to include multiple country-specific building codes.
- Joints can be modelled in two ways, depending on whether the i) prefabricated or ii) cast in place building system is used; the i) indicates that the rotation is not transferred; while ii) can transfer also rotation.

The preprocessing methods require some adaptation, but a similar plug-in that could automate the existing practices or some preprocessing steps is recognized as a great help for a day-to-day business.

7 Discussion & conclusion

Many manual time-consuming procedures are performed for each project from scratch, whereby these tasks are not only similar between the projects, but often across multiple practices. The amount of similarity across practices and a unique solution is hard to define due to lacking documentation and standards. This paper proposes preprocessing methods based on the existing research and practice, which have not been formalized for automation purposes. The new proposal is based on the literature review and use case analysis and is implemented as a prototype tool with a test building model. The tool was received with appreciation and is regarded as a benefit for structural engineering. Further investigation of heterogeneous practices is needed for providing a tool which would satisfy practices beyond the scope of this research.

The BIM paradigm regarding structural analysis tools is still unclear. This paper emphasizes the need for automation of preprocessing, and relating structural design and analysis in a digital and automated way in order to provide prompt feedback about structural building performance, save time and money and reduce errors during building design. The greatest problem in the proposed approach is found in the readiness of structural engineers to fully rely on the analysis with 3d geometry. However, an approach with automated preprocessing methods in a similar way, is recognized as beneficiary and required to improve structural analysis work.

One of the limitations of the provided solution is that it does not consider special cases of structural analysis, like special grounding conditions or heavy machinery. Numerous workflows and projects need to be analyzed in order to determine which workflows and procedures have automation potential. In order to generalize this proposal and the implemented prototype, certain adaptations and extensions based on the results of exhaustive studies might be needed. Unique problems might and will occur for certain building projects, but still, generalized solution needs to be able to cover standard procedures, while the special ones can be manually overridden. Supporting various practices might potentially be realized by using service-oriented system architecture like microservices [26].

Therefore, next steps regarding the software tool is to test the provided methods with additional building models. The methods will be tested with other structural analysis software tools and additional practices. Similar plug-ins are required for other tools, and the proposed prototype may serve as a base. A process analysis is required for each procedure which is to be automated. The proposals changing entirely the existing design workflows, have not been successfully accepted in the AEC community.

8 Acknowledgements

The authors would like to thank Strabag SE, Vienna, and their subsidiary Züblin, Stuttgart, for supporting this research through the project DATAFILTER. We would also like to thank ATP architekten ingenieure, Vienna, for taking part in the panel discussion.

Abstract –

It is inevitable that the decrease in Japan's working population due to the declining general population, low birth rate, and ageing population will lead to a shortage of skilled infrastructure inspectors. Therefore, it is important to improve and equalize the quality of inspection data, which are the basis for understanding the condition of bridges, to allocate appropriate and optimal budgets, and to formulate life-extension repair plans. It is also important to improve the quality of inspection data, which are the basis for assessing the condition of bridges, and to equalize the data so that the progression of damage can be properly assessed, an accurate diagnosis can be made, and appropriate measures can be planned. In this study, we propose a method for supporting the field inspection of bridges by visualizing abnormalities using a heat map based on 3D point cloud data representing the bridge to be inspected. The proposed method is evaluated by infrastructure inspectors, and the requirements and issues for the field support technology are summarized.

1 Introduction

1.1 Background

1.1.1 Status of bridge inspection

Japan has about 730,000 road bridges with a length of 2 m or more. Most of them were built during the period of high economic growth and are rapidly ageing. By 2029, 52% of these bridges will be at least 50 years old. The number of bridges managed by local authorities that are subject to traffic restrictions due to ageing has tripled in the 10 years between 2008 and 2018 [1]. Moreover, there

are many bridges that are still in use 80 years after their construction without major damage due to appropriate repair and reinforcement.

In 2014, a 5-year periodic inspection was stipulated to obtain the information necessary for proper maintenance of bridges in order to avoid damage to road users and third parties, avoid long-term malfunctions and failures, and enact timely measures to extend their service life [2]. During periodic inspections, the condition of the bridge is assessed visually, a diagnosis of soundness is made for reference, and countermeasures to be taken before the next periodic inspection are established. In addition, data on the external condition and the degree of damage are obtained for comparison with the results of previous inspections and to study the maintenance plan. It is also important to transfer the information from the inspection results and repairs. However, because of the large number of bridges and parts to be inspected, it is time-consuming for inspectors.

1.1.2 Use of digital transformation in the infrastructure sector

The Ministry of Land, Infrastructure, Transport and Tourism (MLIT) set up the “Digital Transformation (DX) Promotion Headquarters for the Infrastructure Sector of MLIT” on 29 July 2020 [3]. As a result, MLIT uses data and digital technology in the infrastructure sector to transform social infrastructure and public services in response to the needs of the public, by transforming the work itself, the organization, the processes, and the culture and working style of the construction industry and MLIT, and by promoting public understanding of infrastructure. MLIT has established a policy of promoting public understanding of infrastructure and realizing safe, secure, and prosperous lives. The introduction of advanced and new technologies is indispensable for the introduction of new technologies and the measures to achieve them, such as Society 5.0 and DX. In addition, MLIT is promoting “i-Construction,” which aims to increase the productivity of construction

sites by 20% by 2025 through the use of information and communications technology and 3D data in all construction processes. With these initiatives, sharing information on bridge inspections with 3D data will improve the efficiency of inspection efforts and enable rapid response in an emergency. In addition, the use of 3D data for bridge maintenance and management will make it possible to easily grasp the location and extent of damage, as well as the overall bridge condition, which will be useful for determining the cause and diagnosis of bridge deterioration [4]–[8].

1.2 Objectives of this study

To improve the efficiency of bridge inspection work, this study proposes a bridge inspection field support technology as a method to determine the damage of surface irregularities from the 3D data of bridges, to efficiently evaluate overall bridge damage, and to visually grasp the change and position of damage over time. In this paper, we propose a new method for visualizing the damage of a bridge using 3D point cloud data. The 3D data are acquired by photogrammetry using a camera or a ground-based terrestrial laser scanner (TLS).

To improve the efficiency of the periodic inspection of bridges, we propose a bridge inspection method that uses a heat map to generally check the appearance of bridges before visual inspection and to screen the bridges or bridge components to be inspected.

The contribution of this research is that we have clarified a method to analytically visualize the ageing process using point cloud data sets. The method was applied to support bridge inspections, and actual practitioners (inspectors) evaluated the method.

1.3 Research flow

The research flow of this study is as follows.

In Section 2, we summarize the status and issues of bridge maintenance management since the Sasago Tunnel ceiling plate failure accident, and how to use 3D data to prevent such failures.

In Section 3, we set up field situations and summarize how to make a heat map. In this section, we present the results of experiments based on the contents of

In Section 4, we conduct a demonstration experiment based on the procedures in Section 3. The contents of the experiment, the results obtained, and the issues to be addressed are summarized.

Finally, in Section 5, we interviewed inspection practitioners about the application of heat maps to the 3D damage drawing support system [9] previously developed by the authors. This paper reports the requirements for the field support technology and system, and the issues in applying the system to practice.

2 Status and challenges of bridge maintenance and management

2.1 Status of bridge maintenance

In December 2012, the Sasago Tunnel was closed for a long time as a result of a fallen ceiling plate which claimed the lives of nine people. This incident reaffirmed the importance of maintaining and renewing social infrastructure, and in March 2014, regular inspections by close observation every 5 years became a legal requirement. From 2014 to 2018, mandated inspections were carried out based on the 2014 edition of the *Periodic Inspection Guidelines for Bridges*. Bridges under the direct control of the national government were inspected according to the periodic bridge inspection guidelines, while bridges under the control of local authorities were inspected according to the periodic road bridge inspection guidelines. However, in 2019, the periodic bridge inspection guidelines were revised to streamline the inspection process while ensuring the quality of periodic inspections, in response to the occurrence and oversight of deformations that may affect the safety of third parties after periodic inspections and the development of inspection support technologies, such as photography and non-destructive testing [10], [11]. In the revised guidelines, the focus of periodic inspections is on the damage and structural characteristics, and the inspection targets are narrowed down to streamline the inspection process. In addition, guidelines for the use of new technologies and a performance catalogue [12] have been developed to supplement, replace, and enhance close visual inspection.

2.2 Challenges in bridge maintenance

Bridge maintenance has three main challenges.

2.2.1 Limited budget

The budget for the maintenance and repair of national highways under national government control should be increased to cope with the ageing of facilities, but it has decreased by about 20% from 320.2 billion yen in 2004 to 251.5 billion yen in 2013, in line with the decrease in the national public works budget [13]. In 2012, a disaster prevention and safety subsidy were established, and financial support and budget increases were implemented, such as priority allocation for inspection and repair projects for bridges and other structures. In 2012, the government established the Disaster Prevention and Safety Grant, which provides financial support and increases the budget for bridge inspection and repair projects.

2.2.2 Underutilization of technology that could improve efficiency

The revision of the inspection guidelines has led to the development of guidelines and performance catalogues for the use of new technologies that complement, replace, or enhance close visual inspection, but their use is still limited.

2.2.3 Lack of human resources and skills

As of June 2019, there were no civil engineers involved in bridge maintenance work in about 30% of towns and 60% of villages, and 54% of direct inspections and 42% of inspectors commissioned by local governments had not taken the road management practitioner training course or the road bridge maintenance skills course conducted by MILT. In addition, many bridges have been reported to require repair or reinforcement after the first round of mandated inspections, so human resources have been allocated to repair planning, design, and implementation.

2.3 Using 3D data to solve problems

In this study, we propose an inspection support technology that obtains 3D data of a bridge, creates a heat map from the data, and visualizes damage points as a 3D model to improve the efficiency of on-site work for bridge inspectors. We believe that this technology can improve the efficiency of inspection work by detecting damage from abnormalities identified by the heat map and extracting locations should be focused on during inspections.

To solve the problems of insufficient budget, technical skills, and manpower, local surveyors who do not specialize in bridge design have been commissioned to carry out bridge inspections, and inspections have been

simplified and carried out by local government employees (in-house inspections) [14]. However, potential problems include inspectors lacking sufficient knowledge about bridges and bridge damage, reduction in accuracy of the inspection due to simplification, differences in results between first and second inspections, and damage that had been previously identified being missed. The 3D data can be deployed in a 3D maintenance management system. By recording damage data as a heat map or 3D data and bringing it to the site, the risk of missing previously identified damage will be reduced. In addition, quantitative evaluation of the degree of damage from the heat map will reduce the variability of evaluation among inspectors.

3 Heat mapping and visualization of anomalies

3.1 Visualization of anomalies with heat maps

The process flow for creating a heat map from point cloud data is shown in Figure 1. A camera and TLS are used to measure the bridge. Images or movies taken by the camera are cut out at regular intervals to generate 3D point cloud data with structure from motion (SfM) processing to recover the shape from the images. The difference between the point cloud data generated by the SfM process or the TLS process and the reference data, which simulate the undamaged surface, is visualized by the colour change. The heat map is created using the point cloud processing software CloudCompare. In the comparison, first, by using the align function of CloudCompare, feature points in the acquired point cloud data of two periods are manually selected, aligned, and superimposed. Next, the compute cloud/cloud distance and compute cloud/mesh distance functions are used to

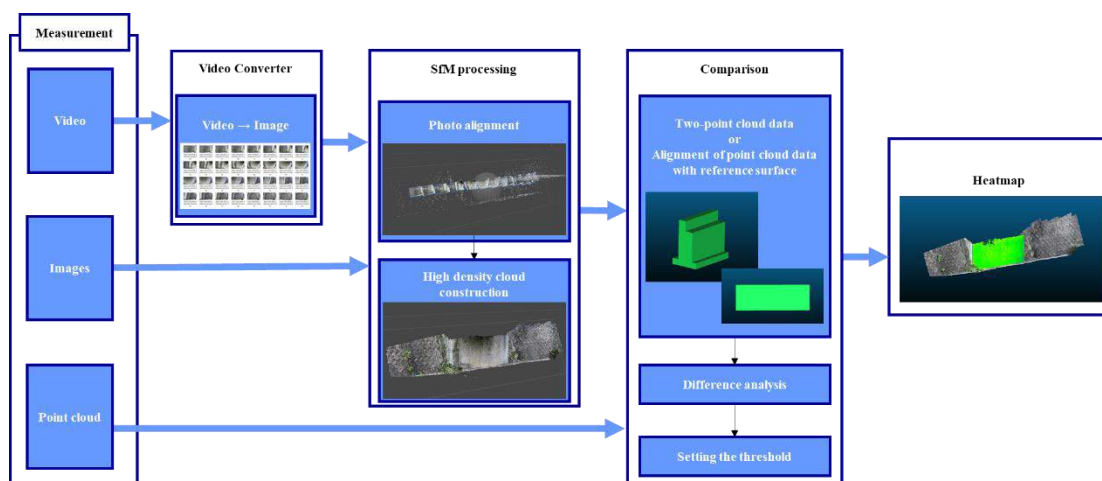

Figure 1. Flow of heatmap creation

perform a difference analysis of the two superimposed data sets and create a heat map. The difference between the two data sets is represented by a change in colour, for example, a change to blue if the bridge is concave or to red if it is swollen.

3.2 Damage to the detection object

Damage that can be detected using a heat map includes dampness, delamination, exposure of steel bars, and cracking of concrete members, as required by the periodic bridge inspection guidelines.

3.3 Equipment used

In this study, to obtain 3D point cloud data for bridges, we use FARO Focus 3D X330 as the TLS and SfM technology to generate high-density point cloud data from images taken by a camera (GoPro Hero9 Black).

3.4 Heat map creation

To create a heat map from the 3D point cloud data of a bridge, two field situations were set up. The first is a case where previous cloud data for the target bridge are available, and the second is a case where no previous point cloud data are available. When previous point cloud data are available, the past and present point cloud data are compared. The flow of the comparison with previous data is shown in Figure 2. The point cloud data of two periods are aligned so that the same positions overlap, the difference analysis is performed using the previous data, and a heat map is generated by setting the threshold. In addition to analysis of differences in the point cloud data by TLS (method (1)) and analysis of differences in the point cloud data by SfM (method (2)), comparison of the

TLS point cloud data and SfM point cloud data is carried out on the assumption that the measurement method is different between the present and the past (method (3)). The heat map patterns are shown in Tables 1 and 2. When previous point cloud data are not available, a reference plane that simulates the undamaged surface is created and compared with the point cloud data. The reference plane should be the same as that of the bridge when it was built, but if as-built data or drawings are not available, the reference plane is made from the current measurement data. The reference plane in this study is created by using the Primitive Factory function of CloudCompare (method (A)), the 3D parametric model [15], [16] constructed for the bridge of interest (method (B)), and the RANSAC function [17] (method (C)) to generate the plane from the point cloud. See Figure 3 for details.

4 Demonstrations

4.1 Content and results of the experiment

The proposed method was tested on two bridges, the Warazuhata Bridge in Sennan City, Osaka Prefecture (22.1 m long by 4.0 m wide), and an unnamed bridge in Saitama Prefecture (2.0 m long by 4.5 m wide), as well as on laboratory buildings on the campus of Kansai University 'Figure 4'. Previous point cloud data were available for Warazuhata Bridge. At the Warazuhata Bridge and the laboratory buildings, paper clay and wall stickers with a thickness of about 1 to 2 cm were attached to the abutments to simulate damage 'Figure 5'. The data obtained before sticker application were as previous data and the data after application of the stickers were used as current data. The camera was pointed at the front of the abutment and moved to the side. In the TLS measurement,

Figure 4. Settings of the experiment

Figure 5. Paper clay and wall stickers pasted on the vertical wall of the abutment of Warazuhata Bridge

the camera was placed in front of the damage and the 3D data were constructed using FARO SCENE data processing software. The heat map of the Warazuhata Bridge is shown in Figure 6.

The colour of the heat map was set so that the amount of difference increases from green to red. The area where the pseudo-damage was pasted is drawn in bright green, unlike the surrounding area. From the figure, the damage can be visualized by the colour change. Figure 7 shows the results for method (2), comparison of SfM point cloud data. Like method (1), a colour change was observed at the point where the pseudo-damage was pasted, but relative to the comparison with method (2), the colour change was also observed at points other than where the pseudo-damage was pasted. This may be due to the inferior accuracy of the SfM point cloud data compared with the TLS point cloud data. Similarly, in method (3), where TLS and SfM point cloud data are used 'Figure 8', damage can be confirmed from the heat map. As with methods (1) and (2), a colour change was observed at the point where the pseudo-damage was pasted, and the damage could be visualized by the heat map. However, because the SfM point cloud data did not measure the

upper part of the abutment, it was not possible to compare the damage of the entire abutment.

On the unnamed bridge, concrete spalls were widely observed on the underside of the deck in the field, as shown by the orthographic image in Figure 9. Extensive delamination and exposure of steel bars were also observed. In this study, the current SfM point cloud data were used to verify the results in the absence of previous

data. Figure 10 shows the results of visualization of the damage by aligning the reference plane created by method (A) using the Primitive Factory function of CloudCompare on the SfM point cloud data.

4.2 Considerations

In this study, the heat map was made according to the flow diagram shown in Figure 1. The experimental results showed that the position of the pseudo-damage and the position of the delamination coincided with the position of the colour change in the heat map, suggesting that the waviness and delamination of concrete can be visualized. This suggests that the proposed method is reasonable. However, cracks in the concrete were not visualized by a colour change in the heat map. It was found that the heat map could visualize damage that created unevenness, such as waviness and delamination, but could not visualize damage without unevenness or small damage such as cracks. By creating heat maps from the point cloud data from two different periods, it is possible to see the change over time and to identify the time when the damage occurred. In the absence of point cloud data from two different periods, it is difficult to determine the most appropriate among the three methods because it takes time to align the planes to visualize the damage, and a suitable for creating the reference plane differs depending on the measured data. As shown in Figure 8, the heat map shows a colour change in areas where the pseudo-damage is not pasted, which is more extensive in the SfM point cloud data than in the TLS point cloud data. This may be due to the difference in accuracy between the TLS and SfM point cloud data. Because TLS point cloud data are more accurate than are SfM point cloud data, it is possible to use TLS as the basic measurement method, and to use a camera when TLS cannot be installed or when measurement is dangerous. The threshold value of the heat map was changed for each bridge or building to make damage detection easier. However, to evaluate bridges with the same standard, the threshold value should be kept constant. Because the SfM point cloud data are different from the actual size of the bridge, it may not be possible to visualize the damage if the threshold is kept constant. As a solution to this problem, we propose a method for visualizing the damage with the same threshold value for all bridges by adding location information to the SfM point cloud data. In addition, it is thought that damage can be quantitatively evaluated by this method.

5 Application as a bridge inspection support technology and as a bridge inspection method

The authors have developed a support system for

creating 3D damage diagrams to enable maintenance workers to grasp and share the location and status of damage intuitively and accurately. Since the heat map information proposed in this study is also based on 3D point cloud data, it can be superposed on this system. Therefore, we conducted an evaluation meeting by practitioners to evaluate the effectiveness of using heat map information on mobile devices for inspection work in the field. The main opinions raised at the evaluation meeting are as follows.

- A heat map showing the areas to be focused on during the field survey will improve the efficiency of the field work and save time.
- By looking at the changes over time, 10 years ago, 5 years ago and now, it is possible to understand the trend of damage and make use of this information in the inspection. However, care should be taken to avoid focusing too much on old damage.
- In the case of inexperienced practitioners, the support is likely to be more effective, while in the case of experienced practitioners, quantitative evaluation is needed, not just finding support.
- Differences must also be able to be correctly evaluated for point cloud data generated by different la-ser scanners and cameras used.
- It is difficult to use this method in general because of the limitation that the results are different depending on the location of the machine and the weather conditions. However, it is thought that the restriction can be solved by organizing the method of measurement, the method of setting up the machine and the method of analysis and formulating the guideline.

For the heat map to be used as a "bridge inspection method" in periodic inspections, it is essential to increase the number of demonstration tests, improve the accuracy verification, and be able to quantitatively evaluate the size and depth of damage. However, it is suggested that the method can be used in some bridge conditions, such as where there is no third-party damage, or where there is little road traffic, or where the bridge is not on an important route.

6 Conclusion

In this study, to help infrastructure engineers carry out bridge inspection in the field more efficiently, we have proposed a method for detecting damage before the field survey by constructing a heat map based on 3D point cloud data measured by TLS and photography during a field survey before the regular inspection. In this study, we measured a bridge using TLS and a camera and constructed a heat map with 3D data. The method of using the results with the 3D data was evaluated by

inspection practitioners, and the issues and points to be noted were summarized. In the future, we will study how to use heat maps to visualize and detect damage with generally smooth features, such as narrow cracks, and how to evaluate damage quantitatively by adding location information to point cloud data. In addition, we plan to conduct more experiments to verify the accuracy of the method and clarify the range of application.

Abstract –

In construction cost estimation, building information modelling (BIM) has been commonly utilized to support automatic quantity take-off (QTO). However, conventional BIM models do not contain all the necessary information for QTO, and the calculation does not follow the descriptive rules in standard method of measurement (SMM), which impact the cost estimation accuracy. Therefore, this paper presents a new data model and knowledge-based system to incorporate the required SMM rules, which greatly facilitates BIM software in automatic and accurate QTO. The proposed new methods involve the development of a generic data model by identifying and incorporating the required information (e.g., geometry, semantics) in SMM. Following this, information checking algorithms are developed to check the information completeness and textural errors in QTO practices. Furthermore, the descriptive rules in SMM are defined to create a knowledge library that guides the BIM software in performing automatic QTO. Results of illustrative examples indicate that the proposed new methods can accurately compute the quantities of building components in compliant with SMM, regardless of different approaches for model creation. The proposed methods also linguistically identify the textural errors of parameters and check the compliance of descriptive rules for better QTO practices. Practitioners can automate the BIM-based QTO process to reduce the inaccuracies, time, and errors of cost estimation.

Keywords –

Building information modeling (BIM); Quantity take-off (QTO); Knowledge model; Model auditing; SMM-compliance

construction projects. The measured quantities are the prerequisites to many subsequent tasks such as cost estimation, material purchase and production planning [1]. The advent of Building Information Modelling (BIM) technology has brought revolutionary impacts on QTO as quantities are extracted directly from the 3D design models which contain geometry and semantic attributes of components. This makes the QTO process faster and more reliable than the conventional methods [2]. However, the automation and accuracy of QTO is still matter of concern as BIM models do not incorporate all the necessary information for conducting an accurate QTO [3], and the calculation of quantities does not follow the descriptive rules in the standard method of measurement (SMM), causing potential inaccuracies and errors.

Therefore, the objective of this paper is to develop a new knowledge-based system to incorporate all the necessary information and SMM descriptive rules for providing automatic and accurate QTO. Through the identification of information requirements and rules definitions from SMM, a generic data model is first developed to represent the 3D geometry and semantic attributes of buildings. Following this, information checking algorithms are developed to extract and linguistically check the completeness and correctness of required information to perform the QTO. Furthermore, the descriptive rules in SMM are mathematically formulated to create a knowledge library, which guides the BIM software in automatic QTO. The proposed methodology is validated through illustrative examples. This research contributes a new approach to check the required information and textural errors as well as to calculate accurate quantities in accordance with SMM for inaccurate BIM models. Another main contribution is the establishment of a generalized approach to enhance the automation, accuracy, and efficiency of QTO.

1 Introduction

Quantity take-off (QTO) is a critical process in

2 Literature Review

Early research on QTO attempted to link the 2D CAD drawings with the bill of quantities automatically to reduce human errors as far as possible [4]. BIM provides the ability to extract quantities from design 3D model directly and therefore is faster and more reliable than traditional methods that are based on 2D drawings. Through a case study comparing BIM-based QTO and traditional methods, Bečvarovská and Matějka [5] concluded that time is saved and errors are reduced after applying BIM. In addition to those extracting quantities from BIM models directly, research in recent years emphasized more on problems of inadequate information in BIM models and rule-compliance of the results. Choi et al. [6] proposed an open BIM-based approach to calculate quantities of structural framing, which would check whether the BIM model contains adequate information before performing QTO. Liu et al. [7] developed an ontology-based system to infer non-expressed information in BIM models to support QTO for wall framing. By studying the New Rules of Measurement (NRM), Abanda et al. [8] developed and used ontology to calculate quantities in accordance with the NRM from BIM models.

While the previous studies have explored BIM-based QTO and the corresponding information interoperability problem, there is still a lack of a generic data model to represent the essential 3D geometry and semantic attributes of buildings to perform automatic QTO. In addition, the inaccuracy of BIM-based QTO due to the lack of SMM descriptive rules is still a matter of concern. Besides, unintended errors in geometric and/or semantic information of design BIM models is another problem, which impacts the recognition of parameters in performing an accurate QTO. Therefore, it is of paramount importance to develop a new intelligent and automatic approach for BIM-based QTO.

3 Methodology

Figure 1 shows the methodology framework for the knowledge-based system. Since QTO is a knowledge-

intensive process [9], the first step is to leverage SMM and domain knowledge from quantity surveyors to build a generic data model which incorporates all the essential QTO-related information. To ensure that BIM models contain adequate and correct semantics to extract quantities, the information checking step is needed before the QTO step, where an information checking method is developed to linguistically check the BIM model information based on the data model. Once the QTO-related information is provided and the BIM models have been checked, the descriptive SMM rules are mathematically formulated in a knowledge library to support the computation of building quantities.

3.1 Development of the generic data model

In this step, the information requirements from the measurement standard for performing automatic QTO, including QTO-related entities, attributes, and the semantic relations among them, are defined. This study adopts the Hong Kong Standard Method of Measurement of Building Works – Fourth Edition [10] as the information source for the generic data model.

Unified Modelling Language (UML) diagrams are adopted as the tools for structuring the data model. Figure 2 shows a data model for taking off quantities of some typical in-situ concrete elements as an example, using UML class diagrams. Beam and suspended slab are two specific components, so here the *In-SituConcreteComponent* class has such two sub-classes, which inherit the attributes from it and have their own attributes to meet the information requirements of different components. Each component may have voids and have different shapes with different dimensions (e.g., rectangular, circle, polygon). The calculations of the beam and suspended slab involve the concrete grade information from each other, so they are associated. A typical beam-suspended slab joint is chosen as an example to further elaborate the measurement rules. As shown in Figure 3, the computation flow is structured in an UML activity diagram, showing the calculation priorities between beams and suspended slabs under different situations in terms of concrete grades.

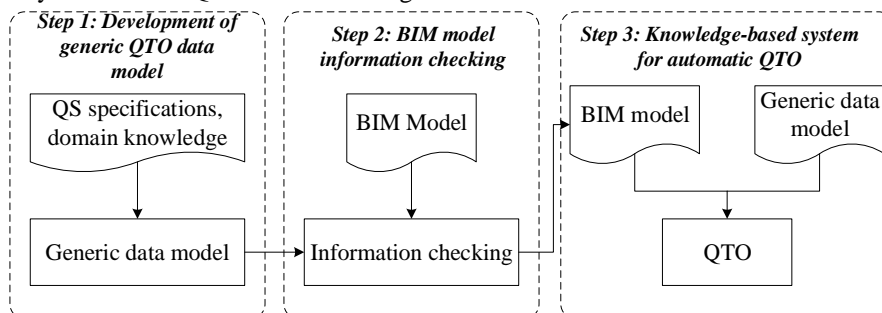

Figure 1. Proposed knowledge-based system

Figure 2. Data model for QTO in typical in-situ concrete beams and suspended slabs

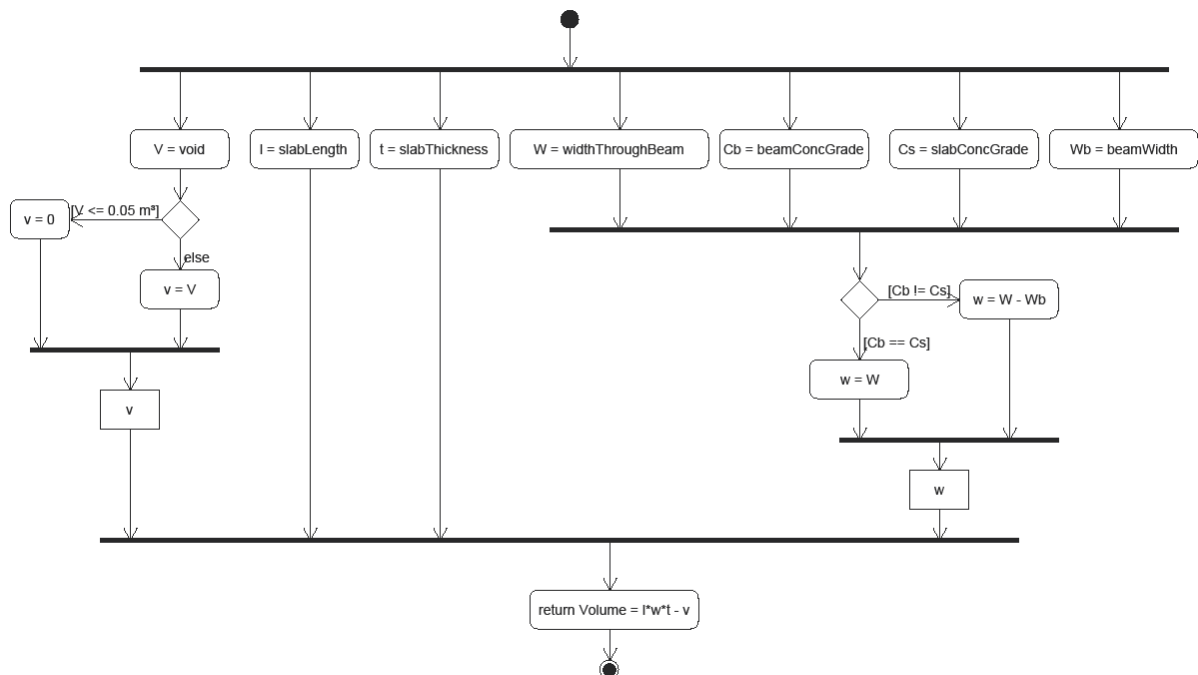

Figure 3. UML activity diagram for measurement of typical beam-suspended slab joint

3.2 BIM Model Information Checking

Then, algorithms are developed to perform the model information checking for QTO, as shown in Figure 4. The semantic attributes are extracted from

design BIM models. The computerized algorithm can automatically check and identify unintended textual errors, and informs users to input more data if the BIM model does not contain adequate information for QTO.

To check the information completeness, design BIM

model information is first extracted. Then, null values and the associated parameters are removed before matching parameter names with the required information derived from the generic data model to filter parameters with names existed but values missed. The required information is concluded as existed if it is matched with the parameter name in the extracted BIM model information or the Levenshtein distance between these two compared strings is less than or equal to 1. Levenshtein distance is a string metric measuring the similarity between two strings [11]. It indicates the minimum number of single-character edits (e.g., delete, insert, modify) when changing from one string to another. The smaller it is, the more similar the two compared strings are. This setting enables a fussy recognition so that the algorithm would not miss the model parameters that have slight differences with the defined required ones but express the same meanings. For example, the QTO process requires concrete grade information, while the “concrete grade” parameter may be misspelled as “concete grade”. In such case, the algorithm can still recognize the existence of this parameter and would not report that it is missed, which reflects the fact of the model.

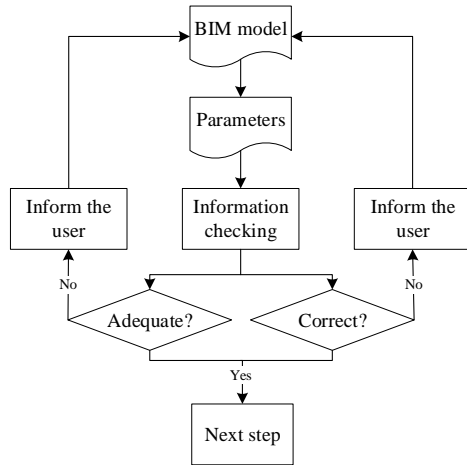

Figure 4. BIM Model Information Checking

Details of the information correctness checking and auto-correction of textural errors are shown in Figure 8. First, the textural parameters are separated into multiple words by a separator list that contains common punctuations such as underline, dash, and space. The separators from the input are kept in a separator container for re-joining the words later. Then, a natural language processing (NLP) checker equipped with different customized domain dictionaries are used to check the correctness of each word. If the result is false, the algorithm will correct the word if the Levenshtein distance between it and the most likely word in suggested candidates from the dictionaries is less than

or equal to 1. This setting is designed to filter numerical parts (e.g., 200mm) that are assumed to be correct since spelling errors of such parts are less likely to happen and checking this part may introduce unnecessary complexity. After that, the corrected forms are added to the word container together with the original forms in previous steps. Finally, the words kept in the word container are joined with the separators kept before to generate the corrected results. Note that single words and correct values also work in this algorithm.

3.3 Knowledge Library for Automatic QTO

This step uses the knowledge from the data model and the data from the BIM model to design QTO algorithms for calculating quantities of the targeted elements. As Figure 9 shows, design information (e.g., geometry, spatial relation, material and properties) is extracted from BIM models and applied with identified rule libraries from the standard and data model to determine required variables for the measurement of quantities, rather than taking the geometric data into the calculation directly.

For example, a rule library identified from the HKSM4 for taking off the quantity of a beam in an in-situ concrete beam-suspended slab joint is shown in equations (1) – (3), V_{beam} and V_{void} are the volumes of the beam and void, respectively, l_{beam} and w_{beam} are the length and width of the beam and slab, respectively, h_{beam} is the calculated height of the beam, H_{beam} is the height from the bottom of the beam to the top of the slab, t_{slab} is the thickness of the slab, C_{beam} and C_{slab} are concrete grades of the beam and slab, respectively. In other words, when the concrete grades of the beam and slab are the same, the slab has higher priority than the beam, and only voids with volumes larger than $0.05 m^3$ are considered in the calculation.

$$V_{beam} = l_{beam} \times w_{beam} \times h_{beam} - V_{void} \quad (1)$$

$$h_{beam} = \begin{cases} H_{beam} - t_{slab}, & C_{beam} = C_{slab} \\ H_{beam}, & C_{beam} \neq C_{slab} \end{cases} \quad (2)$$

$$V_{void} = \begin{cases} 0, & V_{void} \leq 0.05m^3 \\ V_{void}, & otherwise \end{cases} \quad (3)$$

4 Illustrative Examples

Six different models of the same in-situ concrete beam-suspended slab joint are used as the illustrative examples to validate the proposed method through Revit 2021 and Dynamo 2.10 [12]. As shown in Figure 7, they are the same joint created by different modelling approaches, which are not uncommon to see in practice. Besides, Figure 8 shows that the type name is misspelled, and the “concrete grade” parameter is typed as “concete grade”.

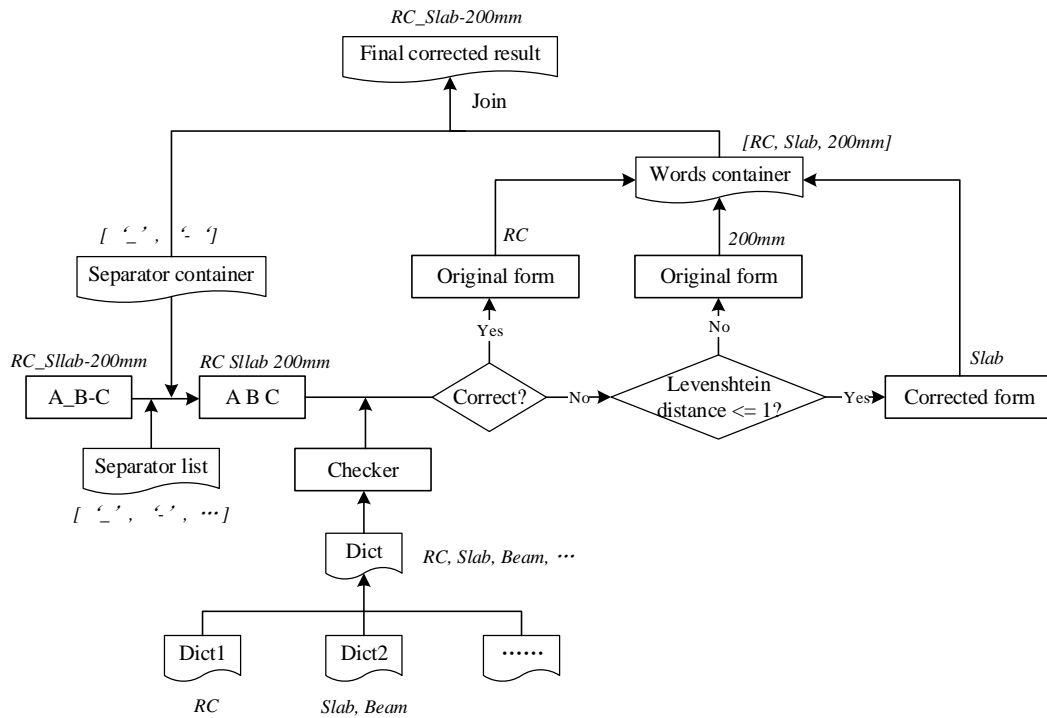

Figure 5. Correctness checking and auto-correction of textural errors

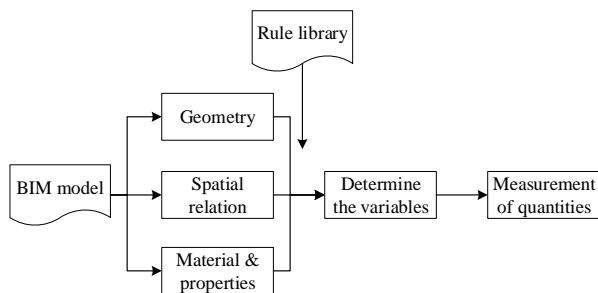

Figure 6. Knowledge-based automatic QTO

Figure 7. In-situ concrete beam-suspended slab joint models in Revit using different model creation approaches

(a). Misspelled type name (b). Misspelled parameter name

Figure 8. Textural errors of parameters

Based on the generic data model, the information requirements for QTO in this structure are summarized and mapped with the Revit parameters to generate a checklist, as shown in Table 1. Since unit is a project-level parameter and every Revit project has units, there is no need to check the existence of unit parameters for the elements. Of note is that in addition to build-in parameters, users can add project parameters or use customized families in Revit to express domain-specific information, and the naming of the same parameter varies among different modelers. For example, “b” is the beam width parameter for the system beam type, while customized beam families may use “width” to represent the beam width parameter. Similarly, “concrete grade” can be added as “conc grade” or “concrete grade”. So, it is important to know how the parameters are expressed and have various kinds of domain-specific expressions for the same required information in the checklist. For the illustrative examples, the beam uses the system beam type. The attributes in the right column will serve as the baseline to check whether the information from the model is adequate or not.

Table 1 Mapping required information with Revit attributes for the beam model

Required information	Revit attributes
Id	Type Id
Name	Type Name/Type
Unit	N.A.
Beam length	Length
Beam width	b
Beam height	h
Concrete grade of the beam	Concrete Grade/Conc. Grade (beam)
Concrete grade of the slab	Concrete Grade/Conc. Grade (slab)
Slab thickness	Thickness (slab)

The information checking algorithms are implemented in Python. PyEnchant is used as the NLP checker to perform the exact and fussy matchings. Results are exported to an Excel file for later uses such as confirmation of checking results and modification of the model. As Figure 9 shows, the beam model contains sufficient information for QTO but there are two textural errors (“bean” and “concete”) needed to be corrected. It indicates that the algorithms can still recognize the existence of the concrete grade parameter although it is spelled as “Concete Grade” that may be missed in the normal keyword checking method, and the algorithms can recognize and correct the misspelled type name “Bean-600×700mm” and attribute “Concete Grade”.

	A	B	C
1	ID	Adequate information?	Missed information
2	658757	Yes	NA

(a). Misspelled type name

	A	B	C
1	ID	Wrong	Correct
2	658757	bean-600×700mm	beam-600×700mm
3	658757	Concete Grade	Concrete Grade

(b). Misspelled parameter name

Figure 9. Information checking results of the beam

After the information checking step, the QTO system is developed using Dynamo. The Dynamo scripts extract the design information from the Revit model, including geometry and material properties, then unionize the geometries together as a whole. After that, the scripts introduce the concept of cutting plane as the rules. For example, if the concrete grades of the beam and slab are the same, the soffit plane of the slab will be used to cut the unionized solid, otherwise, the inner vertical side of the beam will be the cutting plane. Figure 10 shows how example 1 is cut when the concrete grades of the beam and slab are the same.

Figure 10. Solid being cut

Table 2 shows the comparison of the quantities of slab using Revit schedule function and the proposed method under the same and different concrete grades (similar comparison results for the beam). The correct quantities are calculated by the authors according to the Hong Kong Standard Method of Measurement of Building Works – Fourth Edition [10] and verified as specification-compliant by an experienced quantity surveyor. The results from the proposed method are exactly correct, while Revit schedule function gives different quantities in some cases. The reason is that the Revit function extracts quantities according to pure 3D geometries without the consideration of the approaches of model creation and semantic data carried by the model, while the proposed method follows the specifications and is able to validate the information and consider both geometrics and semantics.

Table 2. Results of slab's quantities using Revit schedule and the proposed method

Case	The same concrete grade (m^3)			Different concrete grades (m^3)		
	Revit schedule	Proposed method	Correct quantities	Revit schedule	Proposed method	Correct quantities
1	4.32	4.32	4.32	4.32	3.6	3.6
2	3.6	4.32	4.32	3.6	3.6	3.6
3	3.96	4.32	4.32	3.96	3.6	3.6
4	3.6	4.32	4.32	3.6	3.6	3.6
5	3.6	4.32	4.32	3.6	3.6	3.6
6	3.96	4.32	4.32	3.96	3.6	3.6

5 Conclusions

This paper represents a knowledge-based system for more automatic and accurate QTO. This includes the development of a genetic data model based on SMM and domain knowledge, and a textual mapping method for comprehensive BIM model information checking. The SMM descriptive rules are formulated in a knowledge library to support the computation of building quantities. While BIM models can be created by different methods which cause graphical and/or non-graphical errors and impact the calculation of quantities, the proposed knowledge-based system incorporating the SMM descriptive rules can provide more automatic and accurate results.

Six illustrative examples of the in-situ concrete beam-suspended slab joint shows that the proposed method can automate the QTO workflow with little adjustment of the inaccurate BIM models to get accurate quantities in different situations. However, this paper only covers the in-situ concrete for two basic building components. It has room for improvement in respect of the scalability. More comprehensive cases (e.g., a whole structure, unmodelled elements like formworks, scaffolding, and excavations) need to be tested to deal with the complexity of a construction project and large amount of complex rules in the future.

Abstract –

Identifying hazardous zones is one of the priorities and duties of construction safety monitoring. With the emergence of vision intelligence technology, hazardous zones detected by AI algorithms can support safety managers in predicting potential hazards as well as making decisions. However, the risky area in images/videos continues to suffer from numerous issues as undetected or low accuracy. Further, there are many kinds of hazardous zones that need to be trained for computer vision. This study aims to develop a BIM integrated application of hazardous zone registration for the construction stage, which is represented as construction objects using image stitching. The methodology consists of two stages: (1) during the pre-construction stage, BIM-based safety planning extracts the virtual image with the danger region; and (2) during the construction stage, the hazardous zone may be recorded in the site image using a stitching algorithm. A proposed method has been validated by visualizing hazardous zones from the actual images of the ringlock scaffold systems installed at the ConTIL laboratory. As a result, the BIM integrated application is anticipated to assist vision intelligent warning systems in proactively predefining hazardous zones, ultimately reducing repeated accidents associated with other entities entering dangerous areas.

Keywords –

Hazardous zone; BIM application; Image stitching

1 Introduction

The construction work environment is deemed hazardous, as evidenced by industry-wide workplace incidence statistics. According to the annual report of the Occupational Safety and Health Administration, a total of 1061 of the 5333 worker deaths in the United States in 2019 happened in the construction industry, equating to one fatality for every five construction

employees [1]. Additionally, 50% of all fatal incidents in Korea happened in the construction business [2]. In Europe, the construction industry ranks third in non-fatal injuries, and its total surpasses the average across all industries [3]. Specifically, over 90% of accidents are caused by reckless behavior and unsafe working situations [4]. Various research on construction safety stated that workplace safety might have helped reduce and avoid accidents. However, identifying and managing movement hazards and risks during the construction stage is a critical yet still challenging endeavor.

Technical advancements helped by computer vision have resulted in developing a very effective instrument for automatically detecting and predetermining dangerous circumstances in the construction workplace. It has been researched and may eventually replace existing manual observational techniques in building site OHS monitoring [5]. By analyzing the visual input data using an AI algorithm, it is possible to derive safety information. For instance, Kim [6] suggested a vision-based hazard avoidance system that alerts employees to potentially hazardous situations in real-time. Yan [7] addressed the monitoring of struck-by hazards in terms of the spatial relationship between a worker and a heavy vehicle by employing three-dimensional bounding (3D) box reconstruction and three-dimensional spatial relationship recognition techniques in conjunction with three-dimensional spatial relationship recognition. Additionally, other dangerous scenarios have been investigated continually, including failure to utilize personal protective equipment (PPE), failing to follow safety protocols. In particular, assessing a hazardous area is a priority for preventing a dangerous context.

By incorporating a building information modeling (BIM) methodology into construction planning, safety concerns may be addressed early in the process, such as and safety measures [8], visualizing current plans [9], camera position planning [10], and enabling safety communication. Additionally, workspace modeling has been investigated by adopting BIM. Therein, Getuli [11] defined terminologies of workspace's type (Worker's space, Hazard space, Equipment space, safety space) in

the BIM model. As a result, the hazardous area could be detected prior to construction.

In order to overcome the above limitations, this paper aims to propose a BIM integrated application for hazardous zone registration using image stitching. The proposed method consists of two stages with pre-construction and during construction. The remaining of this work includes the following. Section 2 reviews the related study; the methodology is explained in section 3. A case study is implemented for evaluation following section 4. Finally, the author summarizes the method and discussion.

2 Literature Review

2.1 The current state of construction safety monitoring

Safety monitoring is critical in construction because it identifies and promptly corrects, ensuring safety concerns by eradicating them throughout the causative process. Traditionally, site observations and inspections have been widely utilized to assess the risk associated with ongoing work and context in construction sites [12]. However, these approaches are costly and time-consuming since they need supervisors or safety experts to do manual observations and paperwork. Additionally, manual observation is limited by the inability to obtain complete and accurate information in a timely manner. Recently, implementations enhanced surveillance camera performance to give the best monitoring of people, resulting in labor and cost savings. Nonetheless, identifying dangers such as dangerous circumstances and behaviors requires observers to use their perceptual and cognitive abilities. For instance, observers must examine the monitor system in order to comprehend the dangerous context and then evaluate it by comparing it to rules, guidelines, or the observers' prior experiences to detect unsafe circumstances and actions. Additionally, watching many contemporaneous displays dilutes the safety manager's concentration.

2.2 Hazardous zone monitoring using computer vision

Numerous studies have been conducted on computer vision-based construction safety. For instance, Seo [12] derived a general framework for computer vision-based safety and health monitoring. Zhang [13] reviewed the vision-based occupational health and safety monitoring of construction site workers. Mneymneh [14] presented a unique motion detection algorithm and human classifier for automatically detecting persons who are not wearing hard hats and identifying non-compliance with safety rules. Fang [15] developed a method based

on deep learning for detecting non-hardhat users in far-field surveillance footage. Further, various studies focus on detecting unsafe behavior, unsafe contexts, such as the correlation between hazardous areas and workers [16]. However, there are many types of danger zone with different dimensions that are challenging in practically applying computer vision.

2.3 BIM-based safety planning

Construction safety planning is now being carried out using BIM-based approaches. Fall hazard identification techniques based on building information modeling were created by Zhang [17] to help workers become more aware of potential dangers by visualizing them. Tran [8] proposed a framework for hazard identification of spatial-temporal activities. Besides, BIM is integrated with other emergence technology to improve safety performance effectively. Deng proposed the idea for the assistance of indoor evacuation in fire scenarios, mainly including indoor positioning and rescue route planning by integrating BIM and computer vision. Further, BIM information can assist computer vision performance, such as automatic labeling construction site images [18].

3 Methodology

We proposed an approach for hazard zone registration using BIM, as illustrated in Figure 1. The BIM integrated application comprises two stages following the construction process. The input information is extracted from BIM-based safety planning. As a result, virtual images, including reference objects and hazardous areas, could be exported from the BIM model prior to the construction stage. After that, the virtual image will be matched with the site image. Through reference objects, the hazardous area from the BIM model would be registered in the actual image. The following sections would go into further detail on the structure and substance of the solutions given in this approach and the fundamental rationale for each of them.

3.1 Pre-construction stage

In this stage, existing construction safety-related information can be integrated into BIM to effectively develop safety planning. There are two types of information that are integrating into BIM, including geometry and non-geometry information. For instance, Table 1 shows an example OSHA regulation of an area around a scaffold. Rule 1926.451(h)(2)(i) required employees not to be permitted to enter the area under the scaffold to prevent falling items. Rule 1926.451(f)(6) asks for the clearance distance between scaffolds and

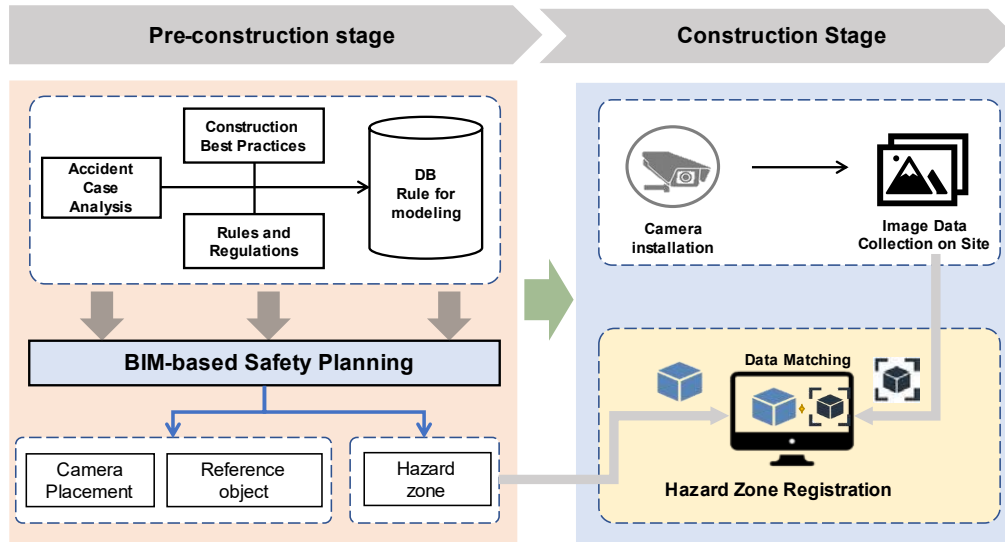

Figure 1. BIM-based Hazardous zone registration approach in construction site image

power lines. Through rule-based modeling, the hazardous zone can be simulated in a BIM environment. Continuously, the BIM model provides surveillance camera placements planning. The camera position, field of view (FoV) are visualized so that the hazardous area in the FoV can be extracted in the virtual image, as illustrated in Figure 2.

Table 1. Example of hazard area around scaffold following OSHA regulations

Regulation	Contents
1926.451(h)(2)(i)	The area beneath the scaffold where things might fall should be blocked, and no person shall be authorized to access the hazard area.
1926.451(f)(6)	The following distances should be maintained between scaffolds and electricity lines.

3.2 Construction stage

In order to realistically implement safety planning in the construction stage, there is a need for a robust monitoring system. Computer vision-based safety monitoring automatically supports safety managers to identify hazard conditions. Construction objects (worker, PPE, rail, opening, etc.) are detected using the CV algorithm. Besides, combining with BIM-based safety planning, the static hazardous areas can also be registered as objects that are used for CV. Hence, the hazard condition based on the correlation between hazard areas and other objects is identified.

Figure 2. Control points in the virtual image.

3.2.1 Image stitching process

Image stitching is a process of composing two or multiple images with the overlapping region to create a new image with useful information from both images. In this case, the hazard zone will be determined after stitching the virtual image and the actual image. The virtual image was extracted from the BIM model (in Figure 2), and the actual image is the image was captured at jobsite by the camera (in Figure 3). The reference objects from the BIM model are employed as control points to stitch with control points from the actual image. The corresponding control points need to be identified from two of these images. As illustrated in Figure 2 and Figure 3, seven control points were selected; these control points need to be evenly distributed in images to increase accuracy. Then, based on the control points, the transformation matrix is estimated to warp the virtual images into the actual image. After blending the warping image and actual image, the hazard zone will be shown on the actual image.

Figure 3. Control points in the actual image

4 Case study

4.1 Introducing case scenario

To validate the applicability of the proposed method, the authors performed a case study for registering hazardous areas around scaffolds installed at the ConTIL laboratory, as illustrated in Figure 4. In the case study, BIM-based workspace planning is developed (Figure 5), including scaffold location and hazardous area. The hazardous area has been highlighted following OSHA regulation by using a visual programming language (Dynamo), as depicted in Figure 6.

Figure 4. Scaffold installation at ConTIL Laboratory

Figure 5. Installation planning scenario

Furthermore, the camera position is shown in a green circle as well as the reference object, which is in

the yellow circle. After that, the camera and reference object are installed in the proper position on the actual site. Using a mapping algorithm in section 3.2.1, the hazardous area could be mapped to the actual image. It means the hazardous area is drawn as an object supporting computer vision.

Figure 6. Highlighting hazardous zone using Dynamo

4.2 Results

After setting up a camera on the construction site, the images have been captured. To identify hazardous zone, the image from BIM-based safety planning is stitching with the site images. Through this, the hazardous zone is mapped with a site image. Figure 7 illustrated the results of the registration process. The orange area is presented as the hazardous zone. Hence, other entities entering this zone could be warned as risk actions.

Figure 7. Hazardous zone registration in reality image

5 Discussion and conclusion

Identifying hazardous zone plays a vital key in achieving safety monitoring success. Current research meets a gap between transforming hazardous zone from planning to the monitoring process. This study proposed a BIM integrated application for registering hazardous zone into construction site images using image stitching. First, the information from BIM-based safety planning (such as monitoring area, reference objects, virtual

image exportation) is extracted. After that, the camera systems could be placed following the planning. Finally, the hazardous zone can be combined into the actual image.

The proposed method was tested in a lab environment. Test results illustrate the hazardous zone in the actual image. However, there are limitations yet to be addressed. First, the approach still has a manual effort that requires the employee to pick control points in the virtual and actual image. Second, the study has not investigated the number of control points need for image stitching and the registration accuracy. Third, the study assumes the camera placement base on the camera installation plans; however, the images captured by the camera may be partially occluded the control points by the dynamic obstructions.

For future studies, the authors would focus on the accuracy of stitching algorithms between virtual and actual images. Then, developing a correlation between hazardous zones and other objects (such as workers and mobile equipment). To reduce manual effort, automatic stitching between reference objects also needs to investigate. Control points from the BIM model would automatically stitch with control points from an actual image using pattern recognition..

Abstract -

IFC-based building energy performance and life cycle analysis require structured data about thermal, ecological, and financial building material properties (e.g., thermal conductivity, global warming potential, construction cost). Dedicated databases to these domains exist, but share no common property sets, making the mapping process of all required properties to the materials in the IFC (Industry Foundation Classes) model, and subsequently to input data of energy performance engines or LCA/LCC software, labor intensive and error-prone. This study introduces (i) IFC property sets (psets) designed to fulfill the material input data requirements for EnergyPlus and the BIMERR LCA/LCC analysis module, (ii) third-party sources for providing the necessary input data, (iii) a building material classification system and ontology to integrate the identified data sources, (iv) a building material mapping approach to map similar building materials across different data sources, and (v) our validation results with three different building material databases and one real-world building.

Keywords -

Building Energy Performance and Renovation; IFC; Property sets; Ontology; Building material databases

1 Introduction

Identifying, evaluating and selecting building renovation measures require a quantitative assessment of their impact in terms of cost, energy savings, comfort improvement, etc. Within the H2020 EU-funded project BIMERR¹, RenoDSS has been developed. RenoDSS is a decision support system which automatically generates potential renovation scenarios based on the as-is Building Information Model (BIM) in IFC4 format of an existing building and rule sets on how to combine the various renovation measures. For each renovation scenario, RenoDSS calculates economic, energy, sustainability, and comfort

Key Performance Indicators (KPIs) which are used to compare candidate renovation scenarios and enable the user to select the one that meets their preferences.

The KPI calculation relies on the availability of data for building materials which are used or replaced during the renovation. These data include among others thermal parameters (e.g., thermal conductivity and specific heat), cost parameters (e.g., purchase costs for the various materials, installation costs or depreciation), and LCA-related parameters (e.g., embodied energy, lifetime expectations or recyclability of the materials).

Although such data can be extracted from existing libraries and databases, often, the required information is not provided by a single source (e.g., the IFC file or a third-party material database). Hence, it is necessary to obtain it from distributed sources (building material databases, vendor information, IFC file, user information, etc.) and map it to the building materials within the BIM-model. The main challenge at integrating different data sources is to correctly map their property sets and to convert property units (e.g., from kg to m³) if necessary. To this direction, we rely on semantic technologies, more precisely ontologies, which are formal and explicit conceptualisations of shared knowledge [1] and allow for heterogeneous data integration providing explicit semantic information by means of well-known standard languages. In this work, we present our contributions to support this information gathering and mapping process:

- development of IFC property sets (Psets) which fulfill the material data requirements of EnergyPlus [2] and the BIMERR LCA/LCC module for calculating the building performance KPIs - see Appendix A,
- identification of third-party data sources which provide the input data required for economic, energy, sustainability, and comfort KPIs calculation - see Section 3,
- development of a building material classification system and ontology which integrate the identified data

¹<https://www.bimerr.eu>

sources (including harmonization of measurement units) - see Section 4,

- development of a building material mapping approach which can be used to collaboratively and semi-automatically map similar building materials across different data sources - see Section 5, and
- validation with three different building material databases (baubook, ökobaumat, ASHRAE) at one real-world building - see Section 6.

The developed approach enables the user to efficiently map building material data across various data sources, re-use mappings which have been created by other users, enrich the IFC-model with the selected building material data, and finally use it for automated performance analysis with EnergyPlus and the BIMERR LCA/LCC module.

2 Related work

This section reviews related work and existing models in the building material domain. In a recent study [3], a BIM-LCA framework that integrates LCA data from the ÖKOBAUDAT database using IFC has been proposed. The authors developed a Model View Definition (MVD), which defines the software subset of an IFC data model to meet the exchange requirements (ER) for a whole building LCA. The research results enable the identification of information exchange requirements to perform life cycle analysis within a BIM-based environment.

The Digital Construction Building Materials ontology [4] is a semantic building material model and aims at describing building elements, construction details, materials and their respective properties. The model follows the IFC material set definition pattern which states that a building element can be decomposed using three types of material definitions: a layer set, a constituent set, and a profile set. Each of these material definitions has one or many materials, each one linked with material properties that describe them. However, no classification of materials is provided.

Another example is the Green Building Material Type and Green Building Material Name ontologies [5]. The main purpose of these ontologies is to manage green building materials information. The Green Building Material Type Ontology (GBMTO) consists of elements that define the material properties, whereas the Green Building Material Name Ontology (GBMNO) describes the material classification system. Although the model allows the classification of materials and the description of some properties, it is not intended to represent building elements in detail.

The Materials Design Ontology [6] forms an effort to represent material science knowledge, mostly from the solid state physics domain.

Finally, the European Materials & Modelling Ontology (EMMO) [7] is a top level ontology which aims at the development of a standard representational ontology framework based on current materials modelling and characterization knowledge. It has been developed from the very bottom level, using the actual picture of the physical world coming from applied sciences, and in particular from physics and material sciences. Although, EMMO and its extensions cover several sub domains, none of them tackle the building materials, energy or LCC/LCA performance simulation domains.

3 Building material databases

In this section, databases that provide the required thermal, ecological, and financial building material data are introduced. The required data is defined by the input data requirements of the energy performance (EnergyPlus) and the BIMERR LCA/LCC calculation module which are used to calculate the economic, energy, sustainability, and comfort KPIs of each renovation scenario. Please see Appendix A for the Psets which are required for each building material.

3.1 Thermal data

In Baubook [8] the building materials are declared according to thermal and ecological parameters and other product group-dependent properties. The information is supplemented with a product description, pictures, safety data sheets and technical data sheets as well as manufacturer and, if applicable, dealer data. The data is entered by the manufacturer and quality-assured by Baubook. The Baubook XML file provides building physics and ecology reference values for (i) generic building materials, (ii) concrete products, and (iii) combined building structures (walls, roofs, etc.). Table 1 shows the data properties provided by Baubook for 1.198 building materials. We use Baubook data to initialize the developed Building Material & Component database with thermal and ecological building material data.

EnergyPlus requires the following entities and properties to simulate the materials' thermal behaviour: material (roughness, thickness, conductivity, density, specific heat), material no mass (roughness, thermal resistance), air gap (thermal resistance), and glazing (thickness, solar transmittance, front side solar reflectance, back side solar reflectance, visible transmittance, front side visible reflectance, back side visible reflectance, infrared transmittance, front side infrared hemispherical emissivity, back side infrared hemispherical emissivity, and conductivity).

AP Acidification potential of soil and water
ODP depletion potential of the stratospheric ozone layer
POCP Formation potential for tropospheric ozone
EP Eutrophication potential

Table 1. Baubook data properties

Such data can be extracted from the ASHRAE 2005 Handbook of Fundamentals; relevant materials and thermal properties data come with the installation of EnergyPlus. We enrich the Building Material & Component database with ASHRAE data to meet the EnergyPlus data input requirements.

3.2 Ecological data

The ÖKOBAUDAT [9] database provides life cycle assessment (LCA) data sets on building materials, construction, transport, energy and disposal processes. Currently more than 1.200 data sets are provided for the different building products - since 2013 conforming to DIN EN 15804, making ÖKOBAUDAT the first life cycle assessment database to completely follow this standard. The data of the ÖKOBAUDAT-database are based on the background databases 'GaBi' and 'ecoinvent'. Table 2 shows the data properties provided by ÖKOBAUDAT. All values are provided per life phase according to EN 15804 (e.g., A1-A3: production). We enrich the Building Material & Component database with ÖKOBAUDAT data to meet the LCA/LCC calculation data input requirements.

3.3 Financial data

The availability of open building material price databases is very limited. Those which are available provide price data only for a certain geographical region or a limited set of building materials. One example is the US National Residential Efficiency Measures Database [10] which provides data on residential building retrofit measures and associated costs. The database offers retrofit measures in the field of: (i) appliances, (ii) domestic hot

Exported thermal energy (EET)

Table 2. ÖKOBAUDAT data properties

water, (iii) enclosure, (iv) heating, ventilation, and air conditioning (HVAC), and (v) lighting. Each retrofit measure is described by properties such as lifetime, physical description, performance data, costs, etc. As costs vary across regions and building projects, a range of costs for the US market is provided. Cost data refers to the sole implementation of the retrofit measure.

As it was not possible to centrally obtain financial data required by the LCA/LCC module (material cost, installation cost, maintenance cost, disposal cost) for all possible renovation scenario configurations (location, project size, building type, etc.), we decided to let the user input project-specific cost for material and installation with regards to the used building materials and components. It is worth mentioning though that the LCA/LCC module provides default cost values based on cost data of similar projects which are stored in RenoDSS.

4 Building material classification and ontology

This section details the materials data model used to harmonize the different aforementioned data sources. The model is implemented as an ontology using the W3C OWL language [11] and has been developed following the LOT methodology [12]. The ontology is published according to the W3C best practices [13] un-

der the URI “<http://bimerr.iot.linkeddata.es/def/material-properties#>”, which will be compacted as “mat:” along this section. Figure 1 presents an overview of the classes (coloured boxes), relations (arrows) and attributes (dashed boxes) included in the materials ontology.

The main purpose of the materials data model is the description of building elements, their materials, and their corresponding properties. The ontology is focused on the building components that follow the material set definition stated in the IFC 4 standard. Examples of these elements include walls, slabs and roofs. The material set definition indicates that an element may have a construction of type `mat:MaterialLayerSet`, `mat:MaterialProfileSet`, or `mat:MaterialConstituentSet`. These construction types can be further decomposed into `mat:MaterialLayer`, `mat:MaterialProfile`, and `mat:MaterialConstituent` respectively, where each of these entities has a set of related materials (`mat:Material`).

The materials can be further described by a set of properties. For this purpose, the model reuses the artefacts provided by the SAREF ontology v3.1.1 [14]. As we can see in Figure 1, the `mat:Material` class is related to the concept `mat:PropertySet`, which group together similar properties or properties that have a common denominator such as “properties for a wall”. The properties are related to specific measurements (`mat:Measurement`), connected at the same time to different units of measure (`mat:UnitOfMeasure`).

Additionally, a classification schema is constructed under the `mat:Material` concept to enable the user to efficiently find a given material and map different building material data sources. Figure 2 illustrates the building material classification schema which was derived from the used data sources Baubook, ÖKBAUDAT, and ASHRAE. In its current version, materials of the third-party data sources Baubook, Ökobaudat and ASHRAE have been linked to the material categories. The developed mapping methodology is described within Section 5.

4.1 Data model instantiation example

Figure 3 showcases how we can use this ontology to describe the materials of a wall. The element described in this example is the wall `data:Wall01` with IFC identifier “WallIFCGuid” that has a construction represented by the concept `data:MaterialLayerSet01`. This wall is composed by several layers, one of them is the layer `data:MaterialLayer01` that has a thickness of 10 centimeters and is in the second position within the structure of the wall, where the ordering starts from the layer that interfaces with the internal spaces of the building.

This layer is made of brick masonry (`data:BrickMasonry01`) as the main material, which

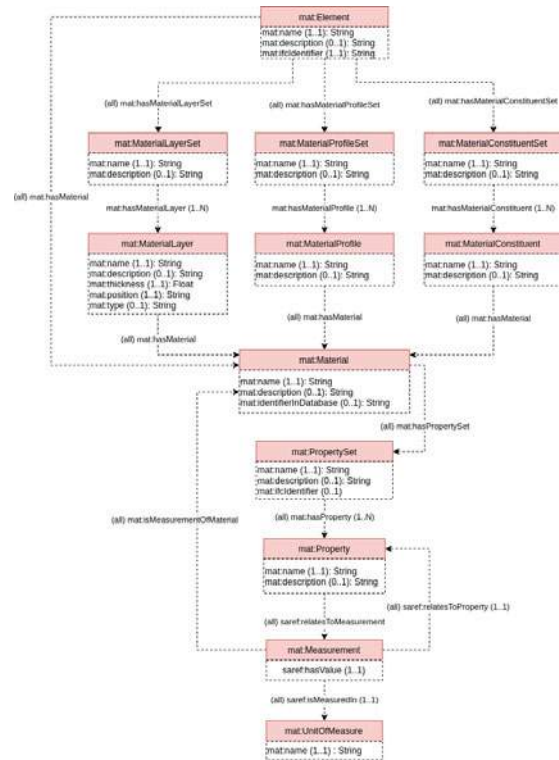

Figure 1. Building materials ontology

has a set of properties that are organized in property sets (`data:PropertySet01`). One of the properties considered in this set is the Density (`mat:Density`), which for this specific material has a value equal to 1922 Kg-per-m3.

5 Category/product matching

In a first step we manually mapped the categories of the building material databases Baubook, ÖKOBADAT, and ASHRAE. This enabled us to group all materials of these databases to a unified classification structure (see Figure 2). The materials properties information is structured according to the materials ontology presented in Section 4. The materials from each database are instances of the `mat:Material` class; the properties for these materials are instances of the `mat:Property` class which are grouped into property sets; and the values and units of measures for those properties are instances of the `mat:Measurement` and `mat:UnitOfMeasure` classes, respectively.

In a second step our goal was to identify similar or equivalent products stemming from different databases within each category. As outlined before, each database has a different focus (e.g., thermal or ecological data) and none of them provides the full thermal, ecological, and financial data set.

The developed building material mapping methodology

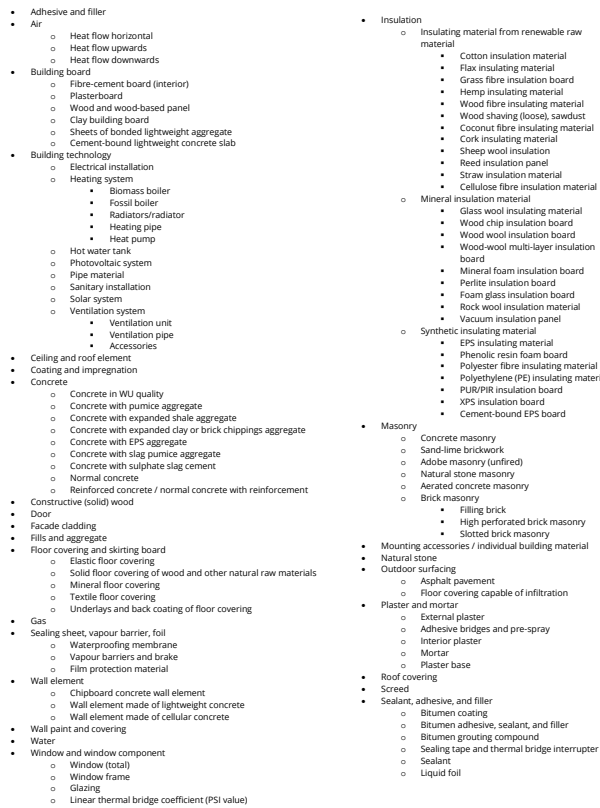

Figure 2. Building material classification system

enables users to efficiently plug-in additional building material data and map missing data points for the LCA/LCC and energy performance calculation. After loading the renovation project and the corresponding IFC file in RenoDSS, the completeness checking of the building material data (thermal properties, LCA/LCC properties, etc.) will be performed.

If building material data is missing from the loaded IFC file, RenoDSS supports the user at completing the data by the following building material mapping approach (initiated by clicking on the green button as shown in Figure 4 and 5):

- For each data point (MRU, GWP, AP, etc.) RenoDSS checks for existing mappings to similar building materials.
- For each data point without an existing mapping, RenoDSS provides the user a list of potential mapping candidates. Each building material which belongs to the same category and provides the missing data point will be shown as a potential mapping candidate. The candidates are sorted by the attribute (e.g., density in case of insulation materials) which has been defined in the admin view for the specific category. The sorting properties are used to order the list of similar

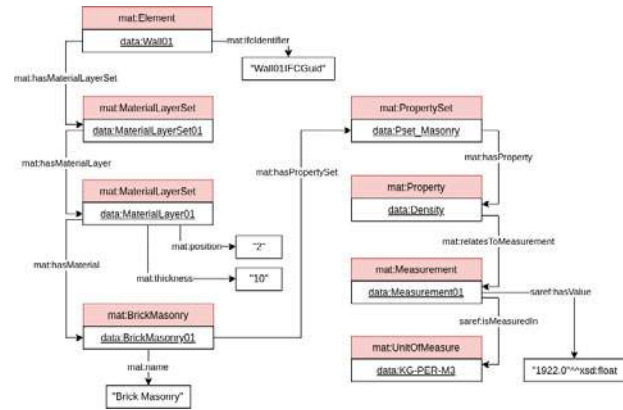

Figure 3. Example of use of the materials ontology

materials so that more similar materials are shown first to the user. This helps the user to find a matching material more easily. Each category/subcategory can have its own sorting property.

- When the user selects an alternative material, the value for which this material was selected is automatically updated with the value of the selected material. If the materials reference units do not match, a unit conversion is done to the selected unit of reference. It is also possible to overwrite existing values with values from other materials or by manually providing the data. A checkbox is provided so the user can decide if they want to keep the original value or replace it with the new one.

Once the mapping is done all mappings are globally stored and thereby accessible to other users to minimize future mapping efforts. Figure 6 shows the completed building material data after the mapping.

6 Validation

We validated our methodology using the IFC file of an existing two-storey residential building, located in Thessaloniki, Greece. The IFC file did not contain any building material properties which are required as input for the EnergyPlus and the BIMERR LCA/LCC module simulations. Listing 1 and 3 show instances of a wallboard and an outdoor air conditioning unit respectively, extracted from the input IFC file. Applying the developed approach, building material and components in the IFC file were enriched with links to the described psets, whereas the developed user interface was used to complete the property values. Listing 2 and 4 present the output of the developed approach applied on the exemplary wallboard and air conditioning unit of Listing 1 and Listing 3, respectively.

7 Conclusion

Within the validation we have shown how the research results can be used to enrich an existing IFC file with the property sets and input data required to run automated and IFC-based energy performance simulations with EnergyPlus and LCA/LCC analysis with the BIMERR LCA/LCC module. The research results enable the user to efficiently gather the required input data by using predefined building material mappings or define new ones based on the developed building material classification system and ontology. The following limitations exist and it is planned to address them in future research: project-specific costs for material and installation must be provided by the user, as it was not possible to centrally obtain this data for all possible project configurations (location, project size, building type, etc.). Currently, the BIMERR LCA/LCC module provides default cost values based on cost data of similar projects which are stored in RenoDSS.

Abstract –

In recent years, an increasing number of unprecedented rainfall events around the world brought about devastating floods that have been a challenge for urban planners and decision-makers. Numerous studies addressed these floods to climate change and investigated its trends at different time scales. In face of many uncertainties caused by environmental phenomena, considering the current magnitude of extreme events is a crucial step towards preventing disasters. In this study, the Dez dam, which is an arch dam on the Dez River in the southwestern province of Khuzestan, Iran, is selected to study if it could be operated more efficiently to store a larger fraction of the feeding river flow. Remote sensing provides means to monitor hydrological and environmental changes over large areas. In addition, it enables researchers to detect vulnerabilities in civil infrastructures. Satellite images are used to estimate the reservoir area of the dam and then to estimate the height and volume of the water behind the dam. The results show a spike in the height and volume of the water behind the dam to 94% of the dam's capacity, which can endanger the dam itself, and downstream urban infrastructure. Therefore, better flood management strategies are required to minimize the risk and destruction created by these flood events. An online Cyber-Physical System should be in place to monitor the dam condition and integrate the data to the runoff stormwater downstream to get a fully functional prediction and prevention framework for extreme floods.

Satellite images; Remote sensing; Flood; Dam sustainability; Volume estimation; Infrastructure monitoring;

1 Introduction

In recent decades, the increasing number of natural and manmade threats are endangering the civil infrastructures that are crucial to the functionality of societies. The vulnerability of critical infrastructures, which generally form 10-15% of the built environment, has been one of the main concerns for scientists and decision-makers. Thus, considering the aftermath of a disaster and its effect on the welfare of the public, overall safety, security, and impacts on economical markets are of great importance [1].

With the growing need for freshwater, constructing dams became a vital part of the survival of modern societies and a key contributor to the better management of water resources under climate change and water scarcity. However, critics of dams point out that benefits have been overvalued and socio-environmental aspects of them are getting neglected [2]. Secondly, the hydropower projects, which are clean and environmentally friendly sources of energy, may not have enough capacity to overcome the tensions caused by deterioration, population growth, climate change, and extreme events. Thus, accurate estimation of inflow to a dam reservoir has significant importance to the management and operation of reservoirs, hydroelectric energy generation, and control infrastructures [3].

New sensing and geospatial technologies such as the Internet of Things, Geographical Information System (GIS), and remote sensing proved to be great tools for smart infrastructure control and monitoring under severe loading conditions [1], [4], [5]. Remote sensing provides means for environmental monitoring over large areas. It is the process of inferring reflected or emitted electromagnetic radiation from the land surface [6]. The availability of high-resolution satellite images provides a new data source for capturing environmental and urban changes. For instance, GIS and image processing approaches, enable aerial and satellite images to be used for object detection, which has an important role for a

wide range of applications [7] such as vehicle detection, building extraction [8], air quality, and traffic monitoring.

Over the 2018-2020 period, Iran has fortunately experienced wet seasons after years of struggling with drought. However, this has brought about devastating consequences such as floods that took place across the northern and western regions. One particular region of significance was the Khuzestan Province, which is the home of some largest dams in the country such as Dez, Karkheh, and Karoon. During the first month of spring (referred to as the month of “Farvardin”, spanning from March 21st to April 20th), Iran was hit by devastating floods in 26 of its 31 provinces. These floods cost about \$3.5 billion U.S. dollars to the economy and caused 78 fatalities [9], [10].

With the recent challenges in water resources management of Khuzestan Province, Dez dam as one of the critical infrastructures located in the middle peaks of Zagros finds socio-environmental importance. The range of the Dez basin is 32°35′ to 34°07′ North latitude and 48°20′ to 50°20′ east longitude [3]. Since data collection is still a difficult task, using remote sensing for flood analysis is a common approach that can be helpful for hazard management [11].

Remotely-sensed data have provided information that can help us uncover many aspects of environmental challenges with an eagle eye. One of which is volume estimation of floods and consequently investigating dam sustainability based on several digital images that have been gathered in a certain period. This can help us plan for the next extreme events, monitor the current state of civil infrastructures based on the experienced load, and prevent possible disasters. However, the control actions (e.g. Dez dam height control) at a given site cannot necessarily guarantee the stability of a complex system [12]. This is why a GIS-based monitoring system coupled with remotely sensed data is necessary to control the flows across the scale of the entire stormwater system.

This study aims to estimate Farvardin’s flood inflow to the Dez dam using remote sensing and evaluate if the dam could be operated more efficiently to store a larger fraction of the feeding river flow. To this purpose, the authors used satellite imagery to estimate water volume stored in the Dez dam before and after Farvardin’s flood.

2 Background

Using remote sensing for predicting potential areas of flash flood hazards is one of the substantial topics that have an enormous impact on sustainability and future developments. Hussein et.al. (2019) used an active microwave and visible/Near-IR (VNIR) remote sensing coupled with land use data and showed that most of the southern Quseir city is in danger of flash floods. Also, several dams are required to minimize the predicted

hazards in that region [13]. Andre (2012) presents a preliminary analysis of the concept of sustainability assessment in the context of dam development [14]. Furthermore, Karami and Karami (2020) suggested that for investigating the sustainability of a dam there should be a framework consisting of social dimensions, environmental dimensions, and economic dimensions [2]. In addition, selecting a suitable site for a dam in the first place can prevent decades of mismanagement in the future. Current trends show a tendency to use new technologies for sustainability purposes. Figure 1 presents an overview of new technologies that are being used for smart flood monitoring systems.

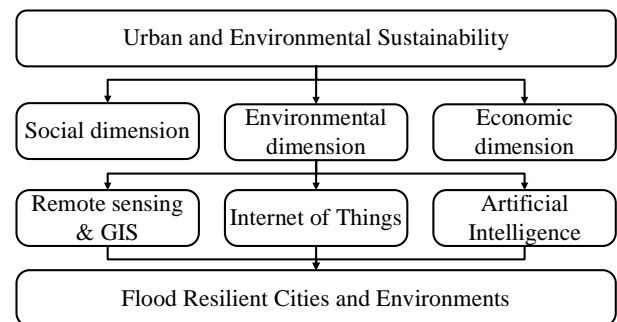

Figure 1. An overview of new technologies being used for smart flood monitoring systems

One of the primary focuses of remote sensing in hydrology is estimating hydrometeorological states and fluxes such as land surface temperature and evapotranspiration [6]. Noori et.al. (2019) used remote sensing, GIS, and multi-criteria decision-making techniques to show the suitable dam site between four potential locations [15]. Capolongo et.al. (2019) investigated the long-term monitoring of a flood event in the Strymonas dammed river basin, Bulgaria, based on a multi-temporal dataset of high-resolution X-band COSMOSkyMed, C-band Sentinel-1 SAR, and optical Landsat-8 images of the region [11]. Mixing Machine Learning techniques and GIS is one of the new approaches that Motta et.al. (2021) used to establish sensible factors and risk indices for urban floods. This new method can be outlined as a long-term flood management strategy for Smart Cities [16]. Also, Mourato et.al. (2021) developed an interactive Web-GIS fluvial flood forecast and alert system that integrates: i) a rainfall forecasting model (WRF), ii) a hydrological model (HEC-HMS), iii) a hydraulic model (HEC-RAS 2D), and iv) a Web-GIS platform to provide responsiveness to disasters and timely decision making [17]. By installing wireless sensor networks for rainfall monitoring, developing an alerts system that can predict flood events is a reachable goal. Ortega-Gonzalez et.al. (2021) evaluated the best options of wireless communication protocols that are suitable in a rainfall-

monitoring device [18]. Flood events are natural disasters that consist of natural risks and vulnerabilities. For preventing infrastructural damages, distresses, revenue losses, injuries, and fatalities, researchers are proposing new solutions based on the Internet of Things (IoT), Big Data (BD), and Neural Networks. Anbarasan et.al. (2020) presented a flood disaster detection system using IoT, BD, and Convolutional Neural Network that gives a very accurate result compared to other methods such as Artificial Neural Network (ANN) and Deep Learning Neural Network (DNN) [19]. Although having IoT devices gather data in larger areas can be challenging, lack of data is a bigger problem that can justify the large-scale installation of IoT. Using remote sensing can give a bigger picture in many cases of flood disasters. Figure 2 presents the architecture for an integrated flood monitoring system.

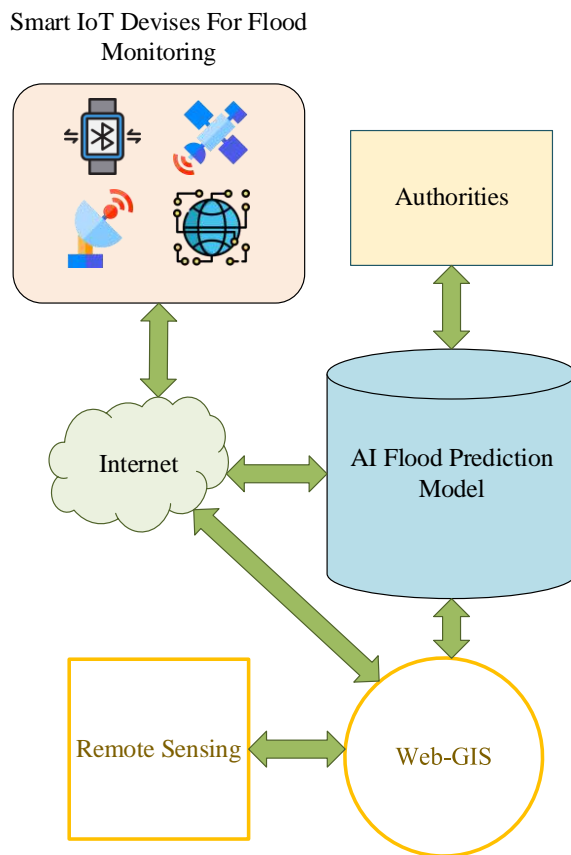

Figure 2. The architecture of Flood Monitoring Systems

Yuan et.al. (2021) used Sentinel-1 data to monitor flood disasters in China [20]. Research on flood disasters using remote sensing and GIS is trending because of its little cost and huge benefits. FloodStroem is a fast dynamic GIS-based urban flood and damage model that can generate a surface network of depressions and flow paths alongside flood depth maps and associated damage

costs [21]. As an application of GIS in determining dam storage volume, İRvem (2011) estimated the reservoir storage volume for the Buyuk Karacay Dam using the Ripple method [22].

Learning from previous studies and integrating them with the recent surveys of the Dez dam one can obtain suitable answers to the sustainability problem. The impacts of climate change in the Dez basin have been investigated by Norouzi (2020), which shows that this basin faces discharge reduction, and modified water management strategies are required to adapt to climate change in this area [23].

3 Research Framework

The Dez River Basin, as a third-order basin, is a subset of the Greater Karun Basin and is located in a larger subdivision of the Persian Gulf and the Sea of Oman. Dez dam is a concrete hydroelectric dam that was built on the Dez River (Figure 3).

The dam irrigates 125,000 hectares of downstream land and plays an important role in controlling upstream floods. The lake of this dam is 65 kilometers long and has an area of about 60 square kilometers and its final capacity is 3.3 billion cubic meters. This dam, with a height of 203 meters, at the time of its construction was known as one of the highest dams in the world.

This research aims to use satellite imagery to estimate the water volume stored in the Dez Dam before and after March's flood. First off, ArcMap was used to extract the underlying river network of the basin draining into the Dez dam. The location of the Dez dam was applied as the outlet of the delineating basin.

One of the principal inputs of the above process is defining the minimum area (A_{th}). A_{th} is applied to determine the initiation point of the first-order channels. The extracted river network from airborne imagery was applied to compare and validate the chosen A_{th} . For this task, Google Earth images were digitized and used. Also, drainage density was calculated to analyze the river networks.

In the next step, multiple river networks were extracted from different A_{th} 's to determine the best A_{th} resulting in the most realistic river network.

For satellite imagery analysis, the number of Sentinel satellites images were downloaded. Downloaded images were digitized for the aim of delineating the boundary of the water storage behind the dam. ArcMap tools were utilized for calculating the area of the polygons obtained in the previous step.

Figure 3. Dez dam study area

For calculating the water levels and volumes from the estimated water surface areas, we employed the data of the Iran Dam Organization, which includes water level and corresponding areas and volumes. In the final step, the changes in the time series of water level and water volume behind the dam were analyzed. Figure 4 shows the data provided by the Iran Dam Organization on the various conditions that the Dez dam has been, in terms of volume, area, and height.

Figure 4. Relationship between Volume-Area-Height of Dez dam

Based on the calculated area and matching it with the Iran Dam Organization Area-Volume-Height chart (Figure 4), the respective height and volume are estimated and presented in Table 1.

Table 1. Respective height and volume for the different areas calculated by the digitization of the Dez dam water reservoir

Date	Area (km ²)	Height (m)	Volume (MCM)
12/27/2018	51.1729	333.403	2301.047
1/11/2019	56.2901	341.049	2665.295
1/26/2019	57.2388	341.906	2710.071

3/22/2019	53.8482	338.846	2541.588
4/8/2019	62.5709	348.759	3140.691
4/21/2019	61.7841	347.718	3089.148

4 Real-case Application of Remote Sensing in Dez Dam

In this study, the Dez River network was evaluated using GIS and network samples were drawn for the study area with different minimum areas (A_{th}). To select the best A_{th} from satellite images, authors analyzed local rivers and selected those A_{th} that are most compatible with the existing rivers. In the second stage, images

related to the Dez dam were received from the Sentinel satellite with a cloud cover of less than 10% from 11 Jan 2019 to 21 Apr 2019. After performing radiometric and atmospheric corrections in ENVI software, the lake area was calculated in ArcMap software at different times. In the first part, the sub-basin of Dez dam lake was estimated through the 2nd-degree sub-basins of Iran, and the digital elevation model (DEM) of the sub-basin was downloaded from the NASA website.

In order to fill the gap points in the DEM and drawing the flow lines and flow accumulation, tools such as fill, flow direction, and flow accumulation have been used. The type of flow lines and flow accumulation in ArcMap was set to D8. To draw the flow lines, first, the coordinates of the outlet point of the Dez dam were found and applied to the flow accumulation. The point closest to the dam's outlet, which is located on the flow accumulation lines, was selected as the main outlet of the flow lines. Then, the raster calculator tool was used to apply the A_{th} in the ArcMap. In this study, the A_{th} is calculated from 500 to 4000 with intervals of 500.

Authors reached the best A_{th} by comparing several tributaries with satellite images. Finally, radiometric and atmospheric corrections were performed on the Sentinel images with less than 10% cloud cover.

5 Results

When it comes to the Farvardin's floods, one of the hurtful mismanagements in the Dez dam was not releasing water from the reservoir in a timely manner. As it is shown in Figure 5 the dam reservoir was not emptied in the last three months of the year and with the increase in rainfall, the volume of water in the reservoir has increased from 65% to 85% in just 38 days.

Figure 5. Dez dam water height in different times

In addition, the estimated water volume shown in

Figure 6 indicates that not emptying the water was a hard decision for the authorities. The danger threatening downstream cities is that they may face floods after releasing this volume of water in the river and eventually reaching cities such as Dezful. In this case, there should be sensor networks that can monitor the rainfall status, stormwater runoff, and capacity of the urban sewer systems to get a sense of the consequences of releasing the water behind the dam. Integrating IoT and remote sensing can provide a framework for these situations and minimize uncertainties of extreme flood events. Such devices are already developed and can be used on a large scale. For instance, Chaduvula et.al. (2021) developed an IoT device for flood alert monitoring systems using microcontroller 8051 [24].

Figure 6. Dez dam water volume in different times

As the country has faced a wet season at the end of 2018 and the beginning of 2019, the Dez dam has contained a number of floods in the last months of 2018. With the increase in rainfall in March and April 2018, a critical situation has been created for this dam and the volume of water in the reservoir in April 2018 reached its maximum capacity with 3.14 billion cubic meters, equivalent to 94% of the total capacity of the reservoir. Any action during a crisis must be planned in the pre-crisis time. The most important executive-managerial damage for controlling recent floods is the lack of a flood management program. Because of the high probability of flooding in March and early April, measures should be taken to reduce future risks and damages. The most important steps that could be taken in this regard are as follows:

1. Predicting the inflow to the dam and then planning on releasing it based on the input and downstream capacity
2. Keeping the volume of flood in control
3. Having a releasing framework and flood

- management program before and after the crisis
4. Establishment of flood warning system in reservoirs of dams and downstream rivers

The lack of images from satellites in some periods and cloudy days made some of the critical times to be considered as missed data. According to our analysis, the critical state happens on the 8th of April 2019. Therefore, the higher the number of photos, the more accurate the results will be. Also, Low resolution of the satellite images makes it very hard to digitize them manually, and this made errors in the final calculation of the area of the reservoir. Therefore, using machine learning techniques to automatically detect the water of the reservoir and calculated the area can be a very good step towards automating the digitization process.

6 Conclusions

Constructing dams is regarded as one of the major contributors to water resources management techniques across the world, especially in arid and semi-arid regions. Despite the significance, there is a lack of comprehensive investigations in regards to impacts of climate change and extreme events on critical infrastructures and appropriate approaches to automatically monitor and control them.

This research focused on estimating flood volume associated with Farvardin's floods in the Dez river basin and consequently obtaining a sensible result on the sustainability of the Dez dam. In addition, using satellite imagery, this study evaluated if the Dez dam could be operated more efficiently to store a larger fraction of the feeding river flow. Having a clear picture of the past and present of an environmental system helps us prepare for similar anomalies that will happen in the future. This is now possible with remote sensing and GIS. Having these technologies coupled with IoT sensors enables us to have an all-in-one monitoring platform at the system scale. This study showed such a system is necessary for controlling future flood events.

One of the many problems in environmental monitoring is accessing real-time data. Most of the time, because of security reasons, governments and institutions do not provide scientists with the data that is required to develop prediction models. Authors suggest that decision-makers install wireless sensor networks in areas with the highest potential flood events as a monitoring system. Next, integrating it with remote sensing and Web-GIS systems to get a synchronized and online platform. This way scientists and urban planners can access data and develop real-time prediction models based on this cyber-physical system. Extreme flood events over the past decade showed an urgent need for smart flood management systems based on IoT, BD, and remote sensing.

As a future study, this research aims to integrate meteorological data such as evapotranspiration, which needs various climatological and physical parameters, with sensors data, which are located in water systems of the urban regions. This can help to find new relationships and schemes of smart water management in the cities. In addition, the decision-makers can predict the consequences of heavy raining events and possible extreme floods and respond appropriately.

Abstract –

As a product of commercialization in prefabricated buildings, the information of the whole life cycle of Precast Concrete (PC) is an important basis for product quality traceability and progress control. During the stage of production, transportation, storage and installation, some quality problems inevitably appear on PC, and according to the degree of damage, there are different procedures to handle the PC. In case of a PC is slightly damaged, it can still be used in the subsequent installation and will not produce quality impact on the building structure; While if the damage is serious, then the PC is needed to be repaired before using in construction. Therefore, the tracking of status information of PC becomes particularly important.

This paper presents a status information management method for PC from production in the factory, loading and transportation to temporary storage and installation on the construction site. The system model of PC information management in the installation stage of the construction site is established by giving each component an identity and then using the image recognition based on Quick Response Code (QR code), so as to achieve the purpose of prior quality inspection and information traceability. In the future research, PC will have visible changes of stage and traceable historical information, just like commodities on the market.

Precast Concrete; Off-Site Construction; Status Information; Tracking Information Management

1 Introduction

1.1 Research Background and Purpose

Prefabricated building generally refers to the building where the components and units processed and manufactured in the factory, are transported to the

construction site and assembled on site through reliable connection. Due to the advantages of prefabricated building, such as short construction period, high production efficiency, high resource utilization rate, environmental protection, in line with the concept of sustainable development and so on, multiple countries have issued relevant regulations and policies to vigorously develop strategic emerging prefabricated buildings. For example, the China State Council proposed that by 2020, the proportion of prefabricated buildings in new buildings must reach more than 15%, and more than 500 prefabricated building demonstration projects should be cultivated[1]. This has greatly stimulated the development of construction industrialization, also gradually reduced the dependence on labor force.

However, some features which are difficult to manage also exist. For example, a large number of components and complex processes need to be systematically managed; as well as the information dynamic change, which means members may be damaged or have other quality problems at any stage of the project. Some of them can still be used after repair measures are proceeded, while some have to be discarded. In the process of prefabricated construction, due to the lack of effective means of communication and the low level of information sharing between on-site process and off-site management, an increase in unnecessary waste of resources and engineering costs can be expected.

Inevitably, in the actual construction process, it is complicated to transfer the status information of component and locate the component. Besides, it takes a long time to manually check one by one according to the drawings[2]. Thus, the real-time status and historical traceability information of each prefabricated component that can be shared with all required participants is very necessary for project planning and schedule.

In addition, Building Information Modeling (BIM) provides scientific and feasible technical support for prefabricated building construction with its dynamic

information, visualization, intercommunication, simulation, coordination, optimization and other characteristics.

The aim of this study mainly concentrates on the tracking of the status of prefabricated components, which are divided into different degree of damage and have corresponding on-site diversion processes in the construction site, and the visualization of project progress. Through the mobile intelligent device, the construction status of all components can be viewed, and the precautions can be confirmed on electronic equipment before installation, which help to get rid of the paper data filling. Finally, the information of each component is integrated and displayed in the model, and the project progress can be seen intuitively. The result should make the information exchange and transmission between on-site and off-site more immediate and effective.

1.2 The Scope and Methods of Research

Therefore, this paper proposes a framework of PC traceability management system. PC may be damaged, cracked and other quality problems during transportation and storage. Therefore, a platform was established to help on-site staff and off-site managers communicate effectively. QR code was used to identify each PC member and manage the information through mobile intelligent devices.

The method and process of this research is:

- (1) research trend
 - preceding research analysis
 - analysis of OSC workers' needs
- (2) a whole-process approach to traceability and information management of PCs
 - components identification
 - tracking management of production and delivery process
 - information management during the installation stage of PCs
- (3) combination of image recognition and PC information check
 - experimental hardware and software
 - build database for image target
 - build information management platform during the installation phase.

2 Research Trend

2.1 Literature Review

In order to eliminate the shortage of manual identification in positioning components, Ergen, E., Akinci, B., and Sacks, R.[3] proposed an automatic system which combines Radio Frequency Identification

(RFID) technology with Global Position System (GPS) technology, so that the system needs the least labor input.

The precast production management system which has been developed by Yin and Tserng[4], using Personal Digital Assistants (PDA) and the application of RFID for preform production management, including incoming material inspection, production process inspection, mold inspection, specimen strength feedback, logistics and receipt management.

Wang Z and Zhang Q[5] proposed a framework integrated with the computer vision methods to monitor the construction process of prefabricated walls automatically. The framework combines target detection, instance segmentation and multi-target tracking to obtain the location and time information of the prefabricated wall from surveillance video. The identified and collected state information is stored in JavaScript Object Representation (JSON) format and then sent to the appropriate BIM to add a timestamp to the wall component.

Li and Xue[6] designed an IoT platform, which used RFID technology to collect data for the on-site installation process of prefabricated components. The captured data is synchronously uploaded to the cloud to provide decision support for relevant site managers and staff. It also uses BIM and virtual reality (VR) technology to develop the functions of visualization for construction process and traceability for PC, which enable managers to monitor on site construction and approximate cost information faster and more accurate.

Li and Lu[7] designed the Proactive Construction Management System (PCMS). It uses real-time positioning technology based on Chirp-Spread-Spectrum (CSS) and data visualization technology based on Unity3D to track on-site construction matters, such as equipment and workers. Real-time feedback and postoperative visual analysis can be obtained.

Kiziltas and Akinci[8] believed that data capture technology, such as smart tags, laser scanners, and embedded sensors, can simplify related processes, and its performance is different from the manufacturer's specifications when used in the construction site due to interference, data reading range, data transmission and other problems such as accuracy, hardware and software interoperability, and memory limitations.

BIM is a very useful tool to help facilitate on-site assembly services (OAS) of prefabricated construction as it can effectively manage physical and model data. However, the advantages of using BIM in prefabricated construction OAS cannot be cultivated due to incomplete and untimely data exchange, as well as the lack of real-time visibility and traceability. To address these challenges, Lee and Xue[9] Designed the Internet of Things (IoT) platform and integrated BIM and IoT into prefabricated public housing projects in Hong Kong. The

data captured on site is transported to the cloud in real time for decision support of relevant site managers and workers. Visualization and traceability features using BIM and virtual reality technologies allow managers to monitor construction progress and approximate cost information in real time.

The table below shows some of the existing studies on PC information management.

Table 1. Research topics and existing methods

Research topics	Relevant Method
PC tracking	Optimization of supply chain; Locating components using Global Position System (GPS); radio frequency identification technology(RFID); global navigation satellite system (GNSS);
PC identity	Identity number; QR code; Barcode; RFID
PC information management	Formalization of the information flow; 4D building information model (BIM); Cyclic operation network (CYCLONE) simulation model

Because this study only needs to read the identity information of each PC, and no need to achieve the effect of data exchange, it is unnecessary to adopt RFID technology which is more expensive and complex to develop. And the development of QR code has been very mature. Furthermore, the data forms after reading QR could be various directly, not limited to data in the form of dozens of bytes. While RFID technology need a data processing system to transform the byte data into a visualized form. So by comparing the general methods, the most feasible QR code representing component identity is selected.

2.2 Analysis of OSC workers' needs

Based on the discovery and observation of the on-site assembly process, Lee and Xue lists the requirements analysis in the installation stage as shown in table 2[9]. Discover that the managers need real-time assembly management services, like the project process, 3D BIM models and components tracing service; and on-site workers need handling service to record emergent condition of on-site PCs.

Table 2. Requirement analysis of on-site assembly by Lee et. al

Requirement	Priority
System needs to keep a record of pending prefabricated elements (with or without ID) for current working day	Preferred
Be aware of prefabrication are safely	Must have
Be aware of prefabrication are erected	Must have
Be aware of place where prefabricated components are held	Optional
Batch upload of photos synchronized or synchronized with hand-held scan data upload	Optional

Also, an interview with a company's employees was done by Moon[10]. The result shows that workers need intelligent applications to help construction, data validation, inspection and guidance, especially in communication support and schedule management. Moreover, it is necessary for on-site workers to have an intelligent system on mobile devices to share information in the process of implementation. Among these, "data confirmation and check" was identified as the most important requirement as shown in Figure 1.

Figure 1. Result of interview by Moon et. al

Therefore, it is very necessary to update the status information of PCs at the construction site for the control and management of installation progress. Meanwhile, in the installation process, it is also important to confirm the quality of each component and check the safety of the installation environment, which can be displayed on the smart mobile device.

3 A whole-process approach to traceability and information management of PCs

Information expression of PCs is expressed through BIM 3D model. As the information carrier in the project, BIM model tracks the model components and manages the whole process of PC from production, transportation, lifting and installation, and records the operator, time, specific location and on-site working pictures in detail. And through the platform to reflect information in the BIM model, so as to achieve information management.

The information traceability of PCs requires the

cooperation of multiple parties. The specific process allocation is shown in Figure 2.

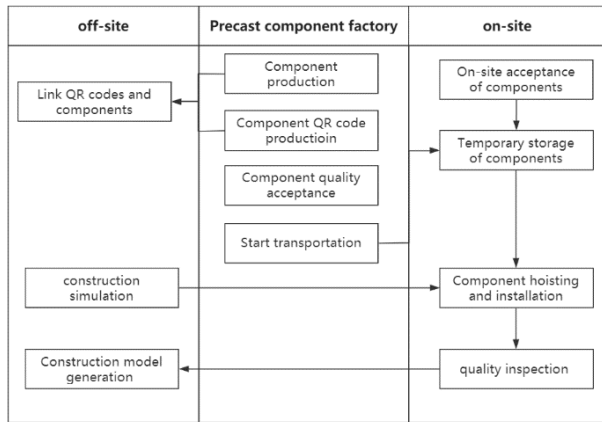

Figure 2. Multi-party collaborative processes for the track of PCs

3.1 Component identify

Current research extensively uses barcode, Quick Response Code (QR code) or Radio Frequency Identification (RFID) technology to give every component identities. Compared with RFID, barcode and QR code are widely used in many industries all over the world because of their low cost and perfect standard system. Since the QR code still could be identified after partial damage, it has a certain bearing capacity for the harsh environment; while, when scanning the code, mobile devices can not only read-only information, but also write information to other layers through the Internet. It can also quickly locate BIM components, query component attributes and related information, which can be updated on PC, and mobile devices can scan QR code to obtain the latest information.

Since this study focuses on the management of PCs after they are manufactured in the factory and transported to the construction site, the simulation method is used to obtain the QR code. Suppose that the manufacturer has already pasted the identification label for each prefabricated component, and has input the basic information, such as name, size, number, location, quality inspection and so on, as available for viewing at any time. The process of QR code application and corresponding responsible parties are shown in Figure 3.

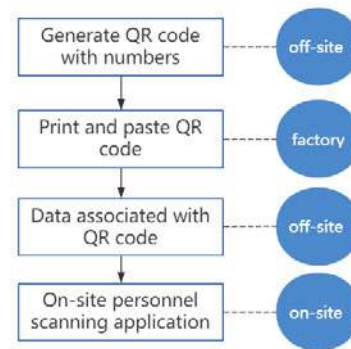

Figure 3. QR code application process and the corresponding responsible party in the whole process

3.2 Tracking management of production and delivery process

Efficient production and transportation scheduling are the key factors to ensure PC to be delivered on time. In practice, however, production and transportation planning are mainly based on experience. In addition, production plants are often reluctant to pursue timely delivery at the expense of costs[11]. Therefore, the implementation of information tracking for PCs to master the progress of engineering materials, in order to adjust the gap between the actual progress and the plan is very important and practical, so it is worth paying attention.

The phased tracking management of PCs during production and delivery is shown in the table 3.

Table 3. The work items of PC tracking management in different stages during production and delivery

process	Work items
Production and quality control	<ul style="list-style-type: none"> • Print the QR code and paste • Scan the QR code and input the information of each prefabricated component
	<ul style="list-style-type: none"> • Quality check and input quality inspection information to upload platform
Leave the production plant	<ul style="list-style-type: none"> • Scan the QR code and input the relevant information of the transport vehicle, as well as the type and quantity of the components loaded
	<ul style="list-style-type: none"> • When the vehicle leaves the factory, the vehicle number is scanned and submitted
	<ul style="list-style-type: none"> • Scan again and confirm the component information and total number to complete the

	registration
Location tracking	<ul style="list-style-type: none"> The location information of the vehicle with components being transported can be obtained through the driver's mobile phone positioning
Enter on-site management	<ul style="list-style-type: none"> Scan the vehicle's QR code and enter the site to register Scan the QR code of components to confirm the quality file and quantity Check the quality of components again, and input the results according to the extent of damage on the QR code pasted by each component Stack PCs reasonably in order of installation

3.3 Information management during the installation stage of PCs

Jeong[12] had constructed an automated concrete crack detection system implementing object detection method using deep learning. Quality of each PC component is being checked and analyzed after reaching the construction site. Rather than filling up the quality inspection checklists annually, an auto-checking and reporting system was proposed to reduce the manpower and time taken for quality inspection works of PC components at construction site. In their study, the main criteria for inspection and analysis is the present of crack on PC component, then each component is divided into three risk levels according to width and length of crack detected on the PC component. Based on the study, level 1 refers to PC component that need to be returned to the manufacture for dismantle or repairment purpose; level 2 refers to PC component that can be repaired on-site or returned to the manufacture for further repairment purpose; level 3 indicates the PC component that is safe to be used regardless of the existence of crack on the PC component.

In this study, a further procedure was proposed to help on-site workers to trace the PC components and manage the relevant information via a smart mobile device after each component is being inspected. All PC components are attached by different QR code respectively. All information can be read or updated by just scanning the QR code with minimum manual input. The installation schedule management in the construction stage of prefabricated buildings mainly relates the BIM model to the schedule plan, compares and analyzes the deviation between the two in real time, and then uses the BIM model to intuitively reflect the construction

schedule. The changes in the state of the PCs on site are closely related to the progress of the project and also related to the information traceability during inspection.

The components on-site process and corresponding state changes of key nodes displayed on the system are shown in Figure 4.

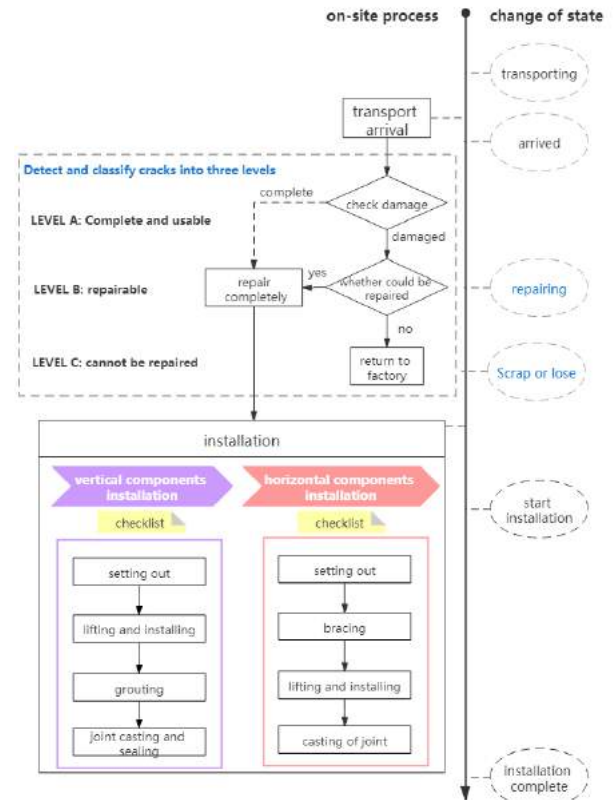

Figure 4. PCs on-site installation process and system display status changes of key nodes

As shown in the figure above, when PC enter a stage, their state changes accordingly. It is worth mentioning that according to the degree of damage, the components are divided into "complete and usable" "repairable" and "cannot be repaired". PCs that need to be repaired would be in the state of "Scrap or Lose"; PCs that are not repairable or lost will be in the state of "Scrap or Lose", and no further state changes.

4 Combination of image recognition and PC information check

4.1 Experimental hardware and software

In recent years, there has been a lot of software about making the management system. Unity was chosen as the development tool in this study, not only because of the need for visualization on the construction site and subsequent research, but also because its powerful user

interface (UI) design can meet almost all the needs. What's more, Unity is a universal, real-time 3D platform for creating visual products and building interactive and virtual experiences, real-time rendering with VR, AR and MR devices[13].

Meanwhile, Vuforia SDK for Unity is also used in this research as a Unity's package. Vuforia's AR Camera can well recognize any static image by extracting image features. Because at present, compared with image recognition, it is still difficult to automatically recognize PC objects[14], so the image with more feature points is selected to represent each PC. Two-dimensional image - QR code is well adopted in this paper.

Unity supports a variety of non-desktop and Web platforms, such as universal windows platform, tvOS, PS4, iOS, Android, WebGL, etc. Since the construction site needs a relatively convenient way to communicate and convey information, the hardware device selected in this research is the mobile device of iOS system.

4.2 Build database for image target

Image target, in this article, refers to the images captured with a mobile device to generate the corresponding checklist that contains PC status and surrounding environment for pre-installation checking. Because PC physical features are difficult to extract, and the difference is not obvious enough. Therefore, the QR image with obvious features is selected as the representative of each component. The comparison of feature point extraction is shown as follow.

Figure 5. Comparison of QR code and PC image effects (yellow points mean feature points extracted by Vuforia)

As shown above, it turns out that the feature points of QR code image could be extracted easily; as for the PC image, due to the lack of distinct feature, only two feature points were extracted. Therefore, if the PC image is directly used, the camera will not recognize accurately, and QR image is a better substitute.

Besides, Vuforia engine developer portal is utilized to build a database for QR code images as shown in Figure 6. In the target manager, target name, type, status and date modified, etc. were shown for further checking.

Target Name	Type	Rating	Status	Date Modified
QR_HORIZONTAL	Single Image	★★★★★	Active	May 28, 2021 14:42
QR_VERTICAL	Single Image	★★★★★	Active	May 28, 2021 14:42
QR_WALL	Single Image	★★★★★	Active	May 24, 2021 11:57
QR_BEAM	Single Image	★★★★★	Active	May 24, 2021 11:57
QR_PANEL	Single Image	★★★★★	Active	May 24, 2021 11:54
QR_COLUMN	Single Image	★★★★★	Active	May 18, 2021 14:12
columns	Single Image	★★★★★	Active	May 18, 2021 11:57
Arduinotek_started	Single Image	★★★★★	Active	May 13, 2021 22:10

Figure 6. Screenshot of the image database

4.3 Build information management platform during the installation phase

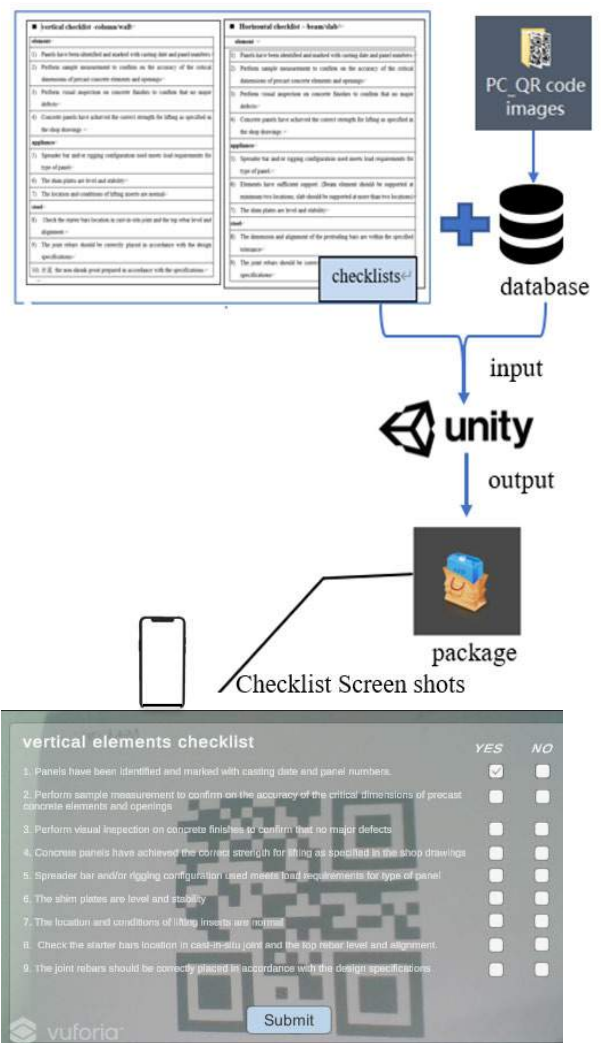

Figure 7. The flow of PC's checklists shown in mobile devices

In accordance with the general order of assembly, there are two pre-installation checklists about PCs, respectively vertical PC checklist and horizontal PC checklist. There are three aspects: component, appliance

and steel, to confirm whether the component can start to be installed. Then import them into the corresponding QR code image in Unity as shown in Figure 7. The finished system is then generated as an installation package and sent to the mobile device.

As shown in the above interface, if all the items are checked "YES", then the checklist of the component can be submitted and the status of the component changes from "Start Installation" to "Installation completed". If any item is selected as "NO", then the "Submit" button will not run and the state of the component will remain "arrived".

5 Conclusion

In this paper, an algorithm was proposed in order to trace and manage the information of PC components which are being transported to construction site. Procedure to handle the PC components of different risk levels was summarized and checklist of information required for PC installation is constructed as well.

In addition, this study only preliminarily establishes the UI of PC information management in the installation stage of the construction site. The summary of the information after the installation of each PC and reflected in the BIM model for visualization is the direction of future research. There are two forms that can be adopted to achieve the purpose of visualization of installation progress: one is through statistical graphics that can reflect the progress, and the other is to establish a connection between each PC and BIM model.

Abstract -

Energy retrofitting is paramount to reduce the use of energy in existing buildings, with benefits to the environment and people's economy. The increasing use of novel technologies and innovative methodologies, such as Terrestrial Laser Scanning (TLS) and Building Information Modelling (BIM), is contributing to optimise retrofit processes. In the context of energy efficiency retrofitting, complex semantic 3D BIM models are required that include specific information, such as second level space boundaries (2LSBs), material energy performance properties, and information of the Heating Ventilation and Air Conditioning (HVAC) system and their layout. All this information is necessary for energy analysis of the existing building and planning of effective retrofitting strategies. In this paper, we present an integrated (semi-)automated Scan-to-BIM approach to produce BIM models from point clouds and photographs of buildings by means of computer-vision and artificial intelligence techniques, as well as a Graphical User Interface (GUI) that enables the user to complete the models with information that cannot be retrieved by means of visual features. Information about the materials and their performance properties as well as the specification of the HVAC component is obtained from a database that integrates information from BAUBOOK, OKOBAUDAT and ASHRAE. The Scan-to-BIM tool introduced in this paper is evaluated with data from an inhabited two-storey building, delivering promising results in energy simulations.

1 Introduction

Following the recast of the Energy Performance of Buildings Directive, the retrofitting of the building stock paves the way to energy savings and reduction in green-

house gas emissions. To accurately predict the actual energy performance of existing buildings and evaluate the impact of potential energy retrofitting scenarios, Building Energy Performance (BEP) simulations are increasingly used. However, the preparation of the input data for simulation suffers from two major drawbacks: (1) it is a very time-consuming process, often requiring more time than is available within project deadlines, and (2) it is a non-standardised process that produces BEP simulation models whose results can significantly vary from one modeller to another.

Over the last decades, Building Information Modelling (BIM) has played a pivotal role on digitalising the Architecture, Engineering and Construction (AEC) industry. Considering the tangible benefits of BIM tools to facilitate communication, collaboration and information exchange between stakeholders, a number of national governments have actively promoted BIM and in some cases established BIM regulatory requirements [1]. As a consequence, the adoption and availability of Building Information Models have significantly increased. The extensive information compiled in BIM models has promoted this methodology as a key enabler to automate the generation of BEP models [2, 3, 4], contributing to the resolution of the aforementioned issues.

The generation of BIM models of existing buildings is challenging due to the complexity and diversity of building geometry. New technologies, such as Terrestrial Laser Scanners (TLS) or photogrammetry (PG), now enable the acquisition of dense and accurate 3D geometric data, in the form of point clouds. This data can be used as guidelines to define the geometry of the building components in the process called Scan-to-BIM [5, 6]. Although Scan-to-BIM is generally a manual process in current industrial practice, there is extensive research to develop algorithms to automatically extract geometric features from point clouds and define the geometry delimiting spaces in buildings [7] [8]. Other authors [6] have gone a step further, pro-

ducing structural BIM entities (e.g. walls) from semantic information extracted from point clouds.

However, for robust modelling and simulation of the energy performance of existing buildings and designing of any retrofitting solution, more information is required than just geometry of the structural (i.e. 'primary') components of buildings (e.g. floors, ceilings, walls, openings). First, Second Level Space Boundary (2SLB) [9] geometry must also be inferred from this. Besides, material types (and energy performance properties), as well as the location of Heating Ventilation and Air Conditioning (HVAC) components and organisation of HVAC systems also need to be captured and modelled. These aspects have received comparatively less interest from the research community. Some works have been published on the detection of 'secondary' components, such as Mechanical (or HVAC), Electrical, and Plumbing (MEP) equipment [10, 11]. But, an important aspect is the integration and codification of structural and MEP information in unified models, ideally in the open IFC format [12], to provide interoperability (which is important as such information may then be employed by various software packages to conduct energy simulation and retrofitting design).

In this paper, we present a Scan-to-BIM approach that is able to: (1) automatically model structural and MEP components, by processing point clouds and photographs of buildings, (2) enables the manual editing of materials and MEP properties using a large online repository of actual components and materials, and (3) outputs the semantically-rich model in standard-compliance IFC format with all the required information for robust energy analysis and design of the retrofitting strategy.

2 Methodology

The approach presented in this paper, illustrated in Figure 1, can be divided into three sub-components:

1. Structural Scan-to-BIM (Subsection 2.1), where structural elements are extracted from a point cloud and an initial BIM model is produced in IFC format;
2. Mechanical, Plumbing and Electrical (MEP) Scan-to-BIM (Subsection 2.2), in which MEP components are detected in pictures and added to the BIM model; and
3. Scan-to-BIM Editor (Subsection 2.3), which is used for manually populating the BIM model with information that cannot be extracted from visual features (e.g. material layers and properties, as well as MEP component properties).

2.1 Structural Scan-to-BIM

The objective of the Structural Scan-to-BIM sub-component (delimited in green in 1) is: the detection in the input point cloud of the main structural components of buildings, their parameterisation, and the codification of the delivered information into an IFC-SPF file. This tool is divided into a number of tasks (or algorithms), which analyse the building from general to specific and are summarised in the following.

- **Storey identification:** The first stage of the Scan-to-BIM process consists in the segmentation (i.e. labelling) of the point cloud (Figure 2a) into storeys. The proposed approach for this operation is based on the analysis of point density along the vertical axis. Similarly to the strategy followed in previous works (e.g. [13], [14]), a histogram is generated and ceilings and floors are extracted. Then, these are used for defining the storeys, and points with a z-value between z_{floor_i} and $z_{ceiling_i}$ are labelled as being part of storey i , as illustrated in Figure 2b.
- **Structural component detection:** Each segmented point cloud representing a storey of the building is processed to model the slabs (Figure 2c) and to extract the wall boundaries.

The points corresponding to the ceiling of each storey are first extracted and subsequently voxelised and segmented into clusters using the Euclidean Cluster Extraction algorithm [15], since no ceiling points are found inside walls. Each of the resulting clusters delimits a space (i.e. room) (Figure 2d).

The boundary of the ceiling of each space is modelled as a boundary representation (B-Rep) and, assuming that walls are vertical, the points defining the visible surface of each wall are searched and labelled accordingly (their projections onto the plane defined by the ceiling lie on the vicinity of the segments).

As a result, the point cloud corresponding to each storey is segmented into polygons that define the Boundary Representation (i.e. 1LSB) for each space.

Finally, these polygons are analysed to define the geometry of walls. This is carried out by matching sets of parallel vertical polygons with opposite normal vectors. If a wall surface remains without any matching plane, then, an artificial surface is created to fully define the wall. The outcome of this process is the set of 3D walls for the given storey (see Figure 2e).

- **Opening detection:** Opening elements (e.g. doors and windows) are then detected in walls by processing point clouds representing both sides of each wall.

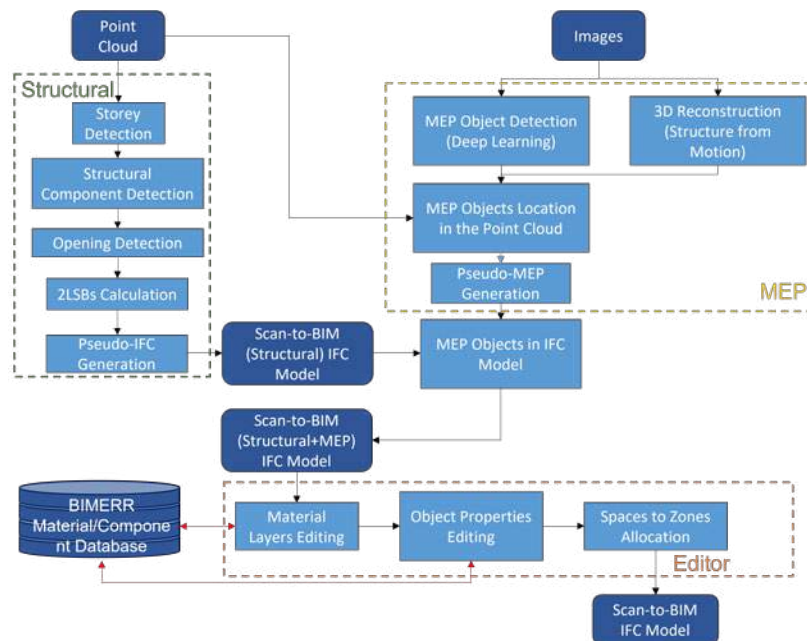

Figure 1. Pipeline of the proposed strategy for the (semi-)automatic generation of BIM models.

Bounding boxes are calculated for all empty areas within the wall surfaces, applying a hole detection strategy similar to that proposed in [16]. Openings are then detected based on the size of the bounding box and the overlap between pairs of bounding boxes on both sides of the walls. The result of this process is illustrated in Figure 2e).

- **Calculate 2nd Level Space Boundaries (2LSBs):** Once structural entities, including openings, are parameterised, the relationships between spaces and surfaces, and subsequently the 2LSBs, are automatically determined (Figure 2f). As discussed earlier, 2LSBs are important for energy simulation and analysis (more specifically to calculate heat transfers). In contrast to the approach of Lilis et al. [9], our process is able to exploit the geometric information and the semantics extracted from the point cloud instead of extracting that information from an existing IFC file.
- **IFC generation:** Geometric and semantic information extracted for the structural entities using the above-described method are codified into a BIM model, following the IFC standard [12].

2.2 MEP Scan-to-BIM

The objective of the MEP Scan-to-BIM sub-component (delimited in yellow in Figure 1) is the detection and localisation of some MEP components (e.g. HVAC systems) in images of the environment, and subsequent codification

of these entities into the IFC-SPF file outputted by the Structural Scan-to-BIM sub-component.

The MEP Scan-to-BIM process encompasses the following steps:

- **MEP object detection:** The first step of the MEP Scan-to-BIM process is the detection of different MEP components in the input images – here principally heating and cooling system components. The algorithm used is based on deep learning and it is structured as follows. First, a Faster Regional Convolutional Neural Network (Faster R-CNN) [17] is trained using a dataset of images labelled with MEP components. The Faster R-CNN uses Neural Architecture Search Net (NASNet) [18] as a feature extractor and has been previously trained on the Microsoft Common Objects in Context (MS-COCO) [19] detection dataset. Then, the trained model is tuned through a cycle of validation and optimisation to achieve the best possible performance on the dataset.
- **3D reconstruction:** In parallel to the previous step, the input images are loaded into a PG Structure-from-Motion (SfM)-based solution to generate a 3D point cloud of the environment [20]. This point cloud is used as a bridge between the images, where the objects are detected, and the TLS point cloud, in whose coordinate system the MEP entities are subsequently modelled. The registration of the PG point cloud to the TLS coordinate system is carried out manually in CloudCompare [21] by selecting four pairs of

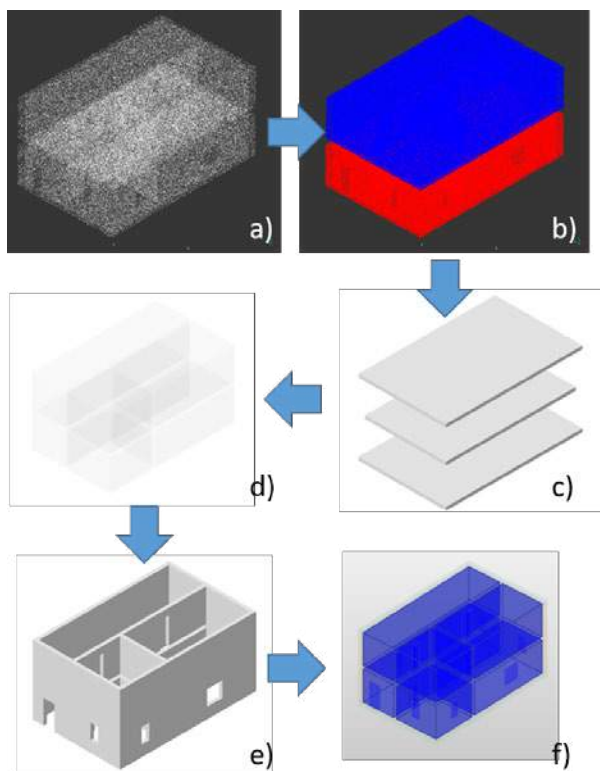

Figure 2. Intermediate results of the Structural Scan-to-BIM process. a) Point cloud; b) Point cloud divided into storeys; c) Slabs; d) Spaces; e) Structural elements with openings; and f) 2nd level space boundaries.

corresponding points in the two clouds. This operation, performed only once per PG model, delivers the transformation matrix between coordinate systems.

- **Locate MEP objects in the semantic model:** The inputs for this process are: the image MEP detection bounding boxes from ‘MEP Object Detection’, the PG reconstruction of the scene (including the external calibration matrices of the camera images), the intrinsic matrix of the camera, the PG-TLS transformation matrix, and the point cloud delivered by the laser scanner. The PG-TLS transformation enables the localisation (location and orientation) of the camera images in the coordinate system of the TLS point cloud and therefore the 3D model (IFC) outputted by the Structural Scan-to-BIM. The internal calibration matrix is then used to reproject the detected MEP objects into the 3D model.
- **Model MEP objects in the IFC model:** The information (i.e. the type of detected MEP object and the projected 3D bounding box coordinates) is coded

and added into the IFC model file of the Structural Scan-to-BIM model.

2.3 Scan-to-BIM Editor

The purpose of the Scan-to-BIM Editor (see Figure 3a), is to enable the user to add information to the generated Scan-to-BIM IFC model that cannot possibly be detected from the input point cloud and images. This includes information about wall layers and materials, material properties, as well as MEP properties. The inputs to this tool are: an IFC file containing structural components (see Subsection 2.1) and MEP components (2.2); and information on materials and MEP entities, which is stored in an online database and harvested by the Editor.

This database, called the Building Material & Component Database, contains data about 1,198 building materials originating from the third-party databases Baubook Vorrarlberg Energy Institute and IBO GmbH [22], Ökobaudat German Federal Ministry of the Interior, Building and Community (BMI) [23], and ASHRAE [24]. Each material is assigned to a class within a unified classification schema, covering the used third-party data schemes and thereby enabling the user to efficiently retrieve material information across all data sources.

The operations that can be performed with the Scan-to-BIM Editor include:

- **Creating and editing material layers:** After selecting a structural component (i.e. slab or wall) in the Editor, multiple layers can be defined and populated with materials from the Building Material & Component Database. An example is presented in Figure 3b).
- **Populating material information in entities located in openings:** In a similar way, after selecting doors or windows in the Editor, material information can be added to these entities. For example, this enables specifying the type of glazing for the windows, which is important for energy analysis.
- **MEP object properties:** For heating and cooling systems, properties related to power, relationships between elements (e.g. boiler feeding a radiator), and other characteristics (i.e. type of machine) can be provided and edited. Alternatively, an MEP object in the model can be matched to an MEP component in the Building Material & Component Database, thereby providing all relevant properties.
- **Assigning spaces to zones:** Finally, the Editor enables the user to create zones (codified as ifcZones) and link spaces (i.e. ifcSpaces) to them, as illustrated in Figure 3c. This information is necessary to perform the thermal zoning, or spatial discretisation, in

which the building is divided into thermal zones (i.e. groups of spaces), representing nodes with averaged values of thermal parameters.

3 Application to a Pilot Site

The approach presented in the previous section has been preliminary tested in one of the pilot sites for the Horizon2020 -funded BIMERR project (<http://bimerr.eu>), called the 'Kripis House'. This is a two-storey building, located in Thessaloniki (Greece). It is a smart home, equipped with one reception, three working spaces, two living rooms, three bedrooms, three toilets and one bathroom. The house has many rooms, including toilets with lower suspended ceilings, and HVAC devices are installed across the building.

3.1 Generation of a BIM model with the Scan-to-BIM tool

A total of 69 scans were taken from strategic locations, both indoors and outdoors, with a Faro Focus 150s Terrestrial Laser Scanner. An unstructured coloured point cloud containing 16M points, with a density of $1pt/cm^2$, was delivered after pre-processing and sub-sampling the data (see Figure 4).

Figure 4. Coloured point cloud of Kripis House.

Besides, a total of 4,080 images were collected of the indoors with a mobile phone camera. The images were then sampled and used for 3D reconstruction and MEP object detection. Figure 5 shows some sample images.

Figure 5. Sample images of the Kripis House.

Following the approach presented in Figure 1, the Structural Scan-to-BIM tool took the point cloud shown in Figure 4 as input and delivered a BIM model in IFC format. As illustrated in Figure 6a, the model is aligned to the point cloud. The main structural entities were detected and modelled in the BIM model: slabs, walls and openings (see Figure 6b), as well as spaces. Finally, the 2LSBs were calculated as shown in Figure 6c.

In parallel to the Scan-to-BIM structural process, the images taken from the Kripis house were used to simultaneously:

- produce a 3D photogrammetric reconstruction (i.e. coloured point cloud) of the rooms (Figure 7a); and

Figure 6. Results of the Structural Scan-to-BIM process for the Kripis house. a) Model aligned to the point cloud; b) Model including structural elements, openings and spaces; and c) 2nd level space boundaries.

- automatically detect the MEP objects installed in the building (Figure 7b).

All the MEP objects detected in the pictures are then reprojected onto the cloud (see Figure 7) and BIM model, and added to the BIM model.

Finally, the Scan-to-BIM Editor is executed to enable the user to provide the structural entities with material information and the MEP objects with additional properties. This additional information is delivered by the BIMERR Building Material & Component Database – the online repository described earlier.

Once the IFC file is completed, further processes are executed in order to evaluate the energy performance of the building and subsequently plan an effective retrofitting. This approach is detailed in the following sections and illustrated in Figure 8.

Figure 7. Initial MEP Scan-to-BIM processes for the Kripis house. a) Photogrammetric reconstruction of a room; b) Reprojection of detected MEP components to point cloud.

3.2 Data quality checking

The IFC file automatically generated by the Scan-to-BIM sub-components may contain some errors (e.g. geometric inaccuracies, missing semantic links or missing/incomplete components) that need to be checked and corrected before being used as input to the BEP model generation processes.

To identify and correct these errors, the produced IFC file is used as input to two of the BIM Management Platform (BIM-MP) [25] online services: *MVD completeness* and *geometric correctness checking* [26]. These tools deliver a report, highlighting the required modifications, which will be used by a BIM modeller to amend the IFC file. This iterative modification of the BIM model is performed in the ArchiCAD [27] BIM authoring tool until a faultless IFC file is produced.

3.3 Use of the BIM model for energy simulation and retrofit design

The final IFC model is used to produce an Input Data File (IDF), which is the main input to the EnergyPlus simulation engine [28]. The IFC to IDF mapping process is automatically performed by means of the Building Energy Performance Module's IDF Generator. The resulting file contains information about the building and the HVAC system to be simulated and it is used together with an EnergyPlus Weather (EPW) file as inputs to EnergyPlus in order to perform the simulation. Results of each EnergyPlus simulation are post-processed to estimate predefined energy Key Performance Indicators (KPIs) used as input to the Renovation Decision Support System (RenoDSS). The RenoDSS, in turn, illustrates the renovation options for the

building, evaluates their impact on the building's performance, and guides the user through various alternatives towards the optimal choice for given boundary constraints (such as size of intervention, budget, target energy savings, etc.).

Figure 8. Processes and tools employed for the generation of an IDF of Kripis House.

4 Conclusions

This paper presented an integrated Scan-to-BIM approach for energy performance evaluation and retrofitting of buildings. The proposed tool comprises three sub-components to create BIM models from point clouds: Structural Scan-to-BIM, to identify and model the structural entities; MEP Scan-to-BIM, to detect and model MEP components; and Scan-to-BIM Editor, to complete the BIM model with additional non-visible features (e.g. materials and properties) and classify spaces into zones. The tool is also integrated within a broader process that includes a BIM Management Platform (BIM-MP) that checks the geometric correctness and completeness of the generated IFC file, as well as the Building Energy Performance Module. The latter, invoked by RenoDSS to estimate the energy performance of the building, it initially receives the IFC file, automatically transforms it to

proper simulation input data files and launches EnergyPlus to calculate predefined KPIs.

The Scan-to-BIM tool, as well as the broader process, was validated in a two-storey building. This showed the quality of the BIM model produced by the Scan-to-BIM tool, which saves time during the modelling phase. Nonetheless, future work remains to increase the robustness of the Scan-to-BIM tool, especially to identify openings more accurately and detect a larger range of MEP objects.

Abstract –

Construction is among the most dangerous industries for the safety of workers. Due to the dynamism typical of construction sites, where workers, materials and equipment resources are often in motion, collisions and contact with moving construction machineries and heavy equipment represents one of the main safety problems. The study described in this paper concerns with the preliminary development of a proximity warning system (PWS) for construction activities, which is based on the implementation of sensing technologies for situation awareness. Preliminary results, the feasibility of the PWS and its practical potential are described, highlighting the needs of a continuous monitoring process and the expectations about the system configuration. The adoption of the Ultra Wide Band (UWB) technology is within the scope of the paper. A front-end loader and an excavator are the construction machineries taken into account for the analysis of the use case, which considers the differences between equipment with fixed and variable geometries in terms of sensor devices. The possibilities for real-time position tracking of workers and equipment in both outdoor and indoor conditions based on the system architecture settings are discussed. Moreover, the compliance of the system architecture with the requirements imposed by the General Data Protection Regulation (GDPR) is described. Future works will validate the system in the context of actual construction sites. Furthermore, factors to be considered when sensing technologies for tracking the position of resources on construction sites are implemented will be evaluated as far as planning and scheduling activities are concerned.

Construction safety; Proximity hazards; sensing technologies; Ultra Wide Band; General Data Protection Regulation

1 Introduction

Construction represents one of the most dangerous production sectors in terms of risks for the safety of workers [1]. In fact, although around 7% of the workforce worldwide is employed in construction, this accounts for between 30% and 40% of deaths at work [2].

Statistics compiled at international level show that construction safety is a global problem. In the United States, for example, census data from the U.S. Bureau of Labor Statistics (BLS) show that a total of 1.061 workers died in 2019 from fatal work injuries in the construction industry, accounting for 9.7% of all work-related fatalities; based on these data, construction ranks fourth among all manufacturing sectors for fatal work injuries [3]. As it emerges from the analysis of the data regularly provided by INAIL (Italian National Institute for Insurance against Accidents at Work) in relation to accidents in the workplace, construction has been always considered a high risk sector, with workers exposed to greater risks to their health and safety than in other work environments [4]. Although recording a slight decrease in 2018 compared to previous years, the Italian construction sector also shows the highest rate of accidents causing fatal injuries. In particular, looking at regional data, the accident phenomenon remains concentrated in northern Italy (60%), where Lombardy and Emilia Romagna alone account for about a third of all accidents (17% and 12% respectively). With regard to the construction sector, albeit with slightly decreasing numbers, in 2018 Lombardy was the region with the most complaints for accidents at work, 1389, followed by Veneto with 1060 (-23.7% complaints compared to Lombardy) and Emilia-Romagna with 982 complaints (-29.3% compared to Lombardy) [4].

1.1 Collision accidents with construction machineries in motion

In this context, proximity of workers to moving

construction machineries and heavy equipment represents one of the main safety problems in construction. More than six hundred construction worker deaths in the United States between 2004 and 2006 were linked to collisions and contact with moving construction machineries and heavy equipment [5]. INAIL data sets also show that the risk for collision accidents on construction sites represents one of the most frequent causes of death [6]. The causes of this kind of accident could be sought in the dynamic features proper to construction site activities, where the involved resources, such as workers, materials and equipment, are often in motion in situations of excessive proximity on a construction site space that is often insufficient, at least temporarily, to guarantee the safe performance of operations.

Collision accidents, in fact, are often due to a poor analysis of spatial interferences during construction planning and workspace design [7] [8]. Moreover, a lack of knowledge of existing specific risk factors, which is aggravated in daily activities by the possible loss of concentration due to fatigue and repetitive tasks, and the fact that no real-time information is gathered during the incident are some of the main factor influencing collision detection on construction sites [5]. Furthermore, visibility for workers driving construction machineries is often reduced due to blind spots and it increases the probability of risk of workers being run over and invested [2]. In fact, procedural non compliances causing fatal injuries are often related to the non-verification of the absence of operators by the driver of the construction machinery and the positioning of workers in the manoeuvring area. Further issues are detected such as shortcomings in the safety devices of the construction machineries (e.g., rear-view mirrors, reversing horns) and inadequate signposting of pedestrian transit routes [6].

In order to prevent workers being undetected in blind spots or in too close proximity, a warning system is needed that will promptly alert workers and equipment operators [5].

1.2 Objective of the research project

The study aimed at the preliminary development of a Proximity Warning System (PWS) for the real-time detection of a potential risk for construction workers because of an excessive proximity to a construction machinery in motion. Such a system has been conceived and developed in the form of a Proof of Concept (PoC) in order to demonstrate, as a preliminary result, its feasibility and practical potential, highlighting the needs of a continuous monitoring process and the expectations of the system configuration.

In particular, sensing technologies are considered in an Internet of Things (IoT) scenario that would allow

collecting real-time data directly from the construction site in order to support workers and protect their safety at work, taking into account the balance between safety and productivity. Moreover, the evaluation of the adoption of Ultra Wide Band (UWB) technology as a continuous monitoring system for the safety of construction workers is within the scope of the paper. UWB technology, in fact, has an optimal trade-off between location accuracy and cost of devices, which makes it the ideal solution for sensing precisely the distance in construction sites. Moreover, the design of a precise location service for the PWS should take into consideration workplace privacy, an aspect generally neglected by similar solutions proposed in literature.

In the following paragraphs the study will be introduced with respect to the research background. The research methodology implemented and the system architecture adopted for the development of the proximity warning system will be then described. Furthermore, the compliance of the proximity warning system with the requirements imposed by the General Data Protection Regulation (GDPR) will be shown. Finally, achieved results, findings and outcomes will be discussed in the light of the objectives of the research work, highlighting its limits with respect to the application domain. Possible future developments will be presented in terms of both the use case and the technological system.

2 Research background

Although accident prevention is a key step in the management of construction safety, traditional methods such as risk analysis, training of workers, site inspections and compilation of checklists, do not always guarantee optimal levels of continuous safety monitoring and effective and timely prevention of accidents during the construction process. Even when all the aforementioned measures are adopted effectively, workers tend not to recognise as a potential source of risk many of the hazards occurring on the construction site during their own activities [9] [10]; among them, there are the proximity of workers to construction machineries in motion [11].

2.1 Sensors technologies for situation and context awareness on construction sites

Strengthening the increasing attention to this type of risk for the safety of workers in the construction sector, the adoption of tracking systems to monitor construction entities (e.g., machineries, workers and materials) is discussed in literature. Vision-based and sensor-based methods exist for this purpose. The former track construction machineries from videos by deploying

cameras on construction sites. The latter refer to tracking entities by various sensors such as GPS, RFID, UWB, and laser scanners [12].

Cameras have become standard equipment on construction sites [12]. However, if currently no vision-based tracking method can achieve processing speed in the tracking of construction machines, especially in the case of multiple ones simultaneously, sensor-based methods for proximity warning systems allows the real-time tracking of construction entities [12]. Moreover, vision systems are also very sensitive to operating conditions (e.g., reduced visibility due to dust on the construction site, or rain) and they require much more maintenance (e.g., frequent cleaning of the system optics). Furthermore, vision-based methods could be more expensive of sensor-based ones (e.g., UWB) and many more cameras are needed to avoid blind spots on the construction site.

Among the sensor-based methods, the use of Inertial Measurement Units (IMU) capable of tracking the kinetic movement data of workers to determine the areas where falls are most likely to occur has been exploited. Other studies have relied on the adoption of Unmanned Aerial Systems (UAS) to identify situations of risk of falling from heights. The increasing use of wearable devices also got the potential to make workers significantly safer on construction sites [13]. The adoption of sensor-based methods has often been referred to proximity warning systems. PWS locate the position of workers in relation to potential safety hazards in the workplace such as proximity to restricted areas and construction machineries in motion. In addition, proximity warning systems use localisation systems not only to monitor the relative position of workers in relation to possible hazards, but also to warn them, by sending notification signals, if they come dangerously close to sources of risk to their safety. Previous studies have shown that the adoption of sensors systems can effectively improve the perception of risks by workers, who are able to take appropriate measures to avoid them once they receive an alert signal [11].

Considering wearable sensor devices, previous studies have used Bluetooth-based Low-Energy (BLE) technology [14] in order to identify the positions of workers with respect to potentially dangerous situations; other attempts, instead, have adopted a real-time localisation system (RTLS) based on Radio-frequency identification (RFID) technology [15] to locate workers and equipment with respect to the position of high-risk or restricted areas, implementing radio-frequency sensing technology also in order to identify possible collisions between workers, heavy equipment and moving construction machineries [5]. Several other technologies, including laser scanning, UWB, Global Positioning System (GPS), and computer vision have been suggested

for similar purposes [11].

2.2 UWB technology

The adoption of the UWB technology is of particular interest. It has been developed to transmit spectrum-dispersive modulated signals over very wide bands (i.e., 500 MHz or more) [16]. UWB applications, in fact, include sensor networks where high data rates are not required but it may be useful to ensure a good coverage range. They also include remote tag localisation systems for applications such as logistics, safety, medical, domestic, security and military.

A typical UWB RTLS is shown in Figure 1. An infrastructure of nodes called *anchors* is deployed in fixed locations while nodes called *tags* are applied to the mobile objects which should be tracked. The network coordinator is the node in charge to allow new nodes to join the network as well as to organise the transmission timing among nodes.

Figure 1 UWB RTLS principle architecture

Usually deployed with a maximum distance of 25 m, anchors send radio pulses to start the location process, which usually has an error within 30 cm with an update rate every 50 ms, depending on the available hardware. Such a result, it is hard to obtain using GPS technology, unless to adopt solution like GPS receivers with Real Time Kinematic (RTK) support, but which costs are not feasible for a large deployment in construction sites. Usually deployed for automatic asset tracking in indoor environments, UWB technology has several benefits that satisfy large part of the use case requirements. UWB is capable of reaching a range of 100 m in outdoor environments. It also does not need additional hardware to operate, such as routers. Generally, dynamic scenarios (i.e., with moving objects) such as construction sites can be monitored adopting UWB sensor technologies, but there may be problems if the environment in which the monitoring is done undergoes major changes that prevent, for example, the reception of signals. Moreover, this technology requires manual anchor localisation and registration in RTLS system for tag trilateration. In the literature there are several solutions to address this issue, by using self-configuration approaches, but, the

complexity, in term of protocol effort, introduced by them is not justified by the considered use case.

3 Research methodology

UWB technology was selected for the development of the PWS. Research activities were managed in six macro-phases, with some of them overlapping during the testing in order to proceed with an iterative process of data collection and analysis (Figure 2).

- Phase 1 - analysis of the use case for the applicability of the PWS in construction site safety management
- Phase 2 – set up of the system architecture
- Phase 3 - on-site tests for real-time proximity analysis
- Phase 4 - iterative review of the system architecture
- Phase 5 - Verification of the compliance with GDPR

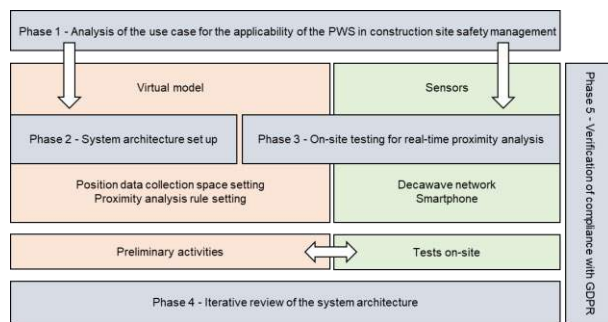

Figure 2 – Research methodology

3.1 Description of the use case

The paper analyses the specific use case related to the risk of a construction worker of being run over or invested by a construction machinery in motion. For the purpose of the study, two construction machineries were considered, chosen because of their different configurations: (1) fixed geometry (i.e., the body of the construction machinery has a fixed geometry and configuration during movement) and (2) variable geometry (i.e., the body of the construction machinery has a variable configuration during movement):

1. front-end loader [Takeuchi TL6R] (i.e., fixed geometry) (Figure 3)
2. excavator [Takeuchi TB640] (i.e., variable geometry) (Figure 4) (Figure 5)

Based on technical documentation and workforce experience, five circular areas around the construction machineries have been defined:

1. *black area* (i.e., the radius of action of the

- construction machinery) within which there is an imminent permanent injuries or death risk;
2. *red area* (i.e., an area of 2 m from the radius of action of the construction machinery in which, according to the manufacturer's instructions, no persons may be present when the equipment is in motion) within which an immediate reaction is needed to avoid permanent injuries or death;
3. *yellow area*, within which operations are allowed but attention must be made as the risk could quickly increase to red and black;
4. *green area*, within which the presence of heavy machinery working nearby is notified;
5. *white area*, within which no risk related to heavy machinery operations is present.

Figure 4 Excavator (variable geometry) – retracted arm

Figure 5 Excavator (variable geometry) – extended arm

3.2 System architecture setup

The system architecture setup is shown in Figure 6 and it is composed by three layers: infrastructure, operator and construction machinery.

Figure 6 The architecture of UWB position detection system

The infrastructure layer is composed by a network of Decawave DWM1001, which can act as both anchors or tags with a suitable configuration (marked as AX for anchors and TX for tags in Figure 6). Tags are connected to a smartphone, running a custom APP developed for the project, by a Bluetooth Low Energy (BLE) link. The positions of tags are, then, locally collected by the smartphone that could perform the calculations needed to identify the area and alert the operator. If a suitable communication infrastructure (e.g., Wi-Fi or LTE) is available, the smartphone could act as a gateway and forward position data via MQTT (Message Queue Telemetry Transport) to a cloud backend in charge of all the computation. The performance difference between a full cloud or a mixed cloud-edge architecture has been analysed in [17][18].

3.3 PWS compliance with the General Data Protection Regulation (GDPR) for data privacy

The development of PWS has raised questions about the risk of violation of the privacy of workers' data due to the continuous monitoring of their position on the construction site to ensure the effective development of an alert system. In this sense, it is underlined that the absolute position of workers is never recorded, while their relative position with respect to a moving construction machinery is recorded: this allows to monitor their exposure to the risk and not their actual location on the construction site.

In addition, each operator has access to data related only to the tags and UWB anchors assigned to a specific worksite. The tag-user association is recorded in the app the PWS is based on and is not exported to other systems; it is also assumed that this association activity is validated by the site manager (e.g., during the delivery of personal protective equipment).

Moreover, each app has a client with a unique ID, which is generated each time the user accesses a specific part of the app. The data saved involves only the tag information regarding the location of the resources and their mutual positioning; if necessary, it is possible to add, as additional data, which client actually sent this location. The tag-media association follows the same logic.

The only information known to all members of the system, therefore, is the type of tag (user/worker, construction machinery) or UWB (which delimits the monitored worksite area). Based on those considerations, the PWS complies, in this preliminary setting, with the European General Data Protection Regulation (GDPR) in terms of data privacy.

4 Results of the application of sensors technology

Figure 7 shows the experimental setup. It is formed by 5 anchors (A, B, C, D, E) and a network coordinator I. The area is divided in two part: an *indoor area* on the left of anchor B and E, and an *outdoor area* on the right of anchors B and E. B and E are positioned in the indoor side of a concrete wall with a 2 m open door in the middle (pink line in Figure 7). The experimental set-up has been defined in order to validate the behaviour of UWB sensors in significant operational environments (indoor as well as outdoor).

Figure 7 UWB test setup

Data have been collected using the MQTT+ backend configuration leveraging an ad-hoc Wi-Fi network to connect the smartphone with a laptop PC acting as backend. Since the type of movement of the workers and of the construction machinery are different, two set of experiments have been performed, to validate the capability of the UWB technology to monitor each of them independently:

1. detection of an operator equipped with a tag on his chest, as shown in Figure 8 (top);

2. detection of a moving construction machinery as described in Section 3.1. For the variable geometry of the excavator (i.e., retracted arm and extended arm) two tags have been installed as shown in Figure 8.

Figure 8 Position of tags for both operator and construction machinery

Figure 9 and Figure 10 show, respectively, the results of the experiments performed during the first and the second set of experiments. In particular, Figure 9 shows the real-time position of a worker walking alone outside and then going inside the building. Figure 10 shows the position of a moving construction machinery, in the same area, without the presence of the worker. The construction machinery started moving in the indoor area. In both the experiments, the position of the workers and of the construction machinery has been sampled each 50 ms.

Figure 9 Position tracking of a worker

Figure 10 Position tracking of a machinery

Thanks to the location accuracy provided by the UWB sensors (nominal location accuracy of 30 cm), the proposed PWS is able to detect the fine details of the movement of the construction machinery. This is the reason of the overlapping trajectories shown in the slashed orange rectangle, which correspond to the operation of the construction machinery.

5 Conclusions

5.1 Discussion of the results

The obtained results aim to demonstrate the applicability of the proposed system in a near to reality testing environment, which includes the presence of workers as well as construction machinery. As demonstrated by the experimental results, the system is able to track the real-time movement of both a worker as well as of a construction machinery, in indoor as well as outdoor scenarios. With the respect to similar proximity warning solutions used in construction sector based on Bluetooth technology [19] [20] [21] [22], ultrasonic [23] or LoRaWAN devices [24], the proposed solution exploits the use of UWB radio to reach a localization accuracy on the order of 30 cm, at an update rate up to 50 ms, as indicate by the technology provider [25] and by scientific literature **Error! Reference source not found..**

According to the technology provider documentation [25], there are several factors affecting the localization accuracy. One of the main sources of uncertainty is the power of the received signal, which is affected by the environmental conditions. The UWB technology is only partially affected by multipath effect, because the UWB pulses are transmitted in the RF frequency between 3.5 GHz and 6.5 GHz. This frequency band is rather immune to multipath effect, but it could experience the radio frequency attenuation of the signal. According to the device technical document [25], an attenuation of the signal varying in the range from -60 dbm to -95 dbm, corresponds to a an error in the location estimation from -20 cm to 10 cm, respectively.

Notwithstanding these limitations, the UWB remains the most feasible solution for a precise location at a low cost. As demonstrated in the paper, the system is able to track, at the same time, the position of operators and of machineries in the area under monitoring. In fact, when the geometrical distance between a worker and each of

the construction machineries located in the site is below one of the security areas defined in Section 3.1, an alert or a warning (depending the security area involved) is raised to the involved operator. The location accuracy provided by UWB devices was taken into account when defining the security areas, to avoid any risks for the workers.

In addition, according to the recent trends in proximity warning system, which achieved some success as a result of contact tracing systems [26], the proposed solution has been designed to take into account the privacy of the workers, as highlighted in Section 3.3.

5.2 Limitations of the study

First of all, the tests described in this paper were carried out in a simplified environment and considering separately the movement and the related real-time detection of the resources "workers" and "equipment" (i.e., construction machineries). In fact, the tests do not fully consider the complexities linked to the dynamism of a construction site.

As regards the technologies adopted, which have been selected for their easy availability on the market and low cost that has enabled them to be used effectively within the time and economic resources of this project, the problem of antenna direction and orientation of UWB tags and anchors to ensure continuous signal transmission regardless of the positioning and movement of the resources has not yet been resolved.

A further limitation of this project is that, to date, no indications have been given as to the actual distances to be maintained between the operator and the moving construction machinery in order to successfully guarantee the safety of workers in the event of the risk of being run over or hit by moving construction machineries. These analyses are in the development phase and need to take into account all the aspects related to the quality of the data as well as the time needed for its recording, processing and subsequent communication in the PWS.

5.3 Future works

Future works will validate the measurement system in the context of actual construction sites, with a focus on a panel of construction activities that requires collaboration between workers and construction machineries (e.g., procedure of excavation).

Moreover, a further series of tests will be carried out that integrate the system architecture with certified telemetry systems in order to set it up a correct monitoring process and assess the effective validity of the digital twin represented in the virtual environment.

A suitable notification system will be set up in order to communicate the presence of a safety risk to the workers, once the PWS detects excessive proximity

between workers and moving construction machineries. These notification systems will have to consider the conditions of disturbance and noise typical of construction sites as well as the risk of a decrease in the attention of operators in the event of receiving excessive notifications.

Furthermore, in order to optimise the PWS in terms of technological equipment, a collaboration with manufacturers could allow acting directly on the construction machinery itself, hypothesising scenarios of gradual slowing down and stopping in the event of danger or sending timely notifications and warning signals directly from the equipment itself.

Finally, from the construction management perspective, future developments could also integrate the assessment of the positioning of UWB anchors in the design of construction site layouts and the planning of construction phases so as to include their installation and possible displacement among the activities to be taken into account in order to ensure signal coverage that is always consistent with the activities currently underway.

Generally speaking, the current and expected outcomes show how the proposed and tested technical solutions could be exploited with a broader digital ecosystem, enabling a data-driven control room for safety management.

Abstract –

Building Information Model (BIM) with rich geometric and semantic information of facilities has increasingly been used to establish the City Information Model (CIM). Although BIMs for new buildings are becoming more available, BIMs for most existing buildings can only be modelled from 2D drawings and specifications. Manual BIM modelling is an error-prone and time-consuming process, which becomes more challenging for the city scale. Recently, automating the 3D BIM modelling process for existing buildings from their 2D drawings has been an emerging research trend. To understand the state-of-the-art and guide future research, this paper presents a systematic review of automated BIM modelling for existing buildings from 2D drawings. Fifty-five publications, including 34 journal articles and 21 conference papers identified from Scopus from 1998 to 2021, were reviewed and analysed. A chronological distribution shows that most papers (60%) aimed to generate 3D geometric models, and BIM modelling with semantic information appeared in 2015 and increased dramatically. This review classified the existing work into three aspects: geometric modelling, semantic modelling, and model quality checking. The results show fully automated conversion of 2D drawings to semantically enriched BIM has not been eventuated, future work may consider overcoming the following challenges: (1) height information is either set as default or entered manually, and complex components such as staircases are barely studied; (2) most research only focused on floor plans and ignored semantic information contained in other drawings; (3) drawing errors have not been well addressed, and the validation of the generated model is still cumbersome.

Keywords –

Building Information Model (BIM); Existing building; 2D drawings; City information model (CIM)

1 Introduction

An accurate 3D information model at the city scale has the potential to support a wide range of applications such as infrastructure planning, policy evaluation, disaster management, energy demand estimation, situational awareness, and multiple domain integration [1]. Building information models (BIMs) of buildings and civil infrastructure have been widely acknowledged as a key data source to establish the City Information Model (CIM) [2]. Although the BIM of recently completed or new buildings has been modelled in the design process and can be directly used for CIM, the BIM of most existing old facilities is often unavailable. Therefore, the automation of BIM modelling for existing buildings has drawn growing attention in the past years.

Currently, there are two main methods of BIM modelling for existing buildings, i.e., (1) on-site surveying and (2) as-built documentation.

The first method is through on-site surveying. To generate BIM for existing buildings, the collection of sufficient spatial information is essential. Various sensors (e.g., laser scanning [3], photogrammetry [4], etc.) have been adopted to collect 3D point cloud data, and then building components are detected and modelled. Although the 3D model generated through on-site surveying could represent the current state of existing buildings, the modelling process is time-consuming and labour-intensive, especially when it comes to digital modelling at the city scale. Besides, those surveying approaches can only detect the exterior and interior surface geometry. Structural components, such as beam and column, are usually hidden from view for aesthetic reasons, which makes measuring their geometry impractical. Additionally, missing points are common in the data collection process, and, more importantly, the point cloud does not contain any semantic information. There have been some strategies suggested to add engineering rules in the modelling process using point cloud, however it is still challenging to develop a

semantically-rich BIM using this approach [5].

The second method focuses on generating BIMs from 2D drawings since as-built documentation contains abundant geometric and semantic information, which better describe the building. Since manually extracting building information from 2D drawings and modelling all facilities at the city scale is error-prone and challenging, automated BIM modelling from design or as-built documentation has seen a growing research interest. Gimenez et al. [6] provided an in-depth review of advanced technologies toward each step of the generation of 3D building models from 2D scanned plans in 2015. However, literature aimed to achieve 3D modelling from drawings has not been well analysed, and many semi-automated and automated methods have been proposed during the last few years. Kang et al. [7] reviewed the recent development of 3D indoor reconstruction but mainly focused on technologies based on on-site surveying. A comprehensive review of recent advances in BIM modelling from as-built documentation is required urgently.

To fully understand the contributions and limitations of current research studies, this paper provides a systematic review of automated BIM modelling for existing buildings from 2D documentations. The 2D documentations refers to various types of drawings, including digital drawings, paper-based drawings, architectural drawings, structural drawings, and floor plans. The structure of this paper is organised as follows: Section 2 presents the overall design of the literature search. Section 3 describes three aspects of BIM modelling: geometric modelling, semantic modelling, and model quality checking. Section 4 discusses the limitations of existing research studies and points out possible further research opportunities. Finally, Section 5 summarises the finding with a conclusion.

2 Review methodology

This research adopted the five-step review methodology to conduct a systematic review [8]. First, a keyword search-based approach was adopted to collect relevant publications. Searching attributes and their corresponding values are listed in Table 1.

The main keywords were, for example, ‘2D’, ‘drawing’, ‘floor plan’, ‘floorplan’, ‘BIM’, ‘building information model’, ‘3D model’, ‘construction’, ‘reconstruction’, ‘creation’, ‘generation’, and ‘modelling’. The Scopus database was selected for literature searching, and papers not published in English were omitted. Since this review focused on the 3D model generation for existing buildings from as-built documentation, only four relevant subject areas, Engineering, Computer Science, Social Science, and Environment Science, were considered. Other subject

areas, such as Mathematics, Material Science, and Physics and Astronomy, were excluded. Journal articles and conference papers are both included in this review.

Table 1 Literature search methods

Search attributes	Values used in the search
Database	Scopus
Keywords and Boolean operators	(“2D” AND (“drawing” OR “floorplan” OR “floor plan”) AND (“BIM” OR “building information model” OR “3D model”) AND (“generation” OR “creation” OR “reconstruction” OR “construction” OR “modelling”))
Search scope	Article title, abstract, or keywords
Published year	From all years to present
Subject area	Engineering, Computer science, Social Science, Environment Science
Document type	Journal article; Conference paper;
Language	English

The initial literature search has resulted in a total of 456 papers. Then, the title and abstract of the literature search results were analysed to identify relevant publications. The filtering criteria are as follows:

- (1) Publications aimed to construct a 3D model from 2D drawings were included.
- (2) Articles that only mentioned creating a 3D model from 2D documentation but did not focus on were excluded.
- (3) Other publications, such as those focused on converting the building design process (from CAD to BIM), were excluded.

In addition, the snowballing technique was employed to find additional papers through the reference and citation lists. As a result, a total of 55 papers, including 34 journal articles and 21 conference papers, were retained for in-depth review and analysis.

Figure 1 shows the chronological distribution of all included papers, which are classified into “Semantic BIM” or “Geometric model”. The group of “Geometric model” included publications focused on construct 3D geometry such as indoor or surface model, other publications aimed at creating a BIM with semantic information fell into the group of “Semantic BIM”. Research on 3D model construction from 2D drawings started in 1998, and all identified papers published before 2015 aimed to create the 3D geometric model, such as indoor or surface model. The semantic BIM modelling from 2D drawings first

appeared in 2015, and a dramatic increasing trend can be observed. Then, all identified publications are reviewed critically according to three aspects of BIM modelling: geometric modelling, semantic modelling, and model quality checking. Key limitations regarding each aspect are concluded, and future work aimed to address these limitations are illustrated.

Figure 1. Chronological distribution of included papers

3 BIM Modelling from 2D documentation

In this section, the state-of-the-art BIM modelling for existing buildings from 2D drawings is summarised in terms of three aspects, namely geometric modelling, semantic modelling, and model quality checking. Geometric modelling aims to construct the 3D geometry of buildings. In contrast, semantic modelling focuses on extracting and attaching semantic information (e.g., room identity, component dimension, construction material, etc.) contained in 2D drawings as properties of objects in the 3D model. Once the 3D model is constructed, the model quality checking process is performed to verify its completeness and correctness.

3.1 Geometric modelling

3D building geometric model has been envisioned as the data management platform for facility management. However, manually modelling existing buildings is error-prone and time-consuming [9]. In the past decades, there has been a growing interest in automating 3D modelling based on 2D drawings. Existing research studies regarding geometric modelling are summarised in Table 2.

The first step in the 3D model generation is identifying and extracting building component information from 2D drawings. Since the geometry of different components is usually divided into different layers during computer-aided building design, layer information in CAD drawings has been widely used for component recognition [9–12]. However, errors on layer

classification need to be corrected in advance, and layer information is unavailable for hand drafting. Another solution is using geometric features and symbols to identify building components. As the most common features in 2D building drawings, line segments were used for identifying walls [13–18], columns [19], and rooms [20]. Symbols were adopted to detect grid lines, then building elements (such as columns, beams, and walls) can be further identified [21,22]. But these methods are not applicable for building components with irregular shape and will lead to false matches due to missing or inconsistent information in as-built documentation. With the rapid development of artificial intelligence (AI), the adoption of AI for drawing analysis shows a significant increase. Walls and openings are detected from floor plan image based on a convolutional neural network [23,24]. Rho et al. [25] developed a machine learning-based classifier to extract text information for component detection and localisation. Zhao et al. [26] detected structural components (e.g., columns and beams) from the framing plans based on Faster R-CNN, further created IFC BIMs for multi-story buildings. However, the existing application of AI only focused on detecting specific part of information. A unified solution for identifying all component information and texts is preferred for automating 3D model generation.

After components were identified, most research projects extruded the labelled 2D floor plan to generate the 3D building model [9,10,12–19,21,23–26]. However, the floor elevation and height of openings were either set as default or entered manually. Lu et al. [22] proposed to generate three orthogonal views (the top, side and front view) of each component from the 2D architectural drawings. Then, the 3D model of all components can be constructed and integrated to obtain the 3D building model. But this method only suits the modelling of simple geometry due to the challenge regarding the generation of three orthogonal views of building components from 2D drawings. In addition, the combination of floor plans and elevation drawing was proposed by Bortoluzzi et al. [20] to create BIM with room layout and exterior openings for existing buildings. Yin et al. [11] constructed a façade BIM model by locating exterior components in floor plans and extracting height information from elevation drawings. However, height information of interior building components (e.g., interior openings, beam) cannot be identified from elevation drawings. The combination of more as-built documentation is preferred to obtain all required information for automated 3D modelling.

Another vital part of 3D building model generation is the matching and integration of different floors. Most existing research studies only considered 3D modelling of one floor, and few papers studied the matching of

Table 2 Summary of geometric modelling

Themes	Approach	Description of the approach	Research
Drawing analysis	• Based on layer information	The geometry of different components is stored in different layers of CAD drawings, but it is not applicable for manual drafting;	[9–12]
	• Based on geometric features	Geometric features and symbols are used to identify building components, but irregular components cannot be detected;	[13–22]
	• Artificial intelligence	Using artificial intelligence to identify building components, which is suitable for all types of drawings and irregular components;	[23–26]
Generating the 3D building model	• Extrusion of 2D drawing	Extrude the labelled floor plan to generate the 3D model, but height information (e.g., floor elevation, the height of openings) is either entered manually or set as default;	[9,10,12–19,21,23-26]
	• Modelling from three orthogonal views	Generate 3D model of components from three orthogonal views, then integrate all component models to obtain a 3D building model, but it's hard to extract the three orthogonal views from 2D drawings;	[22]
	• Combine floor and elevation drawings	Detect building components from floor plans, then extract height information of external components from elevation drawings, but internal components haven't been considered;	[11,20]
Integrating different floors	• Floor plan-based matching	Align other floor plans to the first inputted floor plan based on drawing features or use global coordinates to locate components;	[11,15,16]
	• 3D feature-based matching	Match 3D model of different floors based on geometric features like pips, staircases, corners and bearing walls;	[17]

different floors to generate a 3D model of the entire building. The matching approaches could be divided into two groups.

(1) Floor plan-based matching. For example, Zhu et al. [15] and Li et al. [16] aligned other floor plans to the first inputted floor plan by intersection points between axes; Yin et al. [11] used the global coordinate system to locate components of each floor plan.

(2) 3D feature-based matching. For instance, Dosch et al. [17] proposed to match models generated from different floors based on features like pipes, staircases, corners and bearing walls.

3.2 Semantic modelling

In addition to geometric modelling, semantic modelling is the next stage of BIM modelling for existing buildings. Following the construction of the geometric models, a common approach is to classify building components [10,11,13,18,24,25], or attach identities to space objects [14,15,17,20,22,23]. To generate semantically-rich BIM and further improve its functionality, other semantic information contained in 2D drawings are extracted and modelled accordingly. For example, Li et al. [16] built a profile containing building type, size and other semantic information along with the

constructed 3D model. Lu et al. [21] generated Industry Foundation Class (IFC) model from 2D drawings and further attached material information of components through on-site surveying. By analysing component lists (including column list, beam list, slab list, and wall list) and floor plans, Byun et al. [19] created the IFC model with the material property of concrete and rebar for reinforced concrete structures. Yang et al. [9] focused on the semantically-rich 3D BIM modelling from 2D CAD drawings. Structural components and corresponding axis were first detected and generated, then semantic information of components (e.g., coding number, element cross-section, element reinforcement information) was linked to the axis as parameters.

3.3 Model quality checking

Once the 3D building model is constructed, it should be checked manually, semi-automatically, or automatically to verify its completeness and correctness. Research on model quality checking can be divided into three areas.

(1) Checking the drawing quality before the 3D modelling. Once any errors contained in 2D drawings are corrected, the 3D model generation can proceed using the drawings, mitigating the risk of inheriting errors or

inconsistencies [12,18].

(2) Comparing with ground truth. Gimenez et al. [14] proposed to compare the automatically labelled drawing with manually annotated one to evaluate the component identification results. To evaluate the constructed 3D model, the number of components in the input 2D drawings and output building model are compared [14,19]. Rho et al. [25] and Yang et al. [9] checked the constructed BIM model by comparing it with a manually modelling result.

(3) Checking without ground truth. The philosophy is to evaluate consistency and conflicts according to basic rules, which is mainly used for checking building design results with building codes [27]. Nikoohemat et al. [28] proposed an approach for checking the geometric, semantic and typological consistency of the constructed 3D model based on formal grammars defined through existing international standards.

4 Discussion

Although a number of automatic and semi-automatic approaches for BIM modelling from as-built documentation have been proposed, further research is still needed toward fully automated modelling of semantically-rich BIMs for existing buildings. This section summarises the limitations and challenges of current research along with possible future research directions.

Although building geometric information is distributed in various drawings, most existing research only used floor plans for geometric modelling. The height information, including floor elevation and height of openings, is either set as default or entered manually. Few publications have proposed to extract floor elevation from building elevation drawings [11,20]. To automatically identify the height information of all building components, future research could focus on the combination of various 2D as-built documentation. Another challenging problem is that only common building components are modelled, and complex components, such as staircases, are ignored in current research. The modelling of these building components should be further studied to create a complete BIM model for existing buildings.

In contrast to geometric modelling, semantic information modelling for existing buildings has not been given the attention it needs. Most research studies only detected room identity and component category from floor plans. The generated BIM can be used for energy consumption simulation [14] or indoor navigation [23]. However, to support facility management and disaster simulation, semantic information like space function and activities, occupancy characteristics, building materials, and properties of various building elements are required.

Future efforts are needed to integrate all information in multiple drawings and explore the modelling of a semantically-rich BIM data model.

Errors in drawings are inevitable, and existing research only focused on detecting and correcting specific types of errors [12,18]. A comprehensive illustration of various forms of errors in 2D drawings and their corresponding influences in 3D modelling is preferred. To evaluate the accuracy and quality of the constructed 3D model, comparing it with ground truth is reliable but requires extensive manual work, especially when the reference model does not exist. Compliance checking could be conducted fully automatically and is envisioned as an ideal solution for model evaluation. However, existing research only considered simple building component compliance [28]. To provide a more reliable model evaluation report, a comprehensive analysis of building compliance rules is required. In addition, methods aimed at automatically checking all relevant building compliance aspects are needed in future studies.

5 Conclusion

BIM modelling for existing buildings from 2D drawings and specifications has attracted growing research interest. It has the potential to support the development of CIM. This paper provides a systematic review of 55 relevant publications to understand the state-of-the-art to guide future research. A chronological distribution is used to illustrate the research trend. It has been found that most papers (60%) aimed to construct 3D geometric models, such as indoor or surface models, and semantic BIM modelling first appeared in 2015 and increased dramatically.

Recent advances in three aspects of BIM modelling, namely geometric modelling, semantic modelling, and model quality checking, have been reviewed and analysed critically. Limitations and challenges of existing research on each aspect have also been identified, as follows:

(1) For geometric modelling, the height information (e.g., floor elevation, the height of openings, etc.) are either set as default or entered manually. Besides, most research studies only focused on few categories of building components. Modelling of complex components such as staircases has barely been studied;

(2) In contrast to geometric modelling, semantic modelling has not been given the attention it needs. In particular, since most research only considered floor plans, rich semantic information in other drawings has been ignored;

(3) Errors in drawings have not been well addressed, and the validation of the generated 3D model is still cumbersome.

To overcome these drawbacks, the integration of all

as-built documentation should be solved for automatic semantically-rich BIM modelling. In addition, more research efforts are recommended to explore the quality evaluation of the generated BIM model.

Abstract –

A critical aspect of BIM is the capability to embody semantic information about its element constituents. To be interoperable, such information needs to conform to the Industry Foundation Classes (IFC) standards and protocols. Artificial intelligence approaches have been explored as a way to verify the semantic integrity of BIM to IFC mappings by learning the geometric features of individual BIM elements. The authors through previous studies also investigated the use of geometric deep learning to automatically classify individual BIM element classes. However, such efforts were limited in the number of training data and restricted to subtypes of BIM elements. This study has significantly expanded the training set, to include a total of 46,746 elements representing 13 types of BIM elements. The magnitude of the data set is considered to be the first of this kind. Furthermore, Conditional Random Fields as Recurrent Neural Networks (CRF-RNN), a deep learning algorithm for semantic segmentation, was deployed to enhance the quality of individual input images. Deploying the dataset and segmentation improved the performance of previous model (Multi-View CNN) by 4.37% and achieve an overall performance of 95.38%.

BIM; IFC; Semantic Integrity; MVCNN; CRF-RNN

1 Introduction

Building Information Modeling (BIM) has become the mainstream medium for integrating and disseminating information during the project life cycle of construction projects. Multiple stakeholders today employ a variety of specialized BIM tools tailored to their various needs in the design, engineering, and construction management of their projects.

The Industrial Foundation Classes (IFC), a neutral and open data format, is a critical component in ensuring interoperability within the BIM centric work process.

The absence of such a standard would require local data protocols for each and every pair of applications, quickly making BIM based project execution intractable.

Working under the IFC protocol requires BIM elements, relationships, and their properties to be represented in conformance to its standards. However, due to the lack of logical rigidity of the IFC schema, IFC model instances are prone to misrepresentations and misinterpretations, resulting in a lack of semantic integrity [4].

Such issues continue to be addressed in the domain of ‘semantic enrichment’, which reasons about the relations and meaning implicit in the geometry and topology of BIM models to check and rectify semantic inaccuracies.

In particular, a subset of these studies investigated ways to check the correct mapping of individual BIM elements to their corresponding IFC entities [1-3, 12, 16].

For example, [12] formalized sets of inference rules to check mappings, and subsequently automate inaccurate associations.

More recently, artificial intelligence approaches have been employed as an alternate approach to check the integrity of BIM-element to IFC-entity mappings. This approach has been conducted by extracting geometric features existing in the IFC or using 2D image or 3D shape information of each element for learning model training. [3] conducted a study to classify space in the BIM model using geometric features-based machine learning, and demonstrated that the classification accuracy of machine learning approach was superior to the inference rule-based approach. [11] used images extracted from BIM models to classify building types, and [6] classified BIM furnishing elements using 2D CNN.

The authors also explored the use of different machine learning and deep learning models to determine their applicability [7-9]. Mainly, we trained learning models based on the geometric features of individual BIM elements. In particular, we attained promising results from incorporating Multi-View CNN(MVCNN), a geometric deep learning model that learns from multiple panoramic images of a 3D artifact to learn and distinguish its shape [7].

However, despite its relative high performance, MVCNN still was limited in correctly classifying specific BIM elements despite their distinct geometric differences. The classification errors were attributed mainly to two factors. The first factor was the limited number of training data, as well as the imbalance in the number of samples per element class. Secondly, and more technically, was the lack of definition between the boundary of objects in the individual images, which made it difficult to detect the geometric detail of the elements.

Commensurately, novel approaches were newly explored to rectify these limitations. First, the data set for training was increased by applying data augmentation based on parametric modeling. Secondly, as a data preprocessing step prior to training MVCNN, Conditional Random Fields as RNN (CRF-RNN), a deep learning-based semantic segmentation technique, was applied to sharpen the geometric features of the images for each and every BIM element.

13 types of BIM elements with high utility in the architectural field were collected, and an expanded data set was constructed by performing data augmentation via parametric modeling. Afterward, the deep learning model was applied to the dataset to compare their performances. The first step was to learn the MVCNN algorithm, and the second step was to learn the MVCNN algorithm after applying semantic segmentation based on the CRF-RNN algorithm. Finally, by testing the two deep learning models on a BIM model excluded from the dataset, the classification performance of the developed model was compared to quantitatively verify the degree of performance improvement.

2 Research Background

2.1 Multi-View CNN (MVCNN)

With the recent development of computing technology, it is possible to directly utilize 3D data, and object recognition research using a 3D model-based CNN algorithm is increasing. However, 3D raw data is very large in size to be directly applied to deep learning algorithms, so it must be accompanied by a lightweight process to reduce it to a size suitable for learning [13, 14, 17]. Furthermore, the problem of performance degradation due to the loss of detailed features of objects in the lightweight process also makes it difficult to directly use the 3D CNN model.

MVCNN, designed specifically to resolve this issue, has been proven to provide better performance than directly utilizing existing 3D data. MVCNN utilizes the multi-angled images of a 3D model, while using multiple CNN layers which in effect prevents loss of geometric details [15].

Figure 1 below shows the architecture of MVCNN. A 3D object is rendered as 12 images taken panoramically. Each image is then input to individual Convolutional Neural Networks (CNN_1), which extracts compact shape descriptors representing the characteristics of each image. All extracted shape descriptors are reduced to one shape descriptor in the view-pooling layer, and they are transmitted to CNN (CNN_2) for final classification through the softmax classifier. Each CNN used in MVCNN utilized a VGG-M network composed of five convolution layers (CNN_1), two fully connected layers and, a softmax classification layer (CNN_2).

Figure 1. Multi-view CNN for 3D Shape recognition [15]

2.2 Conditional Random Field as Recurrent Neural Networks (CRF-RNN)

2D image-based deep learning models such as MVCNN have a disadvantage that their performance is highly dependent on the resolution and sharpness level of the data. That is, to improve the classification performance of the learning model, it is necessary to collect high-quality image data for training or to improve the resolution and clarity of the previously collected images. Accordingly, this study aims to improve the classification performance of MVCNN models by applying semantic segmentation to images of individual elements collected.

In this study, the CRF-RNN algorithm was used as a method for semantic segmentation. CRF (Conditional Random Field) refers to an undirected probabilistic graph model used for pattern recognition and structural prediction by labeling and segmenting consecutive pixels in an image. The simple CRF is composed of a lattice form in which adjacent nodes (pixels) in an image are connected by an edge, and due to this, exquisite segmentation was impossible during image segmentation. Accordingly, a Fully Connected CRF methodology that enables exquisite image segmentation by connecting all pixels of an image in pairs has been proposed, but there is a limitation in that the computation time is very long. Afterward, a method was devised to reduce the time required for label inference to 0.2 seconds by simplifying the complex structure by applying mean field approximation to the fully connected CRF.

CRF-RNN is a method of reconstructing two models

into one framework based on a Recurrent Neural Network (RNN) to utilize weights output via CRFs with mean-field approximation as parameters in CNN learning. Due to this, it is possible to reduce the computation time and secure high semantic segmentation accuracy, and for this reason, it was adopted as a methodology for semantic segmentation in this study.

The formula below is the operating structure of the CRF-RNN algorithm for one iteration of the mean field. In the equation below, T denotes mean-field iteration, Q_{in} and Q_{out} denote input and output according to respective one average field iteration, and Q_{final} denotes the final prediction result of CRF-RNN. $softmax(U)$ is the output value of the CNN operation, U is the unary potential value, $f_{\theta}(U, Q_{in}, I)$ is the weight inferred by Q_{in} , I is the image, and θ is the parameter of the CRF.

$$Q_{in}(t) = \begin{cases} softmax(U), & t = 0 \\ Q_{out}(t-1), & 0 < t \leq T \end{cases} \quad (1)$$

$$Q_{out}(t) = f_{\theta}(U, Q_{in}, I), \quad 0 \leq t \leq T \quad (2)$$

$$Q_{final}(t) = \begin{cases} 0, & 0 \leq t < T \\ Q_{out}(t), & t = T \end{cases} \quad (3)$$

After integrating the structure into one deep neural network, end-to-end learning is possible by implementing a back propagation algorithm. Through this process, semantic segmentation was performed on panoramic 12 images for each element, and an example of the result is presented in figure 2.

Figure 2. CRF-RNN-based semantic segmentation

3 Research Methodology

3.1 Parametric Modeling-based Data Augmentation

A goal of this study was to build a sufficiently large BIM element data set to train MVCNN. Ideally, BIM element samples need to be collected from open-source

libraries or existing BIM models. However, such avenues were limited due to copyright issues or lack of high-quality data from attainable BIM models.

Thus, a data augmentation process that creates new data based on existing data was required. In this study, parametric modeling, an element technology of BIM was used.

Parametric modeling applies the concept of an independent parent/child to the composition factors (line, point, spline, plane, etc.) of individual BIM elements and connects them in a mutually related structure [10]. In other words, by defining the dimensions of the element as parameters and expressing their relationship as a function, the user can convert it into a shape suitable for the purpose through parameter setting. Since the operating principle, range, and limit of the result are directly affected by the modeling method in this process, it is necessary to clearly set the shape control criteria [5].

To establish the shape control criteria in this research, 13 types of major building elements were collected from four IFC standard building models and three online BIM libraries (KBIMS Library, NBS, bim object), and their shapes were investigated and analyzed. As a result, 45 parameters and their ranges were extracted from 13 elements, and the results are shown in Table 1. Subsequently, parametric modeling was performed using Revit Dynamo software based on the parameters. Figure 3 shows an example of parametric modeling of a beam element using this method.

Table 1. Parameters and range for each BIM element

Element	Parameter	Range(mm)
Beam	Width	250-600
	Height	400-1,100
	H (web width)	100-900
	B (flange width)	75-400
Column	Width	4-19
	Height	7-37
	H (web width)	200-1,000
	B (flange width)	200-1,200
	t1 (web thickness)	100-900
	t2 (flange thickness)	75-400
Double door	Diameter	4-19
	Width	7-37
	Height	500-1,000
	Frame width	1,800-2,400
	Panel thickness	1,800-2,400
Single door	Opening width	40-60
	Width	15-35
	Height	40-60
	Frame width	900-1,100
	Panel thickness	1,800-2,400
Slab	Opening width	50-70
	Width	20-40
Covering	Length	90-110
	Width	100-400
Wall	Length	100-400
	Width	3,000-11,000
Window	Width	800-1,800
	Height	900-1,600

	Frame width	80-120
	Panel thickness	10-30
	Frame thickness	30-70
	Glass thickness	2-22
Revolving door	Width	1900-2,500
	Height	2100-2,800
	Opening width	500-2,000
Curtain wall	Length	12000-1,7000
	Height	4000-6,000
	Vertical grid	12,100-16,900
	Horizontal grid	4,100-5,900
Stair flight, Member	Shape	U-shape with middle

*Stairs include stair flight, member, and railing, so when parametric modeling is applied to stairs, these elements are applied at the same time.

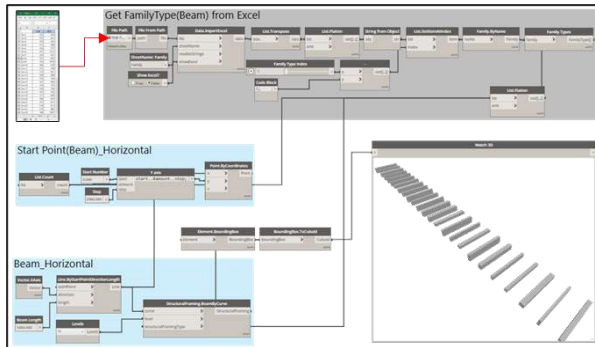

Figure 3. Parametric modeling using Revit Dynamo

The research team named the expanded data set built through this process 'ArchShapesNet', and released this data set in an open source form on the i3LAB homepage (<http://i3l.seoultech.ac.kr>) for other researchers to use.

3.2 ArchShapesNet Overview

12,672 elements of 13 types were collected from the four IFC standard architectural models (Table 2) and three BIM libraries mentioned in Section 3.2. Parametric

modeling-based data augmentation was then performed to finally construct the 'ArchShapesNet' data set consisting of 46,746 elements. The data distribution for each element is presented in Table 3. After constructing an element classification model by applying a deep learning algorithm to the constructed ArchShapesNet data set, the performance was verified for 'Sejong city stadium', which was not used for learning.

Table 2. Five models for training and test

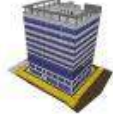

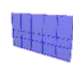

IFC model	Train/Test	Image

Rendering			

3.3 Data Preparation for Deep Learning Implementation

Each element in ArchShapesNet were rendered into panoramic 12 images for MVCNN training. 'KBIM Assess-Lite', an automatic IFC model checking software, was used for this conversion process. The images consist of 10 side images taken panoramically at 36° intervals and 2 images taken from top and bottom.

Table 4 shows the data distribution for each element of the verification model (Sejong city stadium). In other words, model training is performed with the data constructed in Section 3.2, and the performance of the model is evaluated by testing the elements presented in this section. However, the verification model was composed of curtain walls without windows due to the characteristics of sports facilities, and the member and revolving door elements were not included, so verification of those elements were excluded.

Table 4. Status of test data set (Sejong city stadium)

Type	No. of element
Beam	164
Column	171
Slab	61
Wall	308
Window	0
Stair flight	19
Member	0
Railing	24
Curtain wall	63
Covering	12
Single door	19
Double door	4
Revolving door	0
Total	845

3.4 MVCNN Implementation

Figure 4 shows the MVCNN model construction process using the panoramic 12 image data for each element. When the 12 images of individual elements pass

through the neural network (CNN_1), the features of the elements in the image are extracted. Afterward, the features of each extracted image are integrated in the view-pooling layer, which is again passed through the secondary recurrent neural network (CNN_2). Here, CNN_2 is composed of the softmax layer, and through this, the classification results for individual elements are output. The MVCNN implementation utilized python-based Tensorflow, and through this, a first step learning model (baseline) for 13 building elements was established.

Figure 4. MVCNN architecture

3.5 CRF-RNN+MVCNN Implementation

Figure 5 shows the second step MVCNN model learning process using images with improved clarity by applying semantic segmentation. In this step, the MVCNN model was trained after applying the CRF-RNN algorithm so that the model can focus on the shape of the element by clearly dividing the region where the element exists. In this process, CRF-RNN was applied using python-based Keras, and a CRF-RNN+MVCNN model was built through the above-mentioned series of processes.

Figure 5. CRF-RNN + MVCNN architecture

4 Results

Table 5 and Figure 6 below show the results of the MVCNN model validation based on the verification data presented in section 3.3. As a result of verification, the MVCNN model was confirmed to recognize and classify elements in the actual BIM model with an accuracy of 91.01%. However, in the case of slab, covering, and stair flight elements, the classification accuracy were notably

lower than that of other elements.

Table 5. Validation results (MVCNN)

Element	Precision	Recall	F1 score	Accuracy (%)
Beam	0.86	0.99	0.92	99.39
Column	1.00	0.99	0.99	98.83
Slab	0.77	0.33	0.46	32.79
Wall	0.99	0.94	0.96	93.51
Window	-	-	-	-
Stair flight	0.88	0.79	0.83	78.95
Member	-	-	-	-
Railing	1.00	0.92	0.96	91.67

Covering	0.11	0.83	0.20	83.33
Single door	1.00	1.00	1.00	100.00
Double door	1.00	1.00	1.00	100.00
Revolving door	-	-	-	-
Total	0.78	0.87	0.83	91.01

Figure 4. Precision-recall curve (MVCNN)

Table 6 and Figure 7 show the results of the CRF-RNN+MVCNN model verification. This hybrid model recognized and classified elements in the actual BIM model with high accuracy of 95.38% and achieved overall accuracy of over 90%. The model has difficulty for slab elements, with an accuracy of 68.85%. Yet, it still retained a higher classification accuracy compared to the standalone MVCNN model.

Table 6. Validation results (CRF-RNN + MVCNN)

Element	Precision	Recall	F1 score	Accuracy (%)
Beam	0.94	1.00	0.97	100.00
Column	0.99	0.99	0.99	99.42
Slab	0.88	0.69	0.77	68.85

Wall	1.00	0.96	0.98	96.10
Window	-	-	-	-

5 Discussion

5.1 Discussion of the Results

The ACC values of the previously presented MVCNN and CRF-RNN models were 91.01% and 95.38%, respectively, and the F_1 scores were 0.83 and 0.88, respectively. Through this, when CRF-RNN-based semantic segmentation was applied to the MVCNN learning process, the ACC improved by 4.37% and the F_1 score improved by 0.05, so it was possible to confirm that applying semantic segmentation improved MVCNN's ability to classifying the BIM elements.

The 4.37% improvement is meaningful as the increase in accuracy resulted from specific elements that MVCNN by itself had trouble in distinguishing correctly. As shown in the confusion matrix (Table 7), the slab element, which was previously misclassified as either covering or beam, was classified properly, resulting in a significant ACC improvement. Moreover, the classification accuracy of elements with complex geometric features such as stair flight, railing, and curtain wall also increased. Thus, employing CRF-RNN to sharpen images was conducive to enhancing MVCNN's most relevant shortcomings.

Table 7. Confusion matrix of delta values between MVCNN and CRF-RNN+ MVCNN

Predicted \ Actual	Beam	Column	Slab	Wall	Window	Stair flight	Member	Railing	Curtain wall	Covering	Single door	Double door	Revolving door	Total

5.2 Limitations

Although applying CRF-RNN-based semantic segmentation improved the classification accuracy, for elements of similar shapes, namely slabs and covering elements, were still misclassified. This is because many of the two elements are indistinguishable in their shape, apart from their thickness. So, it is difficult to distinguish them due to the characteristics of the MVCNN model, which considers only geometric shapes in the training process. When considering the two elements as a single type, the classification accuracy of the CRF-RNN+MVCNN model increases to 98.22%. The higher value indicates that our model performs is competent in distinguishing geometric features of individual elements. Nevertheless, from a practical point of view, it is necessary to recognize slab and covering as separate elements when verifying the semantic integrity of architectural BIM models, thus improving this limitation is planned by adding additional attribute variables or utilizing relational information in conjunction with the learning process in the future.

6 Conclusion

This study aimed to construct a BIM element classifier using a 3D geometric deep learning algorithm and improve its performance by increasing the definition of individual images using semantic segmentation.

ArchShapesNet, an expanded data set, was constructed by applying parametric modeling-based data augmentation so that learning for each element class was sufficiently performed, and CRF-RNN-based semantic segmentation was applied to properly reflect the geometric features of the BIM element in the learning process. As a result, the ACC of the MVCNN model applying CRF-RNN prior to the learning process was found to be high at 95.38%, which is a 4.37% improvement in ACC compared to the baseline MVCNN model. In detail, the classification accuracy of slab and elements with complex geometry was increased, and

through this, it was confirmed that the application of CRF-RNN improved MVCNN performance. However, there was a limitation in that it was not possible to distinguish similar geometric shapes (slab and covering). Future works will be conducted to solve this issue through model training using additional property variables or relational information between elements that can distinguish between the two elements.

Despite the limitation and future work, the results of this study are then encouraging as the test was performed on an entirely separate BIM model that was not used in the training. Whereas, existing studies conducted testing using a designated portion of the dataset, this study was more stringent in using a BIM model previously not seen by the deep learning models. ACC's of 95.38% suggests that our model can be deployed to classify and check the classifications of newly created architectural BIM models, albeit it be for 13 elements trained in this study.

Abstract

Building design processes usually follow similar workflows with different stakeholders and interdisciplinary design teams incorporating their individual domain knowledge. To improve the holistic performance of building designs considering economic and environmental qualities, design decisions based on simulations and analysis in early phases have a significant impact on the resultant design.

In this context, first, the advantages and limitations of the current approaches are analyzed with the help of a systematic literature review. Then, a framework for optimizing building designs is developed using Building Information Modelling (BIM) as a main source of truth for a multicriterial analysis. The framework compares multicriterial variants to support decisions during the early design stages, including the selection process and feedback communications of design changes. For a holistic variant comparison, several criteria are considered, with the main focus on life cycle assessment (LCA).

Keywords –

BIM, early design, design decision support, LCA, multicriterial optimization

1 Introduction

In modern societies, the built environment is essential in many ways. For example, the real estate industry is not only an important economic sector with 10% of the gross value added but is also responsible for 42% of the final energy consumption, 35% of the greenhouse gas emissions [1]. In order to improve the ecological impact of a building, life cycle assessments (LCA) are used to calculate the environmental impact along the entire life cycle of the building (embodied energy + operational energy). Up to now, these calculations have been carried out manually to a large extent, which is time-consuming on the one hand. On the other hand, the complete depth of information is only sufficiently available in the late

planning phases. This leads to the fact that optimization potentials in the early design phases cannot be used so far [2]. With the introduction and development of new digital methods, such as Building Information Modelling (BIM), and uniform data standards for building models, technologies are available to the construction industry to optimize these LCA calculations. During the BIM process, a semantic data model is created during the planning phase, which provides all current information in digital form for all project participants and the building's entire life cycle. It makes sense to use this already bundled data for such a calculation of the LCA and thus to design the process efficiently.

Building design processes usually follow similar workflows with different stakeholders and interdisciplinary design teams incorporating their individual domain knowledge. Nevertheless, each building project is unique in its context, as national regulations, building owners, and the composition of design teams vary often. This means that design decisions differ from each project while the dependencies and relationships of their consequences in design quality remain the same. For example, decreasing the investment costs of a design may negatively influence the operational costs and environmental impact of the building. Therefore, a holistic consideration of several design qualities must be taken into account during the design decision process.

This paper aims to enable the holistic performance of building designs considering economic and environmental qualities by a model-based design decision approach based on simulations and analysis in early phases. After analyzing existing approaches, a robust framework is proposed based on the findings of the literature review.

2 Background and Related Work

To improve the holistic performance of building designs considering economic and environmental qualities, simulations and analysis in early design stages have a significant impact on the resultant design [3]. At

the same time, the effort and cost of changing the design at these stages are relatively low. During the design process, several disciplines exchange different design information necessary for their specific needs, such as materials of construction elements for structural engineers or U-values for energy efficiency analysis. In this context, Building Information Modelling (BIM) is used as a main source of truth for a multicriterial analysis, while simulation-based on BIM helps the decision-making process in early design stages [4]. BIM facilitates the evaluation of design variants based on the same baseline design to optimize the different qualities of the building design, such as costs or environmental impacts [5].

Nevertheless, in conventional projects in practice, the main focus is still on the economic performance of buildings, while environmental qualities are not widely spread yet. This is the reason to approach the holistic multicriterial variant analysis, in the early design stages, based on existing approaches of BIM-integration strategies for LCA. Current approaches still have limits of fully automated workflow with open BIM models [6]. The main scope of this paper is focusing on the early design phases. To support the decisions at these phases, detailing decisions from more detailed phases are additionally analyzed. Based on the current approaches in the literature analysis, the findings are considered to further extend the approach in the sense of a holistic analysis that is adaptable for further criteria, for example Life Cycle Costs (LCC) or similar.

3 Literature Analysis

To analyze existing methods and identify their missing aspects in context of multicriterial variants using BIM in early design stages, a specific literature analysis is carried out.

3.1 Existing literature reviews

To avoid conducting similar literature reviews, existing ones are first analyzed considering their focus. While the research field of BIM-based simulation of operational energy in early design stages has been ongoing for more than ten years [7], the focus on real-time feedback, e.g., by Machine-Learning-based prediction [8], is getting more important. In the following, the focus is more on the multicriterial analysis, for example, a combination of embodied and operational energy or LCC.

Soust-Verdaguer et al. analyzed eleven papers from 2013-2015 in a structured literature review of the BIM-based LCA method and differentiated between Data input (BIM-LOD, LCA goal & scope, stages, and inventory), Data analysis (BIM software, Energy Consumption Calculation, LCA tool) and Outputs and

communication of results (Environmental impact indicators, sensitivity analysis, embodied and operational CO2 emissions) [9]. Wastiels and Decuyper identified and compared five general different strategies on how to integrate BIM and LCA [10]. These five strategies contain the export of Bill of quantities, import of IFC surfaces, a BIM viewer for linking LCA profiles, an LCA plugin for BIM-software as well as LCA enriched BIM objects. Based on these findings, Potrč Obrecht et al.'s recent literature review is comparing more update approaches and classified them according to these five strategies [11]. Additionally, they divide each of them between manual, semi-automated and automated approaches which gives a holistic overview of the current state of approaches. Nevertheless, this literature review does not focus on the adaption of each approach for multicriterial variant analysis. Cavalliere et al. showed in their literature review the combination of BIM and parametric-based tools for LCA calculation, considering 25 publications between 2013 and 2018 [12]. Parametric-based LCA (PLCA) was first developed for the first time in 2016 by Hollberg et al. and entirely based on Visual Programming Language (VPL), in their case Rhino and Grasshopper, while no BIM-integration was considered [13]. Finally, Llatas et al. include in their systematic review also LCC and social LCA (sLCA) besides LCA and develop their own methodological approach based on their findings [14]. They generally reviewed 36 publications based on the integration of BIM and LCA, while just six approaches included both LCA and LCC, and none included sLCA.

3.2 Classification of literature analysis

Based on the classification and findings of existing literature reviews, a new systematic literature review was started in the field of BIM-based LCA in this paper. In total, 59 recent papers were reviewed, of which 25 from the years 2018-2021 were connected to the integration process of the BIM method for LCA calculations. Besides the described existing literature reviews, some papers have a deeper focus on specific subtopics, like visualization of LCA results, feedback communication into the BIM authoring tool, or LCA benchmarks and databases. To better overview and understand the advantages and disadvantages of the different approaches, a selection of 25 papers was investigated in more detail. A classification was established for better comparison and evaluation. The classification criteria are grouped as following (Table 1):

Table 2 Classification groups of literature analysis

Group	Subgroup	Classification
BIM	Design	Early Phase
	stage	Detailed Phase

	Data exchange	Parametric (VPL)
		LOD
		IFC
		gbXML
		IDM/ BPMN
BIM-LCA integration	Integration strategy	ER/ MVD
		Bill of Quantities
		IFC-Import
		BIM-Viewer – LCA-Profiles
		LCA-Plugin
LCA	Feedback	Enriched BIM objects
		Feedback communication
	LCA Scope	Embodied Energy of Building Construction
		Embodied Energy of MEP/ HVAC
		LCA, including Operational Energy
	LCA Inputs/ Goals	LCA including LCC
		LCA Phases
		Functional Unit
		Case study
		Vagueness/ uncertainty
		Environmental impact categories
		Database

3.3 Findings

After evaluating the different approaches, it turns out that several are mainly focusing on the detailed design stages and do not have their focus on early design stages [5, 15, 16]. This fact does not support the optimization of building design when information is uncertain or missing. Rezaei et al. are suggesting a LCA-workflow for early design stages based on Autodesk Revit, but including an optimization process or other criteria [17].

For the exchange of the BIM models, there are different strategies. Most of the evaluated approaches use the open BIM format, Industry Foundation Class (IFC). In contrast, some use Green Building Extensible Markup Language (gbXML) as an exchange format when considering operational energy [18], others seem to use closed BIM, such as Autodesk Revit [19, 20] or Revit in combination with Autodesk Dynamo [21–25]. Other use VPL like McNeel Rhino and Grasshopper [13, 26, 27] or 3D modeling tools like Trimble SketchUp [28].

For the integration strategy of LCA into BIM workflow, the classification of five different strategies from [10] was investigated. As a finding, two main

approaches are mainly implemented in the investigated approaches. While most approaches using authoring tools use the Bill-of-Quantities integration approach, which was already the tendency of [11], those using IFC for data exchange often enrich BIM objects using Property Sets (PSets) [5, 15, 29]. Lee et al. suggest a new approach giving a BIM template for authoring tools to avoid interface problems [30]. A few also use existing LCA-Plugins in Revit, such as Tally, eToolLCD or One Click LCA [18, 31–34]. Nevertheless, there are mainly two approaches that include a computer-readable feedback communication of the results back into the BIM model, so not just using the model for a down-streaming approach [35].

As this paper focuses on multicriterial design optimization, life cycle assessment of the building construction is not the only criteria, although all analysed approaches include it as a minimum. Kiamili just puts the focus on embodied energy of HVAC systems [22], while others include both embodied energy of building construction and HVAC [16, 26]. Other approaches even include embodied energy of building construction, HVAC as well as operational energy [18, 19, 36]. Another criterium which is relevant to consider next to LCA are Life Cycle Costs (LCC), which are also considered in some approaches [5, 15, 19]. In conclusion, no approach enables an integration of all criteria LCA for building construction and MEP systems, operational energy as well as LCC.

Finally, almost all approaches consider the whole building as a functional unit. But just a few also consider uncertainties [26]. Furthermore, most of the approaches include as environmental impact category Global Warming Potential (GWP), some are not only focusing on CO₂-emission but even consider several more impact categories such as Ozone Depletion Potential (ODP), Photochemical Creation Potential (POCP), Acidification Potential (ADP), Eutrophication Potential (EP) and more [5, 28, 29, 32, 37]. Many different international databases were used, while the German Ökobaudat, ecoinvent and KBOB from Switzerland and product-specific Environmental Product Declarations (EPD) are the most common.

The literature analysis shows a significant potential for multi-criterial optimization in early design stages using BIM models, especially with IFC data. As well, a sufficient representation of a simplified calculation of embodied energy of HVAC is missing as usually it is generalized by 20% of the construction emissions according to the LCA calculation methodology of DGNB [38]. In addition, most approaches consider only one criterion (due to the chosen focus mainly LCA) for optimization using BIM. At the same time, the potential is the simultaneous comparison of costs and environmental impacts with real-time feedback. This

shows the potential for further research on integrating several criteria in one holistic building optimization methodology using open BIM format. Having that in mind, an automated mapping of LCA and IFC data on component level is not developed or solved yet [39].

4 Proposed Methodology

The aim of this paper is to develop a framework for optimizing building designs based on component-specific design variants to support decision-making with the help of multicriterial analyses in early design phases. Necessary information for simulations is based on the same consistent variants and can be executed simultaneously. Furthermore, multiple optimization criteria are considered, while the main focus stays on life cycle assessment (LCA). In more detail, first, the advantages and limitations of the current approaches are analysed with the help of a systematic literature review. Then, a new methodology that facilitates a multicriterial variant comparison and feedback communication of design changes is developed. For a holistic variant comparison, several criteria, including embodied energy, operational energy as well as capital and operational costs, are selected.

The methodological approach shall include open BIM data exchange in early design stages, multicriterial variant analysis (primarily environmental and economic impacts of construction, operation, and End-of-Life phase of buildings), as well as an automated mapping of relevant information from the model. Therefore a robust implementation should take different modeling approaches (planers & software products) into consideration. Furthermore, adding individual cost benchmarks and EPDs (Environmental Product Declarations) shall be addable in a later stage. First drafts of the conceptual and methodological developments are shown in the following.

4.1 General Framework

To perform these criteria, engineers require a set of information to be present in the model. However, typically, a lot of information is still missing or uncertain in the early design stages, which influences the

conducted simulations and analysis results. Therefore, a standard component database that couples all relevant information for the LCA calculation and other criteria, which is subsequently mapped to the corresponding building component, is developed. The database can support exploring the different variants when any information, such as elements or properties, is missing or uncertain by offering a set of possible options or range of values. Accordingly, the performance of the different design variants can be evaluated according to the influence of the incorporated uncertainties on the economic and environmental qualities. In the end, the selected design changes are communicated back to the BIM authoring software to implement them in the design. The proposed methodology leverages the open BIM standards, the Industry Foundation Class (IFC), and model view definitions (MVD) for the exchange of building models and the specification of simulation requirements.

In the first stage, a robust methodology is presented in theory (Figure 1), which already considers all the mentioned work packages. It consists of a use case selection process before the planning starts. This defines which use cases and analysis types should be calculated later on. Necessary exchange requirements are handed over to the planers/ BIM modelers. The next step includes mapping the relevant IFC data to a standard component database (also see Figure 2). In the following steps, different criteria, such as Embodied Carbon (LCA) and others are automated calculated. In the last step, the results are visualized, and design variants are compared for better decision support, including relevant benchmarks. When the final configuration of variants is chosen, the changes of the selected variants are communicated backward as feedback for the planer or BIM modeler.

4.2 Standard Component Database

The standard component database, based on components, elements, layers and materials, shall contain all information, which are relevant for holistic calculation of different criteria and missing in the IFC model. The systematic of the standard component database contains

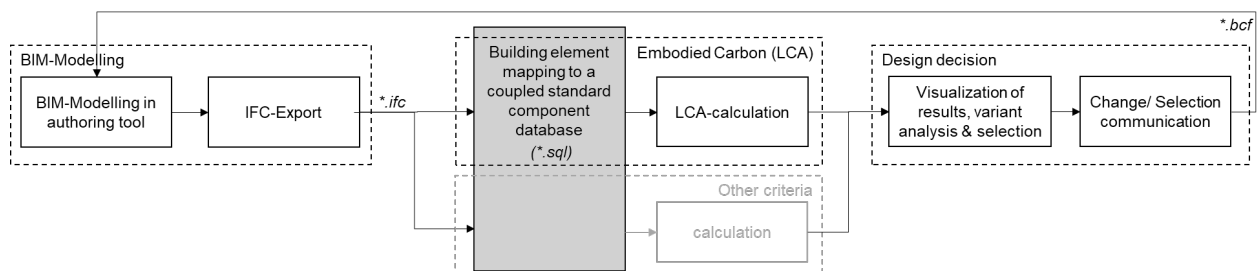

Figure 1: General Framework of the proposed methodology with the focus on LCA

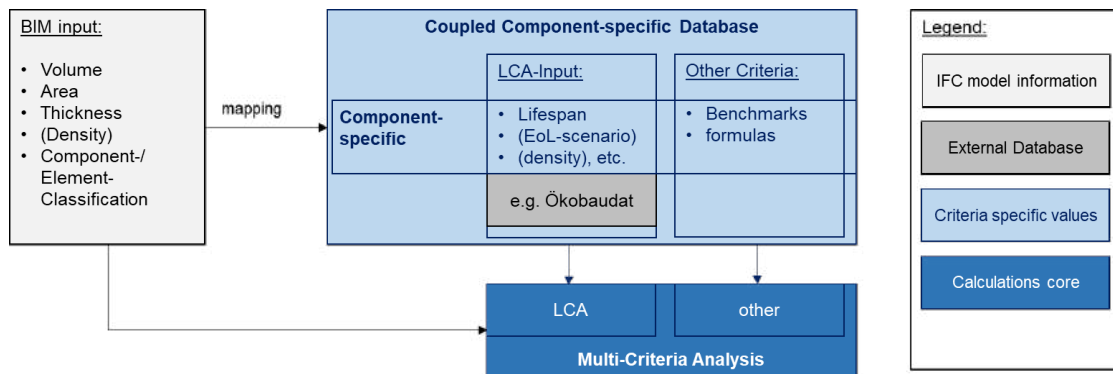

Figure 2. General Strategy for a standard component database for multi-criterial variant analysis

a link with different external databases for example for environmental criteria (Ökobaudat, etc.) (Figure 2). One challenge is to provide all necessary input information for a holistic and correct calculation and analysis, which might be missing in an early BIM model or the IFC schemata. Another challenge is to combine the external databases with different input information representing the domain knowledge of multiple criteria analysis. International databases can be added to the database using this methodology as well as material/product-specific Environmental Product Declarations (EPD) can be linked, too.

The component database provides on a material or component level additional information necessary for a sufficient calculation, like the lifespan of a component, End-of-Life scenarios if missing in the dataset, or densities if missing in the BIM model. The database itself is structured similar to the German Cost Grouping DIN 276 on the third level but provides a material-specific level of different component layers. Different combination possibilities of material layers for each building component are referenced for the variant selection process. By this one, the one-hand side domain knowledge can be represented, and on the other side,

deviations of the materials consider semantical uncertainties in the early design phase. Other criteria information like cost values or U-values (if missing in the model) for calculating operational energy are stored on the material level of the standard component database as well. This ensures that a change of the variants leads to a change in all criteria calculations and shows the complex dependencies of the multi-criterial design decision process.

4.3 Automated Mapping Method

The automated mapping is necessary to avoid time-consuming manual mapping of the BIM components with its correlating components from the database for correct analysis and calculation. The challenge is to correctly map them and find a robust workflow that considers multiple ways of modeling and exporting the BIM model with IFC. The proposed method includes several steps (Figure 3). At first, IFC data are classified using their IFC class types (e.g., ifcWall/ isExternal, etc.). These classifications lead to different groups of standard components in the database, which is oriented to the German norm of cost groupings (DIN 276). According to the German cost grouping (CG) schema, there are two

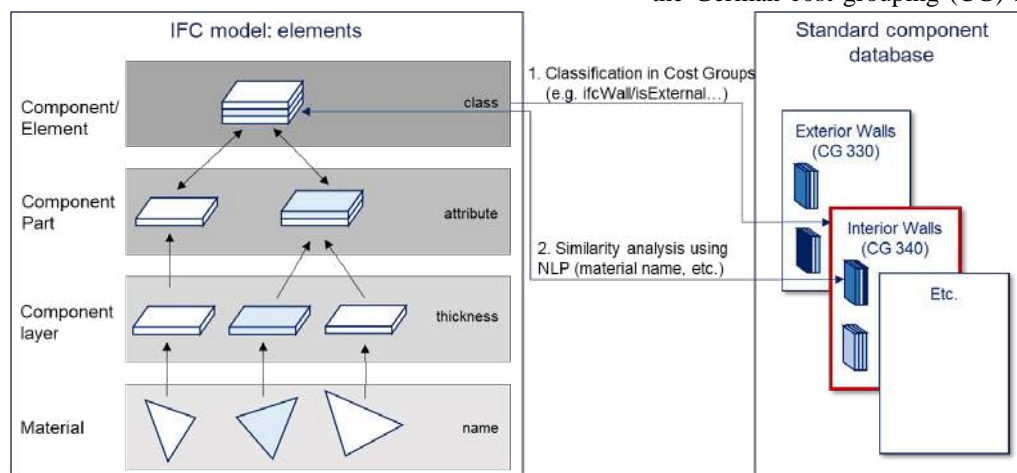

Figure 3. Proposed steps for an automated mapping method of IFC models and the standard component database

options to guarantee a correct classification of all components according to German cost grouping (CG) schema: either it can be defined according to a specific categorization of IFC exchange requirements, or it needs to be automatically clustered algorithmically. In some use cases in Germany, a CG classification already occurs so that it can be used as a byproduct for this framework. If this is not the case, an algorithm can help to cluster relevant components and elements based on their IFC class types automatically to the CG classification to ensure the first step of the automated mapping method with the standard component database.

In a second level, the modeled component layers with their material attributes are mapped to an environmental dataset of the used database. In late design stages, conventional mapping methods usually have a manually mapped UUID for each IFC material from existing databases, like Ökobaumat, as an attribute [16]. Another approach by Georg Reitschmidt follows also automated mapping on material level [40]. In a first step, material names of IFC are tokenized, while every token is searched in the environmental dataset of Ökobaumat resulting in a hit list. In a second step, the listed hit with the smallest the Levenshtein-Distance is chosen as the mapped dataset, if it fulfills a certain threshold to ensure a correct result. All these approaches expect, that all necessary information of all LCA-relevant component layer is modelled which is usually in detailed design stages the case.

In early design phases, information about material layers and their combinations are approximate or missing. An approach for gradually deciding on a specific material value is by defining a material group (according to existing classification system) and evaluate the individual materials within each group [41]. Therefore, instead of checking the similarity between textual words (the same as Reitschmidt 2015) or manually mapping them to existing materials, we propose employing Natural Language Processing (NLP) techniques to measure the “semantic similarity” between materials. Measuring the semantic similarity involves converting the text of every material type to a vector representation (A vector is a list of numerical values, where the combination of them represents the overall meaning) [42]. Afterwards, the similarity between vectors can be measured using the cosine similarity. Accordingly, the similarity of Brick to Terracotta is expected to be higher than the similarity to Concrete or Glass. Measuring the similarity between the numeric vectors has performed remarkably well in different domains [43]. A promising implementation of the state of the art in the field of NLP is the pre-trained neural network model spaCy [44], which represents every word with a vector of 300 dimensions and includes 685k unique vectors in its corpus. In this regard, we will evaluate and extend the

existing model provided by spaCy to deliver an automatic mapping of material layers and evaluate the proposed methodology.

5 Conclusion & Future Work

With the help of a systematic literature review, the key potentials and limitations of current approaches of BIM-based LCA in early design phases were investigated, such as multi-criterial analysis based on open BIM format for holistic building optimization. A new adapted methodology based on open BIM format and a standard component database was proposed based on these findings. The component database is flexible to extend for several criteria like LCC and embodied as well as operational energy and contains missing detailed information of early BIM models based on domain knowledge. For an automated mapping, two different steps were suggested. The first one is to classify each component according to German cost grouping, either manually as an exchange requirement or algorithmically. In a second step, similarity analysis of layers and materials helps to identify the BIM component in the component database automatically with the help of NLP.

As future work, this theoretical approach needs to be validated with a real-life case study. Therefore, the different steps need to be implemented prototypically and tested with several IFC models for validating the robustness. Also, the mentioned standard component database needs to be implemented and validated for further research. Another focus will be on the design decision process. On the one hand side, an intuitive visualization of the results and variant comparison helps for the selection process. On the other hand, the selected variants and changes need to be communicated back to the BIM modeler with a computer-readable interface to the authoring tool.

Abstract

Virtual reality (VR) has been widely applied in the construction industry, enabling users to view unfinished buildings in an immersive virtual environment. A game engine can be used to create a virtual environment with parametric characteristics from building information modeling (BIM), enabling the BIM parameters to be presented in the VR environment. This study integrated VR with BIM to facilitate modifications to an apartment. A cost estimation system for modifications was established. The proposed system can provide customers with a first-person view of possible design changes to a home, minimizing discrepancies in seller–customer perceptions. Costs for customer modifications are calculated in real time using the database and the unit price database.

Keywords –

Building Information Modeling; Virtual Reality; Cost Estimation; Presold Home Customization.

1 Introduction

In recent years, virtual reality (VR) has been widely applied in the construction industry, enabling users to view unfinished buildings in an immersive virtual environment. The use of a game engine (Unity 3D) as a development platform for creating a virtual environment [1,2,3,4] in conjunction with parametric characteristics of building information modeling (BIM) enables the parameters of building components to be presented in the VR environment. In this study, VR was integrated with BIM to facilitate modifications to an apartment. Through the combination of VR and BIM, a cost estimation model for modifications was established. The proposed model can provide customers with a first-person view of possible design changes to a home, minimizing discrepancies in seller–customer perceptions. Moreover, the proposed model shortens the time required for

calculation of change cost in traditional changing process.

2 Literature Review

2.1 Integration of BIM with VR

A BIM system contains all relevant construction data and can thus be used as a VR resource. System efficiency can be enhanced through program compilation. BIM and VR systems can be combined for design evaluation, discussion, construction, and safety evaluation and can reduce rework and improve safety [5,6,7].

2.2 Application of VR in Change Orders

Davidson et. al. [2] incorporated a BIM system into Enscape [8], which subsequently enabled them to promptly update and display the interior furnishing and design. Data from a BIM system can be used to instantly display the costs associated with design changes.

Amed et. al. [3] established a new order process to enable clients to view modified building designs through VR and augmented reality. However, in this study, changes in cost caused by modifications to the structure could not be viewed.

3 Cost Estimation Model for Changing Orders Combining BIM and VR

3.1 Establishment of BIM System

Before a constructed BIM system is imported into the VR environment for cost estimation, it must be equipped with quantity (i.e., total area) data. The following sections detail the establishment of the model and the data importation.

3.1.1 Establishment of the Model

A BIM system includes basic elements such as pillars,

beams, floors, walls, and ceilings. In addition, in consideration of the following discussion on quantity in decoration, the decorative elements must be established to acquire the calculation parameters.

3.1.2 Addition of BIM Data

To acquire the necessary quantity parameters from the decorative elements, information such as the decoration material and unit price and cost must be included in the “entity parameters” of the decorative elements. Elements involving structural changes must be marked in the “Note” field in order to facilitate the calculation of costs associated with the structural changes and decorative materials added to the VR environment.

3.2 Establishment of the VR Environment

The importation of a BIM system into the game engine in an FBX (Filmbox) file format results in the loss of render data; therefore, the system must be rerendered in the Unity game engine [9]. Additionally, a BIM system does not include interior lighting; hence, skylight must be added manually with Unity before the light mapping calculations. Realistic lighting can thus be generated in the virtual environment, and the VR system can still perform efficiently.

3.3 Extraction of Data and Derivation of Formulas to Calculate Construction Quantity

After the connection of the BIM database to the game engine, the program can extract data from the database and create formulas for quantity calculation. Data for and quantity of each element in the virtual environment can be viewed.

3.3.1 Extraction of BIM Data

To enable instant viewing of BIM data in the VR environment, a database can be connected to the game engine after the addition of BIM data to the database. Thus, the parameters of each element in the VR environment can be dynamically accessed either upon the client's request or for quantity calculation in the system (Figure 1).

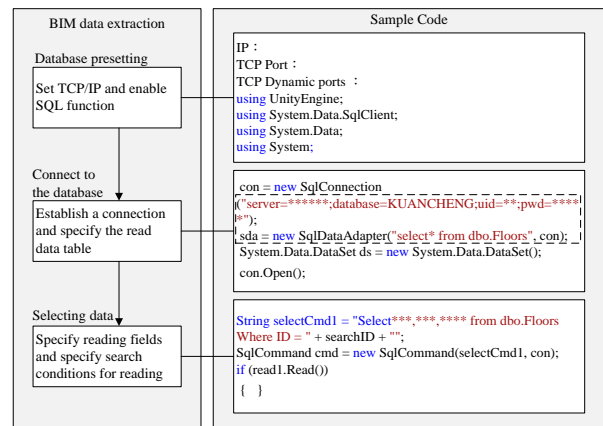

Figure 1. Structural diagram of data extraction

3.3.2 Calculation of Quantity in VR

Quantity calculations can be conducted in the VR environment by using BIM data. The database can be called according to specific requirements (such as the same ID of the component), and the parameters necessary for the element quantity calculations can be accessed when the data match the requirements. Finally, quantities can be calculated, and the results can be displayed in the VR environment.

3.4 Selection of Different Materials

The client can select alternative materials from a materials menu in the VR environment. Items in the materials menu must correspond to the materials data stored in the database, and each material can be selected from the list and applied with a single click. Hence, the client can immediately view the results of the application of the selected material. Through this method, the client and designer can reach a consensus regarding the changed elements.

3.5 Evaluation and Comparison of VR Cost Environments

A database is applied to determine unit prices. In addition, the study system uses a BIM database for the quantity data. These databases are consulted in tandem to calculate the cost of the changes. The unit price database can be based on the company's internal historical unit price database. Generally speaking, the content of the unit price database is an XML format file. Nevertheless, MS Excel can still be used for editing when the data in the database needs to be added or changed.

4 Case Study

4.1 Case Introduction

A residential building constructed in central Taiwan was used to test the system. The building has six apartments on each floor; one was selected for testing. The decorative materials and structure of the space were modified according to the client's preferences to investigate the feasibility of the proposed system. The building is depicted in Figure 2.

Figure 2. Case study model

4.2 Establishment of the BIM System

The BIM system was used to select decorative elements and to identify data required for the quantity calculations. Details are as follows.

4.2.1 Establishment of the System

Revit was used to establish the BIM system including basic elements such as pillars, beams, floors, walls, and ceilings. In addition, a new layer of decorative elements was added to the final structure of each element, as presented in Figure 3.

Figure 3. Placement of decorative elements

4.2.2 Addition of the BIM Data

“Project Parameters” comprised decorative elements; each element contained three entries as the entity parameters: decorative material, unit price, and cost. Parameter data (the name and unit price of the decorative material) were displayed by clicking on each element. For example, the decorative element “composite laminated wooden flooring” comprised the data on the floor decoration material field, whereas “1,000” (i.e., NT\$1000) was entered in the unit price field. In addition, in accordance with the client's preference to reduce the living room space, the word “changed” was entered in the “Note” field for the two walls associated with the modification. This note was a reference for later confirmation of changes in the structure.

4.3 Establishment of the VR Environment

After the BIM system was imported into the game engine, materials and light sources were added to the system. In the properties panel of the rendered model, the object was set to “Lightmap Static,” and all the light sources were set to “Mixed Lighting.” After baking, the baked lights used concurrently with instant lights were judged to create a more authentic virtual environment.

4.4 Extraction of Data and Derivation of Formulas for Calculating Construction Quantity

The element ID was used to look up data for each element as well as to calculate quantities by using the data.

4.4.1 Extraction of BIM Data

After the information from the database (shown as Figure 4) was connected with the program, the ID of each element was used to look up the data for the element and extract the parameters required for calculations of each object. For example, if the client desires to paint a wall, the decorative material, the unit price, and the number of walls would be used to calculate the total cost of the modification. For structural changes, the system automatically searches for elements with a “Note” field marked “changed.” The system can extract the “range” parameters from these elements to the database.

Figure 4. Information from the database

4.4.2 Calculation of Quantity in VR

For the quantity calculations, the element ID and the element data from the necessary fields were first extracted. The calculation formula for each object (such as wall painting, flooring, doors and windows) was then derived. For modifications to the walls, floors, or structure, “range” parameters (means the area of the room) were used as the quantity data. Thus, the quantity of each element could be displayed in VR (Figure 5). Moreover, for structural changes, “range” parameters for walls were added to the elements marked as “changed,” and the total quantity after the living room structure modifications could be viewed in VR and was 1.2 m².

Figure 5. Parameter extraction and quantity calculation

4.5 Selection of Different Materials

In the test case, the client intended to change the living room floor material from “composite laminated wooden flooring” to “polished butter-colored marble flooring.” To change the living room floor in the VR environment, the user must simply click to open the material list (Figure 6) and select “polished butter-colored marble flooring” as the new material.

Figure 6. Replacement with material list

4.6 Evaluation and Comparison of VR Cost Environments

After changing the material and structure, the user could view the changed pattern and cost. As displayed in Figure 7, changing the living room floor from “composite laminated wooden flooring” (NT\$1,000 per unit) to “polished butter-colored marble flooring” (NT\$900 per unit) reduced the cost from NT\$14,202 to NT\$12,780. In addition, structural changes made by the client increased the space of the second bedroom, whereas the space of the living room was decreased. Due to the application of the lightweight drywall partition system (NT\$4,000 per unit), the additional cost of the modification was NT\$4,800. The calculation was the result of multiplying the quantity (1.2 m²) by NT\$4,000. Because the program could instantly display the modified pattern and the cost of the modifications, the client could immediately make comparisons and receive advice regarding the decisions.

Figure 7. Instant feedback regarding modification costs

4.7 Record of changes

The system used in the test case enabled the client to understand the modified pattern and difference in cost due to the instant changes displayed by the system. Data regarding the changes were also recorded in a text file.

The client and the construction company could use the recorded data to discuss further changes. The record of changes is displayed in Figure 8.

5 Conclusion and Future research

5.1 Conclusion

This study proposes a cost evaluation system for building changes that combines BIM with VR. The system facilitates client modifications to both the decoration and structure of the house, in addition to estimating the costs of these changes. No previous work has proposed a system that can achieve all three of these capabilities. The client can also immediately review the changes in an immersive VR environment. Overall, the following two key achievements were obtained.

1. Use of VR to display the modified design

Easy material changes by using the developed application provides the user with multiple materials (such as wood floor, stone, or tile) to select from; the user can then easily add other decorative materials on the basis of their preferences. In addition, the virtual environment enables instant viewing of the modified design and comparisons between multiple options. Thus, the client can discuss their opinions with the designer efficiently.

2. Accelerating cost calculation for change orders

The calculation formulas in the system enable automatic calculation of element quantities and the total bill of quantities made to design elements. The client can thus immediately see the cost of the changes. Furthermore, each modification, cost variation, and total cost of changes can be recorded, and after making changes to the system, the user can provide a record to the client and the construction company when deciding whether to apply the changes. The calculation process can thus be shortened compared with the conventional calculation process.

5.2 Future Research

This study did not consider the situation of multiple users watching in the same virtual reality environment. The benefits of the discussion should be increased if designers, construction companies, customers and other parties can discuss in the same virtual reality environment at the same time. Therefore, follow-up research can take multi-person collaboration technology into consideration.

Abstract –

4D simulation can be used in the planning phase of a project for constructability analysis, which aims to optimize construction processes and improve safety management. The same 4D simulation can be used as a digital twin in the construction phase for progress monitoring and identifying potential safety issues based on micro-schedules. A micro-schedule is a schedule listing tasks of short durations (i.e., days or hours) with the information of the resources assigned to each task (i.e., workers, equipment and materials). The site data can be collected using Computer Vision (CV) or Real-Time Location Systems (RTLS) to identify and recognize the activities of construction resources, as well as to capture the progress of the project. This paper aims to explore the possibility of developing near real-time digital twins of construction sites. The digital twin is developed as a high Level of Development (LOD) 4D Simulation based on CV and RTLS data. A case study is performed to investigate the proposed method.

Keywords –

1. **Digital Twins; 4D Simulation; Computer Vision; RTLS**

Introduction

4D simulation through Building Information Modeling (BIM) is now widely applied and has been proved to be beneficial throughout the lifecycle of construction projects [3]. According to the results of the survey conducted by Jones and Laquidara-Carr [12], performing 4D simulation can result in reducing project cost by at least 5%. 4D simulation can be used in the planning phase of a project for constructability analysis, which aims to optimize construction processes and improve safety management [6,7,10,15,17,18,25]. The required Level of Development (LOD) of 4D simulation for different purposes are different [2,8,9]. Guevremont and Hammad [9] proposed a guideline for defining 4D-

LOD for the construction project simulation based on the requirements. When more details are required, high LODs are required for both the 3D BIM model and the schedule. The highest LOD is required for proximity detection requiring in order to track the equipment movement and their workspaces.

The 4D simulation can be used as a digital twin in the construction phase for progress monitoring and identifying potential safety issues based on micro-schedules. A micro-schedule is a schedule listing tasks of short durations (i.e., days or hours) with the information of the resources assigned to each task (i.e., workers, equipment and materials). A digital twin refers to a digitization technology that integrates cyber space with physical space [1,7,23]. Grieves [7] has defined the digital twin in manufacturing, which has three parts: (a) physical objects in real space, (b) virtual model in virtual space, and (c) connections between virtual space and real space. In a digital twin model, raw data collected from the real world are processed to reveal the reality in the virtual space. Then, further processing is performed to extract useful information for improving the management of the real space. The implementation of the digital twin emerged in the manufacturing industry and became popular as one of the most important technologies toward Industry 4.0. In addition, with the emerging technologies (e.g., IoT, CV, BIM, Big Data), the digital twin becomes applicable in the construction sector [1,14]. In order to improve construction project management, previous researchers have established frameworks of generating digital twins by integrating BIM with other technologies [19,20,21]. The site data can be collected using Computer Vision (CV) or Real-Time Location Systems (RTLS) to identify and recognize the activities of construction resources, as well as to capture the progress of the project.

CV-based activity recognition of resources, such as workers or equipment, is gaining a lot of interest among researchers [5,16,22,24]. Activity recognition can be used for different purposes such as health, safety,

productivity analysis, or workspace planning. There are two main challenges for monitoring the progress of construction projects using CV-based methods. The first challenge is the dynamic environment of construction sites, along with the existence of numerous types of equipment and their associated activities. The research in this area has been mainly focused on detecting the activity of workers [24] or a single type of equipment such as excavators (e.g. [5]), with works addressing more than one type of equipment only emerging recently [13]. The second challenge is that CV methods suffer from light conditions and occlusion problems. Therefore, having an additional source of information (other than the video) can help in enhancing the assumptions of the CV processes and providing a reference for tracking the progress of the project.

This paper aims to explore the possibility of developing near real-time digital twins of construction sites. First, the as-planned 4D simulation is used to provide valuable information about the spatio-temporal distribution of activities on the site, which can help focusing the scope of CV/RTLS processes. Then, the as-built digital twin is developed as a high LOD 4D Simulation based on CV and RTLS data. A case study is performed to investigate the proposed method.

2. Proposed Method

A high LOD 4D simulation can provide valuable information about the type and location of objects and activities from the 3D BIM model integrated with a micro-schedule. For example, the information from the as-planned 4D simulation related to the expected durations, locations, number of resources, and output of tasks, can be used to limit the scope of classes used in object detection and activity recognition. The as-planned 4D simulation can be also used to compare with the as-built 4D simulation based on the information extracted from the CV analysis.

The proposed method has three steps as shown in Figure 1. In the first step, the requirements are identified in the planning phase according to the purpose of the simulation. Based on these requirements, the LOD of the 4D simulation is defined. The definition of the LOD can be divided into two parts: defining LOD of the 3D model and defining LOD of the schedule. In the second step, according to the defined LODs, the 3D BIM model and micro-schedule are generated. Then, the 3D BIM model and micro-schedule are linked to generate the high LOD 4D simulation. The third step, which is in the construction phase, the 4D simulation is integrated with monitoring data from CV and RTLS for different types of applications including progress monitoring, delay claim analysis, and safety monitoring.

Identifying the required 4D LOD based on the requirements

The requirements of 4D simulation vary according to application area. For example, when generating the as-built model for progress monitoring, the focus is on the outcomes of each construction task assigned to the construction team. Therefore, the simulation is required to show the outcomes from each task clearly. For instance, as shown in Figure 2, for the construction of an isolated foundation, the focused outcomes are: (1) building footing formwork, (2) adding footing reinforcement, (3) adding column longitudinal reinforcement, (4) pouring footing concrete, (5) removing footing formwork, (6) adding column stirrup, (7) building column formwork, (8) pouring column concrete, and (9) removing column formwork. The schedule should be developed with outcomes and execution plans on a daily basis to an hourly basis, depending on the required LOD. Table 1 summarizes the requirements of 3D model and schedule for different purposes.

Developing high-LOD 4D simulation

According to the defined LODs and the corresponding requirements in the 4D simulation, the corresponding 3D model and micro-schedule can be developed. The as-planned micro-schedule can be developed in advance by the project manager or the scheduler. The video monitoring of the site can be used as the ground truth of the as-built micro-schedule. The next step is linking the 3D model with the micro-schedule. It is important to note that multiple adjustments should be performed in order to fit the 3D model with the schedule.

Integrating 4D simulation with monitoring data from CV and RTLS

2.3.1 Integrating 4D simulation with CV for productivity analysis

CV-based activity recognition approaches focus on atomic activities, such as hammering for workers [24] or digging for excavators [5]. These detailed low-level recognitions cannot be used for productivity analysis, progress tracking, or generating the as-built 4D models. However, combining a series of these atomic activities results into micro-tasks that have longer durations and can give a higher-level understanding of what is happening on the site. For example, a micro-task, such as building footing formwork, consists of a series of atomic activities, such as transporting wooden materials and hammering them, repeated over and over. In this study, the atomic activities for workers (as an example of construction resources) are obtained using YOWO53 [24] and the micro-tasks are obtained by sliding a temporal

window of adaptive length on the activity recognition results and comparing the prominent atomic activities laying inside the window to the atomic activity pattern of predefined micro-tasks. The micro-task that matches these atomic activities is chosen for the first frame of the window. If no pattern is matched, the duration of

the window is extended until a match is found or until the length of the window exceeds some limits. In addition, if more than a certain portion of the window is occupied by non-value adding activities (e.g. walking or standing), the micro-task is set to idling.

Figure 2. Micro-tasks and the corresponding outcomes

Table 1. Required LOD of 3D model and schedule for different purposes

Purpose	Required 3D BIM LOD	Required schedule LOD	Unit of time
Progress monitoring	• Outcomes after each task	• Tasks	Day to hour
Activity recognition	• Outcomes after each task • Resources (equipment, workers, materials)	• Tasks with related resources	Hour
Safety (Proximity Detection)	• Outcomes after each task • Resources (equipment, workers, materials)	• Tasks with related resources	Hour to minute

Integration of CV-based micro-task recognition and the as-planned 4D simulation helps improving the recognition. CV-based micro-task recognition can give the approximate location of micro-tasks at each frame. The approximate locations of these micro-tasks in the real world can also be derived from the pixel locations using camera calibration matrices. Having this information together with the as-planned 4D simulation helps eliminating recognition errors at different areas of the site. The as-planned 4D simulation also provides a reference for comparing the actual and expected status of the site for productivity analysis and progress tracking. For example, based on the as-planned 4D simulation, the footing formwork construction is scheduled within a specific period (t_1 to t_2) by n workers in a specific area of the site, and m completed footing formworks are expected at the end of this duration. CV analysis can provide similar information using micro-task recognition, tracking, and object detection methods. If the CV results do not match the expectation, this can indicate low productivity and requires investigating the underlying reasons for the poor performance. In addition, the results of CV can also be used to update the as-built 4D model with detailed data as the project moves forward, as shown in Figure 3.

2.3.2 Integrating 4D simulation with RTLS for proximity detection

RTLS have been used to collect accurate position data of workers and equipment for proximity detection. However, decreasing the number of unnecessary alerts is still a challenge. One case where proximity alerts can be considered unnecessary is when the workers and equipment belong to the same team [11]. For example, when a worker is loading materials to a telehandler, the worker and the equipment are very close and the movement of equipment is very slow. Besides, the worker and equipment operator should pay attention to each other during this task. In this case, generating alerts is unnecessary and may disturb the worker and the

equipment operator, which may eventually lead to ignoring the alerts. By integrating the position data with the 4D simulation based on the micro-schedule, more details can be added to the model. This information can be used to improve the performance of proximity detection by eliminating unnecessary alerts.

Case study

The case study is conducted with the data collected from a construction site of an electric substation near Montreal, Canada. The dimensions of the site are 110 m \times 70 m. Cameras were installed on four poles to capture the videos of the site, which were used as reference when generating the micro-schedule. In addition, RTLS sensors were installed on the poles to collect the positions of workers and equipment. Multiple isolated foundations are built in the main construction area. In this section, two examples of generating 4D simulation for different purposes are presented. In the first example, the 4D simulation is developed to act as the ground truth of progress monitoring. In the second example, the 4D simulation with high LOD is integrated with CV as the reference in activity recognition.

Developing high-LOD 4D simulation

Since in this project the simulation is mainly for post analysis, the micro-schedule is developed with site videos captured by the four cameras as ground truth. By observing the videos, the task and activities on the construction site can be identified. The task of constructing an isolated foundation can be divided into multiple micro-tasks as shown in Figure 2. The 3D model of the site is developed using Autodesk Revit based on the 2D drawings provided by the contractor. Then, using the site videos, the progress of the work is used to extract the detailed as-built schedule. Table 2 shows an example of a micro-schedule for the tasks related to building block 1C during the period of September 25 to October 30, 2019. The as-built detailed 4D model is developed using Autodesk Naviswork. Figure 4 shows the example of the 4D high LOD simulation over four days.

Figure 4. Example of 4D simulation during foundation phase

Activity and micro-task recognition using CV

Activity recognition using YOWO53 is first applied to two hours of formwork construction to recognized six different atomic activities (i.e., standing, walking, transporting, hammering, drilling, placing/fixing rebars). The video is recorded on 25th of September from 15:00 to 17:00. Frames are extracted at the rate of 3 FPS. The activity recognition processing is almost real-time with inference time of 2.15 hours. The atomic activities that comprise the *building footing formwork* micro-task are hammering and transporting, and the atomic activities

that comprise the *adding footing reinforcement* micro-task are placing/fixing rebars and transporting. Table 3 shows the activity recognition results. The atomic activity ratio is computed by dividing the number of recognitions for each atomic activity by the total number of recognitions in the entire duration of the video. Next, micro-tasks are recognized for every non-overlapping one-hour segments of the video and are compared to the ground-truths obtained manually from the video. Table 4 shows micro-task ratios for each hour. The micro-task rates are computed similar to Table 3. The unmatched micro-tasks happen when the maximum number of window extensions is reached without finding a match as

explained in Section 2.3.1. Figure 5 shows the location of workers during the same two hours based on CV. It also shows the locations of blocks. The green stars show the blocks are built during the same day, and red stars show the remaining blocks. The figure shows that the site is more congested in the proximity of the blocks that were being constructed at the time. In addition, the congestion near block 2C can be explained by the fact that the materials used for the construction of the formwork are placed at this location and workers travel there frequently.

Reducing unnecessary RTLS proximity alerts based on micro-schedule information

This test focuses on the alerts generated for the proximities between the workers and three kinds of equipment, which are a boom lift (Equipment-1), a telehandler (Equipment-2), and a crane (Equipment-3). Figure 6(a) and (b) show the images of the site and the map generated by the developed system, respectively, on

January 28, 2020, at time 13:47:43. Whenever a worker enters the danger zone of equipment, the IDs of the equipment and the worker are shown on the map. Figure 6(b) shows a detected proximity of 3.21 m (Case 2) between Equipment-2 (telehandler) and Worker-A. As the micro-schedule identified that this worker and the telehandler belong to the same team, the proximity alert is not generated [11].

Summary and future work

This paper explored the possibility of developing near real-time digital twins of construction sites as a high LOD 4D Simulation based on CV and RTLS data. The case study shows that the proposed method can be efficient in developing the digital twin, which can be used for productivity analysis or safety management. Future work will focus on the automatic generation of the as-built real-time 4D simulation.

Abstract

This study was aimed at developing a building information modeling (BIM) process logger that can capture modeling process information as an event log file. BIM log mining is a research area that focuses on utilizing a massive amount of data created from BIM software usage. Several studies have monitored, analyzed, improved, and predicted modeling process based on BIM log mining. However, the BIM logs recorded using current BIM authoring tools do not offer explicit information about modeling commands and object-related parameters. The BIM logger proposed in the current work was developed using the application programming interface (API) of BIM authoring software to create an enhanced log file that can represent the modeling process. The reproducibility of the modeling process in the log file created using the developed logger was evaluated via quantitative and qualitative methods.

Keywords

Building Information Modeling (BIM); BIM Log Mining; Modeling Process Representation; Data Enhancement

1 Introduction

With a massive volume of data created from digitalized industry platforms, a data analysis strategy that utilizes the data to monitor, analyze, improve, and optimize a process is currently in the limelight [1]. Building information modeling (BIM) has become an operational core of the architectural, engineering, and construction (AEC) industries, working as the digitalized platform of the industry. The growing utilization of BIM applications has resulted in the accumulation of a massive volume of computer-generated data regarding the process [2]. One type of such data is BIM logs. BIM logs automatically record

BIM usage data in a BIM authoring tool.

BIM log mining is a young discipline in a research area that focuses on utilizing the event logs created from the BIM usage process. Extensive research has been conducted to perform BIM log mining for various purposes, such as design pattern analysis, design productivity analysis, social network analysis, modeling process visualization, and modeling command prediction.

The data maturity of BIM logs, however, has not been questioned in most previous research [3–11], even though it very much affects the results of analyses in event log mining. The quality of an event log varies according to the purpose of the analysis [12]. For reliable and precise modeling process analysis, the modeling information in BIM event logs needs to be self-descriptive to the level at which it can reproduce the process [1]. During a literature review, we verified that the modeling process data created in the current BIM log file is not explicit enough to reproduce the modeling process for process analysis [13]. In this regard, we focused on increasing the process reproducibility of the modeling log using a custom-developed BIM logger.

In this paper, we propose a BIM logger to create a modeling log that can reproduce the modeling process with the log, itself. In the next section, previous research on BIM log mining and its data usage is reviewed. In the third section, the research method used in this study is described. In the fourth section, the development sequence and algorithm of the modeling logger are explained. In the fifth section, the reproducibility of the log created from the logger is evaluated. Section 6 concludes the paper, along with its contributions, limitations, and future research.

2 Literature Review

Parametric modeling is a process that enables designers to translate and embed domain knowledge about original modeling processes as geometric expressions that can automatically generate modeled objects in modifiable form [14]. Designers can manipulate parametrically modeled objects during or after a modeling process by modulating geometrical attributes and relationships between objects [15]. Parametric modeling is distinguished from BIM logs in that it is implemented on the basis of a designer's knowledge of the modeling process. Conversely, BIM log files record each and every process during modeling process.

Recently, several researchers have made efforts to utilize BIM logs to solve issues during the design phase. Yarmohammadi et al. proposed a BIM log mining method to attain insights into the design process [2][13] by analyzing Revit journal files and BIM log files provided by Revit from Autodesk [16].

Zhang et al. proposed methods to evaluate the modeling productivity of project participants by analyzing the design patterns retrieved from the Patricia tree structure [4]. Pan et al. conducted research on design productivity analysis by identifying implicit command execution patterns from BIM logs using the Efficient Fuzzy Kohonen Clustering Network (EFKCN) algorithm [6] and the Adaptive Efficient Fuzzy Kohonen Clustering Network (AEFKCN) [9].

An analysis of collaborations among designers and the relationships between collaborative characteristics using a social network analysis was another research topic suggested by Zhang and Ashuri [3], and Pan et al. [10].

Modeling command prediction was the most recent research topic in BIM log mining. It was conducted with the application of recent deep learning techniques, such as the long short-term memory neural network (LSTM NN) and recurrent neural network (RNN) by Pan et al. [7] [8].

In all previous research reviewed, the Autodesk Revit journal file was the only source of the analysis. As shown in 'Figure 1', a command executed on the Revit system is specified by the type of general command, event, and specific command. *General command* explains how an activity is executed in the system. *Event* explains whether the command is creating, deleting, or modifying an object. *Specific command* discriminates a command from other commands by a given identifier (ID). From the example, however, the geometric attributes of the modeled object, thickness, or height of the wall, in this case, cannot be verified. Moreover, the object affected by the activity is not

specified in the example. The modeling information provided by the Autodesk Revit journal is not sufficiently specific to reproduce the whole modeling process.

Further reinforcement of information about modeling commands and modeled object attributes is required to reproduce an already-created model. With sufficient modeling information that can reproduce modeling processes and results, the accuracy and reliability of BIM log mining results can be highly increased. The objective of the study is to enhance the modeling information in the BIM log to where the representation of the original modeling process is possible.

3 Research Method

The research method of this paper comprises two steps, as illustrated in 'Figure 2':

1. Development of the BIM logger to enhance the modeling information described in Section 4.
2. Evaluation of the enhanced log described in Section 5.

The development of the BIM logger consists of two phases, including real-time logging and capturing the object information. Through the two phases, the modeling process logger is developed. The details of each phase of the development are explained in the next section.

In the evaluation section, the enhanced log created from the logger is evaluated. The goal of BIM log enhancement in this study was set to the level at which repeating the original modeling process is possible. To validate the equality of the process between the original modeling result and the represented modeling result, the equality of the modeling process is defined. A standard to evaluate the reproducibility of the modeling process is introduced in Section 4.

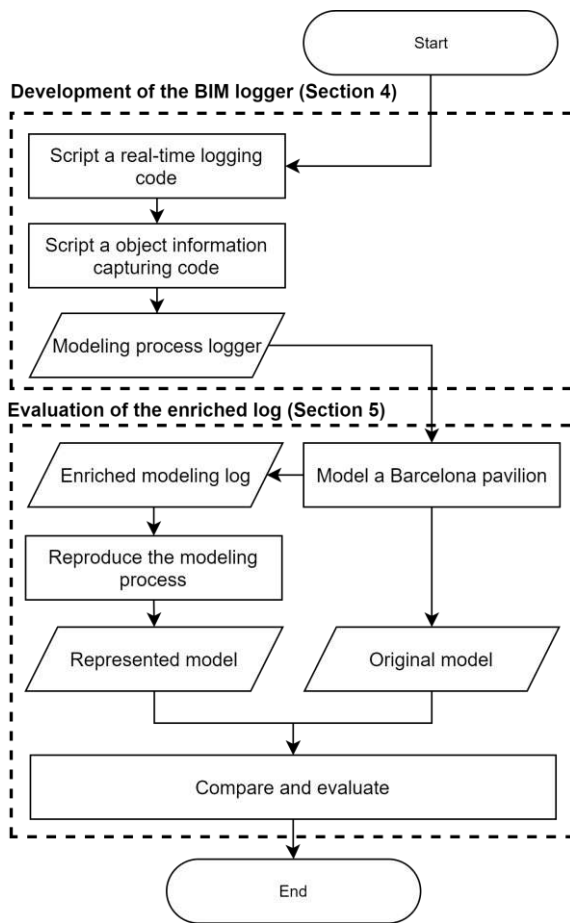

Figure 2. Research flowchart

4 Development of a BIM Logger

Rhinoceros (*Rhino*, for short) [17] is a widely used software for architectural designers in the early stages of the design process. This study used Rhino and Grasshopper—a visual programming module of Rhino—to develop a BIM logger with enhanced modeling information.

To conduct event log mining, the activity, timestamp, and case ID are required [1]. Activity in the event log specifies which activity has taken place. A timestamp records the precise time of each activity. A case ID is a numeric identifier assigned to a unique case.

In the case of modeling event log mining, activity is the modeling-related command. The timestamp is the record of the time when a modeling command is executed. Case ID is defined by the globally unique identifier (GUID) of each modeled object. The

following subsections describe how these information items were recorded.

4.1 Real-Time Logging

Rhino provides a modeling history that works as a user-system communication board. The modeling history shows the process of each command execution. As shown in ‘Figure 3’, the modeling history of Rhino includes a command, subcommand, command options, parameters, system message, and result message. The modeling history shows the ongoing command after “Command:” and reveals the result of the command. The user can easily understand the status of the actions running on the system. It is also possible for users to verify the options and input parameters from the modeling history so they can decide which action to take. We built an algorithm to extract and record a modeling history through the Python-based Rhino API [18] while a modeler is creating a design. Grasshopper executes the script in real-time and stacks each command event. The BIM logger captures commands, subcommands, and parameters from the modeling history, timestamp, and object information. The BIM log can be exported as a comma-separated values (CSV) file. More details on an algorithm to capture object information are described in the next section.

4.2 Capturing Object Information

During the modeling process, a modeled object is affected by the modeling command being created, deleted, or modified. Thus, object information is core information that needs to be clarified to reproduce a modeling process based on a BIM log. Nevertheless, neither the Rhino modeling history nor the Revit journal file includes object data.

The BIM logger developed in this study captures an object’s GUIDs to record objects created or changed through a modeling process. Each object in all BIM authoring tools, including Rhino, has a GUID to discriminate a modeled object from other objects [19].

To add GUID information to the BIM log, a Python script was written. The script identifies the GUID of currently modeled objects by comparing the total list of GUIDs of modeled objects. The total list of GUIDs is recorded based on real-time updates from the Rhino system on command execution. If a command creates an object, the GUID of the created object will be added to the list of GUIDs. The script, therefore, can verify which object is either created, deleted, or modified on command executions.

The developed algorithm of enhanced BIM logger is presented as pseudocode in ‘Figure 4’.

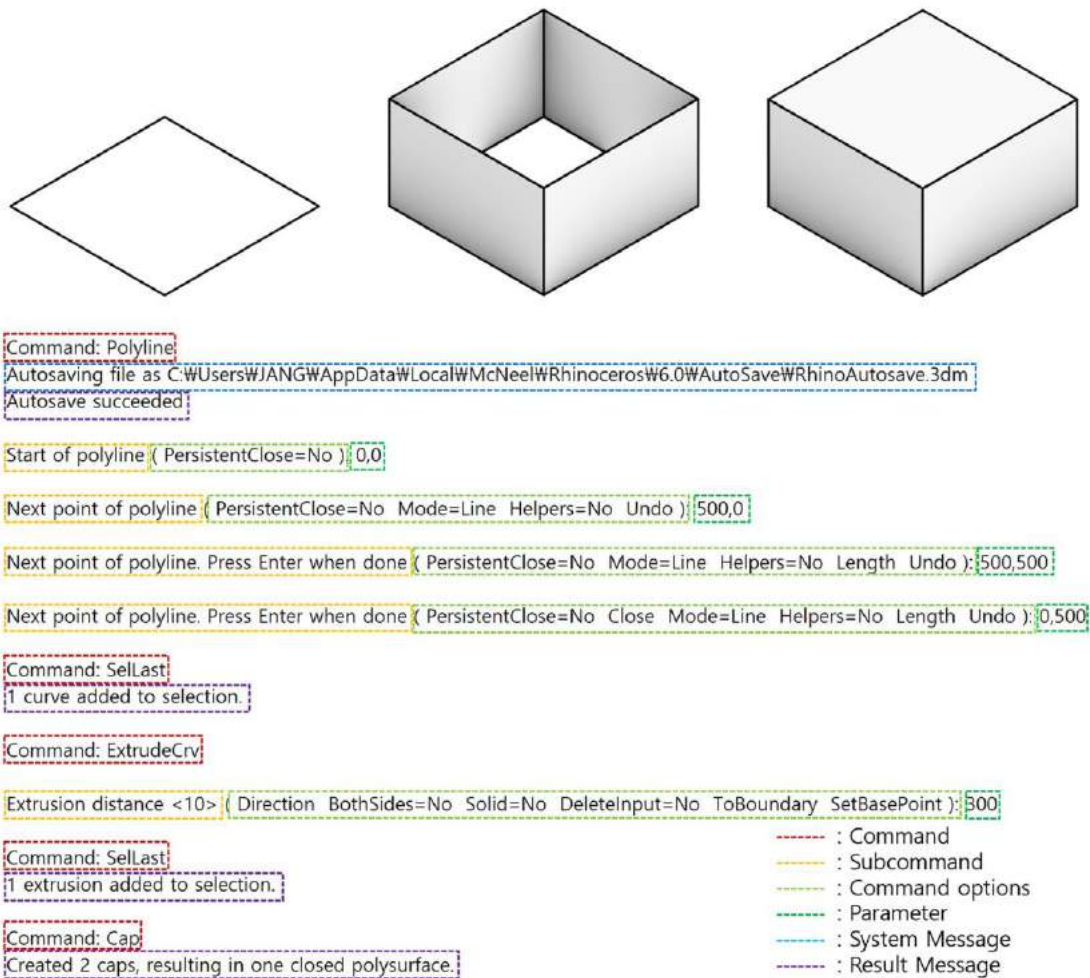

Figure 3. A modeling process and the modeling history of the process

5 Evaluation

This section describes how the reproducibility of the created log was evaluated. Since there is no standard or common method to evaluate the reproducibility of a model, this study proposes the level of reproducibility (LOR) and the intersection of union (IoU) as measurements. Section 5.1 describes LOR. Section 5.2 reports the LOR of the enhanced BIM logger through a test case. Section 5.3 compares the modeling information included in the existing BIM log and the enhanced BIM log.

5.1 Level of Reproducibility

This study proposes LOR to quantitatively measure the extent to which a model is reproduced from BIM log data. The algorithm for calculating the LOR is as

follows:

For the i^{th} object (o_i) from the original modeling process, if the object o_i exists in the represented model, the value of a variable X_i is 1 and otherwise 0.

Additionally, IoU is used to measure the geometrical similarity between an original object and a reproduced object. IoU is a commonly used metric for measuring the overlap between two bounding boxes or masks by calculating the intersected area divided by the unified area of the boxes or masks.

This study used the volume of the intersection and union of the object's volume instead of the area, (see Equation (1)). After the i^{th} IoU (IoU_i) is calculated, the LOR of the model total sum can be calculated, (see Equation (2)).

Input: modeling history

Output: modeling log

log_ord_list: list of event log orders

cmd_list: list of commands

time_list: list of timestamp

guid_list: list of GUID

cmd_ord_list: list of command orders

prm_list: list of parameters

```

for i in modeling history do
    cmh EQUALS i;

$$IoU_i = V_{Inter_i} / V_{Uni_i} \quad (1)$$

$$LOR = \frac{\sum_{n=1}^i X_i * IoU_i}{i} * 100 (\%) \quad (2)$$

5.2 Evaluation of Model Reproducibility

For comparison, the Barcelona Pavilion, designed by Mies van der Rohe, was modeled. A total of 288 instances of commands and subcommands were used, including Polyline, Box, Cylinder, Boolean Difference, Extrude, Cap, SellLast, and Delete. As shown in 'Figure 5', the original modeling process created 27 modeled

objects. The modeling process was represented based on the enhanced log from the logger developed in the previous section through execution of modeling command by code. Among 27 modeled objects, the reproduced model included 24 model objects with 21 correctly created model objects and three incorrectly created model objects. The modeling process reproducibility of the enhanced log shows 64.08% LOR with an average of 0.98 IoU_i .

5.3 Comparison of Log-Containing Information

'Table 1' shows modeling information included in the Revit journal file. Although the file stores data on

27 objects

(a)

24 objects
(with 3 non-value objects)

(b)

21 objects reproduced
LOR = 64.08%

(c)

Figure 5. Comparison of the original model and the represented model

modeling commands, it does not sufficiently represent the modeling process because it lacks a discrimination

of commands. For example, it is impossible to examine differences between commands if there is a command that creates a wall that is two meters long and one that creates a wall that is three meters long. In addition, because an object ID or attribute is missing, the file is unsuitable for specifying which modeled object is affected by command execution. Meanwhile, 'Table 2' indicates that the modeling information, including GUID, commands, command orders for subcommand discrimination, and parameters, is enhanced. With GUID included in the enhanced log file, the object instance of a modeling command can be specified. The Revit journal file and enhanced modeling log both provide the names of commands, but the enhanced modeling log provides the explicit parameters included in commands. For example, if a command intended to create a box from a width, a depth, and a height is recorded by the enhanced modeling logger, the log created from the process will not only record the box creating the 'Command' and 'GUID' of the created box but also record the width, depth, and height as 'Parameter' in separate event logs marked as the same command by 'Command Order'. An enhanced modeling log therefore provides more explicit data about the modeling process than that generated by an ordinary BIM log file.

6 Conclusion

Current BIM logs do not include sufficient data to reproduce a modeling process. This study proposed a BIM logger that could reproduce a modeling process. Enhanced modeling logs from the BIM logger include specified modeling data. The enhanced log is eligible for reproducing the original modeling process at a reasonable level, as shown in the evaluation section.

This study contributes to the body of knowledge by presenting a BIM logger that creates an enhanced log that can reduce the gap between real-life modeling processes and logged modeling processes. The enhanced log, which provides specific modeling information, can be used as a source of future BIM mining research to attain more reliable and meaningful results.

The results of this study demonstrated the possibility of reproducing a BIM model from a BIM log, which cannot be implemented using current BIM logs. However, this study is limited in that the proposed method was examined only on the basis of a small test case. The reproducibility of a model should be tested through full-scale projects to demonstrate the practicality of the proposed method.

Table 2. Modeling information from the Revit journal file

9e7b8788-0dab-4c69-86b0-571820582c0d	Polyline	5	-
9e7b8788-0dab-4c69-86b0-571820582c0d	Polyline	5	0/0

Even though the aim of developing an enhanced BIM logger is to attain a more reliable result from BIM log mining, the application of enhanced logs was not examined in this study. Future research can involve the application of enhanced logs in tasks such as the analysis or prediction of modeling processes. In addition, a more comprehensive BIM logger can be developed to collect not only geometric attributes but also non-modeling events and non-geometric features.

Abstract –

The accurate modeling of critical infrastructure systems (CISs) and their interdependencies is essential to assessing and predicting the behavior of interdependent CISs under various operation scenarios. Existing modeling approaches have limited ability to incorporate CIS domain knowledge and capture the systemic heterogeneity among the CISs, and thus cannot simulate the behavior of interdependent CISs with much detail and accuracy. In this study, a high level architecture (HLA)-based framework for modeling interdependent CISs is proposed that provides a methodology for co-simulating heterogeneous fine-grained CIS domain-specific models, reproducing with high fidelity the complex coupled systems. The results from a case study of two interdependent power and water systems revealed that the HLA-based CISs model could capture and simulate various systemic heterogeneity dimensions and their impact on the systems behavior, thus proving the efficacy of the proposed framework.

Keywords –

Critical infrastructure system (CIS); High level architecture (HLA); Distributed simulation; interdependencies; Domain knowledge; Systemic heterogeneity

1 Introduction

With the growth in scale and complexity of urban critical infrastructure systems (CIS) such as water supply systems and power supply systems, CISs are becoming increasingly dependent on each other for proper operation. Various events in history have shown that tight interdependencies among CISs can significantly increase the systems' vulnerabilities, leading to catastrophic chain of events throughout the complex system of systems. On the other hand, the presence of interdependencies can play a significant role in improving the efficiency of CISs, since the CISs can provide functional and operation support to each other.

Therefore, understanding the nature of CISs interdependencies and the role they play in the day-to-day operations of CISs is essential to assessing and predicting the behavior of CISs in various operational scenarios.

Several modeling approaches have been proposed in previous studies for modeling interdependent CISs and analyzing systems behaviors and interactions. Among these approaches, the agent-based modeling (ABM) and network-based (NB) modeling are the most commonly adopted approaches to develop monolithic interdependent CISs models [1]. A significant challenge when adopting monolithic models is to reasonably model, within a single conceptual framework, the heterogeneous nature and behavior of multiple systems [2]. Heterogeneities in physical network features, transported material properties, operational mechanisms, and disaster response patterns, among the CISs are usually not captured by these models because of the limited ability of these models to incorporate low-level features and domain knowledge of the various CISs within the monolithic model. A few studies have attempted to overcome the limitations of monolithic models by co-simulating multiple CIS models [3, 4]. However, due to the challenges in ensuring the interoperability of complex heterogeneous models, these studies either relied on highly abstracted CIS models or modeled the CISs using general-purpose modeling and simulation tools to facilitate model interoperability. Consequently, the developed models did not incorporate the domain knowledge of each CIS and had a limited ability to simulate the interdependent systems' behavior with sufficient details and accuracy.

This study therefore aims at addressing the challenges in developing interdependent CIS models that can extensively utilize domain-specific knowledge to simulate CISs functions and capture various systemic heterogeneity dimensions among the CISs. The study proposes a framework for modeling interdependent CISs, one that will allow for the integration of multiple fine-grained CIS domain-specific models, leveraging well-tested practices, data, and simulation tools accumulated over years of wide usage in the various

CIS domains. The framework takes advantage of the data management and synchronization capabilities of the high level architecture (HLA) standards for distributed simulation to facilitate the interoperability of multiple CIS models. A case study of two interdependent power and water systems was conducted to demonstrate the efficacy of the framework and reveal the importance of incorporating domain knowledge and accounting for systemic heterogeneity when simulating interdependent CISs behavior.

The proposed framework provides a methodology for developing high-granularity interdependent CISs models that can contribute to unveiling in-depth knowledge on CISs interdependencies, feedback loops, system vulnerabilities, cascading failure mechanisms, and so on, and hence improve the accuracy and reliability of future models for CISs behavior prediction, vulnerability assessment, disaster response management and so on.

2 Background

2.1 Overview of HLA

HLA is an open international standard for distributed simulation platforms, initially developed by the U.S. Department of Defense (DoD) and is nowadays known under the IEEE 1516 family of standards [5]. The HLA simulation environment (federation) allows multiple simulators to work together and seamlessly interact. A typical HLA federation architecture, as depicted in Figure 1, consists of simulators known as federates, a middleware known as the run-time infrastructure (RTI), and a federation object model (FOM). The RTI provides data exchange management, synchronization and coordination services during federation execution. The FOM, which serves as the federation language, contains detailed information about the object and interaction classes, attributes, and data types of the federates, and is designed following the HLA OMT specifications [5].

2.2 Related Work

In his review article, Ouyang [1] reviewed several interdependent CISs modeling approaches. The majority of these approaches model the topological and functional characteristics of CISs, as well as the spatial and functional interdependencies between CISs using generic modeling principles instead of algorithms or nonlinear equations specific to each CIS domain. Wang et al. [6] demonstrated how by doing so, systemic heterogeneities among CISs may not be captured, which could impact the reliability assessment of CISs. This study adopts HLA standards to develop interdependent CISs models using CIS domain-specific models.

In its early stage of development, HLA was used as a gaming environment to simulate joint-attack strategies involving multiple military units, vehicles and aircrafts [7]. Over the years, HLA applications have expanded to a wide range of domains including the modeling and simulation of large-scale computing systems [8], cyber-physical systems [9], infrastructure systems [10], and so on.

Meanwhile, HLA is slowly paving its way into the interdependent CISs domain. A few studies have adopted HLA to develop interdependent CISs models. In these studies the simulator outputs are either directly exchanged between the CIS models through the RTI middleware [11], or merged in an abstract model to reproduce the inter-system interactions [12]. The limitation of the former is that only simple interactions can be modeled when using heterogeneous CISs simulators because the simulators have limited ability to manage and assimilate the data published by the other simulators. The limitation of the latter is that by abstracting the functionalities of the system components, the developed compound model may significantly lose its ability to accurately simulate systems behavior since portions of the data representative of component states, functions and operations are lost. The above limitations arise due to the challenging task of achieving the interoperability of heterogeneous models. Most prior studies therefore either relied on general-purpose simulators, which can provide better interoperability but lack simulation functions specific to the modeled CIS domain, or simply adopted homogeneous models to represent their CISs. Consequently, the developed models could not leverage the CIS domain knowledge offered by specialized simulation tools and could not reasonably account for systemic heterogeneities. Therefore, the HLA-based framework proposed in this study aims to address the above limitations.

Figure 1. HLA federation architecture

3 Methodology

With the aim of incorporating CISs domain knowledge and capturing systemic heterogeneity when modeling and simulating interdependent CIS, this study proposes to integrate and coordinate fine-grained CIS domain models in a compound interdependent CISs

model. The proposed framework presents a federation architecture that describes the structure of the interdependent CISs model as well as its data management and exchange scheme.

3.1 Interdependent CISs Federation Architecture

When studying the behavior of interdependent CISs, the developed interdependent CISs model must accurately represent the topology and functionalities of the CIS, and capture, with high fidelity, the various formalisms governing the CISs interdependencies and their interactions with the external environment. To meet the above requirements, the interdependent CISs model is developed as an HLA federation consisting of a few functionally distinct modules that communicate via a central RTI, as illustrated in Figure 2. A module is a federate or a group of associated federates responsible for simulating a particular system, agent or factor composing the interdependent CISs model. There are three types of modules, namely the CIS modules, User module, and External Environment module.

The CIS module consists of all the models and simulation tools responsible for simulating a particular CIS. These can include a CIS simulator for modeling the system's physical network and component functions, as well as management and control simulators for modeling additional management and control functionalities such as SCADA (supervisory control and data acquisition), backup systems, decision-making, and resource allocation. The External Environment module consists of the simulators necessary to model and simulate various external factors that affect the CISs, such as socio-economic variables, government policies, natural disasters, and so on. The User module consists of the user interfaces necessary to facilitate the interactions between the federation users and federation components such as GUI (graphical user interface), GIS (geographic information system), data output monitor, visualization tools, and so on.

3.2 CIS Module Implementation

Each CIS module comprises three layers, including the application layer, organizational layer, and communication layer.

The application layer consists of the various domain simulators responsible for simulating the CIS and its management and control functionalities. Some CIS models might have the management and control functionalities embedded within their simulators, in which case extra management and control simulators are not needed.

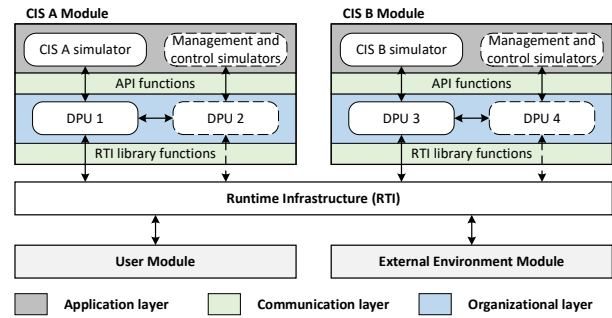

Figure 2. The proposed interdependent CISs federation.

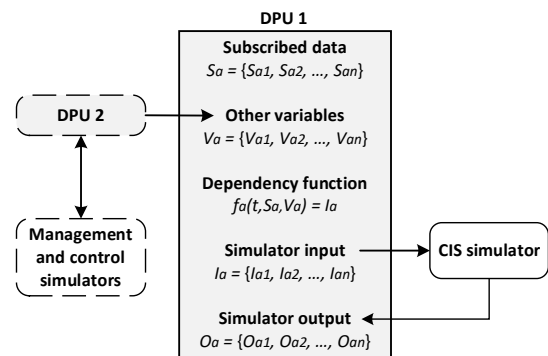

Figure 3. Data management and exchange through the DPUs.

The organizational layer consists of data processing units (DPUs) that process subscribed data to generate input data that can be assimilated by simulators in the application layer. The DPUs can be used to model functions such as failure dynamics of components, data conversions, and so on. The organizational layer can be implemented as a single DLL (dynamic link library) wrapper file that contains all the DPU functions, or as multiple small programs.

The communication layer consists of the application programming interface (API) function libraries and RTI libraries necessary to control the simulators and communicate with the RTI. API functions are specific to a simulator and are used to invoke model functionalities that edit, update or retrieve model attributes. The RTI library consists of the federate ambassador and RTI ambassador that allow the RTI to manage calls and callbacks between the CIS module and the rest of the federation.

The data exchange mechanism of the CIS module, depicted in Figure 3, is controlled by the DPU of the organizational layer. The DPU identifies the subscribed data (S) and other variables (V) provided by the management and control simulators, if any. It then processes the subscribed data by means of dependency

functions (f) to generate the simulator input (I). The input and output data of a simulator are values assumed by entity attributes at time (t) of the simulation. An entity is a model component that plays a particular role during simulation. An attribute is a parameter that characterizes an entity. The DPU can also retrieve simulator output (O) to be published to the rest of the federation as well as generate logfiles for the model users.

4 Case Study

4.1 Case Description

The proposed framework was tested in a case study of the Shelby County's interdependent water and power supply systems. The topology of the case systems was adapted from [13, 14] and considered only the major facilities and trunk distribution elements of the systems, as described in Section 4.1.1 below.

4.1.1 Topology of the Interdependent CISs

The Shelby County power network consists of eight gate stations that act as the system's supply facilities. The electric power is then transmitted via 115 kV and 23 kV transmission lines to 23 kV and 12 kV substations which relay the electric power to end-users loads. The dense power grid of the original system was simplified to avoid undue complexities in modeling by considering only 17 substations, nine of which supplied power to the pumping stations of the water network. Figure 4 depicts the simplified power supply network.

The Shelby County water supply system consists of nine pumping stations which draw water from deep wells and deliver it to six elevated storage tanks and numerous distribution nodes via buried pipes. The node elevations range from 63.6 m to 126.6 m and pipe diameters range from 16 cm to 122 cm. The network was simplified to consider 43 distribution nodes and 71 pipelines that can reasonably represent arterial water mains and major secondary feeders. Figure 5 depicts the simplified water supply network.

4.1.2 System Interdependencies

The power and water supply systems depend on each other to perform their intended functions. The power substations supply electric power to the pumping stations of the water supply system, and thus the power consumption of the pumps was modeled as loads on the power substations. Meanwhile, the generators of the power supply system depend on water supplied at the water distribution nodes, and thus the power generators were modeled as demand nodes on the water network. The interdependent system facilities were coupled based on their geographic proximity. Each pump station and

power generator were linked to the closest power substation and water node, respectively, as depicted in Figure 6.

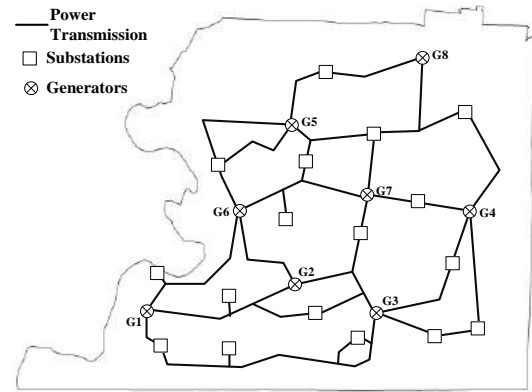

Figure 4. Topology of the power system (not to scale).

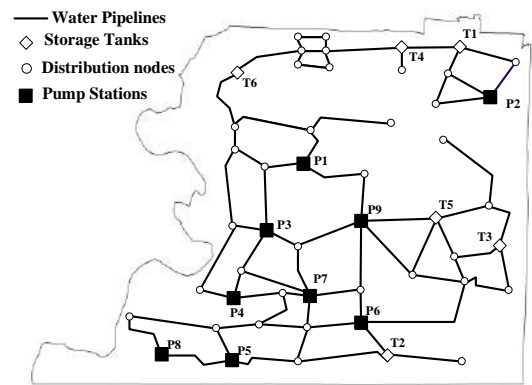

Figure 5. Topology of the water system (not to scale).

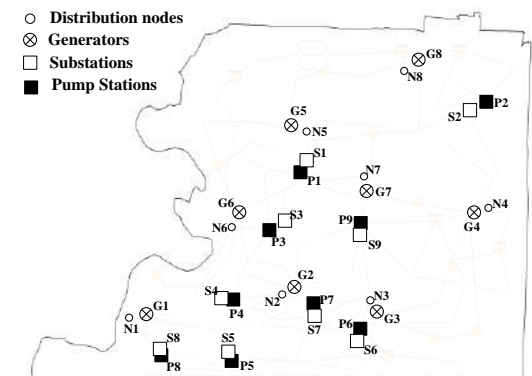

Figure 6. Dependent component pairs of the case systems.

4.2 CISs Model Development

The development of the model followed three steps, namely design of the simulation scenario, selection of the CIS domain models and simulation tools, and implementation of the interdependent CISs federation.

4.2.1 Design of the Simulation Scenario

A simulation scenario is designed that can showcase various system functionalities that are unique to each CIS domain, and hence reveal a variety of systemic heterogeneities among the simulated systems and how they affected system behavior.

Under the designed simulation scenario, the interdependent systems are simulated under normal operating conditions for 48 hours. The water flow and pressure requirements at each node during the simulation period are predefined based on a typical urban daily water consumption pattern, with the least demand between 12 am and 6 am, and peak demand around 8 am and 7 pm [15]. Water is pumped from water wells by the nine pump stations and delivered to the distribution nodes and elevated water tanks. If the actual water flow and pressure at the water distribution nodes is above the demand, the tanks will fill up, otherwise the tanks will empty out to increase the water flow and pressure at the distribution nodes. The operational state (open or closed) of each pump is controlled by the water level in tanks and the water pressure at the distribution nodes. Each pump has a performance curve which determines its power consumption during operation. This power is supplied by the power substation it depends on. To meet the power demand of the pump stations, the substations relay the power generated at the eight power generators of the power network.

4.2.2 Selection of CIS Domain Models and Simulation Tools

Highly specialized simulation tools were selected to accurately model the systems topology and functionalities, and to leverage the domain knowledge of each CIS. The water supply system was modeled using the EPANET v2.2 software, a widely used open-source software application for modeling and simulating water distribution systems that can execute a comprehensive set of hydraulic analyses. The electric power supply system was modeled using the OpenDSS v9.0 software, a comprehensive simulation tool for electric utility power distribution systems that has been used in support of various research and consulting projects requiring distribution system analysis. No additional system control and management simulators were required for this case study since EPANET and OpenDSS could model both the physical network and supervisory control system of the infrastructure systems.

Communication between the federates was established using the CERTI v4.0 middleware, which is an open-source HLA RTI that supports HLA 1.3 specifications (C++ and Java), and partial IEEE 1516-v2000 and IEEE 1516-v2010 (C++) standards. In this case study, interactions between the federation and federation users were completed within the user interfaces of the federates selected above; thus, no additional tools belonging to the User module were required.

4.2.3 Implementation of the Interdependent CISs Federation

Based on the simulation scenario and datasets of the selected domain models, the publish-subscribe schemes of the federates were defined and illustrated in Figure 7. The publish-subscribe schemes and the dependency relationships between the system components were then used to develop the DPU of each federate in MATLAB.

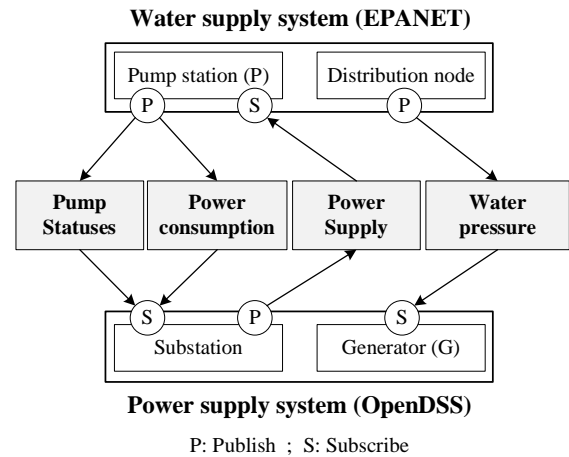

Figure 7. Dependent component pairs of the case systems.

The FOM was developed using an FOM editor tool developed by MAK Technologies and contained information about the data exchanged between the federates (also known as objects), and the event types that affected both systems (also known as interactions). Table 1 summarizes the main content of the FOM.

The federates were then connected to the RTI to create, test and debug the federation. To create the federation, the Master federate (in this case refers to the water system federate) loaded the FOM to the RTI and set a federation name. The federation was joined by both federates which then declared their publish-subscribe schemes. The Master federate initiated the LoadScenario interaction followed by the Start interaction, which triggered the simulators to load the simulation scenario data and simultaneously start executing the simulation scenario. The PauseResume

interaction could be initiated by the Master federate at any time during the simulation to pause or resume the federation execution. The RTI managed the data exchange and time synchronization between the models and printed event logs that were used to debug the federation. The final simulation output of each federate was generated by its DPU as spreadsheets, enumerating all entity attributes of the federate at each simulation time step, for follow-up analysis. After the simulation was completed, the federates resigned from the federation execution and disconnected from the RTI. The federated interdependent CISs model was executed under the predefined simulation scenarios, and detailed results are reported in the following section.

Table 1. Main content of the FOM.

	Class	Attribute/Parameter
	LoadScenario	ScenarioName SimulationTime
Interactions	Start	
	PauseResume	
	Pump	Status PowerConsumption
Objects	DistributionNode	Demand Pressure
	Pipe	Flow Diameter
	Tank	WaterLevel
	SubstationLoad	PowerSupply
	Generators	Status PowerOutput
	Substation	Status Voltages
	TransmissionLine	Resistance

5 Simulation Results

The developed interdependent CISs model was simulated for 48 hours starting at midnight of day one. Figure 8 shows the statuses of the pump stations, Figure 9 shows the pressures at the distribution nodes over the simulation period, and Figure 10 shows the loads on substations supplying power to the pump stations. The initial status of all nine pump stations at timestamp 0:00 (midnight) was open. Then, water was pumped into the network to meet the water flow and pressure requirements at the distribution nodes. During the night period, the demand at distribution nodes was low, and thus the control system of the water network temporally closed pumps P2, P5, P6, P7 and P9 at timestamps 4:43, 3:35, 3:35, 2:59 and 2:59, respectively, as depicted in Figure 8.

Figure 8. Pump statuses.

Around daybreak when the water demand at the distribution nodes began to significantly increase, a gradual drop in the water pressure throughout the network was observed, as depicted in Figure 9. This drop in the water pressure triggered the control system to reopen pumps P2, P7 and P9 at timestamps 14:02, 18:59 and 18:59, respectively. It can be observed that in the late evening and night, when the water demand was low, the pressure at distribution nodes increased rapidly, triggering the closure of pumps P2, P7 and P9 at timestamps 25:04, 23:22 and 24:36, respectively.

It can be observed from Figure 9 that distribution nodes N4 and N8 demonstrated a slightly smoother pressure pattern compared to the other nodes. This difference in the patterns was due to the positions of N4 and N8 within the networks. These two nodes were isolated from the action of the pump stations and were supplied directly by the tanks, resulting in a steadier water flow.

Figure 9. Water pressures at the distribution nodes.

From Figures 8 and 10 it can be observed that when the status of a pump station was closed, the load at the corresponding power substation was at minimal power value close to zero. On the other hand, when the status

of a pump was open, the load on the corresponding substation would vary according to the power consumption of the pump. Changes in pump status would cause a sudden drop or rise of the power substations loads. In addition, it can be observed that during the night time when the pumps were less solicited, the loads reasonably dropped as it would be expected in reality.

Figure 10. Loads on substations in scenario one.

6 Discussions

It can be inferred from the simulation results that by adopting domain specific models to simulate the CISs, the domain knowledge from each CIS was incorporated in the developed interdependent CISs model and significantly impacted the systems' behavior. The system components exhibited unique functionalities, interaction mechanisms and data types because different CIS components followed very distinct physical and/or logical laws specific to their domains. For example, it can be observed from Figure 10 that the power delivered by each power substation was continually changing, implying that the water system model was able to compute and provide specific values of pump power consumption at each time step based on the actual status of the water system. Also, the fact that N4 and N8 exhibited a completely different pressure pattern than other distribution nodes as depicted in Figure 9 shows that the water flow at different sections of the water network was calculated differently depending on the location of critical components such as pumps and tanks. These observations demonstrate a significant improvement in the level of details of the simulated systems behavior compared to existing interdependent CISs models in which only the operational states of system components or harmonized flow indices can be computed. It can therefore be inferred that incorporating a wide range of domain knowledge in the interdependent CISs models can help simulate more realistic and accurate system behaviors.

Previous studies have demonstrated that, by failing to adequately account for systemic heterogeneities when modeling interdependent CISs, the accuracy of the simulated systems behavior might be significantly affected [6]. To verify the efficacy of the proposed framework in capturing systemic heterogeneities among CISs, the simulation results should reveal a variety of systemic heterogeneities among the simulated systems and their impacts on the behavior of CISs. Among the systemic heterogeneities captured by the developed interdependent CISs model, the heterogeneity in material flow properties had the most significant impact on systems behavior. It can be observed from Figures 9 and 10 that changes in the water levels within the water network were relatively slow and gradual, while redistribution of flow within the power distribution system were abrupt. The heterogeneity in material flow properties can significantly affect the way and speed at which the systems respond to the events to which they may be subjected, such as component failures, system restoration sequences, and so on. By adopting homogeneous modeling frameworks and oversimplifying CIS models, the existing interdependent CISs modeling approaches fail to capture most of these critical systemic heterogeneities, resulting in their limited ability to accurately simulate system behavior, hence justifying the need for the proposed framework.

In summary, the developed model was able to leverage the domain knowledge of both CISs and capture various heterogeneity factors among the CISs, thus meeting the objectives of this study.

7 Conclusions

Critical infrastructure systems (CISs) interdependencies have a significant impact on CISs behavior under different operational conditions. As modern CISs are becoming increasingly complex, the modeling of their behavior requires models that can accurately represent the topological, functional, and operational characteristics of the systems. This study addresses the limitations of existing modeling approaches by proposing an HLA-based framework for modeling and simulating interdependent CISs that integrates the domain knowledge of CISs and accounts for systemic heterogeneities.

The case study results showed that by adopting CIS domain specific models, the developed interdependent CISs model was able to model the systems' topology and functions with more details, while revealing the impact of systemic heterogeneities on the interdependent systems' behavior. Therefore, models developed using the proposed framework can help unveil new knowledge on CISs interactions, responses, cascading failures, and so on, pushing the boundaries of

research on interdependent CISOs.

The proposed framework suffers two technical limitations. Firstly, when using off-the-shelf simulation tools to model and simulate the CISOs, the amount of control the user has on the models strictly depends on the available simulator APIs. Secondly, when implementing CISO modules composed of multiple simulators with complex interactions between them, the overall updating rate of the module may be affected, resulting in longer processing time compared to other approaches. These limitations will be addressed in the authors' future works.

From the Graphical Representation to the Smart Contract Language: A Use Case in the Construction Industry

Xuling Ye and Markus König

Department of Civil and Environmental Engineering, Ruhr-University Bochum, Germany

E-mail: xuling.ye@rub.de, koenig@inf.bi.rub.de

Abstract –

With the growing popularity of blockchain technology in the construction industry, smart contracts are becoming increasingly common. A smart contract is a self-executing contract, which contains if-then rules that automatically execute certain processes when certain conditions are met. Such smart contracts serve as programmable blockchain applications. Using blockchain-enabled smart contracts, many processes like construction contracting and payments can be automated. Since research on blockchain-enabled smart contracts in the construction industry is still theoretical, researchers usually assume that users (e.g. clients, contractors) can directly program the conditions in a smart contract. However, it is difficult for stakeholders to program smart contracts themselves due to a lack of knowledge. The smart contracts developed by programmers might not fully represent stakeholders' ideas.

Therefore, this paper proposes an approach that illustrates how graphical workflow notations (e.g. BPMN, YAWL) can be translated into smart contract programming languages (e.g. Solidity, Vyper). In this way, non-programmers can also design and generate their own smart contracts. To test the feasibility of this approach, an illustrative example is presented for generating smart contracts displaying automated the reporting, checking and payment process of construction works. In particular, the smart contracts in this example are translated from YAWL graphical representations into Solidity smart contract languages. Finally, improvements and further developments of the approach are discussed in several aspects.

Keywords –

process modeling; smart contracts; blockchain; construction industry

1 Introduction

Smart contracts can be used in the construction

industry for process automation, for processes like construction, contracting, or payment. However, the applications and uses of smart contracts are still at a conceptual level. Moreover, smart contract languages are programming languages that are difficult to read, understand, or write for the stakeholders of construction projects, as they are usually not programmers. In the current situation of using smart contracts for system development or construction projects in the construction industry, two group of actors need to be involved: construction stakeholders (e.g. clients and contractors) and software programmers. The stakeholders need to decide system functionality, capture requirements, implement smart contracts and analyze the execution of the smart contracts for the system development. On the other hand, the programmers need to interpret requirements from stakeholders, develop and deploy smart contracts, and evaluate the execution of smart contracts. Implementation of proper smart contracts is a challenge for the non-programmers, which is related to a high effort in terms of time and resources. Otherwise, the programmers' interpretation could be wrong, leading to stakeholders having to deal with the consequences of these codes, which stakeholders may not be able to understand. The construction industry is not the only area with these problems. In the finance area, 60% decentralized finance (DeFi) users cannot read or understand the source code of smart contracts [12].

It is worthy and necessary to develop an approach that allows for the automatic translation of human-readable texts or graphics into smart contracts. Compared to pure text-based languages, graphical representations are more intuitive which can simplify complex contexts, enabling non-programmers to read, understand, verify and design them. This study proposes an approach to translate from graphical representations (e.g. BPMN or YAWL) to smart contract languages (e.g. Solidity) with a detailed explanation of translation and checking steps based on the YAWL graphical representation and the Solidity smart contract language. As a graphical workflow in XML-based format for business processes, YAWL (Yet Another Workflow Language) is the language that not only has proper formal semantics to check properties for

academic purposes, but also supports the control-flow patterns for business processes in practice [8]. Solidity is currently the most well-known and most common-used smart contract language, a language designed for the Ethereum blockchain according to the characteristics of smart contracts. The approach is tested via a payment case in the delivery and acceptance process of certain construction works by translating from the YAWL representation to Solidity.

2 Related work

2.1 Graphical workflow

A workflow can be defined as “a collection of tasks organized to accomplish some business process (e.g., processing purchase orders over the phone, provisioning telephone service, processing insurance claims)” [6]. To express the information, knowledge or systems of a business process in a structure by a consistent set of rules, different process modeling approaches have been proposed, including the Business Process Model and Notation (BPMN), the Web Services Business Process Execution Language (BPEL), the Event-driven Process Chain (EPC), the Yet Another Workflow Language (YAWL) and Petri nets [8].

As Lohmann et al. [8] pointed out, academics prefer languages such as Petri nets, which have proper formal semantics to check properties on corresponding models. However, practitioners prefer languages such as BPEL, EPC and BPMN, which usually lack proper formal semantics. As an exception compared to the above languages, YAWL originated in academia but has actually been used in practice [1]. YAWL supports the most common control-flow patterns found in current workflow practices, allowing most workflow languages to map to YAWL without losing control flow details, even languages with high-level structures (such as cancellation regions or OR-joins) [8,17].

Graphical workflows are also used in the construction industry to describe data flows and processes, with Integration Definition for Function Modeling (IDEF), extended EPC, or BPMN being commonly used [3].

2.2 Smart contract

A smart contract, which was first proposed by Szabo in 1994 [14], is a self-executing digital agreement. After Buterin et al. [4] implemented the smart contract concept as a blockchain application to write, verify and enforce transaction conditions that allows non-currency data stored on the Ethereum blockchain platform in 2014, smart contracts become popular in research and practice. Up to 2020, there are already more than 4,119 papers related to smart contract languages, and 24 different

blockchain platforms are being developed with 101 smart contract languages (e.g. Solidity, Vyper) in total [16].

More and more researchers in the construction industry study the possibilities of using smart contracts. For example, Penzes [11] pointed out that smart contracts in construction can be applied in three directions: 1) payment and project management; 2) procurement and supply chain management; and 3) BIM and smart asset management. Badi et al. [2] investigated the smart contract adoption in the construction industry by a survey among UK construction practitioners, and conclude that smart contracts can be useful in payment, construction contract and in general for organization.

2.3 Research on smart contract generation

The existing research on smart contract generation mainly focuses on using either text-based languages or graphical-based languages to translate smart contracts. The text-based languages can be natural languages [10, 15] and other specification languages [7], while the graphical-based languages can be BPMN [9, 12], Petri nets [19], Unified Modeling Language (UML) [5] or Finite State Machine (FSM) [13].

Tateishi et al. [15] proposed an approach that translates from controlled natural languages to a domain-specific language for smart contract (DSL4SC), then to state chart and finally to executable smart contracts with four defined actions: order, ship, arrive and pay by using a predefined template. Monteiro et al. [10] introduced a prototype method by translating natural language processing (i.e. plain text (TXT) or structured text with markups (XML or HTML)) to smart contract code. A specification language called SPESC designed by He et al. [7] defined contract, party, term and type to assist smart contract generation. However, a direct translation from text-based languages to smart contract languages is error-prone, which is not visual and the logic error could be difficult to discover.

Many other researchers focus on translating graphical workflows to smart contract languages [5, 9, 12, 13, 19]. For example, López-Pintado et al. [9] introduced and implemented a blockchain-based BPMN execution engine called Caterpillar to generate smart contracts by a BPMN-to-Solidity compiler. Since BPMN does not have a logic checking mechanism like Petri nets, the generated smart contracts from BPMN could be error-prone without an additional verification step. Skotnica et al. [12] proposed a model-driven approach to generate smart contracts based on a visual domain-specific language called DasContract. It is a complex approach where the users not only need to define data structures in a programming way and draw BPMN graphics, but also define a user form, which could be difficult to use by non-programmers. Zupan et al. [19] presented a method and a prototype tool based on Petri nets for smart contract

generation. Using Petri nets to model smart contracts is a suitable method to minimize logical errors. However, Petri nets cannot specify roles or tasks so well like BPMN or YAWL for business process. Lohmann et al. [5] proposed to generate smart contracts through UML class diagram. Nevertheless, the design of UML class diagrams requires some basic programming background. Another approach designed by Suvorov and Ulyantsev [13] is using FSM synthesis for automatic smart contract generation. Using FSM is good for showing the states and actions of the smart contracts, but lack role specifications.

3 Methodology

3.1 Overview

It is assumed that a workflow is created in a BPMN or YAWL software tool and exported as XML format. The XML files serve as an import for the proposed smart contract language generator system. The overview of the approach is shown in Figure 1.

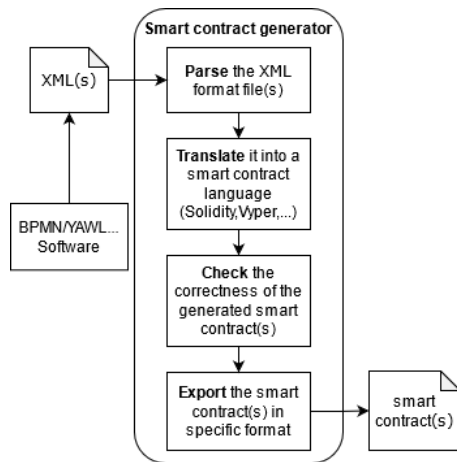

Figure 1. Overview of methodology

An XML-format file is generated via a BPMN or YAWL software tool, and imported into the proposed smart contract language generator system. Such a system needs functionalities for parsing, translating and checking a workflow. Finally, the generated smart contract is exported into the selected format for deployment. Even through the XML structure of YAWL and BPMN are different, the principle of the generation step is the same. YAWL is a graphical representation which not only allows logic checking, but is also easy to understand by non-programmers. Meanwhile, YAWL allows the mapping from most workflow languages without losing the details of the control flow. Therefore, YAWL is used as a graphical representation for the detailed explanation of translation and checking steps in the following two subsections.

3.2 Translation step

After parsing the data from an XML format file, the obtained information is translated into a certain smart contract language. To understand the obtained information, the structure of the XML format file should be explored. Therefore, the XML structure and the format explanation of YAWL and its roles are shown as Figure 2.

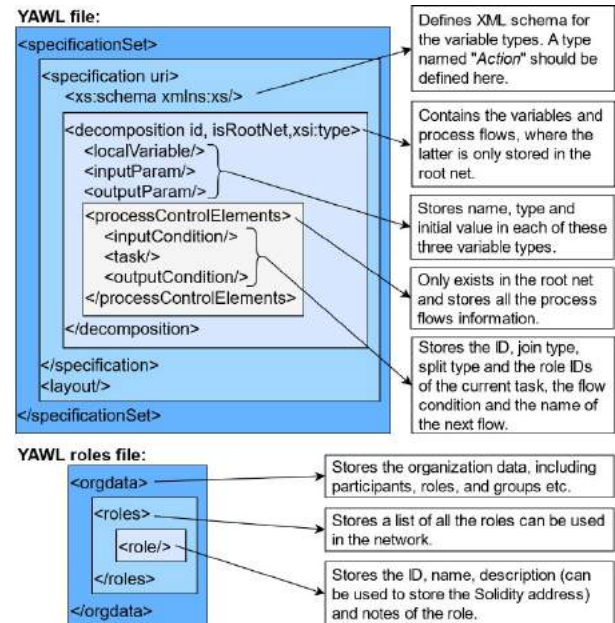

Figure 2 The explanation of the YAWL and the YAWL roles files

In the YAWL file, the stored information can be divided into two parts: specification and layout. The specification stores all the functional information of each task specified in the YAWL, where the layout stores all the geometrical data of these tasks. To aid the automatic translation from YAWL to smart contracts, an action type is designed in this method. As shown in Figure 2, the type named "Action" is defined in the XML schema (xs:schema) of the YAWL file for distinguishing different actions in tasks. The actions can be divided into three types, namely "view", "modify" and "pay". These three actions are defined as variables in the root net. Each task should declare one and only one variable in the "Action" type with one of the three variables to specify the action of this task. In this way, tasks can be automatically translated with the specified action variable. The "view" task specifies that this task is to view some information and no data should be changed in this task. The "modify" task indicates that the value of one or more state variables will be assigned or modified. The "pay" task executes automated payment action with a specific payment amount from one user address to

another user address.

There are two kinds of deposition in the specification, distinguished by with or without the *isRootNet* attribute. The former is the root net that stores the information of local variables and process flows, where the latter kind is a task storing input variables, output variables, and an “Action” type variable. The process flow information is stored in the element called *processControlElements* with the flow information of all tasks. The start and end tasks are tagged as *inputCondition* and *outputCondition* elements, respectively. Each task element stores not only the join type, split type and role identifier(s) of the current task, but also the flow condition and the name of the next task. All roles used in the YAWL file are defined and stored in the YAWL roles file, including the identifier, the name, the description (which can be used to store the Solidity address) and the notes of each role.

According to the explanation of the YAWL and its roles files shown in Figure 2, the information of local variables, roles, tasks with role identifier(s) and variables, and process flows can be extracted. The mapping relationship of the extracted YAWL information and the components of Solidity smart contract language is shown in Figure 3.

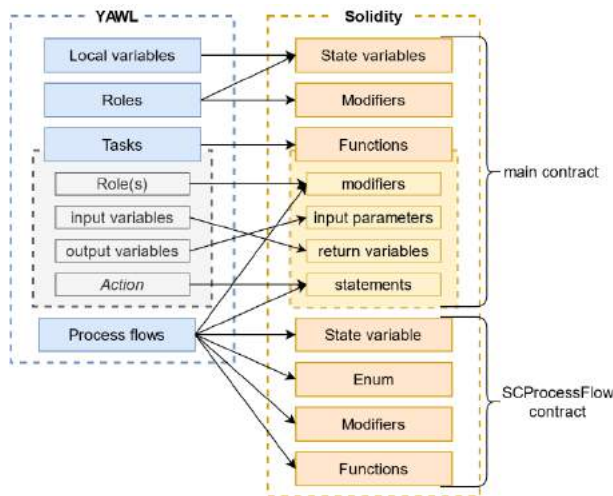

Figure 3 The component mappings from YAWL to Solidity

Solidity is an object-oriented language, which has similar components like all modern programming languages and other smart contract languages. All local variables defined in the YAWL file can be translated as state variables in the Solidity main contract. The roles extracted from the YAWL roles file will be defined as state variables under address type and be declared as modifiers at the same time in the Solidity main contract. A Solidity modifier is used to restrict the executing conditions of a function. When a modifier is called in a function, the function can be executed only when the

conditions stated in the modifier are satisfied. The declared modifiers for roles are used to restrict that only certain roles can execute certain functions. The role(s) and variables of each task will be translated as modifiers, input parameters, return variables and statements based on the variable in *Action* type of each function in the Solidity main contract. Since the logic of tasks in YAWL and functions in Solidity are different, the output variables of tasks are the input parameters of functions. The process flows are translated into state variables, an enumeration, modifiers and functions in the Solidity *SCProcessFlow* contract, which is a parent contract of the main contract, to restrict the executing order of functions in the main contract.

3.3 Checking step

The aim of the checking step is to verify the correctness of the generated smart contracts. In this step, certain rules should be defined for verifying the translated smart contracts. Eight checking rules of a Solidity contract are shown as Figure 4. A translated Solidity contract has five basic components: parent contract(s), enumerations, state variables, modifiers and functions.

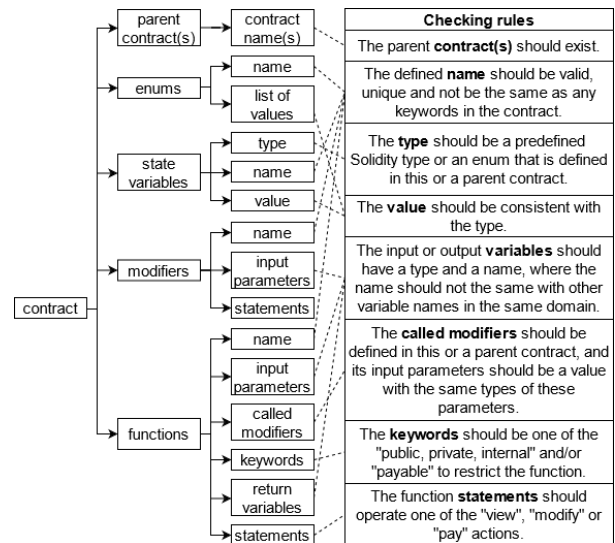

Figure 4 Checking rules of the Solidity smart contract language

When a contract is defined based on one or more parent contracts, the existence of the parent contract(s) should be checked. All the defined component names should be unique and valid. A unique name is not the same as any other names or keywords in the contract. A valid name does not contain any special characters except “_”, or start with a digit. The used types should be preset or defined. The type of value should be consistent with the type of the variable. A declaration of a variable should

be in form “type name;” or “type name = value;”. The modifiers in a function should be validly defined. As mentioned in the previous section, functions translated from YAWL tasks should handle one of the “view”, “modify” and “pay” actions. A “view” function must not change any values of state variables. A “modify” function, on the other hand, should have at least one state variable modified in this function. In the “pay” function, a “payable” keyword must be declared. Moreover, the payer address must be payable, the payer’s wallet must have at least the payment amount, and the payee address must be declared.

4 Illustrative example

An example is illustrated via YAWL to graphically model a workflow, where the workflow is transferred to the Solidity smart contract language. To figure out whether using YAWL can explain the whole process for automated reporting, checking, and payment of construction works, an example is designed in the YAWL graphical representation and shown in Figure 5. The similar workflow was presented as BPMN in the related work [18].

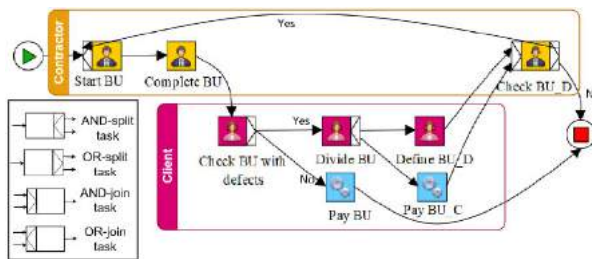

Figure 5. YAWL graphical representation of the example

The example illustrates the delivery and acceptance processes between clients and contractors for a group of construction works, which is defined as a billing unit (BU) with a total payment amount and a completion date. BUs are defined and captured in the billing plan during the contract negotiations. After that, the work can be carried out. As shown in Figure 5, eight tasks and two roles are defined in the example. After certain construction works are defined as a BU, the contractor can start to execute the task “Start BU” and the corresponding construction works. After it is completed, the contractor reports the completion of this BU via executing the “Complete BU” task. The client checks the BU and determines if there are defects regarding the construction works and executes the “Check BU with defects” task. If the BU work has no defects, the task “Pay BU” should be automatically executed, where the client will pay the full payment amount of the BU to the contractor. Otherwise, this BU

will be divided into two parts via a “Divide BU” task. The BU_C is the checked and accepted part, which will be automatically paid with a predefined payment amount via “Pay BU_C” task. The BU_D is the part with defects, which will be redefined by client as a new BU with a new total payment amount and a new completion date in the “Define BU_D”. The contractor can then decide to accept this task or not via “Check BU_D” task. The corresponding local variables and parameters of each task are also shown in the Figure 5.

4.1 Variables

The local variables and declared actions in *Action* type for the example are defined as Figure 6. The initial values of variables can be either assigned at the beginning or later by users. In this case, the *bu_id*, *plannedPayment* and *plannedCompletionDate* variables are assigned in the beginning. The values of “modify” and “view” variables should be the same as their names, where the value of “pay” variable should be the name of payee address variable.

Name	Type	Scope	Initial Value	
<i>bu_id</i>	string	Local	BUID_50b842e6	Local variables
<i>plannedPayment</i>	unsignedInt	Local	14	
<i>plannedCompletionDate</i>	unsignedInt	Local	20210711	
<i>actualStartDate</i>	unsignedInt	Local	0	
<i>actualCompletionDate</i>	unsignedInt	Local	0	
<i>reducedPayment</i>	unsignedInt	Local	0	
<i>isAgreedStart</i>	boolean	Local	<input type="checkbox"/>	
<i>isDefect</i>	boolean	Local	<input type="checkbox"/>	
<i>modify</i>	Action	Local	modify	Action Type variables
<i>view</i>	Action	Local	view	
<i>pay</i>	Action	Local	Contractor	

Figure 6 Defined local variables and three variables with “Action” type

The detailed input and output variables of each task are presented in Figure 7. In a YAWL task, the values of input variables should be assigned before this task, and the values of output variables should be assigned in this task by users. An *Action* type variable is declared in each task as an input variable to tag the action type. In this example, five “modify” tasks, one “view” task and two “pay” tasks are defined. In the “Define BU_D” task, the values of variables *bu_id*, *plannedPayment* and *plannedCompletionDate* are reassigned.

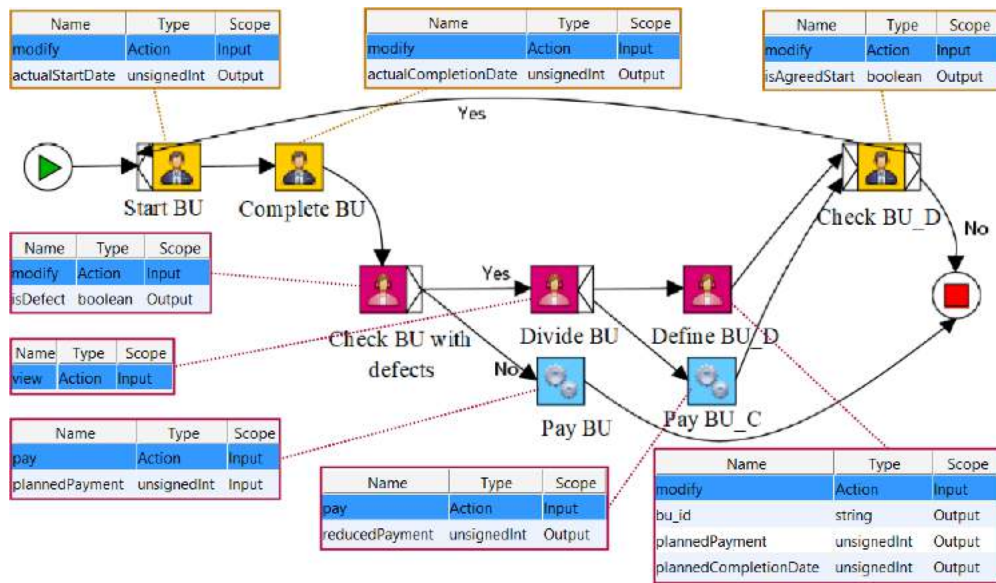

Figure 7 The declared input and output variables of each task in the example

4.2 Implementation

To test the feasibility of the method, a tool of smart contract generation is developed. The implemented smart contract generator and the corresponding results of this example are shown in Figure 8. This generator can be divided into two parts: A) parse & translate, and B) check & export. In subparts A1 and A2, YAWL graphical representation and YAWL roles should first be loaded. After clicking the translation button, the information in

the YAWL and YAWL roles files is translated into the Solidity smart contract language according to the translation step, and the generated smart contracts are shown in subpart A3. The generated file structure is shown as a tree table on the left side of A3, and the detailed codes of the corresponding smart contracts are shown on the right side of A3. In part B, a tree table and error message(s) are generated after checking the generated smart contracts, and then the whole contract folder can be exported.

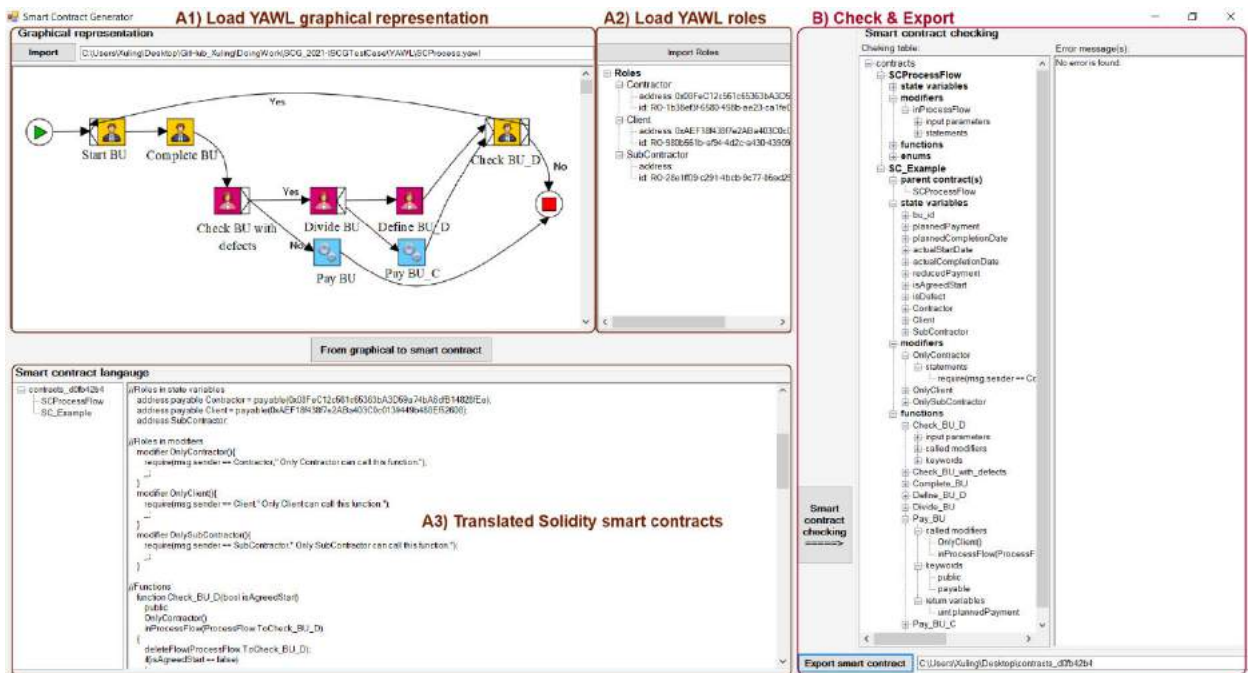

Figure 8 User Interface of smart contract language generator

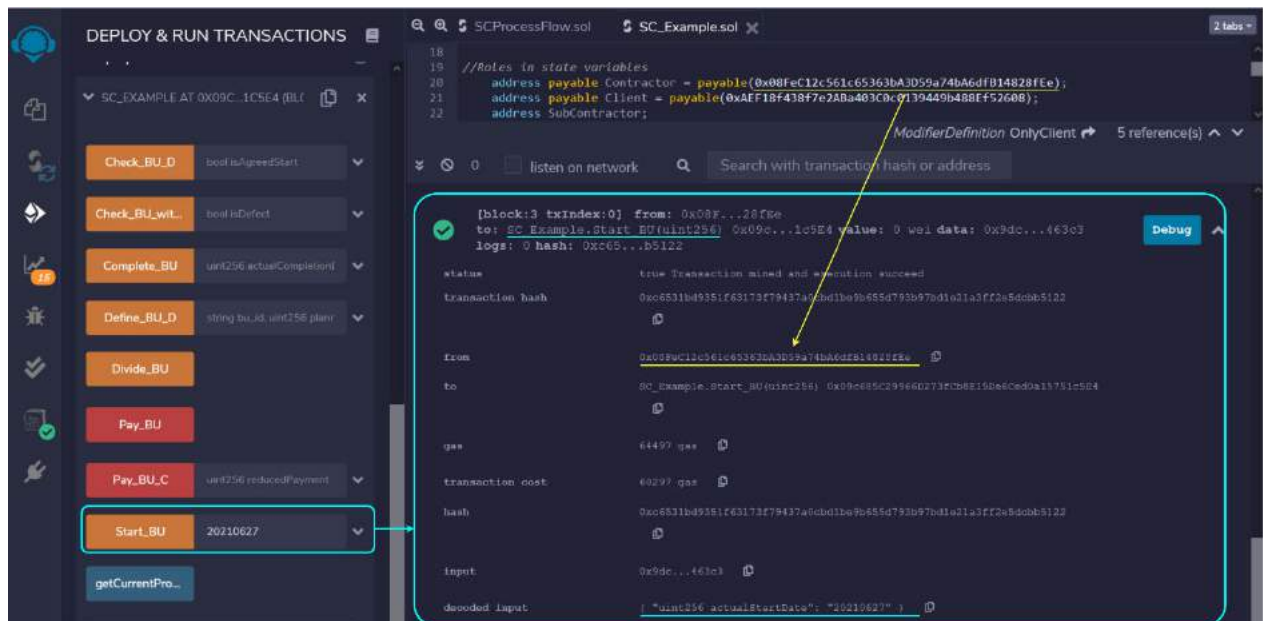

Figure 9 The test result in the Ethereum Remix after successfully executing the BU_stated function

The generated Solidity smart contract files can be simply deployed and tested via the Ethereum Remix in the browser. The test result shown in Figure 9 is after successfully executing the Start_BU function defined in the SC_Example contract. The start date is successfully set as “20210627” by the contractor at the address “0x08FeC12c561c65363bA3D59a74bA6dfB14828fEe”.

5 Conclusion and future work

Smart contracts can automate many construction processes, such as contracting, delivery, acceptance and payment. However, as smart contracts are programming codes, they are difficult to be read, design, program, and verify by non-programmers. This paper proposes a framework for automatically generating smart contracts from graphical representations following four steps of parsing, translation, checking and exporting. The YAWL graphical representation and Solidity smart contract language are used to further explain the translation and checking steps. An illustrative example is presented through generating Solidity smart contracts from YAWL for automated the reporting, checking and payment process of construction works between clients and contractors. The corresponding implemented smart contract generator is illustrated and the execution result of the generated smart contracts in the Ethereum Remix is also displayed.

Future studies should consider a more detailed and practical development of payment functions. For example, in addition to using the currency in the blockchain platform, linking with banks via smart contracts for automatic payments could be more suitable

for the current situation. Moreover, more components of the Solidity smart contract language (e.g., mappings, events, abstract contracts), more smart contract checking rules, other graphical representations (e.g., BPMN), and other smart contract languages should be further taken into account.

Further testing should be conducted with construction stakeholders for feedback on the feasibility of the method and the developed tool proposed in this paper. Compared with the development of the entire smart contract generation system, the development of a plugin application or a library can be more extensible, more convenient, and more widely used. In addition to generating smart contracts from graphical representations, another direction, namely translating smart contracts to XML files or graphical representations, should also be investigated.

Acknowledgement

The study was conducted as part of the BIMcontracts research project funded by the German Federal Ministry for Economic Affairs and Energy (BMWi) within the "Smart Data Economy" technology program (project number: 01MD19006B).

Abstract –

To help project managers better understand non-conformance in prefabrication projects, this research presents a probabilistic empirical study on non-conformance reports (NCRs), their root cause and frequency of occurrence, as well as their impact on the project cost and time. Data from a completed nuclear project were collected and analyzed, where 1,179 NCRs were raised during the three-year fabrication period, consisting of six distinct modules and a ring girder. Five broad categories are used to distinguish general liabilities of those NCRs (internal vs. external) as well as at which stage along the project the non-conformance occurred (material receipt vs. fabrication). A further breakdown of 33 defect codes from those broad categories reflect the specific root cause of each non-conformance. Probabilistic analysis show that geometric-related non-conformance amongst all defect codes represent over half of all analyzed NCRs. Furthermore, in the interest of understanding the impact of these geometric-related issues on the project, 84 NCRs were sampled for evaluation; they were reviewed and assessed individually by an industry expert who is familiar with the nuclear project in this study, to estimate the cost and time impact of the sampled non-conformance. Based on the estimate, the average cost and time impact per non-conformance are nearly \$1,000 and 14.5 man-hours, respectively, accounting for additional resources required to rework, inspect again, and release the assembly. The findings provide project managers with useful implications to identify non-conformance root cause in prefabrication, reduce the risk and impact of these issues, and improve the performance of future projects.

1 Introduction

Construction is an integral industry of the Canadian economy, such that its \$140 billion market contributes to 7.3% of GDP [1]. However, the worker productivity trend does not reflect growth experienced by the construction industry, which has nearly doubled since 1997. Construction labour productivity in Canada increased by less than 10% in the past two decades, while productivity in the manufacturing industry improved by almost 50% over the same time [2]. Efforts to improve construction productivity take advantage of the more established and mature manufacturing processes and techniques, such as modularization and off-site assembly. As civil industry work requirements become more demanding, and modular component tolerance continues to decrease for more complex projects, there exists a need to incorporate and utilize quality control technologies similar to what have been used in the manufacturing and automotive industries for years.

Project physical complexity may be affected by the component and module size dimensions, along with geometry of the overall module. Quality checks in the current modular fabrication sector may occur in the form of documented quality control by qualified staff, or undocumented self-checks by the craft workers themselves. To rework items that failed quality checks, the process includes taking the modules apart, realigning individual components, attaching the pieces together again, and conducting another quality check. This is a significant waste of resources, resulting in reduced overall productivity represented by additional time and manpower spent on correcting the errors.

To improve the productivity and continuous flow of prefabrication and construction, it is necessary to identify and better understand non-conformances along the project processes that would cause reworking. A number of studies have focused on developing real time monitoring technologies and software to detect defects of construction components [3,4]; however, less attention is

received to examine the frequency of defects and non-conformances, as well as their impact on project performance such as cost and time. It is partly due to the lack of empirical project information available for analyzing the non-conformance issues and their impact. To address this gap, this paper collected data from a completed nuclear prefabrication project, and conducted probabilistic empirical study on non-conformances, their root cause and frequency of occurrence, as well as their impact on the project cost and time. The findings provide project managers with useful implications to identify non-conformance root cause in prefabrication, reduce the risk and impact of these issues, and improve the performance of future projects.

The remaining of this paper is structured as follows. Section 2 includes an overview of the relevant studies on reworking in construction in general and specific reworking challenges in prefabrication projects. Section 3 introduces the research methodology and background information of the nuclear project chosen for the empirical analysis. The subsequent analyses include defect root cause analysis in Section 4 and geometric defect impact analysis in Section 5. Lastly, Section 6 summarizes the conclusions and future work.

2 Literature Review

2.1 Reworking in Construction

Due to the nature of work in the industry, reworking is largely inevitable in traditional construction. Unlike manufacturing, where process automation could be achieved and optimized by machinery, the need for human involvement in standard construction projects introduce the risk of non-conformance errors associated with poor workmanship. There are several potential reworking root causes in addition to construction site human error, such as design change, defective materials, and lack of planning and coordination within the project team; nonetheless, their impact on the overall project performance is evident. In a survey of 161 Australian construction projects, it was observed that costs related to reworking contribute an average of 52% to a project's cost growth [5], which may include direct cost (labour and material to rework) and other intangibles such as schedule delays and litigation cost. From the same survey, the mean direct and indirect costs to rework were found to be 6.4% and 5.6% of the original contract value, respectively [5]. Other research studies reflect a similar impact in other types of construction projects, such that the cost to rework represents 4% of contract value in residential construction [6], adds 10% of contract value in civil infrastructure projects [7], and ranges from 3.1% to 6.0% of the project value in building projects [8].

Reworking root causes have been the subject of many

subsequent research efforts to reduce its impact. In a study that analyzed 359 projects with varying project characteristics from the Construction Industry Institute (CII) database, it was found that heavy industrial projects for contractors were most affected by reworking, and the most important root causes are owner change and design error/omission for both owner and contractor reported projects [9]. These issues may result from inadequate planning and poor communication amongst owners, designers and constructors, thus they highlight the need for a comprehensive reworking management system that involves all the stakeholders and different organizational and technological measures at every stage of the project [10]. This recommendation echoed the findings from a survey of 115 civil infrastructure projects by Love et al. [7], where they identified the ineffective use of information technology to communicate as the primary factor contributing to reworking. Therefore, reworking reduction requires the need to better plan and manage the design and documentation process.

To minimize and rectify the impact of reworking, preventative methods must be applied in order to reduce the probability of errors occurring throughout a project lifecycle, and appraisal measures should be implemented to detect defects and assess conformance to the required tolerance level.

2.2 Reworking in Prefabrication

Prefabrication, preassembly, modularization, and off-site fabrication (PPMOF) research and practice have been reaping growing interest over the years. Its potential for increased project performance offers improvement in construction quality, productivity, safety, sustainability, cost, and schedule [11,12], thus becoming an appealing and effective alternative to traditional stick-built construction for owners and contractors alike. As a fundamentally distinct approach to construction, there are varying risks in PPMOF compared to traditional stick-built method, increasing demands and complexity to aspects of project organization, engineering, procurement, planning, monitoring, coordination, communication, and transportation [13]. Therefore reworking in prefabrication must be managed through understanding the risks at different stages of a PPMOF project, as well as recognizing the impact of these risks on project performance, such as cost and schedule.

A study identified and categorized risks into general risk factors, in-plant risk factors, and on-site risk factors, and subsequently quantified and assessed them to propose a risk management framework in modular construction, where the process was simulated to evaluate the exposure of cost and schedule to quantified risk factors [14]. This necessitates monitoring and controlling risks in PPMOF, from both the managerial and technical context. Specific to modular construction,

dimensional and geometric compliance for strict tolerance requirements were examined, in which a structural analysis framework incorporates cost and risk to assess the optimal design solutions [15]. Another risk management framework also includes the evaluation of tolerance-related issues, where the compromise between off-site and on-site costs contribute to the identification of the optimum geometric variability, to improve modularization performance and maximize its benefits [16]. Owing to the advancements in technology research, additional tools can be used to help facilitate detection of non-conformance cases in design (component clashes) and construction (installation tolerance discrepancies), such as building information modelling (BIM) for project design and lifecycle control, robotics automation for fabrication control, and 3D sensing technology for quality control.

These studies emphasized the importance of quick identification of risks and potential quality problems, but a comprehensive understanding of non-conformance issues resulting from those risks has been missing from the current body of knowledge. Therefore, an empirical analysis regarding the non-conformance root cause and their impact on project time and schedule performance is required to fill the gap.

3 Methodology and Project Background

To understand the types of non-conformances, their frequency of occurrence within a project, as well as their impact on the project cost and schedule, the research team collaborated with a major fabricator in the construction industry, and methodology as summarized in Figure 1 is followed throughout the research.

The research team chose one of the industry partner's completed nuclear projects, because of the systematic collection of data during quality control through all stages of fabrication, resulting in a comprehensive data log of non-conformance for this case study analysis. Due to the complex nature of this nuclear project, the information recorded were of higher granularity than other non-nuclear projects. A total of 1,179 non-conformance reports (NCRs) were raised during the three-year fabrication period for this project, which required the fabrication of six distinct modules and a ring girder for nuclear power plants (NPPs) in the United States. The research team obtained a copy of the entire NCR data log for the project, and it formed the basis of all subsequent analyses for this case study.

The nuclear modules range in size from 9,200 lbs (4,173 kg) to 102,000 lbs (46,266 kg). Figure 2 illustrates the 3D design of modules fabricated in the project case study. Each module contains vital components to mechanical systems within the NPPs, such as passive containment cooling, passive core cooling, liquid

radioactive waste, demineralized water, fire protection, residual heat removal, as well as pressurizer safety and automatic depressurization. Given the design complexity of each module and the need to adhere to nuclear operational and safety requirements, they also have several challenges throughout the project, including:

- Management of the high number of system code changes, ensuring the quality requirements of each system are met.
- Module frame construction with “megabeam” and non-standard truss geometries.
- Assembly, welding and inspections of frame, spools and supports in a tight and complex geometry.
- Welding of high strength SA-517 steel requires specialized weld procedures and regimented pre-heat and post-weld heating cycles.

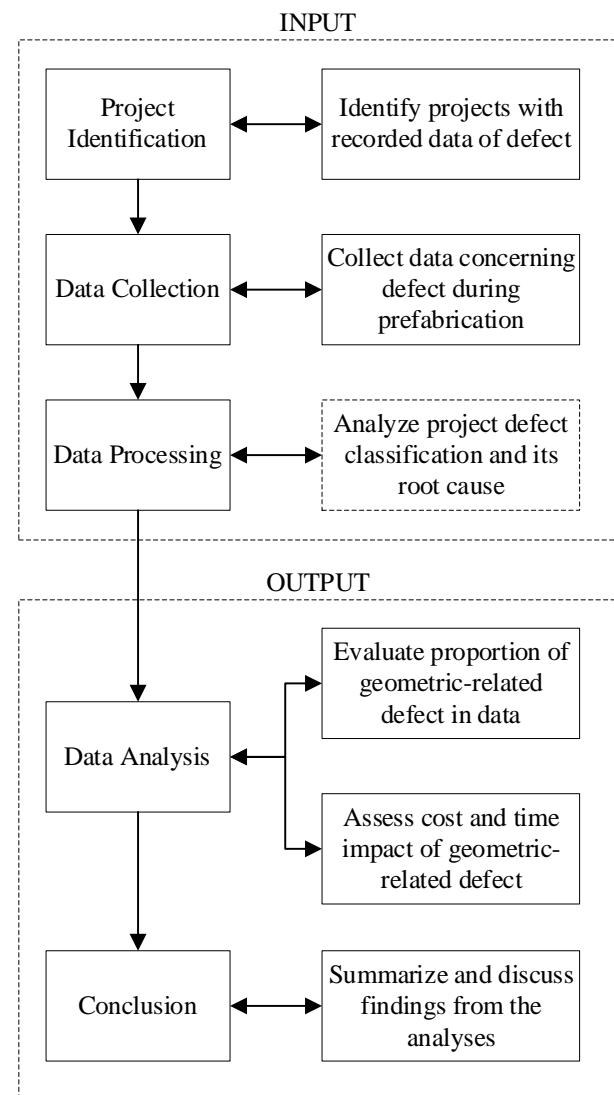

Figure 1. Research methodology

Figure 2. Illustrations of some the prefabricated modules for NPPs in this project case study

Each module in the nuclear project is unique, and their fabrication required highly skilled craft workers to fit and weld all the pressure piping components and supporting structural assemblies. To meet project requirements and deadlines, the fabrication shop was at full capacity with 80 dedicated workers. The workforce included 20 quality control personnel, who are responsible for quality control throughout the project lifecycle, including all activities of material receipt, in-progress fabrication, and final release for shipment to site. The modules are also subjected to additional inspection by third-party Authorized Nuclear Inspectors, who ensure all fabricated components and systems are fit for use for nuclear applications according to design.

4 Defect Root Cause Analysis

In accordance with the industry partner's internal Quality Control Procedure, each NCR is assigned a "defect code" to reflect the root cause of its non-conformance. These defect codes are categorized under five broad types, which are as follows:

1. Procurement Issue (Internal)
2. Material Issue from Vendor (External)
3. Fabrication / Construction Issue (Internal)
4. Engineering / Document Control Issue (Internal)
5. Free Issue Material from Customer (External)

These five categories encompass almost all possible non-conformances a fabrication shop would experience, during the two main phases of (1) material receipt and (2) fabrication. Material liabilities are further differentiated between materials procured through vendors and those supplied by the owner. They are considered as external responsibilities through no fault of the fabrication shop. On the other hand, drafting errors and omissions as well as fabrication miscues are viewed as internal accountabilities, where craft workers such as fitters and welders are responsible for rectifying their identified non-conformance.

A total of 33 defect codes as identified in the Quality Control Procedure reflect the specific root cause of each non-conformance. All 1,179 NCRs from the nuclear project were analyzed for their defect code as well as the specific nuclear module affected. Table 1 summarizes the frequency of each defect code as documented in the NCR data log. Furthermore, for clarity, defect codes related to geometric non-conformance are also highlighted grey.

Through qualitative assessment of all documented NCR, it was found that some of the defect codes were used interchangeably, such as codes 2.3, 2.4, and 2.9, which concerns "damaged material", "material defect", and "dimensional / out of tolerance" issues, respectively. Despite their difference in assigned code description, they are all related to specific tolerance measurements (i.e., dimensions) and relationships of angles and surfaces of the objects. Thus, based on the root cause analysis of non-conformance in this nuclear project, defect codes 2.3, 2.4, 2.9, 3.1, 3.3, 3.7, 5.1, and 5.2 are actually geometric in nature, and they represent the majority of reported issues, as summed at the end of Table 1. Figure 3 displays module difference in geometric defect code proportion, compared to the baseline average for the project.

While it is unclear how module complexity affects geometric non-conformance, it is evident from Figure 3 that defect codes 2.9 (material "dimensional / out of tolerance" issues) and 3.3 (fabrication "dimensional / out of tolerance" issues) are the two most frequently cited non-conformance. The two defect codes together represent over half of the geometric-related issues for each module, except for Q305, which had a higher proportion of non-conformance concerning "material defect". This further demonstrates the strict design and tolerance requirements for nuclear projects, therefore, any tools used for quality control must be able to meet the specific accuracy and precision demand for effective inspection.

Table 1. Non-conformance root cause and their frequency

Defect Codes		Frequency	Percentage
1.	Procurement Issue		
1.1	Purchase Order Error	2	0.17%
2.	Material Issue (Vendor)		
2.1	Missing MTR / Documentation	8	0.68%
2.2	Incorrect MTR (Material Test Report)	4	0.34%
2.3	Damaged Material / Item - Incoming	23	1.95%
2.4	Material Defect	100	8.48%
2.5	Wrong Material / Improper Specification	16	1.36%
2.6	Contamination	11	0.93%
2.7	Identification / Traceability	30	2.54%
2.8	Counterfeit Material / Item	0	0.00%
2.9	Dimensional / Out of Tolerance	191	16.20%
2.10	Improper Material Substitution	3	0.25%
3.	Fabrication / Construction Issue		
3.1	Damaged Material / Item - Production	69	5.85%
3.2	Improper Material Substitution	1	0.08%
3.3	Dimensional / Out of Tolerance	212	17.98%
3.4	Use of Detrimental / Unapproved Product	9	0.76%
3.5	Unqualified Welder / Welding Operator	4	0.34%
3.6	Wrong WPS Used	6	0.51%
3.7	Fitting Error	20	1.70%
3.8	Weld Defect	71	6.02%
3.9	Wrong Material / Consumable Used	10	0.85%
3.10	Lack of Process / Procedural	168	14.25%
3.11	Drawing Error	17	1.44%
3.12	Machining Error	12	1.02%
3.13	Loss of FME (Foreign Material Exclusion)	2	0.17%
3.14	PWHT (Post Weld Heat Treatment) Error	2	0.17%
3.15	Pressure Test Failure	6	0.51%
3.16	Paint Defect	22	1.87%
4.	Engineering / Document Control Issue		
4.1	Drawing or Drafting Error	17	1.44%
4.2	Non-current Revision	1	0.08%
4.3	Process Compliance	26	2.21%
5.	Free Issue Material (Customer)		
5.1	Damaged Material / Item	12	1.02%
5.2	Does Not Meet Code / Specification / Standard / Contract	66	5.60%
5.3	Insufficient / Incomplete Documentation	38	3.22%
Total		1,179	100.00%
Geometric		693	58.78%

Figure 3. Module difference in geometric defects

5 Geometric Defect Impact Analysis

Although each NCR in the data log summarized information such as the module affected, description of non-conformance, remedy proposal, as well as explicit instructions on how to rectify the errors, it is almost impossible to cross-reference a project change order to a specific non-conformance root cause. Consequently, a preliminary estimate was carried out to assess the cost and time impact of correcting geometric-related issues. An interview was conducted with the fabrication manager who oversaw the entire nuclear project, having experience handling almost all the issues reported in the data log, including proposing defect remedies and overseeing their execution.

Out of the 693 geometric-related non-conformances, 84 NCRs were sampled, and this is based on having a confidence level of 95% that the real value is within $\pm 10\%$. While it would be better to have more random samples for a higher confidence level and lower margin of error, the estimate is also constrained by time availability of the project team that has direct knowledge of these NCRs. Nonetheless, the proportion of each defect code within the population of geometric-related NCR is preserved.

During the interview with the fabrication manager, these sampled NCR were reviewed individually for their non-conformance root cause, and further assessed for their impact on the nuclear project. Table 2 summarizes the number of samples from each defect code that

constitute the estimate, as well as the statistics of estimated cost and time impact of the 84 sampled geometric non-conformances.

In general, a baseline man-hour of six hours is applied to each NCR, to account for the time it takes to review the non-conformance, file the report, formulate a solution, and release the assembly after adjustments are executed if required. Furthermore, a base hourly rate of \$65 is assumed for both the quality control personnel and craft workers (i.e., fitters and welders). For each NCR, any additional time is based on labour required to rework, and any additional cost is based on new materials and extra man-hour. As shown in Table 2, the average cost impact of sampled geometric non-conformance is almost \$1,000, and the time impact is approximately 14.5 man-hours. The results of the estimate are further evaluated to characterize the sampled data, which would allow curve fitting of probability distributions. Figure 4 presents the cost and time impact histograms.

Probability paper plotting is used to verify assumed probability distribution. Three common distributions are assessed, including normal, lognormal, and Weibull distribution. Due to the linear relationship of the plot, coefficient of determination (R^2) can be used to measure how well a linear regression model fits the dataset. Comparing the three distributions, it was found that lognormal distribution had the strongest linear association, as it had the highest R^2 value for both time and cost impact metrics. Figure 5 shows lognormal probability paper plots for the impact of sampled NCRs.

Table 2. Estimate cost and time impact of geometric non-conformance

Defect Code		Number of		Cost (\$)			Time (Man-Hour)		
		Population	Sample	Min	Max	Mean	Min	Max	Mean
Material Receipt	2.3	23	3	390	1,040	607	6	16	9.3
	2.4	100	12	390	910	531	6	14	8.2
	2.9	191	24	650	3,250	1,354	10	50	19.3
	5.1	12	1	390	390	390	6	6	6.0

6 Conclusions and future work

In summary, there are some key findings from the non-conformance root cause analysis of the nuclear project case study. According to the industry partner's internal Quality Control Procedure, five categories are used to distinguish general liabilities (internal vs. external) of non-conformance, as well as at which stage along the project the non-conformance occurred (material receipt vs. fabrication). A total of 33 "defect codes" are classified under these five broad categories, specific to the type of non-conformance observed. Upon qualitative analysis of all 1,179 documented NCRs, it was found that defect codes 2.3, 2.4, 2.9, 3.1, 3.3, 3.7, 5.1, and 5.2 per Table 1 are actually geometric in nature, and they represent nearly 60% of all reported issues during the three-year fabrication period. Within these geometric-related NCRs, over half of them are issues concerning dimension and tolerance for incoming materials and fabrication.

In the interest of understanding the impact of these geometric-related issues on the project, 84 NCRs were sampled for evaluation; they were reviewed and assessed individually by an industry expert who is familiar with the nuclear project in question, to estimate the cost and time impact of these sampled non-conformance. Based on the estimate, the average cost impact is almost \$1,000 and the average time impact is 14.5 man-hours; they account for additional resources required to rework and to release the assembly. Subsequent analysis confirms that both of the impact metrics conform very closely to lognormal distribution.

It should be noted that this is the only data log available where all non-conformances are tracked and documented throughout the project lifecycle within the fabrication shop; however, the methodology and findings may be applied to other prefabrication projects in the industry, specifically the classification of defect codes as well as the need to address geometric-related non-conformances during fabrication.

Moreover, the data log does not include non-conformance reported at project site, meaning the impact does not account for fabrication errors that are

overlooked before shipment, or any liability dispute between the fabricator and site installation team. For example, in a high volume and relatively complex project, it may require a crew of four for three months to inspect, count, and bill all materials of the prefabricated spools at the project site. Additional costs may also be considered to rework any errors, which include but are not limited to crew travel, lodging, schedule change, spool and/or module transport, reworking at site and/or back in the shop, as well as performing required non-destructive testing again. These expenses can amount to hundreds of thousands to millions of dollars depending on the project. Consequently, this necessitates accurate and precise documentation of the final assembly, before it leaves the fabrication shop to project site. With 3D scanning becoming increasingly affordable and accurate for industrial use, it could function as a tool for geometric quality control during material receipt and fabrication in-process check, as well as act as an approved internal record to mitigate the risk of legal disputes of assigning responsibility to rework after shipment to site.

Abstract

It is widely considered that the problem of extensive emissions from construction equipment is one of the main threats to human health. Thus, owners of construction equipment must formulate proper replacing and retrofitting strategies to reduce emissions with resource constraints. Therefore, this study proposes an optimization model to help owners of construction equipment to formulate proper replacing and retrofitting strategies, by employing the theory of integer linear programming (ILP). This optimization model incorporates environmental considerations into their decisions making, which can minimize the sum of the economic and environmental costs associated with purchasing new construction equipment, salvaging and retrofitting old in-use construction equipment, operating construction equipment over the period of analysis. The replacing and retrofitting strategies formulated by using the optimization model can also ensure the achievement of the emission reduction target of making the overall emission level of construction equipment fleets at or under a certain level. This study also demonstrates the applicability of the proposed model through a case study, which suggests that the proposed model can make informed strategies of replacing and retrofitting for the case excavator fleet. It is observed that the requirements of various environmental regulations and incentive initiatives do impact the making of replacing and retrofitting strategies and pose a financial burden on owners of construction equipment. Moreover, this study suggests that governments can also adjust subsidy grant levels to allocate the responsibility of reducing emissions from construction between governments and owners of construction equipment.

1 Introduction

Air pollutants, one of the greatest threats to the sustainable development of human beings, can cause health problems such as respiratory, eye irritation and lung diseases (Jacobs et al., 2010; Tian, Yao, & Chen, 2019). As reported by World Health Organization (2014), air pollutants can lead to approximate 3.7 million people died annually around the world. Construction equipment has been widely considered one of the significant air pollutant sources (Fu et al., 2012; Frey et al., 2010; Szamocki et al., 2019). In Hong Kong, non-road mobile machines mainly comprised of construction equipment produced about 8% emissions, as shown in the 2018 Hong Kong Emission Inventory Report issued by the Environmental Protection Department of Hong Kong (2020). According to the United States Environmental Protection Agency (US EPA, 2006), construction equipment emitted approximate 32% of all land-based non-road NO_x emissions and more than 37% of land-based non-road Particulate Matter (PM₁₀) in 2005. According to London Atmospheric Emissions Inventory (LAEI) 2016 (London Datastore, 2019), construction equipment was responsible for 7% of NO_x emission, 34% of PM₁₀ emission, and 15% of PM_{2.5} emissions in London. Thus, it is critical that owners of construction equipment shoulder the emission reduction responsibility through sustainably managing their equipment. Namely, they should incorporate environmental considerations into their formulation of replacing and retrofitting strategies, which traditionally is undertaken only with economic considerations.

On the other hand, to control the increasing emissions from construction equipment, a host of initiatives have been implemented in many countries, in particular forms of grant incentives, tax incentives, modified contracting

procedures and so on. Typical grant incentives include California's Carl Moyer Memorial Air Quality Standards Attainment Program and The Texas Emissions Reduction Plan administered by the Texas Commission on Environmental Quality, which funds equipment for replacement, repowering or retrofitting (US EPA, 2005). Two typical tax incentives are Oregon's Pollution Control Tax Credit Program and Georgia diesel particulate emission reduction technology equipment tax credit program (US EPA, 2005). Moreover, some projects like the Massachusetts Central Artery/Tunnel project adopted a contract requirement to promote the retrofitting of contractor-owned diesel equipment (US EPA, 2005). Thus, owners of construction equipment are being constrained to act strictly in accordance with these initiatives. The revenues or costs incurred by participating in these initiatives change the cash flow of construction equipment and finally have an impact on equipment management (Huang et al., 2021a). However, traditional equipment replacement models fail to consider this environmental impact, which are used to determine when to purchase new equipment and when to salvage which equipment in fleets merely under the economic constraints. With the constraints of environmental regulations and incentives, affected owners of construction equipment are faced with more challenging management of their equipment. They also need to make informed decisions about when to retrofit which equipment and which emission reduction technologies should be adopted. Traditional equipment replacement models are unable to help owners of construction equipment to deal with this challenge. With the problem of extensive emissions from construction being widely concerned, it is predictable that more and more initiatives will be implemented. The need of proposing a model to formulate proper replacing and retrofitting strategies is becoming urgent, which can minimize costs or maximum revenues under not only economic but also environmental considerations.

Previous studies have employed the integer programming theory to make replacement decisions of construction equipment. However, there are no studies, which considered the impact of economic incentives on the replacing and retrofitting strategies and proposed a model for addressing this issue. For example, Gunawardena (1990) uses the technique of Integer Linear Programming to find the optimum replacement strategy for equipment with the objective of either cost minimization.

Therefore, this study aims to propose an optimization model with economic and environmental considerations to help owners of construction equipment make proper replacing and retrofitting strategies for emission reduction. The proposed model can be used to optimize the number of purchased, in-service, salvaged, replaced

and retrofitted construction equipment in each period, so that the total cost is minimized and the emission reduction targets of various initiatives that the owners of construction equipment participate in can be achieved.

2 Methodology

In this section, this study proposes an optimization model with economic and environmental considerations for construction equipment management by employing the theory of integer linear programming.

To take into the economic factors, this study includes the costs of purchasing new construction equipment due to normal depreciation of aging, salvaging old equipment, maintaining and operating in-service equipment during the planning periods.

Owners of construction equipment must limit the emission levels of their equipment according to the requirements of environmental regulations and initiatives that they are constrained to. Thus, to take into the environmental factors, this study formulates an emission cap, which is an important constraint in the optimization model as shown in Equation (4). The proposed optimization model also incorporates the costs and revenues incurred by using retrofitting technologies to control emission levels under the emission gap.

The outputs of the model include the optimal decision on the mix of construction equipment that should be purchased, salvaged, retrofitting and in-service in each period. This model optimizes decisions over a planning horizon with T periods. Each construction equipment is specified by type $k=1, \dots, N$, and age $i=0, \dots, I$, where N and I present the number of types of construction equipment and the maximum age respectively. Purchase, salvage and retrofitting action are taken at the beginning of each period. Decision variables and parameters of the optimization model are as follows:

Decision variables:

$Y_{kij,A-B}$ number of k -type and i -period-old construction equipment retrofitted from US Tier A emission standards to Tier B at the beginning of period j , with $(A-B) \in \{1-2, 1-3, 1-4i, 1-4f, 2-3, 2-4i, 2-4f, 3-4i, 3-4f, 4i-4f\}$;

X_{kij} number of k -type and i -period-old construction equipment used in period j ;

$X_{kij,A}$ number of k -type and i -period-old construction equipment meeting US Tier A emission standards, used in period j , with $A \in \{1, 2, 3, 4i, 4f\}$;

$X_{kj,A}$ number of k -type construction equipment meeting US Tier A emission standards, purchased in period j ;

$S_{kij,A}$ number of k -type and i -period-old construction equipment meeting US Tier A emission standards, salvaged at the beginning of period j ;

Economic parameters:

C_j budget available for purchasing new construction equipment in period j ;

P_{kj} purchase cost of a new k -type construction equipment at the beginning of period j ;

OC_{ki} cost of operating a piece of k -type and i -period-old construction equipment;

r_{ki} revenue from salvaging a k -type and i -period-old construction equipment;

EP subsidy or penalty level for reducing emissions by replacing or retrofitting construction equipment;

hp_k engine power of k -type construction equipment;

D_{kj} number of k -type construction equipment demanded in period j ;

OT_{kij} operating time of a piece of k -type and i -period-old construction equipment in period j ;

$X_{0ki1,A}$ number of k -type and i -period-old construction equipment meeting US Tier A emission standards at the beginning of period 1;

Environmental parameters:

a_m the equivalent coefficient of emission m ;

$e_{km,A}$ emission level of a piece of k -type construction equipment meeting US Tier 1 emission standards in regard of emission m ;

e_{km}^0 emission level of a piece of k -type construction equipment meeting the emission requirement of governments in regard of emission m ;

$R_{k,A-B}$ cost of retrofitting a piece of k -type construction equipment from US Tier A emission standards to Tier B;

The objective function is the minimization of the sum of the economic and environmental costs associated with purchasing new construction equipment, salvaging and retrofitting old in-use construction equipment, operating construction equipment over the period of analysis, i.e. from year one to the end of year T :

Minimize:

$$\begin{aligned} & \sum_{k=1}^N \sum_{j=1}^T \sum_{A=1}^{4f} X_{kj,A} P_{kj} - \\ & \sum_{k=1}^N \sum_{i=0}^I \sum_{j=1}^T \sum_{A=1}^{4f} S_{kij,A} r_{ki} + \\ & \sum_{k=1}^N \sum_{i=0}^I \sum_{j=1}^T \sum_{(A-B)=(1-2)}^{4i-4f} R_{k,A-B} Y_{kij,A-B} + \\ & \sum_{k=1}^N \sum_{i=0}^I \sum_{j=1}^T X_{kij} OC_{ki} - \\ & EP \left\{ \sum_{k=1}^N \sum_{i=0}^I \sum_{j=1}^T \sum_{m=1}^M \left[a_m \times hp_k \times OT_{kij} \times (T + 1 - j) \times \left(\sum_{A=1}^{4f} e_{km,A} S_{kij,A} + \sum_{(A-B)=(1-2)}^{4i-4f} (e_{km,A} - e_{km,B}) Y_{kij,A-B} \right) \right] \right\} \end{aligned} \quad (1)$$

This objective function is subject to the following constraints:

$$\sum_{i=0}^I X_{kij} \geq D_{kj}, \forall k = 1, \dots, N; \forall j = 1, \dots, T \quad (2)$$

$$\sum_{k=1}^N \sum_{A=1}^{4f} X_{kj,A} P_{kj} \leq C_j, \forall j = 1, \dots, T \quad (3)$$

$$\frac{\sum_{k=1}^N \sum_{i=0}^I \sum_{m=1}^M e_{km}^0 a_m hp_k X_{kij}}{\sum_{k=1}^N \sum_{i=0}^I hp_k X_{kij}} \geq$$

$$\frac{\sum_{k=1}^N \sum_{i=0}^I \sum_{m=1}^M a_m hp_k \left(\sum_{A=1}^{4f} e_{km,A} X_{kij,A} \right)}{\sum_{k=1}^N \sum_{i=0}^I hp_k X_{kij}}, \forall j = 1, \dots, T; \quad (4)$$

$$\sum_{(A-B)=(1-2)}^{1-4f} Y_{kij,A-B} + S_{kij,1} \leq X_{k(i-1)(j-1),1}, \forall k = 1, \dots, N; \forall j = 2, \dots, T; i = 1, \dots, I \quad (5)$$

$$\sum_{(A-B)=(2-3)}^{2-4f} Y_{kij,A-B} + S_{kij,2} \leq X_{k(i-1)(j-1),2}, \forall k = 1, \dots, N; \forall j = 2, \dots, T; i = 1, \dots, I \quad (6)$$

$$X_{ki1,4i} = X_{0ki1,4i} - S_{ki1,4i} + \sum_{A=1}^3 Y_{ki1,A-4i} - Y_{ki1,4i-4f}, \forall k = 1, \dots, N; \forall i = 1, \dots, I \quad (28)$$

$$X_{ki1,4f} = X_{0ki1,4f} - S_{ki1,4f} + \sum_{A=1}^{4i} Y_{ki1,A-4f}, \forall k = 1, \dots, N; \forall i = 1, \dots, I \quad (29)$$

$$X_{k01,1} = X_{0k01,1} - S_{k01,1} + X_{k1,1} - \sum_{(A-B)=(1-2)}^{1-4f} Y_{k01,A-B}, \forall k = 1, \dots, N \quad (30)$$

$$X_{k01,2} = X_{0k01,2} - S_{k01,2} + X_{k1,2} + Y_{k01,1-2} - \sum_{(A-B)=(2-3)}^{2-4f} Y_{k01,A-B}, \forall k = 1, \dots, N \quad (31)$$

$$X_{k01,3} = X_{0k01,3} - S_{k01,3} + X_{k1,3} + \sum_{A=1}^2 Y_{k01,A-3} - \sum_{(A-B)=(3-4i)}^{3-4f} Y_{k01,A-B}, \forall k = 1, \dots, N \quad (32)$$

$$X_{k01,4i} = X_{0k01,4i} - S_{k01,4i} + X_{k1,4i} + \sum_{A=1}^3 Y_{k01,A-4i} - Y_{k01,4i-4f}, \forall k = 1, \dots, N \quad (33)$$

$$X_{k01,4f} = X_{0k01,4f} - S_{k01,4f} + X_{k1,4f} + \sum_{A=1}^{4i} Y_{k01,A-4f}, \forall k = 1, \dots, N \quad (34)$$

$$X_{kj,A} = X_{0kj,A}, \forall j = 2, \dots, T; \forall A \in \{1, 2, 3, 4i, 4f\}; \quad (35)$$

$$X_{kij} = \sum_{A=1}^{4f} X_{kij,A}, \forall k = 1, \dots, N; \forall j = 1, \dots, T; i = 0, \dots, I \quad (36)$$

$$X_{klj,A} = 0, k = 1, \dots, N; \forall j = 1, \dots, T; \forall A \in \{1, 2, 3, 4i, 4f\}; \quad (37)$$

The number of in-service construction equipment of each type should be equal to or greater than the required number in every period (Eq.(2)). Cost of purchasing new equipment cannot exceed the annual budget available for buying new equipment (Eq.(3)). The annual emission level of the construction equipment fleet should not exceed the specific environmental cap (Eq.(4)). Retrofitting and salvaging equipment occurs at the beginning of each period. Therefore, at the beginning of each period except period 1, the number of retrofitted and salvaged equipment should not exceed the number of in-service equipment within the last period (Eqs. (5)-(9)). At the beginning of period 1, the number of retrofitted and salvaged equipment should not exceed the number of initial construction equipment at the beginning of the planning horizon (Eqs. (10)-(14)). Eqs. (15)-(19) can ensure that newly purchased age-0 construction equipment can not be retrofitted or salvaged immediately. The number of in-service equipment within any period except period 1 equals the number of in-service equipment in the last period subtracting the number of equipment retrofitted and salvaged at the beginning of this period (Eqs. (20)-(24)). The number of in-service equipment within period 1 equals the number of initial equipment at the beginning of the planning horizon subtracting the number of equipment retrofitted and salvaged at the beginning of period 1 (Eqs. (25)-(29)). The in-service construction equipment of age 0 within

period 1 is the initial age-0 equipment adding the newly purchased age-0 equipment and subtracting the retrofitted and salvaged equipment at the beginning of period 1 (Eqs. (30)-(34)). In each period except period 1, the number of in-service age-0 equipment equals to that of new purchased age-0 equipment (Eq.(35)). The number of in-service equipment in each period is the sum of equipment meeting emission standards of US Tier 1 to US Tier 4f (Eq.(36)). It is assumed that any equipment reaches its maximum age I will be salvaged (Eq.(37)).

3 Case study

In this section, this study uses an excavator fleet belonging to a construction company in Hong Kong as a case to demonstrate the application of the proposed optimization model. The planning horizon is 10 years (T=10). The maximum age of the excavators is 20 (I=20). This fleet consists of 6 excavators. Table 1 shows the number of excavators with some important information.

Table 1 Some important information about the case excavator fleet

Equipment type	Excavator of type 1 (k=1)	Excavator of type 2 (k=2)	Excavator of type 3 (k=3)
Number	2	2	2
Age	8,9	7,11	10,10
Tier	2	2	2
Horsepower	91KW	69KW	80KW
Bucket capacity	0.46 m ³	0.28 m ³	0.39 m ³

Using the historical records of the company, the economic parameters were estimated for the coming year. The input economic parameters are presented in Table 2. In this case, this study assumes that the subsidy or penalty level for reducing emissions by replacing or retrofitting construction equipment is \$6800 per ton.

Table 2 Estimated economic parameters

Parameter	Function	Unit
C_j	16,000,000	\$
P_{kj}	50000+10,000(j-1), for K=1; 40000+10,000(j-1), for K=2; 30000+10,000(j-1), for K=3.	\$
OC_{ki}	231500+3000t, for k=1; 135750+1500t, for k=2; 40500+1000t, for k=3.	\$
r_{ki}	500000*0.85 ⁱ , for k=1; 400000*0.85 ⁱ , for k=2;	\$

EP	300000*0.85 ⁱ , for $k=3$.	
D_{kj}	6800	\$/ton
OT_{kij}	2	piece
	8*250	hours

In this case, this study only considers NOx reduction from the case excavator fleet through making proper replacement and retrofitting strategies, given that only NOx are the main types of emissions in Hong Kong among all of emissions generated by construction equipment (Legislative Council of HK, 2018). In Hong Kong, new imported construction equipment is required to meet US Tier 3 emission standards. In line with this regulation, in this case, the average emission level of the case excavator fleet is limit to US Tire 3.

The retrofitting costs are driven from a report issued by ICCT (2018), as shown in Table 3.

Table 3 The costs of retrofitting construction equipment to meet more stringent emission standards

Equipment type	$K=1$	$K=2$	$K=3$
From Tier 2 to Tier 3	\$1366	\$850	\$1366
From Tier 2 to Tier 4i	\$2227	\$1569	\$2227
From Tier 2 to Tier 4f	\$2808	\$2544	\$2808
From Tier 3 to Tier 4i	\$861	\$719	\$861
From Tier 3 to Tier 4f	\$1442	\$1694	\$1442
From Tier 4i to Tier 4f	\$581	\$975	\$581

By applying data shown in Table 1-3 to the established model in Section 2, the objective value \$9,437,829 is obtained, which represents the sum of economic and environmental costs. The number of newly purchased, salvaged, retrofitted and in-service excavators in each period is provided in Table 4. As shown in Table 4, to minimize the economic and environmental cost and meet the emission reduction requirements, at the beginning of the first year, the owner of the case excavator fleet needs to replace two pieces of type-3 excavators aged 10 years with a new excavator meeting US Tier 4f emission standards, retrofit two type-1 excavators aged 8 and 9 years respectively to meet US Tier 4f emission standards, and retrofit one type-2 excavator aged 10 years to meet the US Tier 4i emission standards.

Table 4 Values of decision variables in the excavator fleet case

<u>Period 1-New purchased excavators</u>
$X_{31,4f}=2$
<u>Period 1-Retrofitted excavators</u>

$$Y_{181,2-4f}=1, Y_{191,2-4f}=1, Y_{2(10),1,2-4i}=1$$

Period 1- Salvaged excavators

$$S_{3(10),1,2}=2$$

Period 1- In-service excavators

$$X_{191,4f}=1, X_{181,4f}=1, X_{271,4i}=1, X_{2(11),1,2}=1, X_{301,4f}=2$$

Period 2- In-service excavators

Period 9- In-service excavators

$$X_{1(17),9,4f}=1, X_{1(16),9,4f}=1, X_{2(15),9,4i}=1, X_{2(11),1,2}=1, X_{389,4f}=2$$

Period 10- In-service excavators

$$X_{1(18)(10),4f}=1, X_{1(17),10,4f}=1, X_{2(16)(10),4i}=1, X_{2(11),1,2}=1, X_{39(10),4f}=2$$

4 Discussion

To reveal how the requirements of various environmental regulations and incentive initiatives impact replacing and retrofitting strategy-making of the case fleet, this study runs the model established in

Section 2 with mere economic parameters. The results are that only the type-2 aged 8 excavators are replaced at the beginning of the first period and the corresponding minimum cost is \$9,086,236. This study also runs the model with economic parameters and the emission reduction requirement constraint and without subsidy grants from the Hong Kong government. The corresponding optimum cost is \$9,623,765. The two type-3 aged 10 years excavators are replaced at the beginning of the first year. Comparing the optimum costs between the replacing and retrofitting strategies with mere economic parameters and with both economic and environmental parameters, it can be concluded that environmental regulations and incentive initiatives with a subsidy level of \$6800 per ton of NO_x reduced will pose a financial burden on the owner of the excavator fleet. However, this financial burden may not be heavy, because only around 3.73% of the optimum cost (\$9,437,829) is the cost of replacing and retrofitting the case excavator fleet for emission reduction after being offset against by the subsidy grants from the government. Comparing the two optimum cost of \$9,086,236 and \$9,623,765, a financial burden of \$5,37,529 over the 10 years are posed on the owner of the excavator fleet if there is no available subsidy grant, which is about 5.92% of the optimum cost of \$9,086,236. The subsidy level of \$6,800 per ton of NO_x reduced can reduce the financial burden generated by the requirements of environmental regulations and incentives to some extent.

From the above discussion, it can be concluded that the strategies of replacing and retrofitting the excavator fleet are informed. In this case, the emission reduction target of Hong Kong limiting the construction equipment fleet emission level at or under US Tire 3 can be achieved through replacing or retrofitting excavators in some periods. Moreover, the costs incurred by replacing and retrofitting excavators also do not put heavy financial burdens on the owner of the case excavator fleet.

The cost-effectiveness of reducing NO_x emission can be examined from the perspectives of the Hong Kong government and the owner of the excavator. The cost-effectiveness of reducing NO_x emission of Hong Kong government equals its subsidy grant level of \$6,800 per ton. Over the planning horizon of 10 years, through replacing and retrofitting excavators, 53.84 tons NO_x has been reduced and the cost of reducing NO_x emission is \$553,726. Thus, the cost-effectiveness of reducing NO_x from the perspective of the owner of the excavator fleet is \$10,284,66. The cost-effectiveness of reducing NO_x emission from an overall societal perspective is about \$17,084 per ton of reduced NO_x emission. This suggests that the government can adjust the subsidy grant level to allocate the responsibility of reducing emissions from construction equipment between governments and owners of construction equipment.

5 Conclusions

The problem of extensive emissions from construction equipment has been widely recognized around the world. As the producer of emissions, owners of construction equipment should shoulder the emission reduction responsibility through formulating proper replacing and retrofitting strategies. Therefore, this study proposes an optimization model to help owners of construction equipment to formulate proper replacing and retrofitting strategies. This optimization model incorporates environmental considerations into their formulation of replacing and retrofitting strategies, which can minimize the sum of the economic and environmental costs associated with purchasing new construction equipment, salvaging and retrofitting old in-use construction equipment, operating construction equipment over the period of analysis. The replacing and retrofitting strategies formulated by using the optimization model can also ensure the achievement of the emission reduction target of making the overall emission level of construction equipment fleet at or under US Tier 3 emission standards.

This study also formulates replacing and retrofitting strategies for a fleet of excavators located in Hong Kong. From this case study, it can be concluded that the requirements of various environmental regulations and incentive initiatives do impact the formulation of replacing and retrofitting strategies and pose a financial burden on owners of construction equipment. Moreover, this study suggests that governments can also adjust the subsidy grant level to allocate the responsibility of reducing emissions from construction between governments and owners of construction equipment. The proposed optimization model is scalable across a range of off-road equipment for its sustainable management, including not only construction equipment but also agricultural and mining equipment.

In contribution, an optimization model is proposed in this study to help owners of construction equipment make informed replacing and retrofitting strategies. governments can also employ this optimization model to determine the subsidy grants levels to motivate owners of construction equipment to participant in various incentive programs initiated by governments.

Abstract –

Designing a reasonable and efficient transportation system of temporary elevators from the perspective of spatio-temporal planning is beneficial for the successful completion of construction projects. Specifically, the determination of the service date and floor of temporary elevators and the consideration of the limited availability of time and space should be taken seriously. The spatio-temporal planning of temporary elevators puts forward higher requirements for the display of planning solutions due to the complexity considering both time and space. However, current display ways are generally abstract, low-dimensional, and static, and even when the 4D model is adopted, the display effect of spatio-temporal planning solutions is still limited. This research presents a spatio-temporal planning simulation of temporary elevators in construction using a game engine to address those challenges. The workflow of the spatio-temporal planning simulation, divided into configuration and operation planning, consists of three steps: 1) import data into the game engine platform, 2) generate the spatio-temporal planning simulation scheme, and 3) conduct the spatio-temporal planning simulation. The results of the experimental test show that the presented spatio-temporal planning simulation way is intuitive and convenient, various planning elements are clearly shown, and corresponding planning information is efficiently conveyed, which can effectively enhance the display effect of spatio-temporal planning solutions.

Spatio-temporal planning; Temporary elevator; BIM; Game engine; Virtual reality

1 Introduction

The organization and control of construction activities taking the use of time and space into account separately have existed for many years [1][2][3]. It

becomes static or plane planning when the use of time or space is ignored. Such separations are likely to cause potential time or space conflicts of construction activities, leading to various challenges such as safety, quality, delivery, and cost [3][4]. For those reasons, the organization and control of construction activities from the perspective of the use of both time and space, namely spatio-temporal planning, has been gradually valued in recent years because it effectively integrates both of them [5][6][7].

The temporary elevator, used to transport workers and small and medium-sized materials, is one of the most common transportation equipment in construction projects [8]. It significantly impacts safety risk, production productivity, and capital investment [9][10]. Temporary elevator planning, namely designing a reasonable and efficient transportation system of temporary elevators according to construction project characteristics and project team requirements, is one of the important tasks in construction [11][12]. The content of temporary elevator planning mainly includes two aspects: configuration and operation planning. Configuration planning refers to determining the number, type, and location of temporary elevators, and it belongs to the macro-level of planning [11]. Operation planning refers to determining the transportation sequence and motion route of temporary elevators, and it belongs to the micro-level of planning [12]. However, from the perspective of spatio-temporal planning, the following two points are often ignored in conventional temporary elevator planning: 1) transportation demands of temporary elevators fluctuate significantly and frequently at different stages of a construction project, and ideally, the service date of each temporary elevator and the loading and unloading service floors of its cabs on each service date are determined accordingly to meet specific transportation demands [11][13][14][15]; and 2) the availability of time and space is limited in a construction project, and it is essential that the workload level of a temporary elevator cab and the demand level of its loading and unloading service floors on a service date related to time availability, as well as the work status of

a temporary elevator cab and the use status of its loading and unloading service floors in a transportation task related to space availability, are considered [12][16].

The typical process of temporary elevator planning is to select tentative planning solutions from a large number of candidates and determine the final planning solution by comparing the selected tentative planning solutions. Currently, the display of planning solutions in the process mainly adopts abstract (e.g., text), low-dimensional (e.g., 2D drawing), and static (e.g., 3D model) ways. However, for temporary elevator planning, such practices cannot clearly show planning elements and efficiently convey planning information, making planning solutions hard to be fully understood by the project team. What is more, the spatio-temporal planning of temporary elevators puts forward higher requirements for the display of planning solutions due to the complexity considering both time and space, which can become challenging to the project team [13]. Even when the 4D model is adopted, the display effect of spatio-temporal planning solutions is still limited. Therefore, a customized display way, especially for the spatio-temporal planning of temporary elevators, is eagerly expected. The game engine is a platform capable of developing visual products with a virtual and interactive experience, and it has the potential to display the complex content of spatio-temporal planning solutions of temporary elevators intuitively and conveniently [17][18].

With that background, this research presents a spatio-temporal planning simulation of temporary elevators in construction using a game engine to address the above limitations. The rest of this paper is organized as follows. Section 2 elaborates the workflow of spatio-temporal planning simulation. An experimental test is provided in Section 3. Section 4 gives the conclusion and outlook.

2 Spatio-Temporal Planning Simulation Workflow

The workflow of the spatio-temporal planning simulation of temporary elevators in construction using a game engine is shown in Figure 1. It consists of three steps: the first step is to import data into the game engine platform, the second step is to generate the spatio-temporal planning simulation scheme, and the third step is to conduct the spatio-temporal planning simulation. They are elaborated in the following subsections.

2.1 Step 1: Import Data into the Game Engine Platform

In Step 1, the data required for the spatio-temporal planning simulation is imported into the game engine platform.

The imported data comes from the project BIM model, the project schedule, and the spatio-temporal configuration and operation planning solutions. The first two categories will be used to generate the 4D model of the project, and the last category will be used to generate the spatio-temporal configuration and operation planning simulation schemes.

Figure 2 shows the data model diagram of the spatio-temporal configuration and operation planning solutions divided into five parts. The “Temporary Elevator” component comprises the specification (i.e., rated velocity, acceleration, and deceleration) of each temporary elevator. The “Service Date” component comprises the service date of each temporary elevator, and each temporary elevator has only one set of service date data. The “Service Floor” component comprises the loading and unloading service floors of each temporary elevator cab on each service date, and each temporary elevator has one or multiple set(s) of service floor data. The “Transportation Task” component comprises the transportation sequence of each transportation task and its assigned temporary elevator cab on each service date, and each temporary elevator has one or multiple set(s) of transportation task data. The “Motion Route” component comprises the stop sequence and resource quantity of loading and unloading service floors in each transportation task, and each transportation task has one or multiple set(s) of motion route data.

2.2 Step 2: Generate the Spatio-Temporal Planning Simulation Scheme

In Step 2, the spatio-temporal planning simulation scheme is generated according to the imported data, and it is divided into the configuration and operation planning simulation schemes.

In the configuration simulation scheme, the configured temporary elevators and the loading and unloading service floors of their cabs on each service date are necessarily involved, and they are directly determined by the imported spatio-temporal configuration planning solution. Meanwhile, the workload level of the temporary

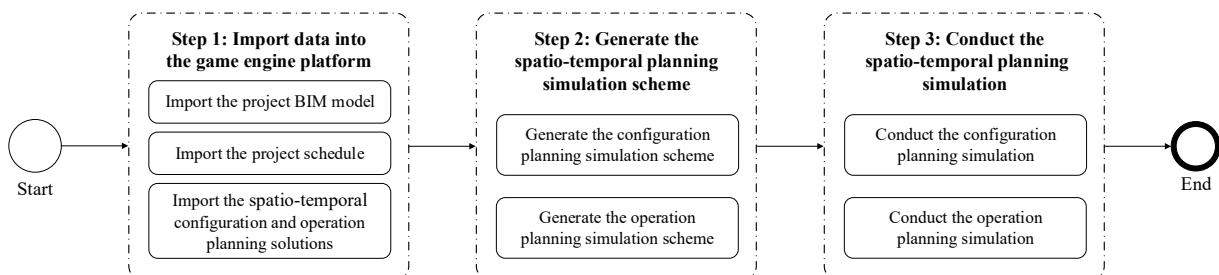

Figure 1. Workflow of the spatio-temporal planning simulation using a game engine

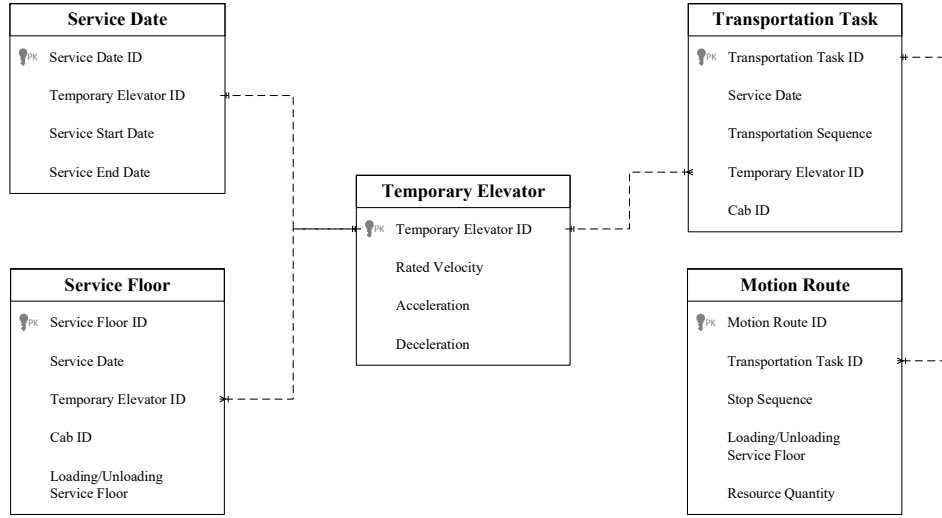

Figure 2. Data model diagram of the spatio-temporal configuration and operation planning solutions

elevator cabs and the demand level of the loading and unloading service floors, related to time availability, are especially focused. The workload of a temporary elevator cab on a service date is measured by the total time of all the transportation tasks it performs. The demand of a loading or unloading service floor on a service date is measured by the quantity of the resources loaded or unloaded on the floor. The workload of temporary elevator cabs and the demand of loading and unloading service floors are divided into three levels: low, medium, and high, and the range of each level is defined based on the actual consideration of the project team.

In the operation planning simulation scheme, the assigned temporary elevator cab and its loading and unloading service floors in each transportation task are necessarily involved, and they are directly determined by the imported spatio-temporal operation planning solution. Meanwhile, the work status of the temporary elevator cab and the use status of the loading and unloading service floors, related to space availability, are especially focused. The work of temporary elevator cabs is divided into five statuses: waiting, no-load moving, loading, loaded moving, and unloading. The use of loading and unloading service floors is divided into four statuses: vacating, vacant, occupying, and occupied. They are both determined according to time details of a transportation task.

In the figuration and operation planning simulation schemes, the time of a transportation task is determined by the motion time of the temporary elevator cab, the operation time of the temporary elevator cab door, and the transfer time of transported resources, as expressed in Equation (1). If the motion distance from the current stop floor to the next stop floor is greater than or equal to the distance required for the temporary elevator cab to accelerate from zero to the rated velocity and then

decelerate to zero, the motion time is determined by the first fraction of Equation (2), otherwise by the second fraction of Equation (2). Equation (2) is derived from the acceleration and deceleration equations, and the condition is that the final velocity at the end of acceleration equals the initial velocity at the beginning of deceleration.

$$T_{d,t}^T = \sum_{s=1}^{N_{d,t}^S} (T_{d,t,s}^M + T_{d,t,s}^O + T_{d,t,s}^C + T_{d,t,s}^B + T_{d,t,s}^E) \quad (1)$$

$$T_{d,t,s}^M = \begin{cases} \frac{V_e^R}{V_e^A} + \frac{V_e^R}{V_e^D} + \frac{D_{d,t,s}^M - \frac{V_e^{R^2}}{2V_e^A} - \frac{V_e^{R^2}}{2V_e^D}}{V_e^R}, & D_{d,t,s}^M \geq \frac{V_e^{R^2}(V_e^A + V_e^D)}{2V_e^A V_e^D} \\ \sqrt{\frac{2D_{d,t,s}^M}{V_e^A + V_e^D}}, & D_{d,t,s}^M < \frac{V_e^{R^2}(V_e^A + V_e^D)}{2V_e^A V_e^D} \end{cases} \quad (2)$$

where $T_{d,t}^T$ is the time of transportation task t on service date d ; $N_{d,t}^S$ is the number of segment s in transportation task t on service date d ; $T_{d,t,s}^M$ is the temporary elevator cab motion time in segment s of transportation task t on service date d ; $T_{d,t,s}^O$ and $T_{d,t,s}^C$ are the times of opening and closing door in segment s of transportation task t on service date d , respectively; $T_{d,t,s}^B$ and $T_{d,t,s}^E$ are the times of boarding and exiting the temporary elevator cab in segment s of transportation task t on service date d , respectively; $D_{d,t,s}^M$ is the temporary elevator cab motion distance in segment s of transportation task t on service date d ; and V_e^R , V_e^A , and V_e^D are the rated velocity, acceleration, and deceleration of temporary elevator e , respectively.

2.3 Step 3: Conduct the Spatio-Temporal Planning Simulation

Based on the generated configuration and operation planning simulation schemes, the spatio-temporal

Table 1. Color code in the temporary elevator configuration planning simulation

Planning element	Workload level	Demand level	Color	
Temporary elevator cab	Low	-		Light red
	Medium			Medium red
	High			Dark red
Loading service floor	-	Low		Light yellow
		Medium		Medium yellow
		High		Dark yellow
Unloading service floor	-	Low		Light blue
		Medium		Medium blue
		High		Dark blue

planning simulation is conducted in Step 3.

Although planning elements, including temporary elevators and loading and unloading service floors, can be dynamically visualized in the 4D model, it does not highlight the planning elements and cannot distinguish changes in their levels and statuses, making the planning elements difficult to identify and the changes in their levels and statuses unable to monitor. The hue (e.g., red, yellow, blue) and value (e.g., light red, medium yellow, dark blue) of colors refer to their appearance and lightness, respectively, which both belong to the basic characteristics of color [19][20]. The colors with specific hues and values can effectively distinguish different marked objects and their changes, respectively [21][22]. In order to display spatio-temporal planning solutions intuitively and conveniently, the display way of combining the hue and value of colors and the 4D model is adopted in the spatio-temporal planning simulation.

In the configuration planning simulation, the color code for the workload level of temporary elevator cabs and the demand level of their loading and unloading service floors on a service date are listed in Table 1. Temporary elevator cabs and loading and unloading service floors are marked using red, yellow, and blue,

respectively. For temporary elevator cabs, the low, medium, and high workload levels are light, medium, and dark, respectively. For loading and unloading service floors, the low, medium, and high demand levels are light, medium, and dark, respectively. In this way, different levels of planning elements on a service date can be highlighted accordingly.

In the operation planning simulation, the work status of a temporary elevator cab and the use status of its loading and unloading service floors in a transportation task are listed in Table 2. Temporary elevator cabs, current and other loading service floors, and current and other unloading service floors are marked using red, yellow, green, blue, and purple, respectively. For temporary elevator cabs, the waiting, no-load moving, loading, loaded moving, and unloading work statuses are light, dark, medium, dark, and medium, respectively. For current loading service floors, the occupied and vacating use statuses are medium and dark, respectively. For other loading service floors, the vacant and occupied use statuses are light and medium, respectively. For current unloading service floors, the vacant and occupying use statuses are light and medium, respectively. For other unloading service floors, the vacant and occupying use statuses are light and medium, respectively.

Table 2. Color code in the temporary elevator operation planning simulation

Planning element	Category	Work status	Use status	Color	
Temporary elevator cab	-	Waiting	-		Light red
		No-load moving			Dark red
		Loading			Medium red
		Loaded moving			Dark red
		Unloading			Medium red
Loading service floor	Current	-	Occupied		Medium yellow
			Vacating		Dark yellow
	Other	-	Vacant		Light green
Unloading service floor	Current	-	Occupied		Medium green
			Vacant		Light blue
	Other	-	Occupying		Dark blue
			Vacant		Light purple
			Occupied		Medium purple

statuses are light and dark, respectively. For other unloading service floors, the vacant and occupied use statuses are light and medium, respectively. In this way, different statuses of planning elements in a transportation task can be highlighted accordingly.

3 An Experimental Test

Based on the presented spatio-temporal planning simulation workflow, an experimental test was performed using Unity. The BIM model was exported from Revit, and the schedule and the spatio-temporal configuration and operation planning solutions were exported from MySQL. The planning simulation schemes were generated and the planning simulation was conducted by the scripts in C#.

The case that two temporary elevators serve three dates was taken as the test of configuration planning simulation. Table 3 lists the configuration planning simulation scheme. By simulation, the configuration planning is shown in Figure 3. On service date 1, cab 1 of temporary elevator 1 is marked in dark red, its loading service floors 1, 5, and 9 are marked in dark, medium, and medium yellow respectively, and its unloading service floors 1, 5, and 9 are marked in dark, medium, and dark blue respectively; and cab 2 of temporary elevator 1 is marked in medium red, its loading service floors 1 and 8 are marked in medium and light yellow respectively, and its unloading service floors 1 and 8 are marked in light and medium blue respectively. On service date 2, cab 1 of temporary elevator 1 is marked in

light red, its loading service floors 1 and 11 are both marked in light yellow, and its unloading service floors 1 and 11 are both marked in light blue; cab 2 of temporary elevator 1 is marked in dark red, its loading service floors 1 and 7 are marked in dark and medium yellow respectively, and its unloading service floors 1 and 7 are marked in medium and dark blue respectively; cab 1 of temporary elevator 2 is marked in medium red, its loading service floors 1 and 6 are marked in light and medium yellow respectively, and its unloading service floors 1 and 6 are marked in medium and light blue respectively; and cab 2 of temporary elevator 2 is marked in dark red, its loading service floors 1, 10, and 12 are marked in medium, dark, and dark yellow respectively, and its unloading service floors 1, 10, and 12 are marked in dark, light, and dark blue respectively. On service date 3, cab 1 of temporary elevator 2 is marked in light red, its loading service floors 1 and 13 are both marked in light yellow, and its unloading service floors 1 and 13 are both marked in light blue; and cab 2 of temporary elevator 2 is marked in dark red, its loading service floors 1 and 15 are marked in medium and dark yellow respectively, and its unloading service floors 1 and 15 are marked in dark and medium blue respectively.

The case that one temporary elevator cab serves two loading floors and two unloading floors in a transportation task was taken as the test of operation planning simulation. Table 4 lists the operation planning simulation scheme. By simulation, the operation planning is shown in Figure 4. In Step 1, cab 2 of temporary elevator 1, loading service floors 5 and 8, and unloading service floors 11 and 12 are marked in dark red,

Table 3. Temporary elevator configuration planning simulation scheme

Temporary elevator	Service date	Cab	Workload level	Service floor	Demand level	
					Loading	Unloading
1	1	1	High	1	High	High
				5	Medium	Medium
				9	Medium	High
		2	Medium	1	Medium	Low
				8	Low	Medium
	2	1	Low	1	Low	Low
				11	Low	Low
		2	High	1	High	Medium
				7	Medium	High
2	2	1	Medium	1	Low	Medium
				6	Medium	Low
		2	High	1	Medium	High
				10	High	Low
	3	1	Low	12	High	High
				1	Low	Low
		2	High	13	Low	Low
				1	Medium	High
				15	High	Medium

Figure 3. Temporary elevator configuration planning simulation

Figure 4. Temporary elevator operation planning simulation

medium yellow, medium green, light purple, and light purple, respectively. In Step 2, they are marked in medium red, dark yellow, medium green, light purple, and light purple, respectively. In Step 3, they are marked in dark red, light green, medium yellow, light purple, and light purple, respectively. In Step 4, they are marked in medium red, light green, dark yellow, light purple, and light purple, respectively. In Step 5, they are marked in dark red, light green, light green, light blue, and light purple, respectively. In Step 6, they are marked in medium red, light green, light green, dark blue, and light purple, respectively. In Step 7, they are marked in dark red, light green, light green, medium purple, and light blue, respectively. In Step 8, they are marked in medium red, light green, light green, medium purple, and dark blue, respectively. In Step 9, they are marked in light red, light green, light green, medium purple, and medium purple, respectively.

Through such displays, not only are the configured temporary elevators and the loading and unloading service floors of their cabs on a service date and the assigned temporary elevator cab and its loading and unloading service floors in a transportation task highlighted, but the changes in the workload levels of the temporary elevator cabs (i.e., low, medium, and high) and the demand levels of the loading and unloading service floors (i.e., low, medium, and high) as well as the work statuses of the temporary elevator cab (i.e., waiting, no-load moving, loading, loaded moving, and unloading), and the use statuses of the loading and unloading service floors (i.e., vacating, vacant, occupying, and occupied) can also be distinguished. Thus, the planning elements are easy to identify, and the changes in their levels and statuses are able to monitor, facilitating the detection of potential problems and the comparison among different planning solutions.

4 Conclusion and Outlook

To clearly show planning elements and efficiently convey planning information, this research presents the spatio-temporal planning simulation of temporary elevators in construction using a game engine. The presented workflow consists of importing data into the game engine platform, generating the spatio-temporal planning simulation scheme, and conducting the spatio-temporal planning simulation. In configuration and operation planning simulation, in addition to the planning elements necessarily involved, their levels and status are especially focused. From the results of the experimental test, the presented spatio-temporal planning simulation was intuitive and convenient, various planning elements were clearly shown, and corresponding planning information was efficiently conveyed, which could effectively enhance the display effect of spatio-temporal

Table 4. Temporary elevator operation planning simulation scheme

Stage	Planning element	Work status	Use status
1	Cab 2, Temporary Elevator 1	No-load moving	-

Abstract

The traditional method of burying underground utilities (e.g., water, sewer, gas pipes, and electrical cables) has been used for many decades. Repeated excavations related to this method cause many problems, such as traffic congestion and business disruption, which can significantly increase the social costs. Multi-purpose Utility Tunnels (MUTs) are a good alternative for buried utilities. Although MUTs are more expensive than the traditional method, social cost savings can make them more practical, especially in dense areas. The construction method is one of the most important factors that should be carefully assessed to have a successful MUT project. Simulation can be used for investigating the different construction methods of MUTs. In this paper, simulation of the MUT construction methods is done using Discrete Event Simulation (DES) to analyze the duration of MUT projects focusing on microtunneling.

Keywords –

Discrete Event Simulation, Multi-purpose Utility Tunnel, Construction Method, Trenchless Technologies, Microtunneling

1 Introduction

Utility networks are installed above and below the ground. Different reports have stated that underground utilities in developed areas have reached or are nearing the end of their service lives, which results in the need of many repair and replacement projects [Gagnon *et al.*, 2008; Ormsby, 2009]. The maintenance or replacement of buried utilities have imposed many street closures and traffic disruption in urban areas (i.e., social cost) [Oum, 2017].

Tunnelling projects are designed to enable the execution of underground work with minimal disruption to surface structures and traffic [Marzouk *et al.*, 2010]. Multi-purpose Utility Tunnels (MUTs) are defined as “underground utilidors containing one or more utility

systems, permitting the installation, maintenance, and removal of the systems without making street cuts or excavations” [Canto-Perello and Curiel-Esparza, 2013]. MUTs are more expensive than conventional methods, but they could be more practical in dense areas due to social cost savings. To make MUTs an affordable and efficient alternative to buried utilities, different factors, such as utility specifications, the MUT location, and construction method, should be investigated. The construction method is one of the most important factors that should be carefully assessed to have a successful MUT project [Thomas *et al.*, 1990].

Construction methods of MUTs can be classified in two main groups, which are Cut-and-Cover (C&C) methods [Cle de Sol, 2005; Ramírez Chasco *et al.*, 2011] and trenchless methods (e.g., microtunneling) [Byron *et al.*, 2015]. Despite the high initial cost of the trenchless methods, avoiding excavation of streets and roads, as well as low social costs, make these methods more practical. Furthermore, using the C&C method is almost impossible or more expensive in dense areas, in deep MUT projects or in some special geological conditions (e.g., hard rocks).

Construction can benefit greatly from simulation. In the construction industry, simulation can be used for planning and resource allocation, risk analysis, site planning, and productivity measurements [AbouRizk *et al.*, 1992; Mawlana *et al.*, 2015]. Discrete-Event-Simulation (DES) is one of the simulation methods, which models the operation of a system as a discrete sequence of events in time (Allen, 2011). The main aim of this paper is to analyse the duration of MUT construction projects using DES focusing on microtunneling.

2 Literature Review

2.1 MUT Construction Methods

C&C and trenchless methods are two main groups of construction methods for MUT projects [Cle de Sol, 2005; Ramírez Chasco *et al.*, 2011]. Trenchless methods

can be divided in two main categories, which are trenchless construction methods (e.g. auger boring, horizontal directional drilling, microtunneling) and trenchless renewal/replacement methods (e.g. Cured In Place Pipe (CIPP), slip lining) [Najafi and Gokhale, 2005].

C&C is the most common method for construction of utility tunnels [Ahmadian, 2018]. C&C tunnels are constructed in the following order: a trench is created, the tunnel structure is implemented, the trench is filled up, and the pavement is restored [EOT, 2008]. The support of the vertical sides is the main consideration with different C&C techniques including C&C using diaphragm walls, C&C using secant pile walls, C&C using soldier piles and lagging, and C&C using steel sheet pile walls [Abdallah and Marzouk, 2013; Marzouk *et al.*, 2008]. One of the oldest retaining systems that is widely used in supporting deep excavations is C&C using soldier piles and lagging technique. Soldier piles and lagging structures are constructed in a cyclic pattern, with soldier piles being placed at regular intervals (2-4 m) and lagging being excavated and installed between soldier piles [FORASOL, 2008]. Sheet pile walls are simply rows of interlocking vertical pile segments that are built to form a straight wall wide enough to support soil. Steel sheet pile walls are used in soft soils, especially when there is a risk of bottom heave in soft clay soil or sand [Deep Excavation, 2011]. One of the most common techniques used in the construction of C&C tunnels is the secant pile walls technique. The secant piles are wide diameter bored piles that are overlapped at near centre and can be used to form a wall [Marzouk *et al.*, 2008].

Microtunneling is a competing alternative to the C&C method from different aspects, such as economics and environmental conditions. According to Stein (2012), "In microtunnelling methods, jacking pipes are jacked from a starting shaft with the aid of a jacking station up to a target shaft. At the same time, an unmanned, remote-controlled microtunnelling machine carries out the displacement or full faced excavation of the working face. In the latter variant, the spoil is transported through the jacked pipe string". Depending on the way of conveying the spoil, there are three types of Micro Tunneling Boring Machines (MTBM), including auger spoil removal, hydraulic spoil removal and pneumatic spoil removal [Stein, 2012]. According to FSTT (2006), the type of ground, ground water level and existence of boulders are three main parameters which should be considered for choosing the type of MTBM. The hydraulic type of MTBM can be used in most situations.

2.2 Process Simulation

Process simulation has been widely used in different fields, such as manufacturing, business, computer science and construction [Banks *et al.*, 2010; Roberts and Dessouky, 1998]. Shannon (1977) defined simulation as: "The process of designing a model of a real system and conducting experiments with this model for the purpose either of understanding the behaviour of the system or of evaluating various strategies (within the limits imposed by a criterion or set of criteria) for the operation of the system".

There are three common types of simulation, which are DES, System Dynamics (SD) and Agent-Based-Modelling (ABM). The DES method is used to model a complex system's operation as a sequential series of events. The SD method is used for understanding and analysing the behaviour of a system over time [Forrester, 1961; Trung Thanh Dang, 2013]. Individual agents are simulated in the ABM method, which is a class of computational models for simulating the behaviours and interactions of autonomous agents [Macal and North, 2006]. In this paper, DES will be used for the simulation of the microtunneling construction of MUT.

The DES paradigm is commonly used to model and evaluate construction sequences in simulation studies. In this method, people, equipment, documents, tasks, etc., are represented by passive objects called entities. These entities move through the flowchart's blocks, where they can be waiting in queues, processed, delayed, seizing and releasing resources, split and combined, etc. [Borshchev and Filippov, 2004]. DES models are developed by breaking down activities into tasks. Each of these tasks' duration is presented by a probabilistic distribution, such as the triangular distribution, instead of a deterministic one [Beck, 2008].

3 Proposed Methodology

As mentioned in Section 1, one of the most important factors affecting the cost and efficiency of MUT projects is the construction method. To address this problem, the proposed method is developed in six steps.

- 1. Analysis of the location of the MUT:** The location of the project is an important parameter for selecting the construction method. The location will be analysed for determining different data, such as soil data (e.g., type of the soil, cohesion, underground water), traffic volume, density of utilities and buildings in the area, etc., using a Geographic Information System (GIS).
- 2. Selecting the construction method:** After collecting the data related to the location of the project, the construction method, suitable for the location will be selected. As an example, using the

C&C method for the construction of McGill University MUT was impossible since it is located under several buildings; therefore, the Drill and Blast (D&B) method was selected for constructing the MUT [Habimana *et al.*, 2014].

3. **Defining the sequence and relationships between activities:** Each construction method includes different activities. Once the construction method is selected and the required activities are determined, the sequence and relationships between different activities, as well as the resources for each of them, will be defined. Since the focus of this paper is on microtunneling, the sequences, relationships between the different activities and the resources needed for them will be introduced briefly.
4. **Defining the probabilistic distribution of the duration of each activity:** In this step, the duration of each activity should be defined. The duration of the activities can be defined by probabilistic distributions.
5. **Calculating the duration of the project:** In this step, the sequence and relationships between activities and the duration of each activity are used to determine the total duration of the project.
6. **Comparing the duration of the construction methods:** In the last step, the total duration of the construction methods will be compared for selecting the fastest method for constructing the MUT.

It should be mentioned that, in this paper, only the fifth step of the proposed method, which is calculating the duration, has been implemented.

The construction of MUTs using microtunneling can be divided into three main steps, which are shaft construction, tunnel construction and placement of the utilities in the tunnel. In this paper, the second step (tunnel construction) has been simulated. The main activities of tunnel construction using microtunneling are: (1) Installation of MTBM in the starting shaft; (2) Pushing the MTBM into the ground: Once the MTBM is installed in the starting shaft, it will excavate the ground through the entrance ring so there will be a free space in the shaft for placing the tunnel sections; (3) Transporting and attaching tunnel sections: These activities are required to transport the tunnel sections to the shaft and attach them to the crane; (4) Lowering tunnel section: This activity is required to prepare the jacking system for tunnel section placement, lower tunnel section to the jacking frame and place the tunnel section on the launch skid; (5) Placing the jacking collar behind the tunnel section; (6) Connecting cables and pipelines; (7) Jacking processes: This activity represents the pipe driving operation, which advances the tunnel. Also, the activities related to handling and separating the materials spoil, which is transported from the working face of the tunnel to the separation plant are

considered; (8) Replacing the jacking collar; (9) Disconnecting the cables and pipelines; (10) Disassembling MTBM: When the tunnel is completely excavated, the MTBM will be disassembled from the receiving shaft; and (11) Cleaning the tunnel.

Figure 1 shows the sequence and relationships between the activities in tunnel construction using microtunneling. The resources required for each activity are shown in blue circles. The grey circles show the queues made for representing the sequence of the process.

4 Implementation and Case Study

This section presents the implementation of the proposed model for analyzing the total duration of tunnel construction using microtunneling. Among the different activities involved in microtunneling, jacking the tunnel sections into the ground has the biggest effect on the total duration of the project. Also, the diameter and the length of the tunnel sections and the geotechnical conditions of the soil can directly affect the duration of this activity. Therefore, two different diameter and three different geotechnical conditions have been evaluated to analyze the total duration of tunnel construction using microtunneling.

Some assumptions were made to analyze the total duration of the tunnel construction. The proposed method was implemented for two different assumed diameters (3 m or 4 m) and three different geotechnical conditions including the presence of fine sand, sand and gravel, or clay/marl in the location of the project. Also, it was assumed that the resources required by each activity are always available and free to be used. Table 1 shows the other assumptions used in the case study.

Table 1 Assumptions made for the case study

Attribute	Value
Type of MTBM	Hydraulic
Tunnel length	100 m
Tunnel diameter	3 m or 4 m
Length of tunnel sections	4 m
Depth of the tunnel	10 m
Working hours per day	12 h
Soil type	Fine sand, sand and gravel, or clay/marl

To assume the duration of each activity, four different microtunneling projects introduced by Dang (2013) and Marzouk *et al.*, (2010), as well as the fourteen projects monitored by the French National Research Project *Microtunnels* [FSTT, 2006] have been reviewed. Table 2 shows the characteristics of these projects.

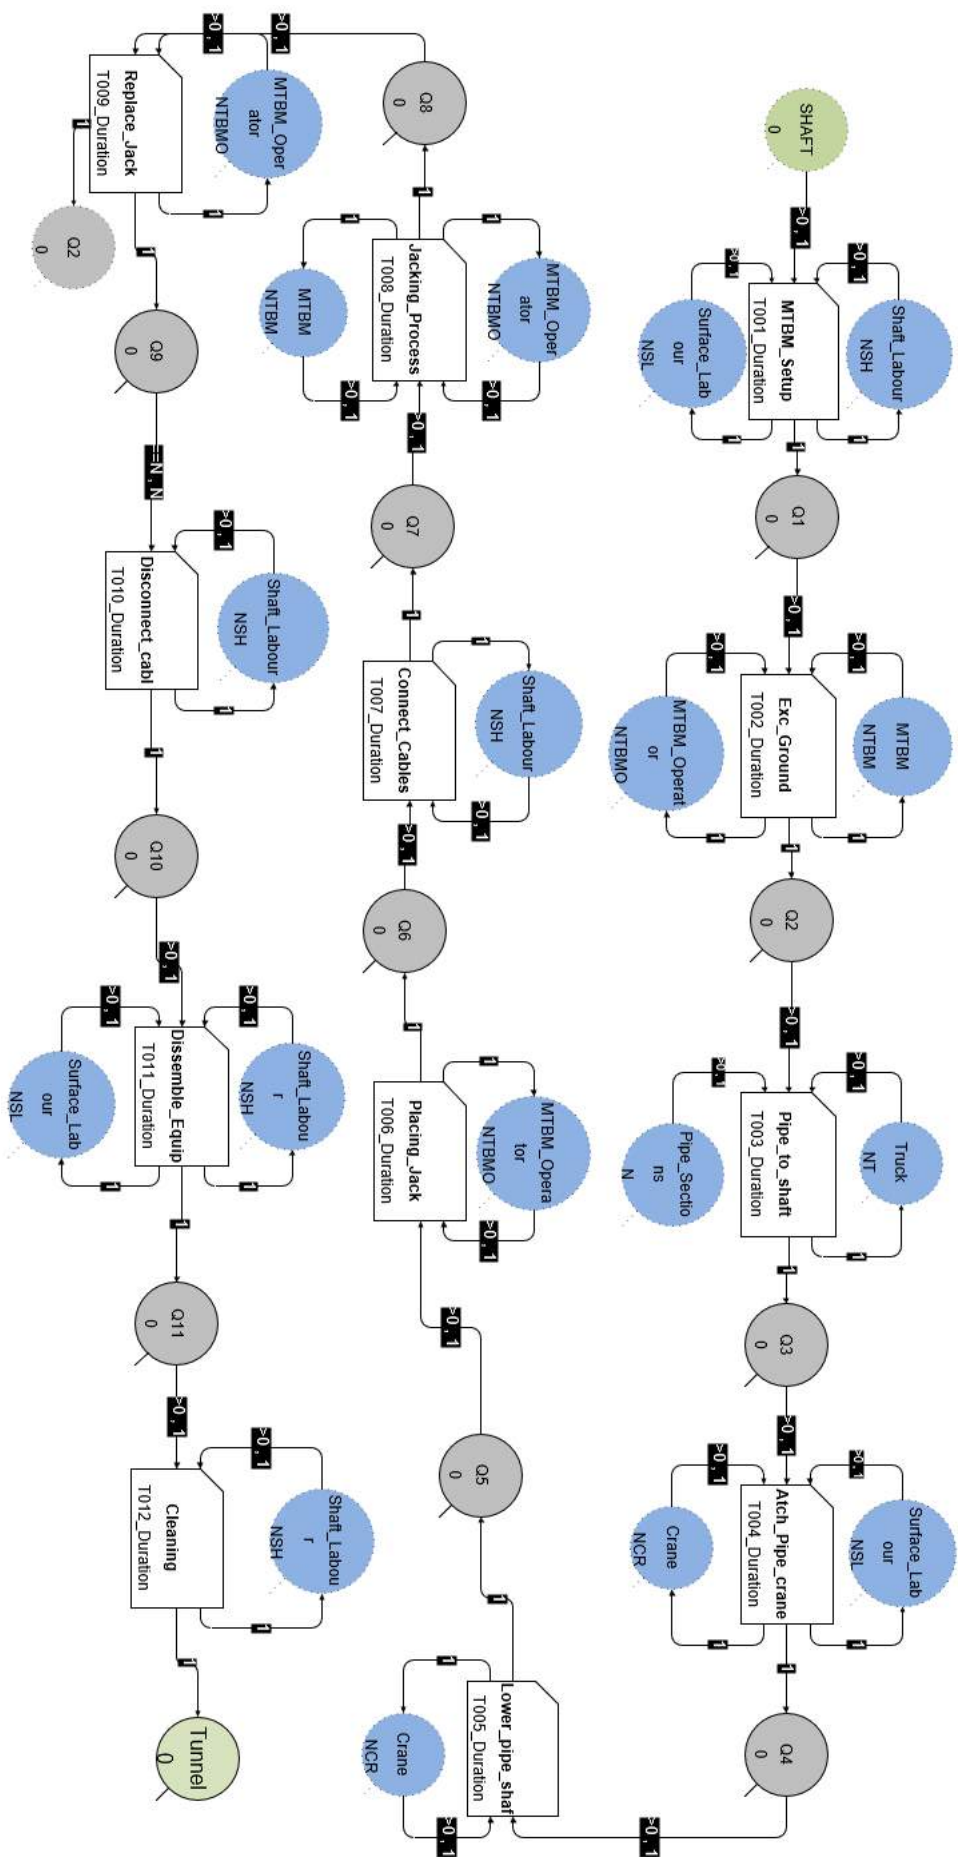

Figure 1. Tunnel construction sequence in microtunneling method

It should be mentioned that because of the difference between the dimensions of the assumed tunnel and those of the tunnels in reviewed projects, the jacking duration was modified according to the diameter and length of the sections. Table 3 shows the assumed durations of the

jacking activity for different tunnel diameters and different geotechnical conditions. For other activities, the average durations of reviewed projects have been used (Table 4).

Table 2 Characteristics of the reviewed microtunneling projects

Project	Type of MTBM	Length (m)	Diameter (m)	Length of sections (m)	Depth (m)	Geotechnical condition
BV Recklinghausen V.5.1*	Hydraulic	79.4	2.2	3.5	7.4	Fine sand

Table 3 Assumed durations for jacking tunnel sections

Geotechnical condition	Jacking duration (minute)					
	3 m diameter			4 m diameter		
	Min	Mode	Max	Min	Mode	Max
Fine sand	72.03	129.96	226.95	86.86	157.20	275.23
Sand and gravel	151.95	216.85	233.71	196.63	277.41	295.92
Clay/marl	301.35	354.74	449.28	386.33	433.53	548.15

Table 4 Assumed durations for microtunneling activities

Activity	Duration (minute)		
	Min	Mode	Max
MTBM installation in the shaft	N [10080,1440]		
Bringing sections to the shaft	10.00	20.00	40.00
Attaching and lifting sections by the crane	1.60	1.70	2.32
Lowering and laying sections in the shaft	2.44	3.38	4.49
Placing jacking collar	4.36	5.64	6.73
Connecting cables	28.88	36.18	48.13
Replacing jacking collar	5.18	6.38	7.33
Disconnecting cables	16.41	18.53	20.97
Disassembling MTBM in the receiving shaft	N [10080,1440]		
Cleaning the tunnel	N [3600,720]		

N [a,b]: Normal distribution; a is the mean; b is the standard deviation

The assumed data were fed to the DES model using EZStrobe software and 100 simulation replications were made to calculate the total duration of tunnel construction. Figure 2 shows the results of the simulation for the two assumed diameters and three geotechnical conditions.

For the 3 m diameter tunnel, the estimated average total duration of tunnel construction are 40.88, 43.32 and 48.39 working days for fine sand, sand and gravel and clay/marl geotechnical conditions, respectively. For

the 4 m diameter tunnel, the average total duration of tunnel construction are estimated as 41.66, 45.49 and 52.37 working days in fine sand, sand and gravel and clay/marl geotechnical conditions, respectively. In addition, it can be observed that the total durations in clay/marl and sand and gravel are greater than in fine sand. Also, according to Figure 2 it is obvious that by increasing the diameter of the tunnel the total duration of construction will increase.

Figure 2 Results of DES of MUT construction using microtunneling

5 Conclusions and Future Work

This paper presented DES of MUT construction using microtunneling for different tunnel diameters and geotechnical conditions. The proposed model estimates the total duration of tunnel construction project. The main conclusions of this paper are: (1) by increasing the size of the tunnel, the total duration will also increase; and (2) the type of the soil affects the total duration of the project. By increasing the cohesiveness and hardness of soil, the duration of tunnel construction will increase. Future work will simulate other steps in MUT construction (e.g., shaft construction and placement of the utilities) and compare microtunneling with C&C method using DES.

Abstract -

As part of the Architecture, Engineering, and Construction (AEC) industry, heavy civil engineering with its equipment-intensive processes is a current focus of discussion concerning emission reduction. Adopting Industry 4.0 technologies for resource scheduling can significantly increase the savings potential significantly. One of these digital technologies is the Discrete Event Simulation (DES). DES is a proven tool to analyze complex systems in advance but is not widely used in practice. Therefore, the presented work aims at presenting a three-part hybrid simulation framework. One part of the framework, the meso-simulation, has been evaluated using a case study in the field of pile drilling production. The work not only captures the drilling process, and therefore shows the importance of planning the secondary processes in AEC.

Discrete Event Simulation (DES); Agent Based Modelling (ABM); Hybrid simulation; Modeling of manufacturing operations; Production planning and control; Job and activity scheduling; Project schedule optimization

1 Introduction

Given the current climate change, the resource-saving scheduling of equipment has become the focus of optimization methods [1]. In particular, potential is shown by equipment-intensive applications in heavy civil engineering, such as pile drilling production. Large-diameter bored piles for the foundation of buildings are produced by heavy rotary drilling rigs. These processes are of high complexity, characterized by a multitude of influencing factors and are, therefore, treated as a "one-piece flow line on a single machine" [2]. Fischer et al. [2] emphasize that digital technologies can help optimize the scheduling and operation of equipment, which is now heavily based on the experience of the specialty foundation contractors.

Digital technologies in the context of "Construction 4.0" of the European Construction Industry Federation (FIEC) [3], the counterpart of "Industry 4.0" in the Architecture, Engineering and Construction (AEC) industry, can be categorized into three groups: The technologies that (1) col-

lect the data, (2) analyze the data, and (3) predict the data. The data collection is done by sensors, divided into vision-, motion-, and audio-based sensors [4]. The data analysis uses different algorithms of Artificial Intelligence [4]. The data prediction is possible with the help of simulation. In addition to the definition of Jazzar et al. [5], simulation can be defined as an additional Construction 4.0 technology. Simulation enables production processes and material flows on the construction site to be mapped in an abstract manner. In this way, it helps to reduce complexity in advance and makes it visible to the planner so that concrete recommendations/instructions for action can be derived from it [6]. Different scenarios help to plan the optimal use of equipment. The simulation is fed with input parameters from planning and production, e.g., from as-planned or as-built data from Building Information Modeling (BIM) [7] or directly from the data obtained on the construction site, processed as a probability density distribution [8]. The trend is toward an integrated approach of Construction 4.0 technologies for continuous operable functionality across construction phases [5].

Therefore, this paper presents a three-part hybrid simulation framework that allows the integration of input data depending on the level of detail of the current construction progress. We begin with a review of the literature in order to analyze different simulation techniques. Next, the underlying three-part conceptual model is presented. Using case-study data from a real pile drilling project, we describe the implementation of one of the three simulation model parts, which is the meso-simulation. Building up material supply and disposal, we show the importance of the secondary processes within an alleged one-line production flow of the rotary drilling rig. The results of the simulation study help to schedule the optimal amount and type of equipment.

2 Related Work

In addition to common simulation methodology, hybrid simulation or multi-method modelling is a combination of two or more basic simulation methods, such as System Dynamics (SD), Discrete Event Simulation (DES), and Agent-Based Modeling (ABM) [9]. The three simulation

methods can be briefly defined as follows: SD is mathematically based on differential equations and uses interacting feedback loops to describe system behavior; ABM consists of agents that represent entities in a complex system and behave individually; DES consists of events whose state changes only at a given time [9].

In combining the three simulation methods, the following different levels of abstraction can be served: High abstraction (strategic level), medium abstraction (tactical level), and low abstraction (operational level) [9]. Using hybrid simulation, a simulation study considers the system under study at different levels and perspectives, leading to a comprehensive understanding of the system [10].

For all of the three models, examples of applications in the field of AEC industry exist. The presented work only concentrates on process logistics mainly represented by discrete variables as used in Tommelein [11], conscious of ignoring continuous site effects [12]. For example, Alzraiee et al. [13] and Scales [14] present a framework combining ABM for scheduling resources of active events and DES for modelling the event's relationships. However, the presented research focuses on the time discontinuous simulation methods of ABM and DES like the following related research.

Zankoul et al. [15] modeled an earthwork operation according to ABM and DES. The comparison of the results show similarities but also the pros and cons for future studies that combine both simulation techniques.

Marzouk and Ali [16] analyzed the pile production with the help of ABM. The rotary drilling rig, the crane, and the pile were defined as agents. A* search algorithm was implemented to find the optimal pile drilling duration. They also considered uncertainties by using probabilistic functions. However, in using only ABM, the simulation model itself showed a very high abstraction level of modelling the pile drilling production and its varieties. The framework was not intended to use external input data to update the model while in execution.

Matejević et al. [17] has combined ABM and DES to evaluate the productivity of concreting including the concrete plant and the concrete trucks delivering the pump on-site. The hybrid model was realized by using the commercial simulation software AnyLogic, which provides block diagrams representing the material flow in DES but also agent state diagrams representing the logical rules of the material flow. The model was applied for the design phase, not considering input data.

3 Research Objective

The research objective is to develop a digital tool for heavy equipment resource scheduling. Based on the literature review, a hybrid simulation approach seems suitable, combining the advantages of the level of detail of ABM

and DES. In particular, the modeling of secondary processes is of interest, as these are often not the focus in practice. Furthermore, according to AbouRizk [6], the framework is modular for ease of use to update the model with different external data sources.

The presented work is based on the preliminary works of Wimmer [18], Wenzler and Günthner [19], Fischer et al. [20], and Fischer et al. [21]. These works describe a macro-simulation for scheduling (ABM), a micro-simulation for tracking equipment's telematics data (DES), and a framework to integrate this data via a developed middleware. This hybrid simulation model is perfect for updating the models during execution. However, it is not able to vary uncertainties and construction-specific variables in advance. By adding an additional level of abstraction, named meso-simulation, the new three-part hybrid simulation model allows the calculation of different modes, including different resources and durations. These modes then serve as input to the macro-simulation for computing multi-mode resource-constrained project scheduling problems (MRCPPSP) [19].

4 Conceptual Model

Although characterized by its uniqueness, a construction project includes similarities or repetitive processes for simulation [22, 23]. Modularizing them helps to reduce the simulation effort [6]. To finally adopt the simulation in the AEC industry, [24] and Abdelmegid et al. [25] emphasize the role of conceptual models for reproducing the simulated system independently of the software used.

4.1 Overview

The conceptual model of the hybrid simulation model is as follows, see Figure 1: (1) During the planning phase, the user initializes the meso-simulation model, creates different alternative scenarios, e.g., by varying the number of equipment used, and computes each total duration. (2) Dynamically shared via MySQL database, the resource constraints of each scenario serve as the basis for the macro-simulation computing the optimum schedule. (3) During execution, the optimum schedule is transferred to the micro-simulation using table formats. (4) According to the ISO 15143-3 [26], current available telematics data is requested by the middleware which passes the data to the micro-simulation via TCP/IP protocols. (5) Based on this data, the micro-simulation calculates the construction progress. (6) The current state is then passed to the macro-simulation which calculates the optimal resource scheduling and its total duration. (7) Based on the optimized schedule, the user has the opportunity to compute different modes via the meso-simulation which serve as the basis for decision-making in the execution.

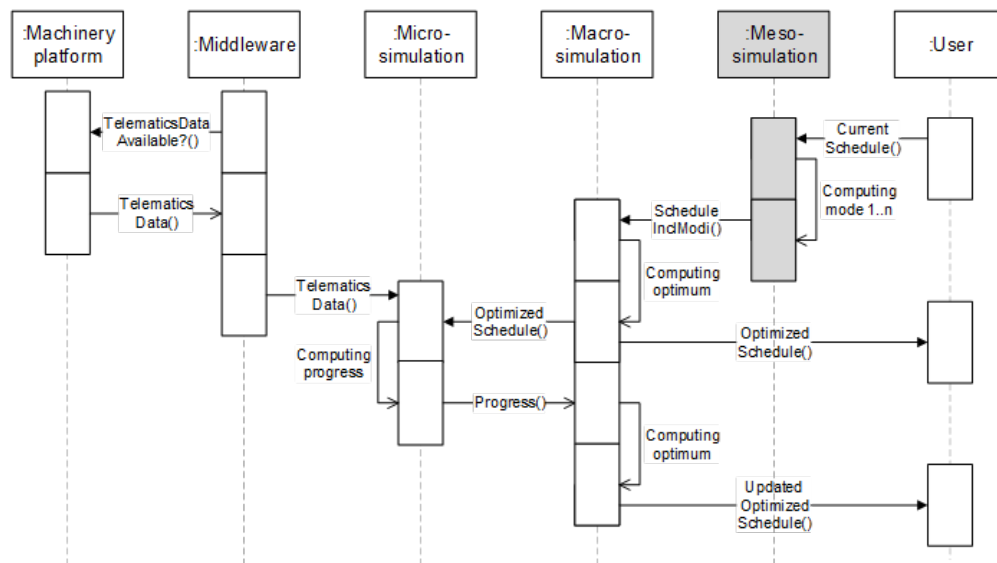

Figure 1. Conceptual model based on Fischer et al. [20] including the new third part, named meso-simulation, of the hybrid simulation approach (gray)

In the following, only the meso-simulation model is described in detail. The essential basis of the meso-model was developed and implemented in previous research projects [27, 28]. However, to the authors best knowledge, there exists no publications on this model exist. This model is the basis for further work which is presented in the following and is described in more detailed in [29] (a co-author of this paper).

4.2 Modularization

According to Wimmer [18], the meso-simulation has a modular structure based on the following main elements, see Figure 2: (1) A standard window including elements for initialization; (2) elements representing characteristic process steps of use cases, such as earthworks or pile drilling; (3) a visualization of the construction site layout.

According to the different characteristics of construction projects, a new model can be quickly established, thereby saving the development duration. Elements in the standard window are aimed to process the data and are explained in the following.

Settings include two components. One component stores the standard data specific for the current project in a list, e.g., the position, length, and number of associated piles. The other component stores the data from each of the specific project entities in a list, e.g., information about each bored pile.

The element *Integration* connects the input data and the simulation. Therefore, one component aims at calculating the detailed data of each entity (such as the bored pile)

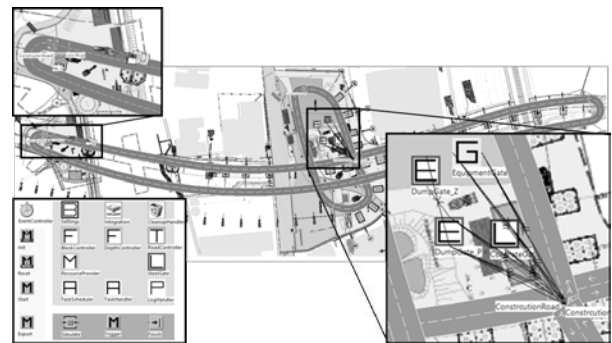

Figure 2. Meso-simulation model including the standard window, construction-site specific elements, and the construction site layout

based on the standard data. Furthermore, an import and an export component exist to either import the data from the database to the model, or to write the simulation results into the database.

The element *RoadController* helps to assign the route of the movement elements. First, the position with the shortest distance between the bored pile and the roads is determined, and then a sensor is placed next to it. For example, when a vehicle whose target is the current bored pile reaches this sensor, the current vehicle moves into the network of the bored pile. This is also true when the vehicle leaves the bored pile, i.e., the vehicle moves from the network to the sensor location.

ResourceProvider is an element that lists the resources needed for the current operation and marks the resources

for the next operation.

The *TaskScheduler* helps the model start the single operation. If construction processes have the same predecessor, the process with the lower ID is preferred. When this task is completed, the corresponding element is deleted from the construction layout or *TaskHandler*. All tasks are sorted again from the previous work and stored in the *Tasks* table. It is possible to access all data at any time during the simulation to see the completed processes, the working process and the processes that have not started yet. The current model is limited, as two construction processes can not be executed in parallel.

4.3 Simulation Logic

The simulation logic is shown in Figure 3. The construction project in the simulation model is hierarchically ordered according to the bill of quantities. Tasks are all listed after data processing in a list in the *TaskScheduler*, where their status of them can be checked at any time during execution. The duration of each subprocess is determined by the selected probability distribution: normal distribution, lognormal distribution, gamma distribution, or Weibull distribution. To ensure that the results of the simulation are close to reality, the input data should come from experience. However, the execution follows the bottom-up principle, i.e., the element of a subprocess is created on the layout sheet first. When all subprocesses of a process are completed, a message is issued to create the corresponding module of the current process. It is then deleted before the execution of the next subprocess. When all processes are completed, the simulation program calls the element of the project. But the elements concerning the processes and the project do not consume any time consuming within the simulation, so the authenticity of the simulation time is guaranteed.

5 Case Study

A case study was used to implement and evaluate of the presented meso-simulation. The simulation model was realized with the help of Siemens' commercial simulation software Tecnomatix Plant Simulation version 15.1 [30].

5.1 Construction Layout

Data from the real bridge project "Westtangente Rosenheim" (WTRO) in Germany was used to validate the hybrid-simulation. This project was also used in a previous work of the authors [20]. From south to north, the project consists of 32 bridge piers including between 5 and 17 large diameter-bored piles of the same type, ranging from 26 m to 50 m in length. Only the production of the bored piles is focused on this paper. Due to the lack of data, 29 piers with 232 bored piles were simulated within

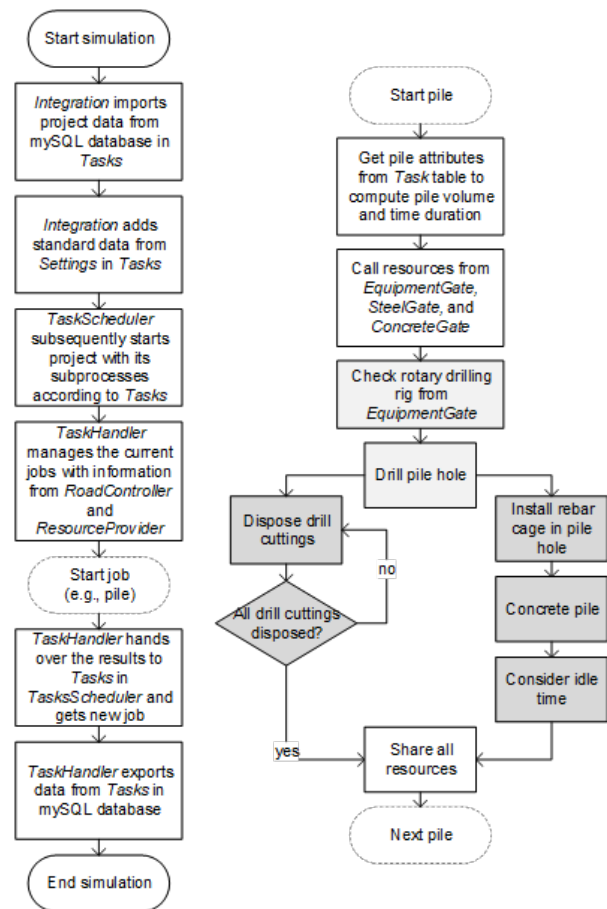

Figure 3. Simulation logic

the meso-simulation. The project layout is implemented in the simulation model, see Figure 2.

A two two-lane track represents the transportation path from the construction storage location to the pile drilling location. Mobile units of transporter and entities of moving units represent the equipment and the material resources. Piles are modeled by a standardized network element, including the single process steps of the pile drilling.

5.2 Material Flow

The descending sequence is as follows: (1) project; (2) pile conglomerate (bridge pier); (3) single pile. Figure 3 shows the implemented logic for producing a single pile. When the production of bored piles begins, the rotary drilling rig, excavator, and concrete truck are transported to the location of the related bridge pier through two-lane roads. They park in the warehouse, waiting to be called to work. Once the related process is finished, they leave the location of the bridge pier back to the construction storage location, ready for the next process.

Table 1. Overview of the parameter setting

No.	Equipment type	Parameter	Values
(1)	Rotary drilling rig	Drilling time	50 %, 100 %
(2)	Hydraulic excavator on tracks	Capacity (m ³)	0.3, 0.56, 0.87, 2.5
		Costs (€ TSD)	85.8, 13.25, 182.5, 457
		Number (-)	1 – 4
(3)	Hydraulic excavator on wheels	Capacity (m ³)	0.3, 0.55, 0.65, 0.99, 1.7, 2.5
		Costs (€ TSD)	89.4, 132.5, 178.5, 223, 335.5, 447
		Number	1 – 4
(4)	Wheel loader	Capacity (m ³)	0.7, 1, 1.25, 1.5, 1.9, 2.1, 2.2
		Costs (€ TSD)	61.4, 78.7, 100.5, 140, 145.5, 178, 211.5
		Number	1 – 4

5.3 Parameter Setting

The parameter setting refers to the different modes as input for the macro-simulation. These modes include information about the equipment used, the duration for every single process, and the relationship between the processes. Table 1 presents a summary of the parameters varied in this work and distinguished between four different equipment types. The information about capacity and cost price of different equipment types are based on the BGL [31]. Concrete delivery is excluded.

5.4 Results

(1) The duration of drilling depends on the type of equipment. Thus, two different types of rotary drilling rigs were simulated by reducing the drilling time of one type up to 50 % to analyze and detect the impact on the final project duration. The results show that by reducing the drilling time, the calculated total duration is reduced from 168 days to 131 days (– 28 %). It is clear that the use of a more efficient rotary drilling rig is more conducive to reducing production time.

(2) The analysis depending on different earth-moving equipment is shown in Figure 4. The reduced amount of each experiment is associated with the demand and capacity of the equipment. For this purpose, the demand or type is varied for the individual bored pile; thus, the duration for one bored pile needs to be checked. The single price for each type is also presented in the diagrams.

As can be seen from the three experiments, there is no duration data when the capacity is too small. This is because the smaller volume increases the delivery time and creates conflict with the main process. Therefore, it is not possible to get the corresponding time data for small volumes. In terms of amount, the time is significantly reduced when the demand is two as opposed to just one. The effect on the event is weakened by continuing to increase the demand amount. At the same time there is a clear trend that within the same equipment, the larger the capacity is the more expensive the equipment will be. Therefore, simply choosing equipment with the largest capacity is not the most economical solution.

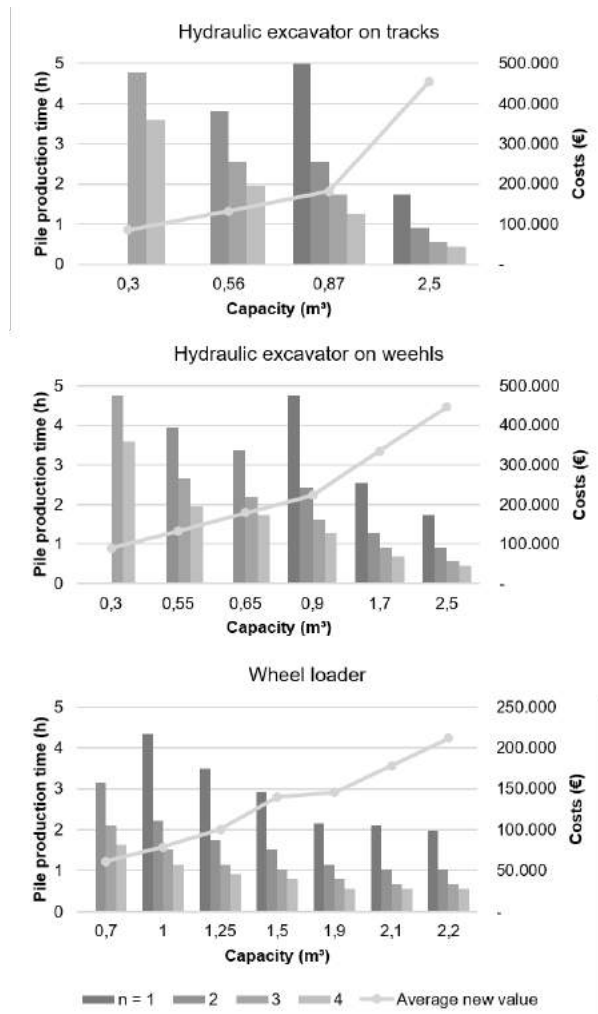

Figure 4. Pile production time depending on the number, capacity, and costs of different earth-moving equipment

6 Discussion

Through the meso-simulation, the project planning data can be generated with empirical values and further trans-

ferred to the macro-simulation. The resource requirements and the capacity can be defined within limits according to the requirements. Due to the validated probability distributions, a relatively stable construction time can be obtained. However, the application of this model is limited. Because the build time is hardly affected by a change in resources, only one mode of each process can be simulated during execution with respect to a set of empirical values. If there is a need to change the mode, the corresponding experience values in the data store must be changed. In addition, parallel construction is not possible. For the bridge construction project WTRO, the construction works of each bridge foundation are independent of each other. Therefore, it helps to improve efficiency if independent processes can be carried out in parallel.

7 Conclusion and outlook

The presented study shows the extension of an existing hybrid simulation model. This extension, called meso-simulation, is able to capture the required input data for optimizing a resource-constraint schedule. The presented conceptual model has been evaluated with the help of a real use case related to pile production. This model was further able to capture the material flow on-site in advance. The variation of different equipment types depending on number, capacity, and single price, allows the calculation of process duration for different modes. Future work will extend the hybrid model to analyze the resource sequencing.

Abstract –

Cross-laminated timber (CLT) is used as the primary structural element for high-rise mass timber buildings. The mass timber buildings that are under construction are largely unprotected as they are not yet equipped with active or passive fire protection systems. With the addition of Types IVA, B, and C, the 2021 International Building Code (IBC) adopted stricter requirements for mass timber buildings that are under construction. However, to date, limited research has been conducted to demonstrate the impact of passive fire protection for CLT buildings that are under construction. To facilitate a better understanding of construction fires and their consequences, it is necessary to develop a numerical modeling solution for the early phases of a CLT construction project, which can be achieved by using building information models (BIM) together with fire dynamics simulation (FDS). Therefore, this study proposes a numerical modeling solution that uses the FDS tool to simulate and assess the fundamental fire behavior in CLT structures. The FDS models are developed and evaluated by benchmarking against the experimental data obtained from compartment fire tests. The FDS analysis results are expected to validate the practicality of simulating the fire behavior in CLT structures using the numerical model proposed in this study. The overarching goal of this study is therefore to develop a comprehensive numerical modeling solution to simulate and assess fires in CLT buildings that are under construction.

Keywords –

Cross-laminated timber (CLT); Building information modeling (BIM); Fire dynamics simulator (FDS); Benchmarking of numerical models.

1 Introduction

Over the past decade, fires have caused significant loss of life and property in timber buildings that are under construction [1]. A 7-story wooden frame building under construction in Oakland caught fire twice in 2017. Similar fires have occurred in other buildings around the

country [1]. The leading causes of construction fires are arson or electrical fault and heat sources that are near combustible materials on construction sites. Fire safety planning on a job site is the responsibility of the design team during the design phase of a building. However, traditional fire safety planning relies on frequent manual observations on a job site, which is labor-intensive, time-consuming, and thus highly inefficient. Furthermore, fire safety knowledge is difficult to transfer to people working on site using safety regulations alone [2,3]. Additionally, the development of an effective fire safety plan is often impeded due to designers' inadequate knowledge about jobsite safety procedures as well as limited design-for-safety tools that are available to designers [4].

Mass timber buildings under construction are largely unprotected as they are not yet equipped with active or passive fire protection systems. Multiple floors of those buildings under construction are left exposed since the fire protection can be applied only after the mass timber structural elements are erected. Recently, with the addition of Type IVA, B, and C buildings in the 2021 International Building Code (IBC), the IBC also adopted stricter requirements for fire protection measures of mass timber buildings under construction. Particularly, International Fire Code (IFC) Section 3308.9 requires that at least four stories of any mass timber construction more than six stories above grade is protected with noncombustible material [5]. This stipulation limits the speed of construction and emphasizes the need for data-driven guidelines for mass-timber construction fire safety that has a huge impact on construction labor safety and protection of project-associated property.

Cross-laminated timber (CLT) is commonly used as a primary structural element for high-rise mass timber buildings. However, limited research has been conducted to demonstrate the impact of passive fire protection on a CLT building construction jobsite. To facilitate a better understanding of the behavior of fire within a mass timber building under construction, it is necessary to develop a numerical modeling solution for the early phases of a CLT construction project, which can be achieved using building information models (BIM) together with fire dynamics simulation (FDS). Therefore,

this study focuses on the first step of the numerical modeling solution that uses a FDS tool to simulate and assess the fundamental fire behavior in CLT structures.

The remainder of the paper is organized as follows. Section 2 provides a comprehensive review of the relevant literature. Section 3 details the modeling process of FDS models including scenario configurations and essential modeling parameters. This is followed by a numerical implementation and benchmarking of the proposed model. The final section draws conclusions and offers recommendations for future research.

2 Relevant Literature

2.1 Modeling in Construction Fire Safety

BIM has been used to improve construction safety in multiple ways. Li et al. [6] used BIM to improve and optimize safety planning on job sites. Park and Kim [7] proposed a BIM-based quality checking process to assist with eliminating construction safety hazards. Deng et al. [8] developed a BIM-based simulation module to assess the emergency rescue plans for construction accidents and formulate a corresponding emergency management plan. Researchers have also investigated the possibility of using BIM for fire safety. For example, to improve building fire rescue efficiency, Chen et al. [9] proposed an integrated framework integrating BIM together with sensor-based Internet of Things (IoT), Virtual Reality (VR) and Augmented Reality (AR) systems.

However, the research on using BIM in construction fire safety is still in its infancy. Due to the complexity of fire modeling, there are several obstacles to simulating and designing for construction fire emergencies. These complexities include data interoperability as well as the technical limitations of the currently available BIM software that prevents seamless integration with fire dynamics modeling solutions. Therefore, this study proposes a solution that uses a commercially available FDS tool while enabling seamless information exchange with BIM software.

2.2 The FDS Tool for Fire Modeling

PyroSim [10] is a comprehensive FDS software that can be used to simulate fire-driven fluid flows and generate fire dynamics outputs in an efficient manner. The first version of this FDS tool was used by National Institute of Standards and Technology (NIST) and Underwriters Laboratories (UL) in a research program for fire modeling in a building [11]. In their study, the FDS modeling outputs were compared to the full-scale experimental results. Furthermore, they used the FDS modeling outputs to supplement the data collection, including volume flows and air pressures, that were not

measured during the experiment. The FDS models were also used to conduct a sensitivity analysis for various testing parameters. In conclusion, FDS for numerical experiments, either as an alternative or complement to traditional experimental fire tests, play an important role for research in fire science [12].

2.3 Numerical Experiments and Traditional Experimental Fire Tests

Full-scale and small-scale experiments have been used with great success to increase the understanding of fire chemistry and fire dynamics in mass timber buildings. Nevertheless, numerical models and simulations are very valuable, particularly when used to complement large-scale tests that are expensive, resource demanding, and time consuming [13]. However, current numerical solutions for mass timber compartment fires have not been benchmarked against data obtained from traditional compartment fire experiments. For example, in [14], fire properties of flammable materials used in the FDS simulation were determined based on the laboratory measurements and validated through fire tests. Similarly, Fernd and Liu [15] assessed their FDS models against the previous experimental work presented in [16] to investigate the effect of different droplet sizes on fire suppression mechanisms. An FDS–finite element method (FEM) simulation approach proposed in [17] was compared to experimental results and used to predict both the thermal and structural responses of a steel column in a fire test. Numerical modeling is a promising approach in fire research. Traditional and numerical experiments are complementary and not competitive. Thus, a combination of these two approaches is necessary to analyze a certain fire phenomenon.

2.4 Motivation and Objectives

FDS is a feasible tool for developing numerical models and simulating the fire behavior in CLT structures because the physical building information can be imported from BIM software into PyroSim seamlessly [18]. However, the numerical modeling technique must be benchmarked against experimental data first to then extrapolate the modeling technique to explore other parameters. Consequently, the scope of this paper is to develop and benchmark a numerical modeling solution against a mid-scale CLT compartment fire test presented in [19] by applying the FDS tool to simulate the fire behavior of CLT panels. In future work, the benchmarked numerical models will be used to conduct analytical parametric tests and to develop and test a BIM-based fire simulation framework for CLT structures under construction.

3 Research Methodology

Figure 1 illustrates the proposed BIM-based simulation framework for modeling the fire behavior in CLT structures under construction. The first task of the framework is to validate the practicality of using the FDS tool together with BIM software for fire dynamics simulation in a building, which was illustrated in our previous work [20]. The second task, detailed in this paper, is to develop and benchmark the proposed numerical models using PyroSim, an FDS software, to simulate the fundamental fire behavior of CLT panels and benchmark the simulations against the experimental data presented in [19]. The second task detailed in this paper details the modeling approach for the numerical experimental configurations and the definition of modeling parameters in the FDS, which will be used to develop the proposed modeling solution for the final task of the simulation framework in future work.

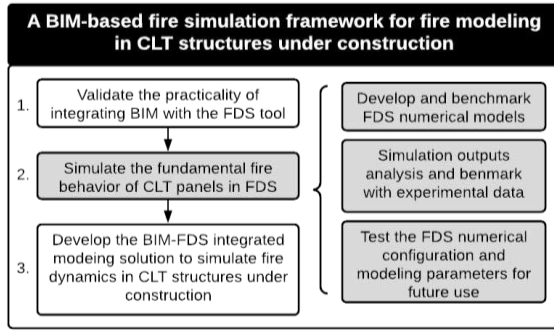

Figure 1 The proposed simulation framework

3.1 FDS Numerical Configuration

The first step of the modeling approach is to develop a 1:1 FDS numerical scenario corresponding to the one presented in [19]. Figure 2 illustrates the FDS scenario for a cuboid numerical compartment developed in PyroSim.

Figure 2 A front view of the FDS scenario (in cm)

The compartment is assumed to be constructed using CLT panels with a thickness sequence of 4.5-2-2-2-4.5 cm and a density of 425 kg/m³ used in [19]. The numerical compartment has internal dimensions of 50 cm (width) x 50 cm (depth) x 38 cm (height), with a single opening of 30 cm (width) x 28 cm (height). A kerosene pool fire was designed to be continually ignited inside the numerical compartment. Figure 3 shows the numerical compartment walls including the ceiling (C), two lateral walls (LW and LW2), and the back wall (BW). The walls inside the numerical compartment are designed to be covered with two layers of 12 mm Knauf FireShield plasterboards that would not combust in the fire.

Figure 3 The cuboid numerical compartment

3.2 Modeling Parameters

The thermal properties of the CLT panels and Knauf FireShield plasterboards used in the FDS simulation match the experimental data presented in [19] and are summarized in Table 1. To investigate the effect of exposed CLT area on fire propagation and magnitude, the authors tested eight experimental configurations with varying exposed CLT area matching those in [19]. Table 2 summarizes the FDS numerical configuration matrix with different CLT surfaces exposed to fire. To compute those configurations in FDS, the solution to determine the percentage of various exposed CLT surfaces is calculated as follows (see Equation (1) to (5)):

$$\text{Exposed CLT area} = \frac{\sum A_{CLT,exposed}}{A_{Total}} * 100\% \quad (1)$$

$$A_{Ceiling} = A_{Floor} = 50 * 50 = 2500 \text{ cm}^2 \quad (2)$$

$$A_{Wall} = 50 * 37 = 1850 \text{ cm}^2 \quad (3)$$

$$A_{Opening} = 30 * 28 = 840 \text{ cm}^2 \quad (4)$$

$$A_{Total} = A_{Ceiling} + A_{Floor} + 4A_{Wall} - A_{Opening} = 11560 \text{ cm}^2 \quad (5)$$

where $\sum A_{CLT,exposed}$ is the sum of area (in cm²) for exposed CLT surfaces, that are not fire-protected, are treated as fuels in the FDS models.

Table 1 Thermal properties of CLT panels

Material type	Density kg/m ³	Specific heat kJ/(kg·K)	Charring rates mm/s	Pyrolysis rate -	Effect heat of combustion kJ/kg
Yellow pine	425	1.36	0.025	0.7	13

Table 2 FDS numerical configuration matrix

Configuration	Description	Exposed CLT area	
		cm ²	%
1 Baseline	All CLT surfaces are fire-protected that are not exposed.	0	0
2 Exposed C	The ceiling is exposed to fire.	2500	22
3 Exposed LW	One lateral wall is exposed.	1850	16
4 Exposed LW, C	One lateral wall and the ceiling are exposed.	4350	38
5 Exposed LW, BW	One lateral wall and the back wall are exposed.	3700	32
6 Exposed LW, BW, C	One lateral wall, the back wall, and the ceiling are exposed.	6200	54
7 Exposed LW, BW, LW2	Two lateral walls and the back wall are exposed.	5550	48
8 Exposed ALL	All walls and the ceiling are exposed.	8050	70

3.3 Measurement Devices

To compare the results from the FDS model to the experimental tests conducted in [19], the authors defined output recording locations in the same locations where sensors were located during the experiments in [19]. Figure 4 illustrates the measurement devices and locations created in a three-dimensional (3D) FDS model.

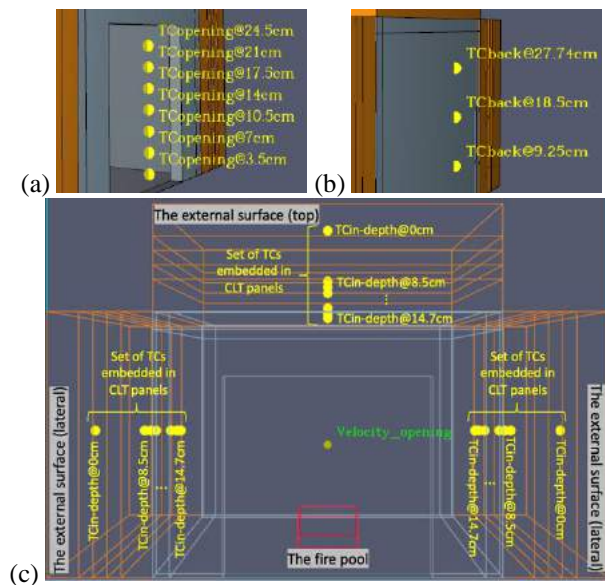

Figure 4 A screenshot of numerical measurement devices of (a) 7 TCs at the opening, (b) 3 TCs at the back wall, and (c) 3 x 8 TCs embedded in CLT panels and one velocity meter at the opening of the compartment (the 3D model (c) is shown in wireframe rendering mode for better viewing)

There are 34 thermocouples (TC) and one velocity meter to measure temperature and air flows respectively. Further details are below:

- 7 TCs are uniformly distributed along the vertical axis of the opening of the numerical compartment at different heights: 3.5 cm, 7 cm, 10.5 cm, 14 cm, 17.5 cm, 21 cm and 24.5 cm above the floor (see Figure 3a);
- 3 TCs are placed along the vertical axis of the back wall (BW) of the numerical compartment at different heights: 9.25 cm, 18.5 cm, and 27.74 cm above the floor (see Figure 3b);
- 3 sets of TCs (8 TCs per set) are embedded in each side wall of constructed CLT panels (the top and two lateral sides) to measure the temperature profile evolution. The depths of each set of TCs with respect to the external surface (not the fire exposed surface) are 0 cm, 8.5 cm, 9.5 cm, 10.5 cm, 13 cm, 14 cm, 14.5 cm and 14.7 cm (see Figure 3c).
- One velocity meter was placed at the opening of the numerical compartment to measure the bi-directional velocities of inflow and outflow (see Figure 3c).

During the simulation, PyroSim writes post-processing simulation outputs as 2D plots of fire dynamics over time including the heat release rate (HRR), flow velocities, and temperature profiles. Those outputs are obtained through the measurement devices defined in FDS numerical models. These numerical models are then used to supplement the observations of fire dynamics through 3D animations. Besides, the cell size of FDS numerical models is defined as 1 mm to obtain reliable and accurate simulation outputs without increasing the computational time exponentially. The details of the

numerical tests are included in the following section that discusses the analysis and benchmarking of FDS numerical models.

4 Simulation Outputs and Benchmark

4.1 Overview

This study conducts an FDS analysis to benchmark the proposed numerical modeling approach using the data measured experimentally in [19]. The research results presented in this section demonstrates that the proposed modeling approach is correlates well with experimental measurements and confirms relevant experimental findings. Particularly, three major experimental findings of [19], that are summarized next, are evaluated: (1) CLT panels contribute significantly to the total heat release of the fire, (2) the presence of a ceiling increases the flow velocities of fire spread, and (3) the internal temperature of the compartment does not necessarily increase with the increase of the exposed area. The validation of the study results aims to provide a modeling solution basis, including FDS numerical configuration and modeling parameters, towards the proposed simulation framework for modeling the fire behavior in CLT structures.

4.2 Heat Release Rate

Figure 5 illustrates the comparison of HRR between the FDS numerical outputs and the experimental results obtained in [19].

Figure 5 The comparison of HRR between FDS outputs (in black color) vs Gorska et al. [19] (in grey color)

The FDS outputs of HRR, computed in numerical models, corresponds to the HRR of experimental data for

different sources. Figure 5 shows the comparison of different HRRs from [19] compared with those predicted by the FDS model, including the HRR contributed from the CLT (HRR_{CLT}), kerosene ($HRR_{kerosene}$), the summation of the HRR from the CLT and the kerosene (HRR_{Total}), and total HRR measured during the test (either in [19] or FDS model) (HRR_{Model}). Particularly, HRR_{Model} was used to determine if there were HRR losses within the compartment during the experiments in [19] by comparing HRR_{Model} to HRR_{Total} . As shown in Figure 5, the experimental result of $HRR_{Model[19]}$ in [19] has a satisfying prediction of $HRR_{Total[19]}$ (grey lines); in FDS numerical models, both $HRR_{CLT(FDS)}$ and $HRR_{Kerosene(FDS)}$ contribute to $HRR_{Model(FDS)}$, with satisfying computational results for $HRR_{Total(FDS)}$ (black lines). Furthermore, the fact that CLT panels contribute significantly to HRR_{Total} , as demonstrated in [19], is confirmed in the FDS analysis as it corresponds to the trend of HRR_{CLT} with varied exposed CLT area.

4.3 Flow Velocities at the Opening

The flow velocities at the compartment opening as a function of the exposed CLT area are shown in Figure 6. These flow velocities compare the numerical output to the experimentally measured flow velocities.

Figure 6 Computed flow velocities (in black color) at the compartment opening for different configurations compared to Gorska et al. [19] (in grey color)

To conclude, the numerical model can predict the flow velocity trend obtained in [19] reasonably well as seen in Figure 6; the flow velocities increase as the exposed area increases. The increase in velocities is due to the mass flow exchange driven by burning CLT panels; hence, all CLT surfaces exposed to fire would increase the flow velocities.

Additionally, the presence of an exposed CLT ceiling increases the velocity of the fire spread compared to other exposed surfaces with similar surface area. This finding aligns with the second finding in [19]. This can be due to CLT ceiling's exposure causing heat loss, which is released through the upper boundary of the numerical compartment. This behavior also implies that CLT panels' burning rate is not only associated with the area of

exposed surfaces but also with their location, e.g., ceiling vs. vertical walls.

4.4 Gas-phase Temperature Profiles

Figure 7 presents the mean gas-phase temperature (°C) measured at different heights (m) and at different locations of the compartment for all test configurations in [19]. The x-axis is the mean gas-phase temperature, and the y-axis is the height of the compartment. Each test configuration has varying CLT exposed surfaces. As stated in the previous section, both the area and the location of exposed CLT surfaces affect the burning rate.

Figure 7 Gas-phase temperature profiles against heights inside the compartment (solid lines) and at

the opening of the compartment (dashed lines) compared to the results obtained in Gorska et al. [19] (in grey color)

As shown in Figure 7, the curve trend of measured temperatures in FDS numerical models support the temperature profiles measured experimentally in [19]. Referring to [19], the internal temperatures of the compartment are not necessarily higher when the exposed surface area is larger; however, in FDS numerical models, more exposed CLT surfaces indicate higher temperatures both inside and at the opening of the compartment compared to the measured values in [19]. This is possibly due to the thermal properties of FireShield plasterboards that are defined as non-combustible in FDS models, hence prevent fireproofing applied CLT panels from burning immediately.

Essentially, both the burning of combustible elements and the external heat flow can impact the internal temperature of the compartment. Referring to [19], the excess of pyrolysis gases from the burning panels is expected to induce an increase in external heat release rate due to a potential growth of the external flames. Hence, future research should investigate the effect of massive heat flow, which may trigger the collapse of plasterboards and ignite fireproofing applied CLT panels that would raise the internal temperature of the compartment.

In addition, the evaluation of the temperature profiles indicates a thermal gradient within the CLT panels themselves with higher temperatures on the surface of the CLT panels exposed to the fire. It can be observed from Figure 8 shows that the temperature of the CLT increases with increasing depth into the CLT from the external surface to the fire exposed surface. The data shown also indicates that at the depth of 14.5 cm away from the external surface, the thermal gradient levels off and the temperature slightly decreases while the CLT panels start to char.

Figure 8 Linear temperature profiles in the CLT panels at 15 mins (dashed lines) and 20 mins (solid lines) after flashover compared to Gorska et al. [19] (in grey color)

4.5 3D Animations for Fire Dynamics

In addition to the HRR, flow velocities, and temperature at different elevations of the CLT compartment, the numerical simulations can provide additional information that cannot be obtained through an experiment. First, the numerical simulations can provide additional insights into the fire dynamics in the compartment through 3D animations that can supplement the observations on fire dynamics from the test. Figure 9 is an example of 3D Smokeview for fire dynamics for “Exposed C” configuration. It shows that the CLT panels are burned away over time.

Figure 9 An example of 3D Smokeview for fire dynamics at the simulation time of (a) 400 seconds, (b) 600 seconds, (c) 1200 seconds, and (d) 1800 seconds.

In addition, a numerical model enables users to collect time dependent information about fire dynamics at any location. During a fire test, it is difficult to collect real-time observational data that can inform researchers about the fire development and progression. Images, such as those shown in Figure 9, can supplement photos and videos taken during a fire test that may be skewed or difficult to interpret due to elevated temperatures.

The second way these numerical models can supplement experimental data is through additional temperature measurements. Experimental data quantities are limited by the capacity of the laboratory's data acquisition system. This capacity is often limiting for the number of measurements that can be taken throughout the test. The FDS models described in this paper can output infinite amounts of temperature data, thereby allowing researchers to obtain additional temperature measurements.

Lastly, large-scale compartment fire tests are costly and time consuming. Benchmarked FDS models, such as those described in this paper, allow for researchers to adjust modeling parameters in numerical models to support conducting parametric experiments that are

valuable for fire science research, particularly when the corresponding large-scale tests are expensive, resource demanding, and time consuming.

To conclude, the main advantage of numerical experiments is being more resource efficient compared to traditional experimental fire tests. With an appropriate level of control of the experiment, several numerical experiments can be carried out through computational tools at a time.

5 Summary and Future Research

Construction fires are a big threat to construction worker safety and property loss. To date, several studies have demonstrated the impact of passive fire protection on a job site for CLT construction. To develop a BIM-based simulation framework for modeling the fundamental fire behavior in CLT structures, the FDS tool, that is interoperable with BIM software, can be used to simulate fire dynamics efficiently. Hence, this study provides a modeling solution that uses PyroSim, an FDS program, to simulate and benchmark the fire behavior in CLT structures regarding HRR, flow velocities, and temperature profiles in a numerical compartment model. The FDS numerical models are benchmarked with previous experimental configurations as well as data measured experimentally in [19].

To conclude, the numerical outputs support the data measured experimentally and confirm the three major experimental findings of CLT burning phenomenon tested in [19] including: (1) the CLT panels contribute significantly to the total heat release of the fire, (2) the presence of a ceiling increases the burning rate at a higher rate compared to other exposed CLT surfaces, and (3) the internal temperature of the compartment is not necessarily higher when the total exposed area is larger. Additionally, this study provides FDS outputs that can supplement the experimental tests and observations including 3D animations of the fire spread. Such animations provide a better view of numerical modeling outputs that can be utilized for multiple purposes regarding fire safety, such as transferring knowledge about fire behavior of building materials or enhancing construction fire safety education. Therefore, the validation of numerical results in this paper confirms the practicality of modeling the fire behavior in CLT structures using FDS numerical models. The FDS numerical configuration and modeling parameters will be implemented in the next step of this study to simulate and assess fires in CLT buildings that are under construction.

There are several limitations to this study which should be investigated in future research. First, there are limited number of publications presenting the results of compartment fire tests for CLT structures. To improve the reliability of FDS numerical models, experimental

data from multiple sources can be used for benchmarking. Second, the numerical models in this study simulate the fundamental fire behavior of CLT panels in a mid-scale compartment. However, the burning behavior of large CLT structures could be different. Thus, this phenomenon should be further studied. Third, due to the complexity of fires, the influential factors of fire dynamics in a building are complex, hence, the modeling parameters should be investigated in detail when developing the numerical models. In addition to the modeling parameters tested in this study, future research should provide additional insights regarding a CLT structure fire, e.g., the effect of external heat flows, the charring phenomenon among others.

E-mail: kp2393@nyu.edu, semiha@nyu.edu, cfeng@nyu.edu

Abstract –

Modular construction aims at overcoming challenges faced by the traditional construction process such as the shortage of skilled workers, fast-track project requirements, and cost associated with on-site productivity losses and recurrent rework. Since manufacturing is done off-site in controlled factory settings, modular construction is associated with increased productivity and better quality control. However, because every construction project is unique and results in distinct work pieces and building elements to be assembled, modular construction factories necessitate better mechanisms to assist workers during the assembly process in order to minimize errors in selecting the pieces to be assembled and idle times while figuring out the next step in an assembly sequence. Machine intelligence provides opportunities for such assistance; however, a challenge is to rapidly generate large datasets with rich contextual data to train such intelligent agents. This work overviews a mechanism to generate such datasets in virtual environments and evaluates the performance of AI models trained using data generated in virtual environments in recognizing the next installation step in modular assembly sequences. Performance of the trained MV-CNN models (with accuracy of 0.97) shows that virtual environments can potentially be used to generate the required datasets for AI without the costly, time-consuming, and labor-intensive investments needed upfront for capturing real-world data.

Keywords –

Scene understanding; Virtual Environment; MV-CNN; Computer Vision

1 Introduction

While productivity in other industries has doubled in the past decades, productivity in the construction industry has remained flat [26-27]. In addition, more challenges are faced with the shortage of skilled workers and tighter

construction sites in urban settings that impact productivity in general. As a solution to this situation, the industry shows an interest towards modular construction, whose principle is to preassemble work pieces into volumetric units (or preassembled panels) off-site and stack them on-site. The advantage of off-site production is the controls over the working environment, so it is not affected by weather and site-specific conditions, and there is an opportunity to increase productivity because a relatively fixed production line can be maintained as compared to the conventional construction sequence. In addition, it is environmentally friendly with 15% less construction waste as compared to on-site construction [1]. Despite these advantages, the inherent unique nature of each construction project brings the same challenge to the modular construction processes, too. To enhance the productivity in modular construction factories and minimize rework and idle times of workers while identifying ever-changing work pieces and assembly sequences during manufacturing, intelligent agents can be used for assistance to identify the next step in an assembly sequence for workers. However, training such intelligent agents requires extensive information about features of a construction site, construction processes, and also geometries of assembled pieces [2]. This requirement, coupled with the variations in these due to the uniqueness (e.g., design, materials) of construction projects, increases the cost of gathering a large scale but contextually rich dataset needed for training of reliable AI models. Since quality and quantity of data are essential for training intelligent agents [3] and real-world data (which naturally has all the context needed for the training process) is expensive to capture, there is a need for alternative ways to rapidly generate realistic and context-rich datasets.

In this study, we formulated an approach that leverages virtual environments reconstructed from real factories to rapidly and systematically generate large scale context-rich datasets and provided the results of a predictive model built for recognizing the assembly step in a sequence using the dataset generated in virtual environments.

2 Literature review

This section provides (a) an overview of datasets generated by leveraging virtual environments for AI training, and (b) a brief synthesis of research studies at the intersection of AI and modular construction.

2.1 Overview of datasets generated by leveraging virtual environments

Although real world generated datasets effortlessly represent the rich complexity and the context required for AI to learn properly, they are expensive and require a longer upfront time to capture them. Virtual environments on the other hand provide a huge advantage of rapidly replicating real environments and representing a wide variety of objects in scenes. Realistic representation of the real environment in the virtual space is critical for data quality obtained from these environments. There are generally two main sources to bring reality to virtual environments: (1) a scanned environment [6-8,19,22], where a real environment is scanned and reconstructed as-is; and (2) a synthetic environment [5,20-21], where virtual environments are constructed through 3D modelling from scratch that reflect the principles of real world such as lighting, textures, and colours.

Various datasets have been generated in virtual environments for scene understanding and object recognition purposes. Since the first generation of large dataset are limited to the 2D perspective images, many research groups put efforts on establishing large-scale 3D datasets that contain rich contextual information about the scenes to provide the datasets and benchmark systems to improve the scene understanding. These next generation 3D datasets are captured in different settings; such as scenes from urban environments [18], indoor settings from households [5], and indoor settings from offices [7] and can be applied to various problems such as object detection, scene understanding, and room layout estimation. Also, since the type of intelligence (e.g., self-driving, construction robot, household AI) expected from AI is determined based on the context of a dataset, the 3D environment should provide rich contextual information to AI. For example, for a construction robot to be tasked with understanding the next step in an assembly sequence, the dataset should include variations in geometric shapes that assemblies contain, variations in the views the sequence is captured, variations in the background where modules are assembled such as the location, surrounding objects, and congestion.

For a smooth learning workflow, data should be well-structured with RGB-D (Red, Green, Blue and Depth), annotations on objects in scenes (e.g., 2D-3D bounding boxes and classification labels, semantic labels),

relationships between objects in scenes (e.g., scene graph generation from objects) [4]. Actively used datasets for experiments include, Matterport3D [6], AI2-THOR [5], Gibson env. [7], and Replica Dataset [8]. These datasets can be widely used for simulation such as scene understanding, robot navigation, and robotic manipulation. For instance, Gibson env. was utilized for creating 3D scene graphs containing semantic information of household furniture and rooms to serve the purpose of scene understanding [4]. Matterport3D provides 194,400 RGB-D real-world captured indoor images primarily for scene understanding purposes. On the other hand, AI2-THOR is providing digital models of 89 apartments with 600 objects and interactions such as opening refrigerator. The purpose of this dataset is to train robot manipulator in the household context. Subsequently, Gibson env. provides laser scanned data of 572 buildings which has semantics, depth, and normal of faces. This data aims to train sensorimotor robot AI models. Likewise, the Replica contains 18 scanned apartments models with depth and semantics of objects for scene understanding.

The commonality of these datasets is that they were generated in virtual space that resembles the real-world for giving sufficient sensory information to AI to have perception to solve problems such as scene understanding, robot navigation, and robotic manipulation. In this paper, we reconstruct the 3D modular factory environment based on the actual factory and train AI model to understand the work progress in the modular construction factory context.

2.2 Overview of AI based research in the modular construction domain

Related research studies reveal that, machine learning techniques have been applied to various challenges such as automatic identification of construction activities [16,23-24], classification of subtypes of BIM objects [9,25], and detection of modules that are being stacked at a construction site [17]. In relation to modular construction domain, several machine learning algorithms such as Support Vector Machine (SVM) on video and audio data [16], LSTM [23-24], and Multi-View Convolutional Neural Networks (MV-CNN) [9] have been evaluated. High model performances in these studies showed the applicability of deep learning in construction related problems with a relatively small dataset and computing resources by transfer learning from the models trained with larger datasets from the computer vision domain with an F-1 score of up to 0.93. However, the models are limited to inference of generic objects (e.g., door, wall) and the usability of these models to the problem of assembly sequence identification and classification is yet to be evaluated. However, in general

previous research studies provide a sound point of departure, indicating (a) an opportunity to utilize feature engineering to enhance the classification results, (b) a high performance of models that utilize 2D perspective images captured from 3D models, and (c) a high performance of models in real world settings that are trained with synthetic data originated from virtual environments.

3 Training AI for recognizing steps in module assembly sequences

In this section, we overview our approach to generate synthetic data and then train vision-based AI progress classifier within virtual factory environments. We generated data from a virtual factory environment and trained a classification model to classify an recognize steps in module assembly sequences. Module assembly progress classifier detects the assembly step of a volumetric unit (or a panel assembly) given any stage of the assembly. So, this intelligent agent will detect the assembly step when the agent navigates in a factory setting and sees a module that is being assembled. This is an essential step in robotic assistance during the assembly process for determining the next piece that is needed in the sequence of an assembly.

3.1 Data Generation Platform

We leveraged VR environments to generate large amounts of data with minimum reality-gap and in a short time frame. Generating realistic virtual environments (e.g., scanning, reconstructing, etc) has an upfront time investment that is justified by the a) elimination of relocation of the camera system from station to station in a factory setting or having to purchase a large collection of cameras to cover all stations; b) elimination of the time wasted while waiting for the real fabrication timing of modular pieces in order to completely capture assembly sequences; and c) elimination of bounding to the fixed number of viewpoints, as experienced while capturing real images in factories.

Figure 1. Scanned modular construction factory (top); Virtual factory environment (bottom)

In order to generate datasets in virtual settings, we first created 3D factory environments from a modular construction factory that was scanned with terrestrial laser scanners and converted them into VR (Figure 1). This environment has been detailed in [12].

For simulating the module assembly processes, we obtained real volumetric module designs and separated the volumetric units into panels and work pieces in BIM authoring tools, and then exported them as IFC files. The volumetric modules in IFC format were integrated into the virtual factory environment while the virtual factory environment was reconstructed. Within the virtual environment, multi viewpoint images containing labels (as the steps of the module assembly sequence) were generated using scripts implemented in a 3D graphics tool's API. Subsequently, generated images were split into training and test dataset using the 8:2 ratio.

Figure 2. Overview of data generation and training process

To capture multi-view images in the virtual environment, we set virtual cameras that focused on the volumetric modules (see Figure 3). The details of the entire multi-view camera-based platform that was developed by the authors are provided in [12]. In a nutshell, this platform is composed of a randomized camera system and rendering tools. The data is generated by systematically rotating camera views from 12 distinct locations. Using this platform, we generated 84,000 images and separated them into training and testing data set using the 8:2 ratio.

Figure 3. 12 viewpoint camera system to capture images

3.2 Multi-View Convolutional Neural Networks (MV-CNN)

There are two main approaches to provide 3D geometric information to deep learning to identify given objects: 1) point clouds-based approach, which directly inputs raw point clouds [15]; 2) view-based approach, which inputs images from multiple viewpoints [10]. There is essentially no difference between these methods for object classification problems [8,13-14] even though point clouds have more accurate geometric information in 3D coordinates with the disadvantage of time consuming and expensive data capturing process. Furthermore, earlier studies showed that, MV-CNN has a higher overall accuracy as compared to point clouds-based model or machine learning model (SVM) to

identify and label 3D model elements [8,13-14]. Hence, in this study, MV-CNN was adopted to build the model to identify and label the steps in a module assembly sequence.

In a nutshell, MV-CNN enables 3D shape recognition by retrieving geometric features from multiple 2D images and combining them into a single set of features. Each image is processed through CNN_1 and pooled over images from multiple viewpoints process through CNN_2 for shape descriptor [10]. A single input for MV-CNN architecture in this work consists of 12 images captured from multiple viewpoints at a location and the corresponding label for those 12 images, which indicates the module assembly step (see Figure 4) (i.e., 1 input). We retrained the model upon the pre-trained MV-CNN that utilized generic 3D objects for training (e.g., chair, sofa, door, etc.).

3.3 Ensuring context variation: sequence of module assembly, background environment

The sequence of volumetric unit assembly used in this study is shown in Figure 5. The volumetric unit is composed of 14 pieces (e.g., frame chassis, wall panel, wall panel with door). Therefore, the generated dataset includes volumetric module assembly sequence captured at different times during the assembly process, at different backgrounds and from viewpoints while these fourteen 3D objects were being assembled in the factory.

Figure 4. MV-CNN model architecture

12 images captured in VR per label (left); Processed into MV-CNN architecture (middle); Classification: each label is a step in the assembly sequence (right)

Figure 5. Module work pieces and numbered steps in the assembly sequence

Because the classification model identifies module progress within the given factory environment, we placed modules for each assembly step of the fabrication randomly on the assembly area in the virtual factory (Figure 6). These randomized scenes are providing different background visual representation of input image data (e.g., lighting, background objects, etc.) for models to learn under different contexts. In addition, the materials (texture, color) of these varying background objects (e.g., factory walls, floor, ceiling) have been configured to bring more variance to the context.

We generated 84,000 images which are 7,000 set of inputs (where each set has 12 images captured from different views per input). For each step of the assembly, we had 500 inputs, resulting in $500 \times 12 = 6,000$ images to use in the training. Therefore, each label (module assembly step) has 500 inputs that were separated into 400 training sets and 100 training sets.

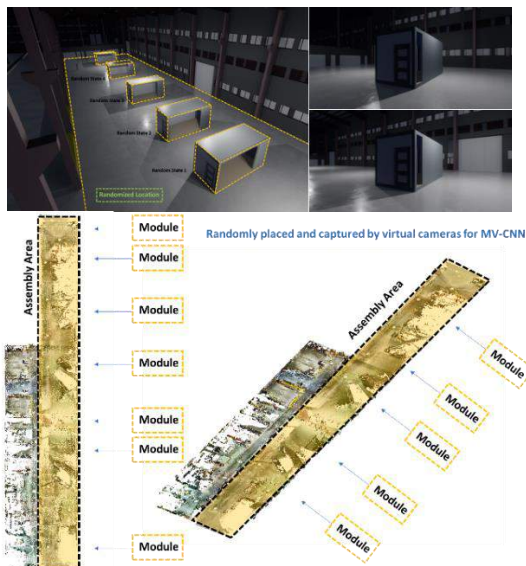

Figure 6. Randomized location of modules to capture images

4 Results

The accuracy, precision, recall, and f1-score of model result are 0.97. The testing results are shown in Table 1 as a confusion matrix. The prediction results of module assembly step 9 and step 13 are relatively lower than the other predicted labels (0.82 and 0.84, respectively). As the wrong predictions occurred later assembly steps, it is because majority viewpoints images are duplicated as completed parts are occluding the other parts (e.g., viewpoints image from 3 sides are same). Even though the background environments change, the model shows accurate results, which provides a strong evidence for suitability of using virtual environments for dataset generation.

Table 1. Confusion matrix for module assembly sequence classifier

Actual	Predicted steps in the assembly sequence													
	1	2	3	4	5	6	7	8	9	10	11	12	13	14
1	100													
2		100												
3			100											
4				100										
5					100									
6						100								
7							100							
8								2	96		2			
9										82	17		1	
10											97	1		2
11												1	98	1
12													100	
13														1
14														

Since transfer learning is used, the training requires less computational resources and data. The accurate model with less cost through transfer learning shows that, the model can be tuned faster to adjust changes in volumetric units (or panels) to be assembled. This classifier can be used as a baseline to retrain classifiers for subsequent assembly sequences.

5 Conclusion

In this study, we evaluated the viability of training AI models for classifying module assembly sequences using the datasets generated in virtual environments within the modular construction context. Given the test dataset with possible variances, the model shows accurate results and

provides a clear point of departure for utilization of synthetic datasets for training models. This is an essential step towards robotic assistance where robots intelligently assist human workers to bring the next required workpiece in the assembly sequence by understanding the step at which the assembly is at any point in time.

This paper provides the initial findings of an ongoing study and reports the following limitations. Since the training and test datasets were fully generated in virtual reality, verification in real-world settings is needed. We will evaluate the performance of this approach to generate and utilize datasets reflecting complex assembly lines (with various geometric representations and component types). We aim to utilize this approach for complicated module assembly sequences, where occlusions are more apparent and geometries are unconventional (e.g., spherical or cylindrical shaped work pieces).

Using Image Processing to Classify Roofs based on Damage Level.

K. Mostafa and T. Hegazy

Department of Civil and Environmental Engineering, University of Waterloo, Canada
E-mail: ktmostafa@uwaterloo.ca, tarek@uwaterloo.ca

Abstract:

Roofing systems are considered one of the items that in most need of frequent inspection and rehabilitation due to its ongoing exposure to the elements. Manual roof inspections are time consuming and subjective. This study uses Convolutional Neural Network (CNN), an image-processing technique, to classify roofs according to their damage level. The proposed model analyzes images showing general views of roofs to determine (on a macro level) whether the roof has sustained no (or low), moderate, or severe damage. Based on this analysis, more detailed roofing inspection can be conducted if needed. The study was applied on more than 200 images of roofs of the University of Waterloo campus, collected using a drone. Different CNN architectures were examined where the number of convolution kernels (i.e., the depth of the CNN layer) has been the main variable. This experiment has revealed that complicating the model by changing the depth of the layer causes the model to overfit with no performance improvements on the validation dataset. The proposed model, using only 5 kernels in the first convolution layer, has achieved 90% accuracy level. The developed model serves as the initial step of a larger roofing inspection framework, reducing the need for more time and resource intensive assessments. The end goal of the proposed inspection framework is to provide a fast, objective, and reliable roofing inspection and assessment, helping asset managers of large portfolios better assign the allocated rehabilitation funds.

1 Introduction

Roofs are frequently exposed to extreme temperatures, rain, snow, and other severe weather events. As such, roofs are considered to be among the most vulnerable building components [1, 2]. While the average life expectancy of a roof is a function of its type and material, having an adequate maintenance program is essential to ensure the roof would live up to the expectations and maintain an adequate level of service throughout.

Currently, most inspections are done manually. Manual inspections suffer from a plethora of shortcomings. First of all, manual data collection and processing is a time-consuming process [3]. Kamarah [4] estimated that an average inspection site visit takes about 3 hours, and Abou shaar [5] estimates that for every hour spent on site for data collection, three more hours are spent in analysis. Second, manual inspections are subjective as they rely on the inspector's training and experience [6]. This often means that two inspectors can produce two different reports for the same asset [6]. Third, roofs are sometimes difficult to access and, if accessed, often pose safety risks to inspectors [7]. This puts extra overhead on the inspection company in terms of special training and/or insurance. Hence, automation of inspection is a must.

Computer vision (i.e., image-based analysis) allows computers to extract and analyze information directly from pictorial data such as images and videos [8]. Hence, and because images are easy to collect (e.g., using a cell phone camera), computer vision has been under investigation as a way to automate supervision and inspection tasks in the construction domain. For example, [9] developed a computer-vision-based pavement crack inspection model capable of achieving 92% accuracy using a commercial grade GoPro as its data collection source. [10] developed a convolutional neural network (CNN) based classification model capable of detecting

concrete cracks as well as distinguish them from handwritten markings on the concrete surface. As a step towards a more comprehensive assessment, [11] was capable of detecting multiple defects such as cracks, concrete delamination and rebar exposure. Other Examples of computer vision applications towards automating asset inspections include defect detection in concrete structures [12], pavements [13], and sewers and pipelines [14, 15]. Unfortunately, however, little to no work was done on roofing condition assessment despite roofs being one of the most vulnerable building components. As such, this paper aims to fill this research gap by utilizing CNN technology towards roofing condition assessment.

As a step toward automating roofing inspections, this paper proposes a computer vision approach that utilizes a Convolutional Neural Network (CNN) for preliminary classification of roof condition. The proposed system relies on images that show the roof general view to categorize the roof into one of three categories; Clear/Minor, Moderate, or Severely Damaged. Based on the classification, more detailed inspection can be conducted as needed. This aims to reduce the time and resources spent on the inspection process because, using this method, not all the roofs will need to undergo the same detailed inspections. The remaining part of the paper explains the model development and testing process, starting with the motivation, followed by the data collection process and the proposed CNN architecture, and concluding with analysis results and discussion.

2 Existing Roof Management Systems

While buildings, in general, are considered to be durable and expected to last for decades, a key for that durability is continuous and effective maintenance and

repair programs. This is because periodic maintenance and rehabilitation increases the building's lifespan and improves the level of service of its components [16]. As such, the last few decades have witnessed the development of a variety of building management and inspection systems that cater to a variety of needs. Examples include de Brito et al. [17] concrete bridge management system, Curt et al. [18] dam safety assessment, and Bortolini and Forcada [19] and Faqih and Zayed [20] building inspection systems. However, these systems still rely on manual inspections as the main source of data.

As seen in Fig. 1, most roofing systems used in non-residential buildings such as schools and hospitals are considered to be low-slope roofs. Among those roofs, the built-up roof (BUR) system is the most common type of roofing in [21]. BURs are generally composed of alternating layer of bitumen and reinforcing fabric that create a finished membrane (often referred to as "roofing felt") which is finally covered by gravel to reduce its exposure to the weather elements.

Originally developed by the US army, ROOFER [22] is one of the most common roofing-based asset management software. Despite its capabilities, it still relies on manual inspections as its sole source of data. To reduce the subjectivity of manual inspections, [21] developed a pictorial database of common roof defects, ranked by their severity. Other examples of roofing rehabilitation systems include the works of [1] and [23], who defined the most common roofing defects, along with possible causes and remedies. However, these models, like their predecessors, still rely on manual data input. As such, computer vision technology provides the opportunity for automation of roof inspections, leading to cost, time, and subjectivity reductions.

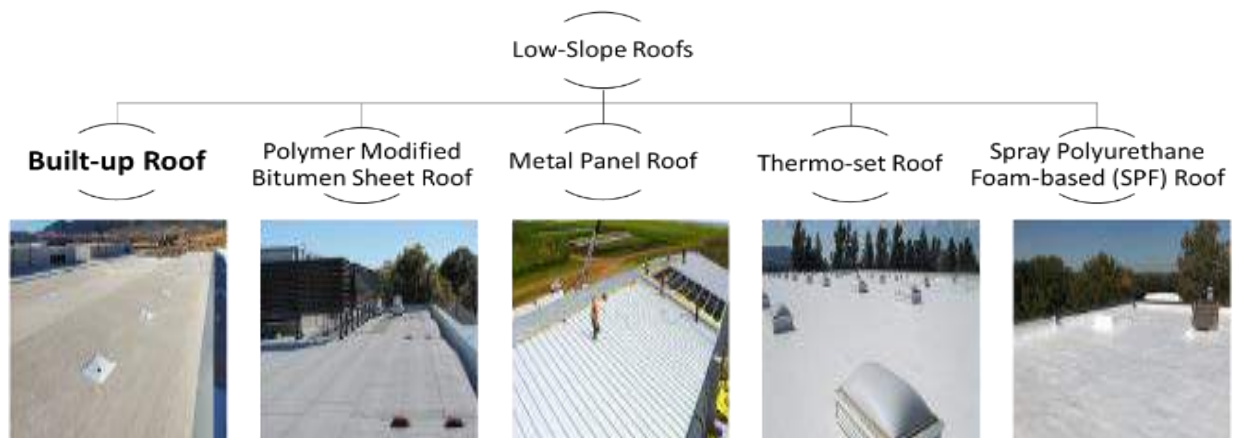

Fig. 1: Types of Low-Slope Roofs

3 Data Collection

University of Waterloo is one of the largest universities in Canada, having a total of 80 buildings. The pictorial dataset used in this study comes from 20 buildings that are highlighted in Fig. 2. Two different data collection methods were used. First, the authors were allowed to physically access the building roofs and take photographs using their personal cameras (16 Megapixel phone camera). The second method was only used for a group of five buildings (highlighted by the red star in Fig. 2) as the roof was inaccessible. In that case, the images were collected by a commercial drone. The drone was set to record a video of its flight, then one of each 10 frames were extracted. The images collected were subject to the weather conditions (e.g., lighting) prevalent at the time of the data collection, which took place over the span of multiple days. The

camera angle differed depending on the method of collection. Images collected by the commercial drone had, on average, a 45-degree angle relative to the roof surface (subject to wind conditions and extra tilting of the drone for navigation purposes), while images collected manually had a 60-degree angle. While the camera angle was kept constant relative to the surface being captured, the images collected were subject to the weather conditions prevalent at the time of the data collection, which took place over the span of multiple days. As such, the total number of images used in this study is 346 representing three damage categories: low, moderate, and severe. Examples of the images representing the three different categories are in Fig. 3. One third of the data set (114 images) was used for validation and testing purposes, while the remaining two-thirds were used for training.

Fig. 2: Image Locations - University of Waterloo (Red Star-Images Collected by a drone)

Fig. 3: Examples of the Collected Images Representing the Three Different Damage Categories

4 Proposed CNN architecture

The composition of CNN elements is an important task to achieve maximum performance level. While increasing the complexity of the CNN by adding more layers or convolution kernels can improve performance, over complicating the model might lead to performance degradation and overfitting. Inspired

by AlexNet [24] and LeNet [25], three CNN architectures are tested, all followed the architecture demonstrated in Fig. 4. The only difference was in the number of channels in each layer (i.e., the value of N). N took three different values; 5, 6, and 8. For notational convenience, the three different CNNs that were experimented will be referred to as CNN_N. For all CNNs, RELU was used as the activation function

for the fully connected layer. Other studies reported that changing the kernel size has a minimal effect on accuracy [26]. Hence, the size of the kernel was fixed at 10×10 with zero padding and a stride of two.

5 Implementation Details and Results

All experiments were performed using the python programming language (CUDA 7.5) on a laptop with Core i7-10750H@2.6GHz CPU, 16GB RAM, and 4GB NVIDIA GeForce GTX 1650 Graphical Processing Unit (GPU). Learning rate was set to be 0.0002 while the batch size was set to 22 images. All experiments were run for 500 epochs. Accuracy (i.e., number of correct classifications) was used as the evaluation metric.

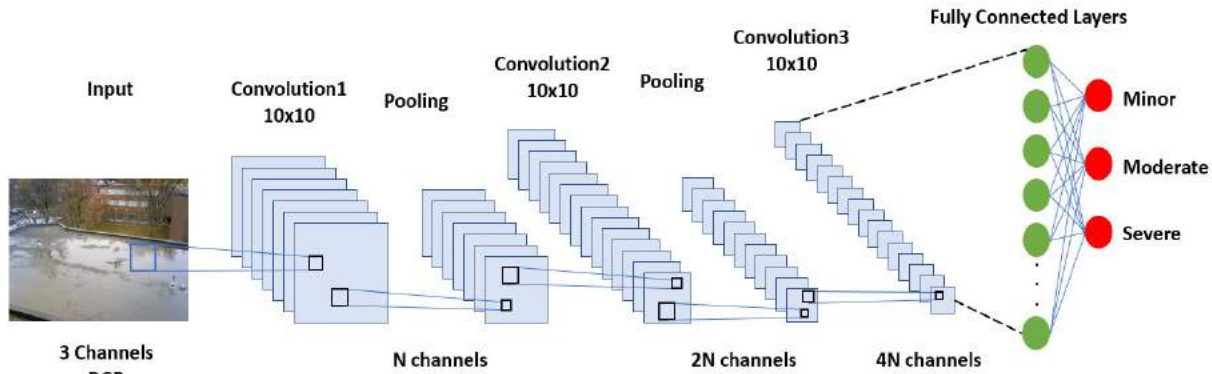

Fig. 4: Proposed CNN Architecture

5.1 Comparing the different models

Table 1 shows the performance of the different CNN models in terms of correct classifications for the training and testing datasets. Since there was no function to terminate the training process when convergence or performance degradation takes place, the epoch where the optimal performance is reached is reported in Table 1 as an indication for the speed of the training process. It is important to note that all three models took approximately the same time per epoch (approx. 18 seconds).

Table 1: Performance Comparison of different models

	CNN_5	CNN_6	CNN_8
Training Accuracy (%)	91.8	91.4	96.5
Testing Accuracy (%)	89.5	86.8	88.6
Epoch	469	326	331

Table 1 shows that CNN_5 took the longest time (i.e., highest number of iterations) to reach an optimal performance, followed by CNN_8 and CNN_6. However, the performance of CNN_5 is considered to be the best of the three for two reasons. First, CNN_5 is reporting the highest testing accuracy, which speaks to its generalization ability. Second, comparing the training and testing accuracy reveals that CNN_5 has the smallest variation (2.3%). Unlike CNN_8 which, despite having the best performance on the training dataset, has the highest difference between the training and testing accuracies (8%) which raises some overfitting concerns. From the data shown in Table 1, it can be deduced that, for this particular application, creating a simpler model by using less number of channels yields models with higher generalization abilities and more resilience against overfitting.

The number of channels refers to the number of convolutional kernels used in each layer. Each of these

convolutional kernels work independently and aim to capture significant features of the image to help reach a correct classification. As such, changing the number of channels correspond to changing the number of significant features captured by the CNN to guide its classification activity. The data in Table 1 suggests that the distinctive features that differentiate between images showing different degrees of roof damage are not many, and therefore require a relatively simple model to avoid “going deep in the weeds” and losing generalization ability. This is supported by the sample images shown in Fig. 3, where the differences between the damage levels are noticeable even to non-inspection experts. As such, macro-level roof inspection (i.e., holistically analyze roofing conditions from images that capture the entire roof surface) can be quickly and effectively used to triage the different roofs before investing in relatively more resource-intensive analyses for micro-level inspections.

5.2 Analyzing the Optimal Model (CNN_5)

After analyzing the three different models as shown in Table 1, CNN_5 was selected as the “optimal model” and the results were analyzed in more detail. Table 2 shows the confusion matrix of the model’s result on a 110-image dataset collected by the authors. Two observations can be drawn from Table 2. First, the overall accuracy of the model is 90%, which is acceptable compared to other models in the literature. Second, the model is not exhibiting any major biases, as the chances of “under classifying” and “over classifying” a roof are equally likely to happen.

Table 2: Confusion Matrix for CNN_5 predictions

Predicted Label	True Label			Total
	No/Minor	Moderate	Severe	
No/Minor Damage	40	2	2	44
Moderate Damage	4	8	2	14
Severe Damage	1	--	51	52
Total	45	10	55	110

The performance of the proposed model (CNN_5) is compared with models from the literature in Table 3. Due to the absence of models that address roofing condition assessments, the model was compared with other defect detection models that are intended for

other purposes such as pavements and concrete elements. Based on Table 4, the performance of the proposed model is on par with the state of the art. However, this model has the advantage of the lower data collection burden. While all models in the literature perform micro level assessments and thus require scanning a relatively small area of the structure to detect the defects. The proposed model only looks at a few snapshots that show the entire roof. This means that the analysis can (and should) take place frequently to produce updated assessments.

Table 3: Comparison with Models in the Literature

Model	Purpose	Accuracy
[9]	Pavement Crack Detection	92%
[27]	Building Defect Detection	89.1%
[28]	Concrete Defect Detection	89.7%
Proposed	Roofing Defect Detection	90%

6 Conclusion

In this study, a CNN-based model is proposed for holistic roofing condition assessment. The proposed model relies on a few snapshots showing the general view of the roof and classifies the roof accordingly into one of three categories (No damage, Moderate, Severe). The proposed model is part of a three-step roofing inspection and rehabilitation framework that aims to aid asset management practitioners with prioritizing assessment and rehabilitation events under limited budgetary constraints. The proposed model addresses the first step which is prioritizing the inspection efforts. Using only a few snapshots, the model can triage the roofs according to their condition and suggest more rigorous inspections for the ones that deemed worthy, thus saving on the total time spent on inspection site visits and their accompanied office work (four hours per building according to [4] and [5]). First, three different CNN architectures were examined, and one was selected as the better performer due to its higher accuracy on the testing dataset as well as its lower susceptibility for overfitting. While the model addresses an important research gap which is the lack of image-based roof inspection frameworks, its performance is on par with other models in the literature that are intended for other purposes such as concrete or pavement defect detection. All without the need for detailed images like the other models in comparison.

Regarding the proposed model, future work includes automating the data collection process by maximizing the drone usage as well as, if possible, testing the validity of live satellite images. The proposed model is the first of a three-step assessment

and prioritization framework (Fig. 5). First, the proposed model is used to holistically assess the roofs and determine their need for more detailed assessment. More detailed assessment can then be conducted for roofs that are deemed worthy, which leads to a more granular assessment for the roof condition highlighting the different damage types and sizes [29].

Using cost and crew information (e.g., RS means) work packaging estimates for the required rehabilitation can be developed. Finally, this information is aggregated with other text-based data mining information (e.g., building age, description) to optimize the use of the limited rehabilitation budget.

Abstract -

In monitoring disaster sites, mobile robots represent a fast, reliable, and practical option to remotely inspect active areas in disaster management for applications such as risk management, search and rescue, and structural assessment purposes. Mobile robots can efficiently collect laser scan data and reconstruct the state of ongoing disaster relief in the form of 3D point clouds. Current point cloud processing methods are mostly designed to work as a post-processing step and are inefficient when applied in real-time. Additionally, object segmentation on point cloud data from the disaster sites is challenging due to data impurities and occlusions. To overcome these issues, this paper proposes an instance point cloud segmentation method that incrementally builds a 3D map for robotic scans of infrastructure. In the first step, the proposed neural network, named Dynamic Graph PointNet (DGPointNet), is trained to classify objects in the disaster environment while building up a semantic 3D map of the environment. Additionally, the proposed method predicts object instance labels by using a sequence of predicted semantic point cloud data. The proposed method shows strong performance over the state of art segmentation models in terms of semantic segmentation, instance segmentation, and processing time using point cloud data collected from a custom-built laser-scanning robot at an outdoor simulated disaster site.

Point cloud segmentation; laser scanning; robotics; disaster site; deep learning

1 Introduction

In disaster sites, mobile robots represent a safer and more labor-efficient option to carry out inspection tasks such as risk estimation and assessment of damaged building in post-disaster sites for reconstruction of damaged constructions. According to the NOAA's National Centers for Environmental Information, the natural disaster costs the U.S. over \$600 billion in the last 5 years (2016-2020) [1]. Current damage assessment and quality inspections often involve a long inspection activity that requires inspectors to collect data on the disaster sites due to difficulty

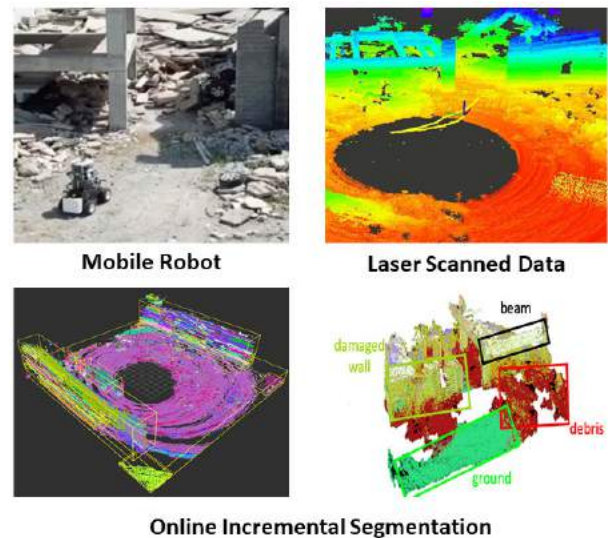

Figure 1. Overall framework for collecting and processing 3D point clouds from disaster sites.

in accessing disaster sites. The inspection process often involves safety concerns such as exposing toxic chemical to human being and building collapse.

Due to the safety concerns and recent development in computing technology, mobile robots can be used to collect laser scan data and reconstruct the as-is state of various building entities on the site in the form of 3D point clouds [2, 3, 4]. Several methods use mobile robots to monitor the condition of damaged building in the disaster sites such as mapping disaster sites with ground robot [5] and with an aerial robot [6]. Even though a large amount of point cloud data can be easily collected, the process of automatically organizing and extracting useful information from the noisy data remains a challenging task. Especially in the disaster sites, the collected data often includes incomplete objects such as collapsed buildings and damaged objects. The mobile robot needs to perform segmentation of the acquired data to carry out obstacle detection, object recognition, and other scene understanding tasks. Current segmentation methods are mostly designed to process

point cloud data one at a time and are applied only as a post-processing step. In addition, segmentation methods that are trained with complete models of objects do not work well because robotic scans are usually noisy or occluded.

This paper proposes an incremental point cloud segmentation method for robotic scans of disaster sites using a 3D Light Detection and Ranging (Lidar) sensor. The scans are first registered based on simultaneous localization and mapping (SLAM) and stored in a voxel-based lookup table. The registered point cloud is then passed to the proposed deep learning model, named Dynamic Graph PointNet (DGPointNet) that predicts semantic object labels. The DGPointNet is robust to detect objects with data impurities and occlusions by learning both local neighbor and global point features. The output of the deep learning model is then processed with incremental segmentation algorithm that merges new scan points into existing points to form instance clusters based on similarity in feature space. The proposed method is incremental in that each new scan is processed and combined with information from previous scans without having to recompute the entire scene. Results are then used to create a 3D object-level map of the disaster site. The proposed method is validated using point cloud data collected from a laser scanning robot at an outdoor simulated disaster site shown in Figure 1. The key contributions of the proposed method are summarized as follows:

- Fast online instance segmentation that directly takes an input of Lidar scanned data and outputs predicted instance object labels
- Development of a light weight deep learning model suitable for dataset from an outdoor environment with impurities and occlusions.
- Evaluation of semantic and instance segmentation methods using dataset from a real-world simulated post disaster sites environment.

2 Related work

2.1 Geometry-based segmentation

In the past, several approaches use geometric segmentation methods that rely on surface normals, curvatures, and edge. Hough Transform and the Random Sample Consensus have also been widely employed as fundamental algorithms for detecting simple geometric objects based on their model parameters [7, 8]. Until recently, RANSAC-based algorithms for the plane segmentation has continued to be improved [9, 10]. Clustering is another common step for point cloud segmentation. Region growing which progressively gathers nearby points regarded as the same class

or regions with cohesive features, has been a widely used, and even a learnable model for region growing has been developed [11]. Using density-based spatial clustering of applications with noise (DBSCAN), Czerniawski *et al.* [12] proposed a method to detect planar objects in indoor scenes. However, the methods referring to geometry features have limitations in being robustly applied to a disaster site of highly unstructured environment, containing varied noise and deformed objects with complex geometry not fitting to predefined geometry features.

2.2 Data-driven models for segmentation

With the growing popularity of data-driven models, deep architectures for classifying each 3D point into semantic categories have made significant progress [13, 14]. Compared to ones using hand-crafted features, these deep architectures show better performance and robustness, but still are in active development due to issues such as sparsity, randomness, and the unstructured nature of point clouds. As an indirect method, to facilitate convolutional neural networks for the segmentation, researchers have converted a point cloud into a regular structure prior to the processing, such as multi-views [15], voxel grids [16]. However, since these data conversion cause information loss and computational complexity, PointNet [17] directly process each point by extracting robust features from the transformation and permutation of the point cloud. Since then, many methods based on PointNet have been proposed, referring to the direct processing of each point [14]. To find optimistic receptive field for the segmentation task, Qi *et al.* [18] adopted a multi-scale concept which recursively extracted local features using PointNet layer, and enhanced the results of segmentation, but, the inference time increased several times. Regarding a point cloud as structured graph data composed of a series of nodes and edges, Wang *et al.* [19] proposed DGCNN by replacing multi-layers of PointNet with stacks of edge convolution from Graph Convolutional Networks. It shows a significant effect in extracting analogous features but increases the complexity of the network as well as number of the training parameters. Since the methods based on GCNN, compare to others, have advantages in examining the boundary feature, researchers have now increasingly adopted these graph-based algorithms [20, 21]. Other data-driven models such as Point Transformer [22] and SCF-Net [23] are not considered in this study due to the slow inference speed of the models.

2.3 Incremental Segmentation

Although researchers have proposed many segmentation models so far, to leverage them integrated with robotic scanning in real-world sites, one thing that needs to be

Figure 2. 3D point cloud processing framework.

added is incremental segmentation, which progressively updates class labels of the point in a dynamic fashion while collecting data simultaneously. To understand scenes even when the entire site is not scanned, researchers have proposed a method to supplement the segmentation results with online data in varied situation [24, 25, 26]. Finman *et al.* [24] proposed a method to combine partially segmented results by iterative voting from RGB-D maps. Dube *et al.* [25] selectively updated dynamic voxel grids online and adopted incremental fashion in region growing algorithm while caching the geometric consistencies. Unlike others, Multi-view Context Pooling Network based on PointNet, Chen *et al.* [27] proposed, implicitly updated an instance id of each point online using the deep network that was directly trained from the raw point cloud annotation. By suggesting a pooling operation to assemble local features from neighbor points to the global features, MCPNet updated each point while reflecting the contextual information of neighbors.

However, these methods were applied on limited dataset of indoor environments or confined outdoor sites. The goal of the proposed method is to perform incremental instance segmentation on real-world disaster sites. The proposed method directly consumes points from the scanned data and performs the incremental segmentation while fusing local features to the global features, especially using online data collected by the unmanned ground vehicle from challenging disaster site environments with a significant amount of debris and deformed objects.

3 Methodology

3.1 Overview

This research proposes a robotic scanning and point cloud segmentation framework for identifying construction related objects from post disaster sites. Figure 2 shows an overall data collection and processing framework where each distinct object is segmented into an object instance. In the first step, an input point cloud is captured by a laser scanning device using a mobile robot. Then, the simultaneous localization and mapping (SLAM) module takes

the point cloud data and registers points to reconstruct a 3D map of the damaged building structures around the robot. For each point cloud scan, the semantic segmentation module (DGPointNet) classifies object classes in the registered point cloud and outputs a set of semantic object labels. In the final step, the instance segmentation module uses the predicted semantic labels to estimate object instance labels by grouping points from the current and previous laser scans. The end result of the point cloud data processing framework is a densely labeled 3D map of the disaster site that contains information about the obstacles, building elements, and debris in the surrounding environment. The following sections provide more details regarding methods and design choices.

3.2 3D input data and registration

The proposed 3D data registration method is visualized in Figure 3 where the input data is a raw laser scanned point cloud that is represented as unordered 3D points that contains position vectors (x, y, z) . As the mobile robot is moving around the disaster site, laser scan data is collected along with Inertial Measurement Unit (IMU) and Global Positioning System (GPS) measurements. A SLAM module based on the LeGO-LOAM [28] algorithm is used to localize the robot using sensor measurements. Each laser scan is registered on to the global coordinate system by applying a transformation matrix based on the robot's pose at each time step. These registered point clouds are used to train and evaluate semantic segmentation model described in the next sections.

Figure 3. Automated point cloud registration step to generate the input dataset for our framework.

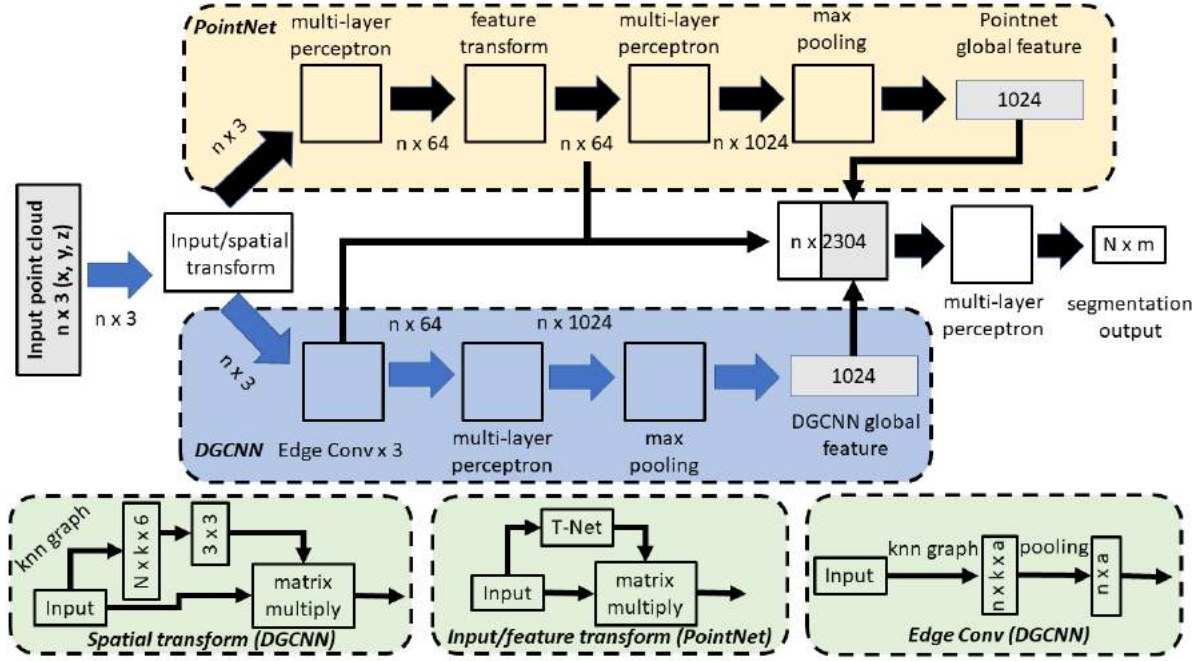

Figure 4. The proposed DGPointNet architecture for point cloud semantic segmentation.

3.3 Semantic segmentation with DGPointNet

Semantic segmentation is performed with a deep neural network to assign semantic class labels to each point. The semantic labels consist of classes such as *ground*, *clutter*, *wall*, etc. that are used to differentiate between different objects on the disaster site. The proposed deep learning architecture is shown in Figure 4. The proposed network combines elements from both PointNet [17] and DGCNN [19], integrated into a single neural network. The advantage of this model is that it combines the benefits of PointNet for learning the global context of the input point cloud data and DGCNN for learning the local context of the input point cloud using the edge convolution layers.

The proposed model first takes a set of n points with feature vectors including position vector (x, y, z) and normalized z position to each data scene (a real number ranging from 0 to 1) and passes them through input and spatial transform layers. In the PointNet module (yellow box in Figure 4), both input and feature transform use a T-Net that applies an affine transformation to the given point cloud inputs. The points are then passed through a series of convolution layers and multi-layer perceptron. The points features are aggregated using a max pooling layer to obtain a global feature. The outputs of the intermediate multi-layer perceptron and global features are concatenated to a shared multi-layer perceptron. Similarly, in the DGCNN module (blue box in Figure 4), the points are passed through a series of edge convolutions and multi-layer perceptrons. The edge convolution layer applies k

nearest neighbor algorithm to group input points into k feature clusters and aggregates the features by a max pooling layer. The outputs of each edge conv layers and global features are concatenated to a shared multi-layer perceptron. The model predicts $n \times m$ vectors as outputs for n input points and m semantic classes.

3.4 Incremental instance segmentation

An incremental instance segmentation module is responsible for clustering the predicted points from the semantic segmentation module into individual object instances. For example, given a set of points corresponding to wall objects, the instance segmentation module will cluster the points into *wall #1*, *wall #2*, *wall #3*, etc. This step is important for identifying the number of building elements on the disaster site and for assigning damage information to each individual building element. The overall algorithm is specified in Algorithm 1. The method first initializes a voxel grid dictionary v to remove duplicate input points from the segmentation outputs. The voxel grid allows the proposed method to only update the instance labels for the newly-scanned regions and reduce computation time so that the method can run online on the mobile robot. The update list u is used to store new points that are used in the clustering method. The distance limit k is used as a neighborhood threshold to append all neighboring points in the x, y, z position for each point in the updated points list. The surface normal threshold and semantic label are both used to group the updated point into existing clusters.

If the updated point does not match with an existing object instance, a new object instance is created.

Algorithm 1: Incremental instance segmentation

Input: Point cloud data with semantic segmentation labels
Result: Point cloud data with instance segmentation labels
 Initialize updated points list $u \leftarrow \emptyset$
 Initialize voxel grid dictionary $v \leftarrow \emptyset$
 Initialize neighbor points list $w \leftarrow \emptyset$
for each point in input data **do**
 | **if** point does not exists in voxel grid **then**
 | | Append point to the end of v and u
 | **end**
end
for each updated point **do**
 | Append all points within k distance from update point to w ;
 | **for** each nearest point **do**
 | | Compute surface normals
 | **end**
 | **if** updated point $>$ surface normal threshold and updated point class ID $==$ neighbor point class ID **then**
 | | Add to the existing object instance
 | **else**
 | | Initialize a new object instance
 | **end**
 | $u \leftarrow \emptyset$ $w \leftarrow \emptyset$
end

4 Results

4.1 Experimental setup and dataset

A field experiment was conducted at the Guardian Centers disaster training facility (Figure 5). The Guardian Centers facility consists of numerous damaged concrete structures that are cracked, deformed, or collapsed. In this experiment, a 4-wheel ground mobile equipped with a 3D Lidar sensor, IMU, and GPS sensor is used to collect laser scan data at the site. The 3D Lidar sensor is a Velodyne VLP-16 which has 16 beams, angular horizontal and vertical resolution of $0.1^\circ - 0.4^\circ$ and 2° , accuracy of $\pm 3\text{cm}$, and measurement range of 100 m. The semantic object classes consist of 8 different categories such as clutter, ground, wall, beam, girder, slab, column, door. The collected point cloud data is downsampled to 0.1m to reduce point cloud size. To eliminate sparse Lidar data, each scanned data is limited by $\pm 15\text{m}$ in x, y, z coordinates.

To evaluate the performance of semantic and instance segmentation, a total of 9 robot scanned data with the Velodyne Lidar at a different part of the disaster sites scene are collected. 7 point cloud scenes are used as the training set and 2 point cloud scenes are used as the test set. Each scanned data consists of 2-3 minutes sequential points that cover a part of the simulated test sites.

Figure 5. A mobile robot deployed to collect laser scans at the Guardian Centers disaster training facility.

4.2 Semantic segmentation results

The proposed method is compared with PointNet and PointNet++ models in terms of point accuracy and average Intersection over Union (IoU) using the test dataset shown in Table 1. These baseline models are the state of art deep learning models that directly take point cloud data with geometry features and output predictions of semantic point labels. The input points size of these models are set to 4096 points with a block size of 10×10 (m). The input points consist of feature vectors with x, y, z position and normalized z position to each test data scene. The clustering hyper-parameters k used in the DGPointNet is set to 20.

In terms of mean IoU and point accuracy, the proposed method shows the highest mIoU score of 55.1 % and the highest point accuracy of 77.8 %. Table 2 shows results of individual IoU performance per object class. The proposed method achieves the highest IoU for every object category. The proposed model shows strong performance on the small objects such as beam, girder, and door categories. The performance of the proposed method is visualized in Figure 6.

Table 1. Segmentation results evaluated in terms of mIoU and point accuracy on the Guardian Centers dataset using the test dataset.

Method	mIoU (%)	Point Acc.(%)
PointNet [17]	41.4	68.6
PointNet++ [18]	28.2	57.9
Proposed DGPointNet	55.1	77.8

4.3 Instance Segmentation Results

The instance segmentation results are evaluated using the metrics of normalized mutual information (NMI), ad-

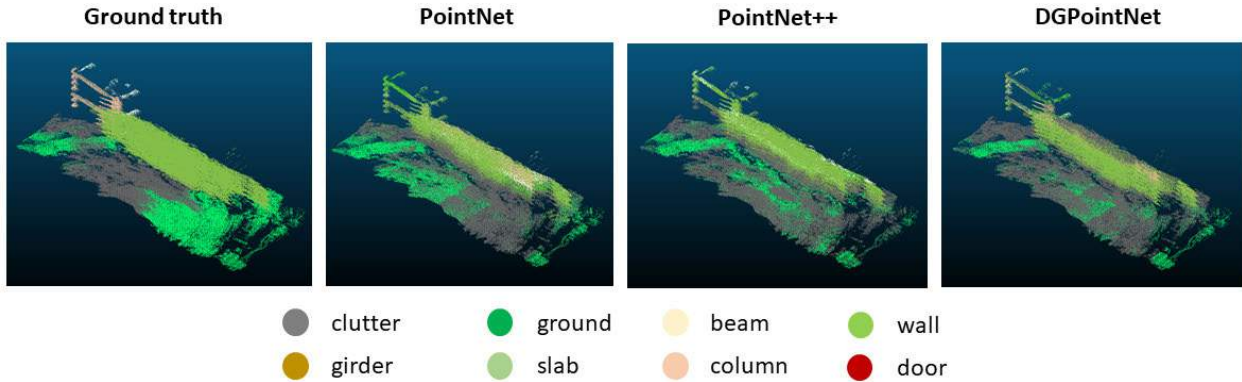

Figure 6. Results of semantic segmentation on the test dataset.

Table 2. Semantic segmentation results of each class on the Guardian Centers dataset. The evaluation metric is IoU(%) on the test dataset.

Object Class	total	clutter	ground	beam	wall	girder	slab	column	door
Test points	-	293673	127929	24495	261549	12212	147952	57449	2477
PointNet [17]	41.4	53.2	63.2	48.6	61.2	23.9	47.6	22.7	11.1
PointNet++ [18]	28.2	52.3	51.9	33.6	37.2	12.8	29.1	8.4	0.0
Proposed	55.1	63.3	68.7	55.5	68.2	45.7	66.0	46.1	27.3

justed rand index (ARI), and V measure score (VMS) [29, 30]. In Table 3, the proposed method is compared with other baseline deep learning models to validate the evaluation metrics. The result shows that the proposed method achieves the second-best result among the baseline models. The results of instance segmentation using DGPointNet is visualized in Figure 7. The bounding boxes show individual objects are separated from each other.

Table 3. Instance segmentation and classification results on the test dataset.

Method	NMI	AMI	VMS
PointNet [17]	34.4	33.7	34.4
PointNet++ [18]	37.1	35.7	37.1
Proposed DGPointNet	35.3	33.9	35.3

4.4 Computation time evaluation

Table 4 shows the computation time and average points processed per scan measured on Intel® Core™ i9-10980HK CPU and NVIDIA GeForce RTX 2080 GPU. The proposed method has a relatively fast computation speed of 1.18 s per scan compared to the PointNet++ models while the average processed points are 5742 points.

This result shows that the proposed method can be applied in near real-time.

Table 4. Computation time and average points processed on the Guardian Centers dataset.

Method	Time (s)	Points per scan
PointNet [17]	0.43	5627
PointNet++ [18]	15.72	6052
Proposed DGPointNet	1.18	5742

5 Conclusions

In this work, the proposed method shows a novel process that directly takes raw point cloud data and predicts instance labels in near real-time. The semantic segmentation network learns from both local neighbor and global point features through PointNet and DGCNN. This model also shows strong performance on semantic segmentation of small object with data impurities and occlusions. Additionally, the incremental segmentation method clusters semantic prediction labels into an object instance by integrating a sequence of Lidar scanned data. The proposed method shows that the semantic and instance segmentation can both run in near real-time to classify objects on

Figure 7. Results of Instance segmentation. Each object instance is assigned a different color.

disaster sites data.

While the proposed method shows a fast online segmentation performance, the experiment results indicate that the model could be revised to improve efficiency for real-time performance in future research. Additionally, ablation studies such as hyper parameter tuning of the segmentation model can be considered to optimize performance of the proposed method.

Abstract –

Progress quantification of construction projects is critical for project managers to manage projects effectively. The trade-off between computation time and accuracy is a key aspect while selecting the quantification method. Though accuracy is essential, project managers require real-time information about quantities of work completed on various building components to make timely decisions. Several researchers have developed individual pipelines using vision-based technologies for automated progress quantification. However, they face significant implementation challenges, including higher computational complexity, skilled personals, and costly equipment. Hence, this study aims to define an easy-to-implement pipeline to quantify the holistic progress and element-wise progress of a building. For executing this, the method utilizes point intensity as a fundamental parameter. The progress of a specified element is calculated by comparing the number of points in the as-built model and the number of anticipated points from the as-designed model of the same point intensities. The method directly integrates the as-designed BIM model with the scan data through a user-friendly visual programming tool - Grasshopper3D for progress quantification. The workflow provides one-click progress report generation with minimal inputs from the users for basic alignment of the imported as-built data. As the point clouds are directly addressed as a single entity, and to-be intensity has been calculated through an intensity-based randomized approach, the method utilizes less computation for the whole process.

Automated Progress Monitoring, Point-Intensity, Scan-vs-BIM, Progress Quantification, Visual Programming, Single-Click Report Generation, BIM-Based Tracking, Point Clouds, Automation in Construction Management

1 Introduction

Monitoring of construction projects is a key aspect of management. Construction progress monitoring has been attempted through various technologies [1]. These technologies are based on bar codes, QR codes, RFIDs, range imaging, photogrammetry, videogrammetry, laser scanning, etc. These technologies are much advanced than primitive pen and paper-based or Daily Progress Report (DPR) based progress monitoring.

Though several advanced technologies have been developed, there has been little evidence of their application at construction sites. Currently, a majority of construction projects predominantly use pen and paper-based or daily updated Excel sheet-based (DPR-based) methods for progress monitoring. However, these methods are time-consuming, non-systematic, less accurate, and require too much human intervention making the process inefficient [2].

The on-site adoption of advanced methods like Scan-to-BIM or Scan-vs-BIM has been to a lesser extent. These methods require significant computation of data, certain specific skills as well as domain knowledge for implementation. In addition, their current industrial version requires substantial human intervention, making them tedious to run at frequent intervals.

Lately, most of the sites have used 3D spatial data to visualize and monitor progress. For quantification of progress, Scan-to-BIM and Scan-vs-BIM are the two-key techniques found in the literature. These methods process the point cloud data to generate an as-built BIM model or compare it through a computationally extensive process. However, due to the complex task of as-built modeling and quantification of progress, on-site implementation of the vision-based progress monitoring pipelines has been the bare minimum.

This study recognizes the gaps discussed above and aims to present a novel pipeline for progress quantification that can be easily implemented at project sites. The pipeline is focused on detecting the volumetric progress using point cloud data directly. For this paper, the scope is limited to quantifying the

progress of building projects. Hence, the two objectives of this study are as follows:

1. To develop an on-site implementable pipeline to utilize as-built 3D point clouds and their derived properties for progress quantification.
2. To experimentally validate the pipeline and present the key factors which make the pipeline more adoptable.

This paper is organized as follows. After the introduction, Section 2 discusses the state-of-the-art quantification methods and their challenges for on-site implementation. Section 3 presents the methodology. Section 4 presents the system architecture for the proposed pipeline. Section 5 presents the experimental results and discussion. This is followed by a conclusion highlighting the features of the proposed pipeline along with future work given in Section 6.

2 Existing progress quantification approaches

Progress quantification is essential for managers to make decisions about the use and allocation of project resources. However, quantification on construction sites is still a tedious and time-consuming process due to conventional techniques. Moreover, the automated and semi-automated methods present in the existing literature have not been widely adopted in construction projects due to various factors.

Recently there has been a variety of progress monitoring approaches pipelines that have been developed in recent years. Although many implement progress visualization using Augmented Reality (AR) [3], Virtual Reality (VR) [4], Mixed Reality (MR) [2], and Extended Reality (XR) [5] environments, only a few attempted quantification.

Existing approaches have used quantification using image processing [6], object detection [7], model-based recognition [8] based methods. Apart from the image-based techniques, these methods are generally part of the two main methods, i.e., Scan-to-BIM and the Scan-vs-BIM approach. Quantification has also been attempted by integrating the two approaches [9]. Existing methods in both techniques require converting into BIM or comparing the point cloud model by overlapping, which is computationally expensive and requires complex algorithms. The state-of-the-art of both methods is discussed in this section with the various challenges faced for on-site implementation.

2.1 Scan-to-BIM

The Scan-to-BIM approach is based on converting an as-built point cloud to a BIM model. This is

implemented by detecting the elements from the point clouds using various heuristics [10][11] or learning-based algorithms [4][12] and then replacing them with corresponding BIM elements. The progress quantification can be easily done by directly generating the bill of quantities [13].

The Scan-to-BIM approach uses a lower order point cloud model to convert to a more informative BIM model. This process is computationally expensive, time-consuming and expert experience is required to implement it successfully.

In heuristic-based modeling, a set of primary input data about the common elements in the point cloud is required to initiate the process. This data must be manually fed into the logic to detect elements requiring significant time and effort. Secondly, the heuristics-based method cannot be expected to recognize all the elements as some are unique to a particular project.

Few studies have recently explored learning-based methods for detecting elements from point clouds [14] [15]. However, the site-wide implementation of these approaches has not been possible due to various factors. Firstly, for learning-based methods, a large dataset of existing elements for training is required, which is not available currently and is difficult to generate for various elements. Through an approach to systematically generate training data have been suggested [16]. Secondly, computational requirements are high to process and test the large dataset. Lastly, a skilled workforce is required to implement and operate these pipelines regularly.

2.2 Scan-vs-BIM

On the other hand, the Scan-vs-BIM approach detects progress by overlapping the as-designed and as-built BIM models [17]. This is done either by applying thresholds [2] or point occupancy-based methods [4]. Once the elements are detected, they are labeled as complete or incomplete in the as-designed model. The quantification can be performed by generating the quantities of completed elements.

Likewise, Scan-vs-BIM uses a comparative approach. Though the comparison in this process is computationally less costly than Scan-to-BIM, there is a lot of pointwise processing to apply thresholds or check the model occupancy.

On the one hand, progress quantification is critical to project managers for efficient management. On the other hand, existing quantification methods are not easily implementable at construction sites. Therefore, this study intended to fill this gap by proposing a pipeline for vision-based progress monitoring, which is easily implementable at construction projects, with much less computation and skills. The details of the pipeline are discussed in the next section.

3 Methodology

An easy-to-use pipeline has been developed in this study for holistic and element-wise progress monitoring in the construction execution phase. The primary focus of this study is to compute the progress using the point intensity approach; however, the essential data acquisition and preprocessing steps are mentioned to complete the pipeline structure. The overview of each step and the core concept of the pipeline have been discussed in this section.

3.1 Data acquisition, preprocessing & registration

Figure 1 shows the overall pipeline adopted in this study. As an input, the pipeline receives site-acquired as-built point cloud data, captured using suitable vision-based technology.

Next, for preprocessing, firstly, the point clouds are extracted in a suitable file type format. Secondly, if multiple point clouds are to be stitched together, they should be registered using existing registration approaches. For our pipeline, noise and outlier removal is recommended but not mandatory as these points do not lie within the boundary region of any elements. However, it is suggested to sub-sample the point cloud through the scope-box method to a range of interest.

Lastly, the as-built point cloud and as-designed model can be registered using manual, automatic, or semi-automatic registration approaches. For this, our method uses the developed 3-point align script, which is a semi-automated approach and works on aligning a defined plane between the two models.

3.2 Progress quantification

Figure 1 shows the overall concept of this part graphically. The key concept of quantification in this pipeline is based on a spatial comparison of as-built point clouds against the as-designed BIM model. The as-built point intensity (points per unit area) can be derived through the scan data, and the equivalent intensities are transferred to as-designed BIM for point count calculation. Using arithmetic ratios of these point counts, holistic or elementwise progress can be derived in percentage completion.

The method first utilizes the as-designed BIM model to derive boundary representatives (B-Reps) of all the elements in the as-designed model. In the BIM model, the elements are usually represented by 3D meshes that show the boundary of the solid elements with infinite thin surfaces called B-Reps.

To calculate points that should be present on the surfaces of element B-reps, a specific threshold has been considered to formulate an offset geometry that

can include the points within specified spatial limits. This offset geometry has been addressed as the boundary region of the element in this study.

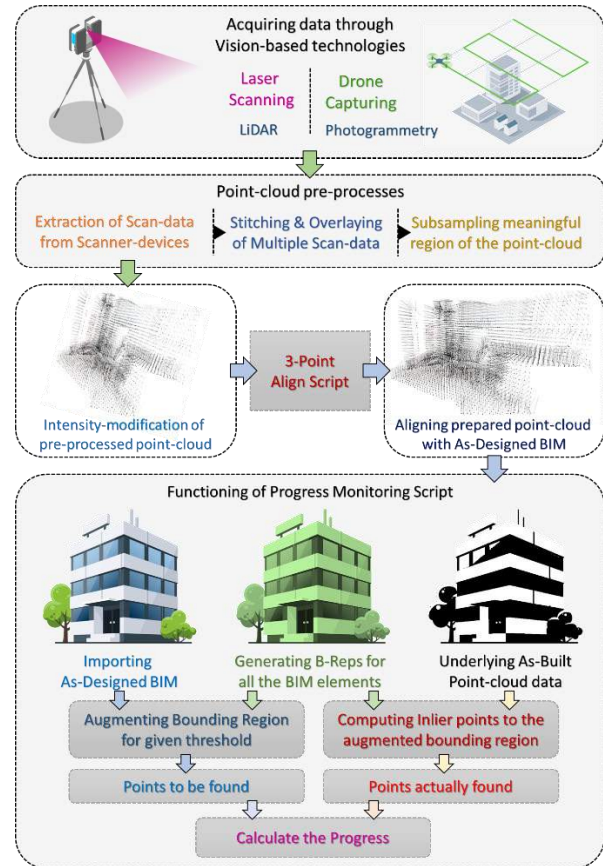

Figure 1 Overall pipeline for point-intensity based progress monitoring

Using few parametric toolsets, B-Rep surfaces or mesh-faces are populated with the given number of randomized points. Multiple researchers are widely using this method to produce accurate synthetic point clouds for experimentation. For uniform generation on each surface, point count is defined by surface area multiplied by the desired intensity. This study utilizes this concept to anticipate point counts on the required surfaces by directly performing basic multiplication of area and intensity instead of actually producing all synthetic points. For anticipating the point count in the as-designed model, users are expected to note and feed the same intensity that has been used while performing the laser-scan or cloud construction through photogrammetry.

Additionally, anticipated points were calculated only through the area of exposed surfaces of the elements. It has been considered that overlaying a portion of such surfaces usually being occluded by exposed surfaces when a realistic scan is being performed in real. To eliminate such partial or complete surfaces, surface

intersection with co-planarity has been utilized as base logic. Figure 2 shows this graphically.

Figure 2 Exposed and occluded surfaces

After aligning the imported as-built point cloud, volumetric bounding regions are overlaid on the scan data. Each bounding region is engaged with an element. The portions of the as-built point cloud being covered were sub-sampled and classified with the particular element identity. Then, as-built point counts for all the elements were derived from the cloud statistics of all the relative sub-samples.

The point counts derived from the BIM model and the scan data are addressed here as 'As-designed Point Counts (PC_{AD})' and 'As-built Point Counts (PC_{AB}).' Graphical visualization of these and their overlay is shown in Figure 3. Both of these entities have been utilized to calculate progress status in three different levels of detail:

1. Holistic progress tracking (computes progress of overall project)
 - a) Cumulative progress calculation (provides unified progress of all the elements)
 - b) Element-wise progress calculation (provides progress elementwise as a list)
2. As-requested progress tracking (provides the progress of the specifically requested elements)

In the following sub-section, the idea is technically elaborated with a logic-flow diagram and pseudocode created for the developed algorithm.

3.3 Core concept

Figure 4 shows the logic in sequence to compute the progress quantities for holistic and as-requested progress tracking. Suppose the preprocessed as-built point cloud and an as-designed BIM are available to compute the progress of a particular element E_i . In that case, the core idea is to compare the number of points that are in the as-built point cloud (N_{ABE_i}) with the expected number of points with the same intensity for the as-designed point cloud (N_{ADE_i}), which can be computed using the equation 1:

$$N_{ADE_i} = \text{surface area of } E_i * \text{intensity of points} \dots \quad (1)$$

Then, the percentage progress for of a particular element E_i can be obtained as

$$\% \text{ Progress of } E_i = \left\{ \frac{N_{ABE_i}}{N_{ADE_i}} \right\} * 100 \dots \dots \dots \quad (2)$$

3.3.1 Pseudocode

The concept described above has been implemented using the following pseudocode.

Computing as-built progress quantification

Inputs: BIM_{AD} , E_r , PC_{AB} , I

Outputs: PH , PE_i , PE_r

Geometry BReps (GB) extraction & Offset Bound (OB) generation for all as-designed BIM - (BIM_{AD}) elements into a list

- 1 For i in range (count.Elements(BIM_{AD}))
- 2 ... $GB_{AD}[j] = \text{append}(GB_{AP}(i))$

```

3  ...OBAD[ ] = append (offsetbrep.(GBAD(i))
4  UGBAD = BRep.Union(GBAD)

```

Exploding BReps into surfaces (Surf)

```

5  For i in range (length.list (GBAD))
6  ...Explode B-Rep into m surfaces → Surfi(i), ..., Surfm(i)
7  ...For j in range (m)
8  .....SurfList [ ] = append (Surfi(i))

```

Retaining only exposed surfaces (ExpSurf)

```

9  For i in range (length.list(SurfList))
10 ...SurfList' = pop(SurfList(i))
11 ...overlay=Intersection.(SurfList(i), SurfList') && Co-
    planarity.(SurfList(i), SurfList')
12 ...If overlay=FALSE
13 .....ExpSurf[ ] = append(SurfList(i))
14 ...SurfList' = SurfList

```

Computing point-counts on exposed surfaces (ExpSurf) as per adopted point intensity (I) and defining to-be point counts for elements

```

15 For j in range (length.list(ExpSurf))
16 ...PCExpSurf [ ] = append(Area.ExpSurf(j) * I)
17 For i in range(length.list(GBAD))
18 ...For j in range (length.list(ExpSurf))
19 .....Inclusion = inlying.surfinbrep(ExpSurf(j), GBAD(i))
20 .....If Inclusion=TRUE
21 .....PCAD [ ] = append(PCExpSurf(j))

```

Counting inlying points from as-built point cloud (PC_{AB})

```

22 For i in range (length.list(GBAD))
23 ...partcloud = subsample.brep(GBAD(i), PCAB )
24 ...PCAB [ ] = append(count.partcloud)

```

Computing holistic progress (PH) , Element-wise progress (PE_i), and As-requested progress (PE_r) (for the requested elements E_r)

```

25 PH = count.subsample.brep(UGBAD, PCAB ) / sum.PCAD [ ]
26 PEi = append (PCAB(i) / PCAD(i))
27 Find i for each rth element in Er & add to r[ ]
28 PEr = append (PCAB(r) / PCAD(r))

```

4 System architecture

As shown in Figure 5, the system architecture consists of three basic types of 3D processing environments to accomplish multiple technical tasks.

1. BIM modeling environment – For operating and visualizing as-designed BIM model. Autodesk Revit application has been utilized as a BIM platform in this method.
2. Point cloud processing environment – For visualizing and preprocessing the extracted point clouds. An open-source toolset called Cloud Compare has been used in this method.
3. Parametric 3D modeling and Visual Programming – The core logic of the method has been developed

in terms of logical loop sequence to find inlier points within the bounding region of particular element geometries. A combination of a 3D modeling application called Rhinoceros3D and visual programming tool called Grasshopper3D have been utilized to produce the entire script sets.

4.1 Technical execution

As shown in Figure 5, the method primarily takes two inputs in terms of a BIM model and a point cloud into a .xyz / .e57 file type format. Specific additional toolsets to the Grasshopper3D called 'Rhino.inside.Revit' (RiR) and 'Tarsier' have been utilized to integrate BIM functionalities from Revit and the inbuilt cloud processing functionalities of Tarsier. Additional toolset called 'TT Tool-box' have been employed for enabling the script to auto-generate cumulative / elementwise and as-requested progress monitoring report in the form of a spreadsheet.

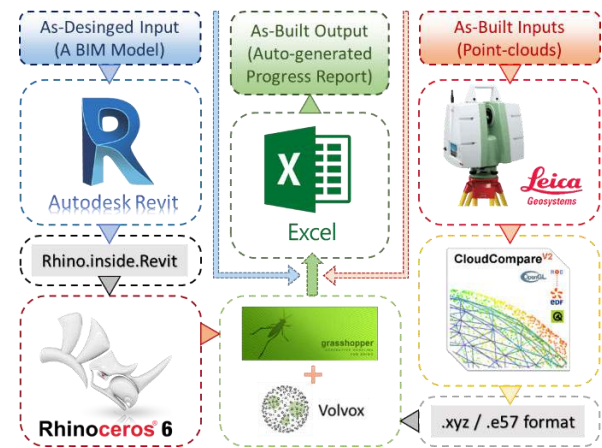

Figure 5 System Architecture Diagram

Technical logic has been fully developed as visual code scripts inside the Grasshopper3D environment. Users are first required to align imported point cloud with as-designed BIM file parallelly opened into Revit BIM environment. For better alignment, the script has been equipped with semi-automated 3-Point align functionality that asks the user to feed three planner points defining a relatively large planner surface in the point cloud and the same planner face in the as-designed BIM model. After the alignment, the user can compute holistic and element-wise progress through a single toggle and can produce a spreadsheet report with a single click.

To produce a partial progress report covering specific elements only, users need to choose the desired element or a set of multiple elements for which an as-requested progress report is required to be generated.

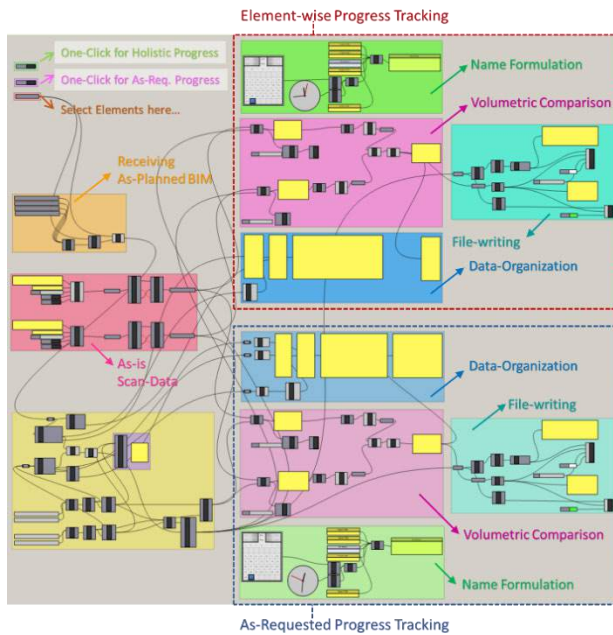

Figure 6 Grasshopper Script Anatomy

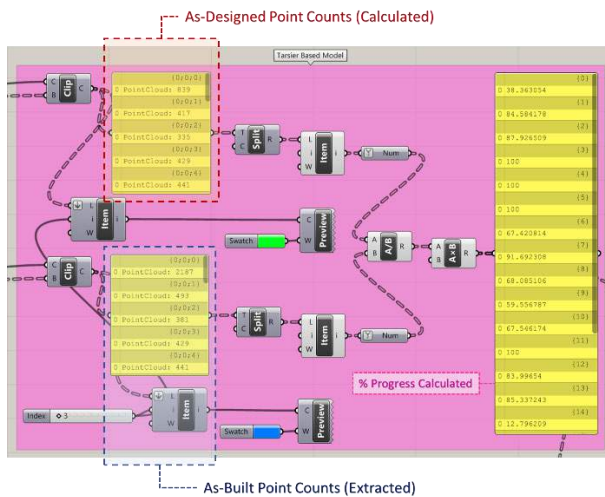

Figure 7 Script for Volumetric Comparison

The developed grasshopper script consists of five different sections shown with different colors. Each of them is automating one particular task in the workflow, as shown in Figure 6.

1. Obtaining BIM Model and current element selection to generate request list.
2. Producing lists of element ID, UUID, and Types for all and requested elements. (Orange & Yellow)
3. Importing scan data from the given storage location and semi-automated alignment. (Red)
4. Deriving counts of spatially present points inside bounding region of elements and percentage progress calculation (Pink)
5. Integration of data into a spreadsheet.
 - a. Data-tree management (Blue)

- b. Automated workbook writing (Pine Green)
- c. Formulating filename (Green)

In the script, the volumetric comparison is a core-functional part that checks for points' spatial presence and prepares element-wise count lists. It finally performs all required arithmetic operations and frames results in terms of percentage completion. A detailed version has been reflected in Figure 7.

4.2 Data-flow

The data flow in the pipeline is as shown in Figure 8. Algorithmic logic embedded in the script first derives bounding regions of element geometries in terms of shell geometries.

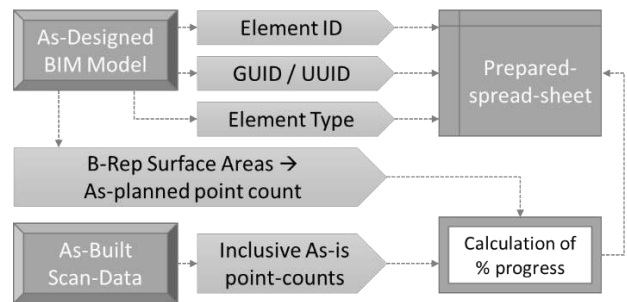

Figure 8 Data-flow diagram

All the BIM elements from the Revit environment usually contain GUIDs (Globally Unique Identifiers) and UUIDs (Universally Unique Identifiers). These identities were extracted using the element passport function from the RiR toolset. Bounding regions of the elements have been generated first by converting mesh-geometries into B-Reps made with infinitely thin surfaces and then offsetting the produced B-Reps at a limited distance to both sides of the solid element surfaces. The offset region is aimed to include representative points of the real scan data for the particular elements. Thus, an inclusion logic to determine the count of inlying points has been included in the workflow through the crop-box subsampling functionality of the tarsier toolset. To calculate point intensity on the exposed surfaces, deconstruct B-Rep functionality has been utilized to find surface areas to multiply them with scan-intensity of the point clouds.

5 Experimentation

The developed method has experimented with an as-designed BIM model (Figure 9a) of a hypothetical building structure and a synthetically produced point cloud (Figure 9d). The actual progress on a given date was formulated through an incomplete version of the same BIM model (Figure 9b). As shown in Figure 9d, the assumed as-built model was produced using the

concept of point intensity (Figure 9c). The produced point cloud data were randomly replaced in the Universal Cartesian System (UCS) and rotated in the XY plane to achieve a more realistic approach to align the point cloud with as-designed BIM.

Then the "one-click progress monitoring" script was executed to generate the progress report. The script was processed using an Intel i5-6600K processor with 32 GB RAM, Disk Speed – 420MB/s Intel SSD, and Nvidia Quadro K620 Graphic processor with 2GB graphic memory. The report was obtained at the specified location. The results obtained are discussed in the following sub-section.

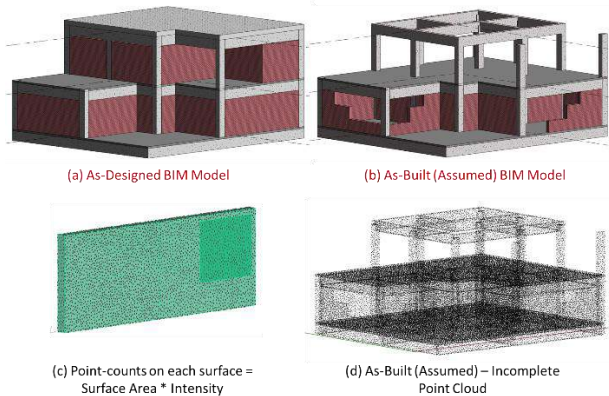

Figure 9

5.1 Results and discussion

The output is an Excel report generated, as shown in Figure 10. It shows the element-wise progress against each element ID.

#	A	B	C	D
1	ElementID	UUID	Element Type	% Complete
2	346045 000542bd	Revit Host Type : Basic Wall : Generic - 300mm		87.10822
3	346046 000542be	Revit Host Type : Basic Wall : Generic - 300mm		83.541804
4	346330 000548da	Revit Host Type : Basic Wall : Generic - 300mm		78.61525
5	347597 00054dcd	Revit Host Type : Basic Wall : Generic - 300mm		13.658537
6	351173 00055bc5	Revit Component Type : M_Concrete-Rectangular-Column : 450 x 600		83.471074
7	351413 00055cb5	Revit Component Type : M_Concrete-Rectangular-Column : 450 x 600		99.134199
8	351457 00055ce1	Revit Component Type : M_Concrete-Rectangular-Column : 450 x 600		81.303116
9	351530 00055d2a	Revit Component Type : M_Concrete-Rectangular-Column : 450 x 600		83.543662

Figure 10 Generated Progress Report

One of the intermediate outputs is shown in Figure 11, which shows that the script computes the point count for the model for comparison. Similarly, Figure 12 shows the visualization of only the requested elements and gives the percentage progress labeled against each component. The synthetic model had 81 elements, with almost one million points. The report for the holistic progress was generated instantly (less than a second), whereas, for element-wise progress tracking, the report took few seconds to get generated.

The key focus of this study is to focus on factors that make the pipeline for quantification more implementable at sites. Though accuracy is important, it is not the key concern of this study.

Figure 11

Figure 12 Interactive progress visualization

The pipeline presents a single-click solution to progress monitoring using the point intensities. The two levels of progress monitoring are provided, i.e., holistic quantification and element-wise quantification. The holistic quantification could provide top management with an overall progress estimate, facilitating project-level decisions to fast-track the project. The element-level progress can help site managers to schedule and assign the resources on the lagging activities effectively.

The most important factor in making the pipeline implantable is the computation complexity required to process the 3D data. Small and medium firms in construction cannot provide a dedicated facility for the computation of this data. Firstly, our method directly utilized the point cloud to evaluate volumetric progress without converting it into mesh/surface/Constructive Solid Geometry (CSG)/voxel/BIM models. Secondly, the pipeline does not use segmentation or clustering of the point clouds; instead, it uses as-designed BIM overlap. Thus, saving a significant amount of processing power.

Currently, the pipeline has been experimented on a synthetic building project point cloud. However, because it avoids any kind of reconstruction and does a point intensity-based comparison, it can be used on other types of infrastructure projects also.

6 Conclusion

The paper presents and illustrates a novel approach to monitoring the progress of the critical components of a building utilizing point cloud intensity. The pipeline is designed to compute and visualize elemental as well as holistic progress of the building. The holistic progress gives an overall quantification of the percentage

progress, and elemental progress gives an element-wise progress chart of a building. Both these extents provide detailed information to project managers to make timely and informed decisions.

The pipeline was developed using a user-friendly visual programming tool - Grasshopper3D. The core concept used here was to compare the point intensity in the as-built and as-designed point cloud models.

The pipeline provides a door to wider adoption, less computation cost, and quicker progress quantification. The pipeline is completely automatic and works using minimal computation and skills.

A limitation of this method is that currently, the operational state of the element cannot be recognized. However, with some modifications, temporary fittings like shuttering and formwork can be detected. This will be included in the future study as it will make the pipeline more effective. Also, an effort to implement the current pipeline on point cloud data obtained from the site will be made to see the robustness of the results.

Abstract –

Progress monitoring is key to any successful project. Often this is a hectic task which involves manpower in preparing Daily Project Reports (DPRs) to physically monitor the activities on site. Recent developments in the fields of photogrammetry and point cloud processing techniques have laid a new path in using point-clouds for visualization and progress monitoring of projects. However conversion of point clouds to an accessible BIM format is still a researchable topic. Present techniques include manually creating models by visualizing the point cloud which is still a time consuming task. This paper tries to provide a new methodology in using photogrammetric point clouds for progress monitoring with very little manual intervention. The proposed methodology uses Revit's Dynamo and cloud processing techniques to successfully estimate the progress and the cost of activities on site. This method effectively uses the STL file format as a key to convert models and compare the as-built and as-planned Models. Using this method, we were able to estimate the progress of concreting activities with 100% accuracy and estimate the progress of masonry wall construction with 95% accuracy.

Key words –

Point-cloud; Quantity estimation; Progress monitoring; Mesh; STL file; Dynamo; Revit.

1 Introduction

Adhering to project schedules and budgets is the performance metric that owners and contractors most highly value. Accurate data collection and efficient utilization of the data are some of the most important tasks in progress monitoring on Construction sites. This data collected is widely used to detect the progress, compare it with the actual schedule, and is also used to identify the key off-schedule activities that are affecting the progress of the whole project.

Often Progress monitoring is a difficult task, and its accuracy decreases with the increase in the size of the project. The present-day techniques involve people

manually collecting data in form of DPR (Daily Progress Report) and estimating progress. Even though this process is accurate it consumes considerable time and resources. Recently the development of photogrammetric, point cloud processing techniques and the introduction of laser scanners into the construction field has opened up an advanced way of data collection using point clouds [1, 2, 3, 4]. Further development in Computer vision techniques and availability of smartphones have led to methods that use images to reconstruct a point cloud [5, 6]. Even though these methods reduce the time consumption for data acquisition on project progress, the subsequent part of using this data for understanding and computing progress is still a manual task. Often people have to import the point cloud, register it, develop a BIM model from it and compare it with the actually planned model for the progress/quantity estimation.

This paper tries to create a new method of replacing manual development of BIM models from point clouds to a semi-automated one, through the combined use of generative programming tools with BIM authoring software. This method can have any of the 2 Lidar point clouds or photogrammetric point clouds as input. These point clouds are compared with the as-Planned Mesh model and an as-built mesh model is derived. This Mesh file is accessed using Dynamo and volumetric/Areal comparison is done. This method can reduce the development phase of as-built BIM models which in turn reduces the time consumed in progress monitoring. The major objectives of this study include

1. To develop a semi-automated method of quantity estimation for any construction project which takes point cloud data as input and derives the quantity of materials that have already been placed.

2. To determine the accuracy of the proposed method using a case study.

2 Literature Review

In order to overcome the disadvantages and manual errors in the collection of data, researchers have reviewed most of the current methodologies of automated data acquisition technologies. Examples of such technologies are Radio-frequency identification

RFID and GPS (Global Positioning System), barcode and GIS (Geographical Information Systems), LIDAR ([1], [2], [3], [4]) and photogrammetry ([5], [6]).

A laser scanner consists of a light source which emits laser beams, these reflect back from the source and the time taken for the laser to come back to the station is used to find the distance to the object. These techniques require very little manual intervention and the data is highly accurate. Lidar technology is vastly used for site data acquisition. Recognizing objects from point clouds can provide great accuracy in progress estimation. Bosche (2010) [12] developed a semi-automated system for recognizing 3D CAD model objects in site laser scans. Object detection and segmentation are used to detect cad models from Lidar point clouds and object progress can be found by as-planned point cloud retrieval rate% [13]. Bassier (2019) in [14] used laser scanned point clouds to determine progress of a structure. 5 classes such as non-existing, anchor, rebar, molding, and built, are used to determine the progress of a point in the cloud and the category to which it belongs. Mahmoud (2011) [23] concludes that laser scanning technology has additional advantages such as low training time, high resolution and quality of scanning. However its high purchasing cost and varied climatic conditions on site shifts the balance in favor of methods that use images to create point clouds and subsequently, building models. The ease of taking pictures/Images with the development of computer vision techniques opened up a path towards photogrammetry.

Photogrammetry is the science of obtaining reliable information about physical objects through interpreting photographic images. These images are further used to create point clouds. Images can be collected manually using Mobile phones, on-site cameras, and using Drones. Though using drones is the most preferred method in present-day sites, smaller sites can also use other techniques.

2.1 3D reconstruction of image to a Sparse point cloud

Conversion of an image to a point cloud consists of a series of steps which can be divided into 2 parts namely sparse reconstruction and dense reconstruction. Sparse reconstruction takes images as input and tries to estimate a sparse point cloud with camera positions. SFM (Structure from Motion [9]) Pipeline is mostly used for sparse 3D Reconstruction. Figure 1 represents the steps included in the sparse reconstruction process.

Once the images are captured, features/interest points are extracted. The set of features extracted from this step are now compared with features from the different images and the algorithm tries to find common features between images. Verification step transforms the 2d point into a 3d point using a transformation matrix. The pair of images used to start the reconstruction play an

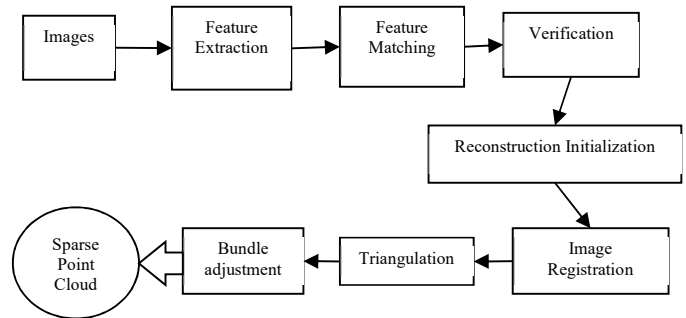

Figure 1 Sparse Reconstruction Pipeline

important role in the point cloud generated. Therefore the image pair with high common features are generally used for initialization of reconstruction. Image registration tries to stitch the remaining images to the initial image pair with high common features. A triangulation process is used to define the 3D coordinates of the new images, this takes a pair of registered images with common points and tries to estimate the camera position and adds new points to the existing cloud creating a sparse point cloud.

2.2 Dense Reconstruction

Dense reconstruction is done using a combination of PMVS and CMVS algorithms. Many multi-view stereo (MVS) algorithms do not scale well to a large number of input images. CMVS [10] takes the output of a structure-from-motion (SfM) software as input, then decomposes the input images into a set of image clusters of manageable size. A PMVS (Patch Based Multi-View Stereo) software can be used to process each cluster independently and in parallel, where the union of reconstructions from all the clusters should not miss any details that can be otherwise obtained from the whole image set. CMVS should be used in conjunction with an SFM software Bundler and an MVS software PMVS2 [11] (PMVS version 2). Thus a combination of CMVS/PMVS is used for a dense 3D reconstruction.

The applications of this technique to the field of construction management are many. Golparvar (2011) [15] used unordered images with SFM+ MVS pipeline to generate a point cloud, fed into a Bayesian model. SFM-MVS pipeline and SFM-CMVS-PMVS pipe lines are compared to one another by Hafizur(2019)[16]. Registration is always an important task while using point clouds, often this is done manually ensuring greater accuracies. An automated methodology of using Principal component analysis or coarse registration and Iterative Closest Point (PCA) for fine registration is employed in Bosche (2010) [17]. Usage of point clouds is often followed by machine learning algorithms to detect materials or elements from the point cloud. Colour features are generally used for the detection as shown in

Kim (2011) [18] and Akash (2018) [19]. Bin clustering and height of a point are used in classifying the point cloud into structural elements such as floors, beams and columns in [20]. Instead of processing point clouds there are methods in which the 3D BIM model is modified with a predetermined discrepancy. The BIM Model can be converted into a mesh and the point cloud coverage rate is used for progress estimation [21]. Bohn & Teizer have explored the advantages and challenges of camera-based progress monitoring [22].

Most studies that have used point clouds for progress monitoring have directly compared point clouds of as-built and as-planned models to give an estimate of overall progress of the project. However the individual progress of the activities are not determined. Some studies have concentrated on segmentation of point clouds in finding construction elements such as beams and columns in order to find the progress of the activities [18],[19],[20]. However these studies depend to a large extent on the accuracy of the point clouds which cannot be guaranteed under varying site conditions. The larger the size of the project, the more the number of laser scans that are required to generate accurate point clouds which in turn increase the time to capture data. With respect to photogrammetric approaches, while point clouds can be generated rapidly, using these point clouds for progress monitoring involves considerable manual intervention in creating as-built BIM Models [24]. In order to counter these drawbacks and the consequent gaps in our understanding of how to seamlessly create and use point clouds, this paper focuses on developing a framework to make the process of determining construction progress using point clouds easy, feasible, understandable, cheap and accurate.

3 Methodology

As a building contains many elements and non-

linear construction schedules, it is comparatively difficult to progress monitor as compared to linear construction such as roads. Elements that are predominant in the erection of a super structure are Walls, Beams, slabs and columns. In this paper we restrict ourselves to finding out the progress of these elements by volume interpolation from their surface area. As the progress of elements are found separately, the output of the study can be further used for cost estimation and earned value analysis of the project. This study is only restricted to activities that can change the as-built point cloud of the building. Activities such as painting, tiling, and plastering are excluded in the study as they only change the colour of the point cloud but do not implement a physical change. This section describes our proposed approach in detail. The methodology proposed to be adopted for the current study has been illustrated in Figure 2.

We start by collecting images from the site. These images are to be collected with an overall overlap of atleast 20%, so that common features can be easily detected between images making image stitching and registration easy. These images are loaded into the respective software which is REGARD 3D in this study. The images are converted through a series of steps as mentioned in Figure 1 into a point cloud.

An as-planned BIM model of the project is then developed in Revit. In our approach, the as-planned model is developed and is converted into a mesh model using Dynamo. The above obtained as-built point cloud and as-planned mesh are then used for the process of registration.

Registration of point cloud is considered the key step in the process. It is the process of translating and scaling the point cloud into the global co-ordinate system. For this, an already registered model is required which in our case is the as-planned model. Both the as-planned mesh and as-built point cloud are loaded into Cloud compare a 3D point cloud processing software designed

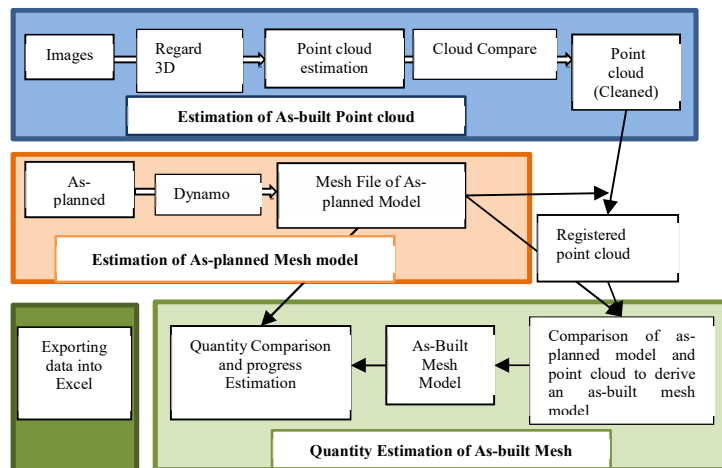

Figure 2. Proposed Methodology

to perform comparison between two models point clouds or meshes for coarse and fine registration.

Both the registered point cloud and as-planned mesh are used as inputs into a manually code developed in python to result in an as-built mesh. The code typically tries to check a preliminary condition with a point. It iterates through each point and with co-ordinates of the point, and tries to create a mesh from the as-planned model that encloses this point. Once this condition is satisfied, it counts the number of points that belong to a mesh. This number should be greater than 1 in any case. The point cloud may be erroneous which might lead to false positives. To account for this the progress of the mesh is considered. Progress of a mesh is found as the ratio of maximum height of all points of a mesh to the height of the mesh. An element is said to be constructed if the progress is greater than 0.9 or 90%. Third condition computes number of points at centre and should be greater than a minimum threshold. Threshold depends on the total number of points in the point cloud, area of the mesh. The resulting output is the as-built mesh in .ply format and is further used for quantity estimation.

The resulting As-built mesh is used to find the surface area which is then compared to the as-planned model's surface area, from which the progress of the project is estimated. This is done through developing code in Dynamo. To find as-built quantities of different construction elements, their technological dependencies are used. We use the surface area of each category of element in the as-planned model to estimate the as-built surface area. An example is provided below explaining the dynamo code to estimate as-built quantities of elements separately.

Example: Let the total surface area of the as-built mesh computed from the methodology be 300 m² irrespective of the number of elements in it. Let us assume that the total surface area planned for that day (columns – 50 m², slab – 100 m², beams – 50 m², walls –

300 m²) is 500 m². Dynamo code first considers columns and checks if the as planned column area (50 m²) is less than total surface area (300 m²). If this is true it assumes that all columns that are planned are constructed amounting the columns progress as 100%. Next the code checks the next element that is technologically dependant on columns which are slabs and beams. It now checks the total area of slab and beams (150 m²) and compares it to the effective surface area left (300 – column area (50) = 250 m²). As the area of beam and slabs is lower than the available surface area, it assumes that all slab and beams that are planned are constructed completely making the progress of slabs and beams 100%. Next it finds the area of the next element (walls). The area of walls planned is 300 m² but the effective surface area is (300-column area (50) – slab and beams area (150) = 100 m²). As the planned area is greater than the effective area, the code assumes that walls are not completed as planned. The area of constructed walls is 100 which is the as-built quantity and progress of walls is 100/300 = 33.33%. The output from the dynamo is programmed to be exported into an excel sheet which makes it easy for the end users to reuse the data for cost estimation.

4 Validation

There are 2 ways in which validation is done using a Virtual point cloud and a Real time point cloud. Validation is divided into 2 parts due to inaccessible construction sites, labs and lack of computation power for real time point cloud development.

4.1 Validation from virtual Point cloud

For a virtual point cloud, a Revit model is developed for a single storey residential building with an estimated area of 99m².

Figure 3. Row – 1 : As-planned mesh model for week 1,4,5 ; Row – 2: As-built virtual point clouds for week 1,4,5 ; Row – 3: As-built mesh model for week 1,4,5.

Initially a schedule for the project is planned for 5 weeks, where all the external elements of the superstructure such as columns, beams, slab and walls are to be constructed completely. The mesh models are different for different weeks depending on the week's schedule. These are formulated in Table 1. As the point

Figure 4. Plan of the residential building used for virtual point cloud

clouds are to be created virtually, random elements are selected for each week and are converted into a point cloud with points sampled on the mesh as mentioned in figure 3 -Row - 2. Example to construct an as-built point cloud: For week 1: out of 12 planned columns, we assumed only 6 columns are constructed completely which mean a 50% progress. Assumed Progress of the week – 4 and 5 are 100% and 45% respectively. Both as-built point cloud and as-planned mesh are used as inputs to the code which resulted in an output as shown in figure 3-Row - 3. The mesh model Obtained from the code is used as input for Dynamo code to calculate surface area which in turn estimates quantity and progress. The resultant excel output is shown in Table 1. The obtained quantities and progress are compared to the actual quantities constructed as shown in Table 2. The deviations are found minimal.

Table 1. Excel output from the proposed Methodology

Day	0	1	2		3

4.2 Validation from actual Point cloud

We then validated our model on a real construction site. The site considered is a residential building (150 m²) in Hyderabad. A small part of the project with an estimated area of 33 m² is considered. Construction has just begun

and 4 columns with slab have been successfully erected. The project is being delayed due to the ongoing pandemic. Images were collected on a sunny day expecting a greater

Figure 5. Site Images (left), Features detected (Middle), Feature matching and image stitching (right)

Figure 6. As-built point cloud (left), as-planned Mesh model (Middle), as-built Mesh model (right)

clarity of the point cloud. Images were taken using a mobile camera with a minimum overlap of approximately 20 % by picturing each element's 360° view separately. Number of images considered are 100 and are uploaded into Regard 3D and the point cloud is acquired. Images collected, Feature extraction and Image stitching are shown in the figure 5. As-built point cloud,

developed as-planned mesh model and the as-built mesh model is shown in the figure 6. The area of the derived mesh model is used to interpolate the quantities which in turn estimates the progress of the project. The excel output from the methodology is shown in Table 3. Table 4 represents validation of the obtained data with the actual quantities. There are no errors in the matching process.

Table 3. Excel output from the proposed methodology

1	Structural Columns	2.94	100	2.94	100	0	0
2	Floors	6.63	100	6.63	100	0	0

5 Results and discussion

The performance of the proposed framework was tested on virtual and actual point clouds. Results from the methodology are 100% accurate in case of concrete structures as seen in the table 2 and 4 and for walls the accuracy is estimated to be 95%. Accuracy in the methodology majorly depends on the stage of construction of the element and the distance between point clouds of that element to the nearest point cloud of other constructed elements. Moreover, actual data considered is too small, so the results need to be improved using larger point clouds. We have also assumed a simplistic construction sequence and this assumption must be revisited as we extend this method to more complex structures with different dependencies between members.

This study has presented a semi-automatic system for progress and cost estimation, with a goal to improve the process of progress monitoring using point clouds and Mesh models. The proposed method describes the usage of Dynamo to automate the progress monitoring, reducing time and computation power making the process easy and cheap. The combination of a generative programming tool such as Dynamo with existing photogrammetry techniques to analyse project progress is the main innovation and contribution of this paper. However this paper only represents a start. Our methodology must be extended to more complex structures and building elements and also to activities such as sub-structures, connections, joinery, finishes and so on. RGB values of the point cloud can also be incorporated for quantity estimation of activities such as tiling, plastering etc.

Intelligent Archiving of Interior Design Images using Panorama Picture Sources

Eunseo Shin^a and Jin-Kook Lee^a

^a Department of Interior Architecture and Built Environment, Yonsei University, South Korea
E-mail: silverw0721@gmail.com, leejinkook@yonsei.ac.kr

Abstract –

This paper aims to propose an approach to establishing an intelligent interior design reference image database using 360-degree panorama picture sources. Building interior design reference images are usually taken by people in an ad-hoc way and stored/used for various purposes as non-standardized design communication resources. As several web/apps provide such resources, in this paper we suggest a certain organized way to build an interior design image resource that can improve design communication between architects and other stakeholders. Recent daily-life web/apps have collected architectural design images uploaded by users, but stored images hardly used for professional design purposes due to issues of sufficiency, quality, consistency, copyright, liability etc. In this paper we focus on the sufficiency and quality issues by using a deep learning enabled auto-classification of interior pictures extracted from a high-definition panorama picture source. The input image also can be generated by photo-realistic render software if it is a planned design. This paper describes an approach to simplify the process of establishing such an archive; 1) preparing panorama image, 2) auto-extracting entire interior reference images, 3) auto-classification and/or detection of the context represented in each picture to enrich pictures' dataset, and 4) archiving image data with generated information to be used for various design purposes. This paper also demonstrates an intelligent archiving of interior design reference images process implemented as a web/app software prototype.

360-degree panorama picture; Data Archiving; Interior Design Reference Image; Auto-classification; Deep Learning

1 Introduction

Understanding the intention of architectural design is usually hard to people because of various reasons, including jargons and/or notations used by experts [1]. That is simply why architects and designers have used effective design visualization tools to make their communication easier for people. Design visualization is one of the key factors of decision-making in the architectural design process [2], and it is represented in diverse forms including standardized drawings, images, videos, and often with text [3]. As growing digital design techniques, such a design communication has been mainly involved with various visualization methods and media such as 3D models and live-action rendering techniques [4,5]. Especially in the perspective of interior design visualization, a high level of detail and realistic visualization that is very close to the as-built state of design is strongly necessary [6]. Our objective of this research is not on the intrinsic aspect of design, but on technical aspect of such visualization data. Thus in this paper we propose an intelligent approach to archiving interior design images using 360-degree panorama pictures of real spaces and photo-realistic renders of design models, and demonstrates an actual implementation of the process suggested.

In the case of the architecture domain especially in the construction phase and the facility maintenance phase, 360 panorama images are mainly studied and used in the Architecture domain, and utilization in the design phase has also been recently studied [7]. However, for 360 panorama images, it is difficult to verify images without distortion without specific devices such as HMD. In addition, these devices can cause users to experience discomfort such as motion sickness when worn. Therefore, rather than using the 360 panorama images circular image, this study converts the image post-processing process into a more easy-to-see and familiar form and enables it to be used as a reference image.

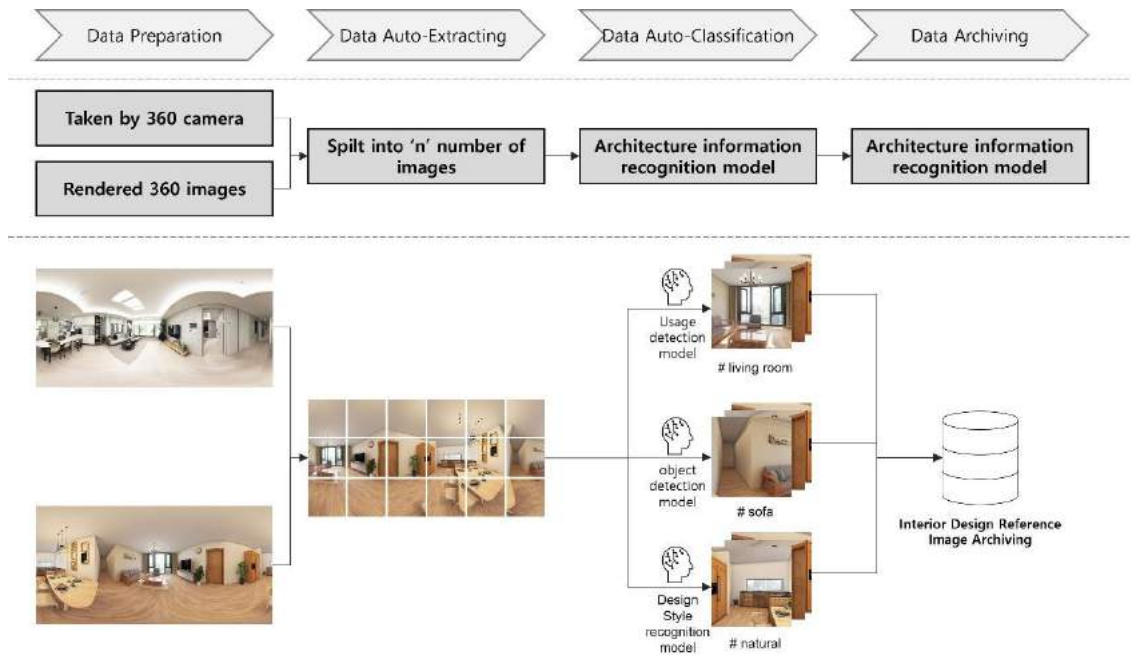

Figure 1 Intelligent archiving of interior design reference images process

As a preliminary study for the implementation of this approach, this paper explores the ways to segment 360 panorama images into ordinary images and to infer design reference images or pictures using the deep learning-based model. The scope of this paper is on training deep learning models that recognize space usage of images, calculate visual similarity with other images, and propose an approach to visual input-based auto-labeling on segmented images.

For training such intelligent models, this paper utilizes a deep convolutional neural network (CNN) model that showed the successful performance of understanding general object [8], context [9] and even design attributes of interior design object [10] on visual data [11]. The feature map data is used as input data to train models recognizing design attributes of space usage. The results of recognition are used to label segmented images from 360 panorama images. The labelled images are stored in an interior reference image database.

2 Background

2.1 Interior Design Reference Image

Interior design visualization methods have changed over a long period of time [12]. What is now known as the beginning of the design representation is a painting of the architecture of ancient Mesopotamia on top of shells [13]. To date, various tools and technologies have emerged, and the methods of design visualization have

changed accordingly. As design visualization methods change, various studies and developments have been conducted on databases that store drawings and photographs, which are the results created through design representation results.

2.2 A Panorama Image as Interior Design visualization Method

360 panorama image is characterized by a single image expressing various views. It has the advantage of being able to acquire multiple angles of view from one image based on those features and the various information contained in the panorama images. Based on these advantages, there has been active discussion on how to utilize 360 panoramic images in the AEC-FM (Architecture, Engineering, Construction, and Facility Management) industries. It is used in various stages of design, construction, and maintenance.

In the design stage, it is used to implement virtual reality that allows users to experience virtual design created through CAD and BIM authoring tools more realistically. The development of three-dimensional model-authoring and rendering visualization tools has made it easier to create panorama images. A study is conducted to encourage non-expert consumers to participate in the design process using augmented reality [14]. There is also a prior study to develop a unified design process for laboratory layouts using Virtual Reality (VR) instruments to create ways to interact with users' thoughts [15].

In the construction stage, it is used for on-site

management, such as reviewing the progress of construction at the construction site, reviewing the quality of construction, and safety management. The prior research was conducted on architectural and design visualization using VR, construction health and safety education, equipment and operation work training, and structural analysis for training workers at construction sites [16]. Many studies have been conducted on the use of VR in the field of safety management. To protect workers at construction sites, which are sites of high-risk industries, complex tasks were visualized in advance and risk factors could be eliminated in advance [17].

During the facility maintenance stage, it is being used in various fields such as change history management of space changes through regular filming and virtual VR home tours. Studies have been conducted to use VR to visualize the applicable technical information related to the wear and tear aspects of materials defined over a specific period for each element of the structure [18]. In the maintenance stage of the building, not only academia but also various industry sympathizes with the advantages of panorama images and actively utilize them.

3 Preparing Input Image

3.1 360 panorama picture sources generation

There are a variety of spaces that are subject to 360 panorama images for interior design visualization and tools used to author source images. In this paper, apartments, a typical residential facility in Korea, were designated as the target space for source image authoring. There are two methods of creating panorama images: 1) photographing the actual space with a 360-degree camera, and 2) generating it using 360-degree rendering in a 3D model authoring tool. The former method is used for the maintenance of facilities in the space in use. In the latter case, the architecture after completion in the initial design stage can be experienced in advance. Subsequently, written models and images may be used as data to manage the entire life cycle of a building until the maintenance of a facility.

3.1.1 360 cameras

In 2015, 360-degree cameras began providing 360-degree video playback services on the 'Y' platform, a video playback platform, and various models and products appeared in the market. We select as the target space for generating input images using 360 cameras an 84-square-meter apartment located in Seoul, South Korea. Input images were collected and proceeded with e-model house images that existed on the web without being photographed directly by researchers. Due to the

covid-19, the Korean real estate market has been actively using the e-model house. The process of creating an e-model house to sell apartments can be seen in Figure 2. Figure 2 shows the location of the panoramic image of the apartment on the floor plan of the apartment and the source image was taken. For small spaces, the entire space can be represented by a single panoramic image. However, for larger spaces, such as living rooms in apartments, the images taken without blind spots can be obtained by dividing the space into grids. It also enables the collection of input data taken by a space from various angles of view.

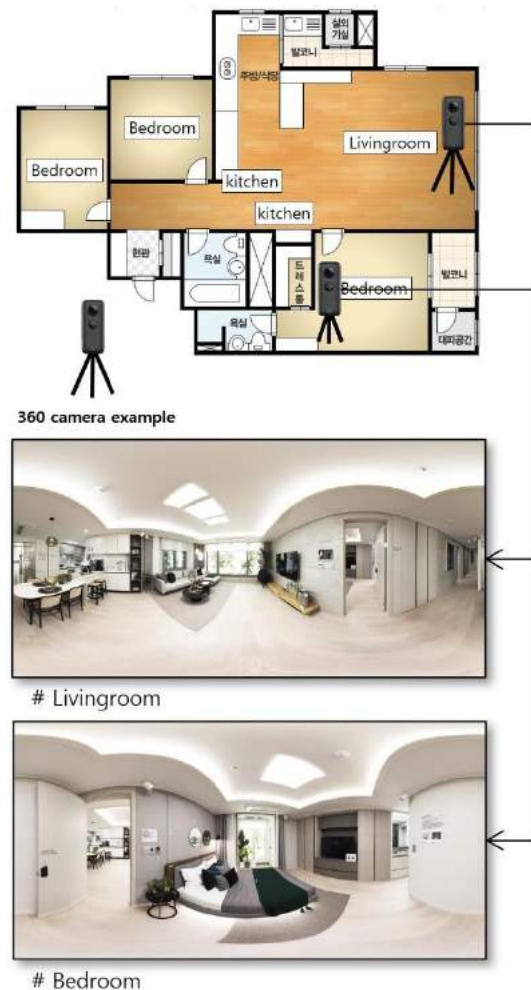

Figure 2 Real space 360 panorama images taken by 360 cameras

3.1.2 Rendering 360 images using CAD/BIM SW

The target space for creating source pictures using 360 landing is also an 84-square-meter apartment in Seoul, South Korea. Figure 3 shows the generation of 360 panorama images based on three-dimensional modeling authoring tools. Generating 360 rendering

based on three-dimensional model authoring tools is now supported by various tools due to advances in computing technology. In this paper, we used the 'H' program, a web-based three-dimensional modeling authoring tool. A three-dimensional model was created based on an apartment floor plan (Figure 3).

For three-dimensional models, three virtual design proposals were created based on the same apartment floor plan to show various examples. After the modeling is completed, a 360 panorama source picture is created based on cloud rendering. Cloud rendering is a technology that transmits 2D or 3D graphics rendering from client servers to cloud servers. This has the advantage of being fast and being able to perform other tasks during the operation by proceeding to render on the server's computer without using the client-side computer. The reason why we used the 'H' program in this study is that it provides the most realistic cloud rendering service. In addition, web-based interfaces make it easier for users to access three-dimensional modeling.

Figure 3 360 panorama images of virtual design alt images

3.2 Extracting of panorama images

For 360 panorama images created using the two mentioned methods, it is difficult to utilize them as interior design reference images. While VR devices allow for immersive observation of visualized spaces, images themselves that can be observed with planar displays are distorted and represented. Post-processing is required to utilize the generated source images as an interior design reference image without the help of other devices. Post-processing methods of panorama images vary according to their attributes and purposes. Based on the web interface, this study proposes not only segmenting 360 panoramic images into images of multiple typical angles of view but also restoring distorted images to their original shape.

Figure 4 shows two methods of extracting 360 panorama images. The first method is to divide the 360 panorama images by inputting the desired angle of view, left and right angles, up and down angles, and the size of the image. This method has the advantage of allowing users to cut out specific parts using the location, angle of view, size, etc. they want. The number of images that are divided can also be set arbitrarily by the user. For the second method, source panorama is divided into cube maps which are hexahedrons. For this method, a 360 panoramic image is divided into the ceiling, and the floor, and four sides of the wall. It also has the advantage of being able to easily return to the existing source panorama images by combining all the extracted images.

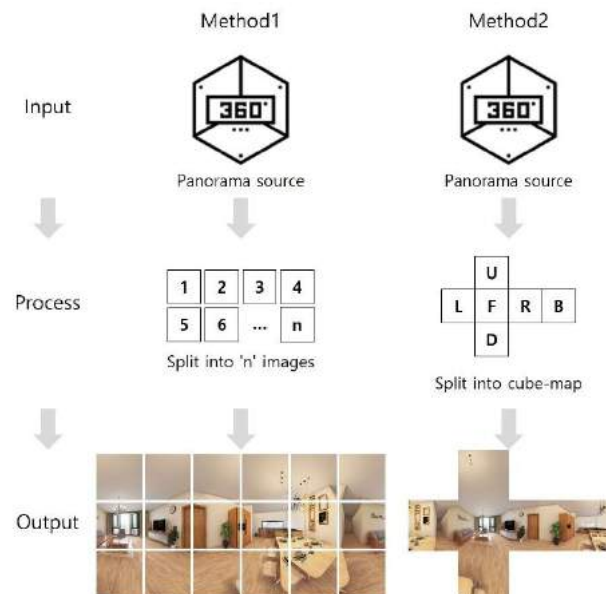

Figure 4 Auto-extracting from source 360 panorama pictures

4 Intelligent Archiving of Interior Design Images

4.1 Auto-classification

This paper proposes an approach to auto-labeling architectural information such as space usage and object of extracted images. The architectural information contained in photographs varies, including metadata, geometric data, and topology data, but this paper deals only with space usage data. If the usage of the space is inferred, a variety of architectural information, including the furniture object information placed there, can be obtained together.

In this paper, the feature map data derived from apartment images are used to get semantic information of picture and visual similarity information. To get test images we use segmentation tools which method are written above. These images are input image into the deep convolutional network [19]. We use VGGnet [20] model that previously trained the ImageNet dataset [11].

Table 1 Results of auto classification of space usage

Image	Livingroom	Kitchen
	<u>99.64%</u>	0.36%
	21.87%	<u>78.13%</u>
	<u>99.37%</u>	0.63%
	26.81%	<u>73.19%</u>

The number of data used to train the model is 300

pictures of each living room and kitchen. Image crawling is used to collect train and test images. An extension program is used for image crawling. The program allows users to download images that are available from G's search engine. Table 1 shows the results of the trained model. The accuracy of the test model is 88%. Table 1 shows the resulting values from two 360 panorama source pictures as input values for the classification model. We show each image and probability of having the highest probability of living room and kitchen among images extracted from two source pictures.

4.2 Archiving image data

We propose a method for recognizing the architectural information of extracted images and storing them with text. Storing recognized information with extracted images is important in terms of archiving data. Storing recognized information with extracted images is important in terms of archiving data. Storing images based on recognized information is a requirement in terms of accumulating and utilizing structured data.

The prototype developed in this paper is to label the usage of the space using the deep learning-based classification model. Figure 5 shows a developed web-based prototype. The prototype usage is as follows; 1) the user enters the source 360 panorama picture, 2) the

Figure 5 Web-based image extraction and labelling prototypes

image is extracted accordingly when the user chooses

the image segmentation method, 3) Among the split images, the living room and kitchen are labeled with the most likely living room and kitchen using a classification model, 4) the result is shown to the user.

5 Conclusion

This paper proposed the approach to developing a database of interior design reference images using indoor 360-degree panorama picture sources and deep learning-based image recognition. The suggested process of developing database is as follows; 1) Collecting 360-degree panorama images. 2) Image-processing to extract significant parts of a 360-degree panorama image as design reference. 3) Recognizing design-related information on extracted parts of image using CNN-based image classification model. 4) Archiving processed images with recognized information. This paper also implemented and demonstrated the prototype app that automatically archive interior design reference data from inputted 360-degree panorama images.

Results of this study can be summarized as follows. As source of the 360-degree panorama images in this process, not only the high-definition taken picture using 360-camera but also photo-realistic rendering virtual images that are generated by CAD or BIM are utilized. The methods to divide given indoor 360-degree panorama image include a parametric way and pre-set cube-map way. Through the first method, given image are divided into grid with specific view angle and image size. On the other hand, the cube map method generates only 6 images with difference view and static image size. Trained deep learning-based CNN models label design-related information such as space usage, design style etc. on each of divided images. The divided images are automatically archived with labelled data at database.

The paper contributes to facilitating to archive and utilize massive and qualitative 360-degree panorama image data in the field of architectural design. Especially, it is expected to standardize the way of archiving interior design reference that are dealt with an ad-hoc way by people. As the future works, the author are extending the scope of recognized information (e.g. each design-related object) from given interior design images, and developing way to utilize archived data in design process.

kash@ece.concordia.ca

Abstract –

Efficient progress monitoring and reporting require detailed and accurate reports from construction sites in a timely manner. These reports include important information to assist decision-making through comparison of as-built information to as-planned state. Manual reporting is time-consuming, error-prone, costly and is highly dependent on site personnel expertise. Advances recently made in artificial intelligence, data processing and digital cameras have paved the way for introduction of image-based methods for automated monitoring and progress reporting in the construction industry. Object recognition has achieved significant advances and considerable growth by the introduction of deep learning algorithms such as the Convolutional Neural Networks (CNN). This research proposes a method for automated recognition and segmentation of HVAC ducts utilizing digital images by developing Mask Region-based Convolutional Neural Network (Mask R-CNN) architectures. 3D BIM models are utilized for generating 1,143 synthetic images to train the developed Mask R-CNN model. To enhance the training dataset capability and overcome the overfitting problems, various data augmentation techniques are considered. The developed deep learning-based object recognition method automates monitoring of HVAC ducts installation, making use of generated synthetic images for training the algorithm to overcome the need for large datasets of actual images.

Keywords –

Deep Learning; Convolutional Neural Networks (CNN); Mask R-CNN; Progress Monitoring

1 Introduction

Constant progress monitoring of different activities at jobsites influences the project budget and schedule for reducing cost and delays. It also improves the quality control, documentation, and communication in construction projects [1]. In conventional progress monitoring schemes, the current state of the project is compared with the as-planned state to assist in evaluating the project's performance. It includes tracking, reviewing, and organizing the activities for determining the areas where timely corrective actions are required [2, 3].

However, due to different site activities, monitoring the construction progress is a complicated and challenging task that requires correct information in a timely manner to support project managers in identifying scheduling deviations in an early phase to avoid possible delays. Accurate and in-time construction site data collection, efficient data analysis, and visualization applications in an interpretable format are essential requirements for efficient progress monitoring [2, 3].

Currently, many construction sites are equipped with economical digital cameras that produce a large number of images and videos containing considerable amount of information from the job sites. These images/videos can ultimately benefit the project management system. However, due to various difficulties in data analysis and processing, practical use of this abundant of data is quite challenging. Hence, project managers would apply manual and costly methods for construction activity analysis [4].

Through improvements in deep learning algorithms and advances in device capabilities (processing power, memory storage and high image sensor resolution), computer vision methodologies have gained widespread interest in various construction research areas [5].

Consequently, by increasing efficiencies in extracting

information from the captured images and videos, computer vision methods that use deep learning algorithms have been applied for automating construction monitoring purposes such as in progress tracking, productivity analysis, safety assurance, and quality control [6, 7].

In particular, there is an increasing shift towards utilizing deep-learning based object recognition algorithms for automated identification of construction elements from digital images to assist project reporting and updating schedule by accessing to as-built information [4, 7–9].

However, despite advances in different object recognition algorithms, the open dataset of images from construction job sites, including different building elements, is not available to train and validate the algorithms [4]. This research has developed a method to automatically recognize HVAC ducts using Mask R-CNN architecture and evaluate the model by utilizing quantitative performance metrics.

Towards this end, 3D BIM models were utilized to generate and extract synthetic images to train the CNN algorithm. Moreover, image augmentation techniques such as geometric transformations and kernel filters were applied to artificially increase the training dataset size for a stable network training and prevent overfitting. Two experiments were conducted to evaluate data augmentation impact in the ultimate HVAC ducts recognition performance.

2 Related Work

Computer vision methodologies can facilitate the construction monitoring systems through detecting and tracking material, equipment, and labor in construction job sites [1, 4, 7, 10–14]. In computer vision, the detection and classification of objects in images/videos can be categorized into traditional (feature-based) algorithms and deep learning algorithms [7, 15].

In traditional algorithms, human-engineered features such as edges, corners, and colors are extracted to determine the correct class of objects [12, 15]. This is achieved by utilizing examples of feature descriptors such as Haar-like, the histogram of oriented gradients (HOG), Speeded-Up Robust Features (SURF), color histograms, among others. These feature descriptors mostly are combined with machine learning algorithms that have shallow structures such as the K-Nearest Neighbors and the Support Vector Machine for conducting the classification tasks [7, 15, 16].

A number of research studies have utilized feature descriptors and machine learning algorithms to detect construction resources from digital images [1, 17–19].

Deep Learning (DL) algorithms such as the Convolutional Neural Networks (CNN), have shown

promising performance in object detection areas and are widely applied in the construction industry. These methodologies provide more practical solutions through self-learning capability and higher accuracy when compared to the traditional algorithms [12]. Different studies have used deep learning algorithms to detect objects of interest in construction sites. The reference [4] has detected the structural components such as beams and columns by utilizing Deeply Supervised Object Detector (DSOD), [9] has applied Mask R-CNN, a deep convolutional neural network to detect Walls, Doors, and Lifts from images for creating an as-built model.

Finally, the reference [10] has developed a framework including Convolutional Neural Networks for detecting the existing building objects in the jobsite, and then the extracted objects were superimposed on the as-planned model through BIM and Virtual Reality to evaluate the progress state. Despite the significant performance of deep learning algorithms to detect construction components with high accuracy, there is still currently lack of large, labeled image datasets from job sites including different classes in the construction industry [20]. Hence, the application of synthetic images for training deep learning algorithms for performing object detection purposes has received a significant amount of interest to overcome the above issues [21, 22].

3 Developed Method

Figure 1 provides an overview of the developed method. It consists of three main modules, namely: “Synthetic Image Generation and Data Labeling”, “Mask R-CNN Training”, “Testing and Evaluation”. Each of these modules and components is described in the following sections.

3.1 Synthetic Image Generation and Data Labeling

Similar to the recent research conducted in [23], 3D BIM models are utilized to extract synthetic images for overcoming absence of construction elements real image datasets for training the deep learning algorithm. In our work, the BIM models are taken from an online open-source website [24]. The HVAC ducts and other building elements properties such as shape, material and size are defined in Autodesk Revit 2019 as a BIM software.

Different viewpoints that consider various occlusions and illuminations are selected and rendered using Enscape v2.8, which is a real-time rendering Plugin installed in the Revit software. A total of 1,143 synthetic images are generated and used for network training. The dataset consists of one class, namely HVAC duct which is a common and widely used element in building construction. It has 1,887 duct instances captured in

1,143 images. The training set distribution shows that from 1,143 images, 56% of images contain only one HVAC duct in each image, 32% have two ducts, 9% three ducts, 2% four ducts, and 1% five ducts. 172 images are randomly selected for testing and validation purposes. The test set data follows nearly the same distribution of the training; 54% of images having one HVAC duct, 44% having two ducts, and 2% having three ducts. The images are manually annotated using the VGG Image Annotator (VIA) web tool to specify the HVAC ducts regions and locations in images through polygon shapes. In each image, all the pixels that have not been assigned to HVAC duct class are categorized as background.

The annotation files are downloaded as JSON format containing polygons' coordinates of all the images for further model training.

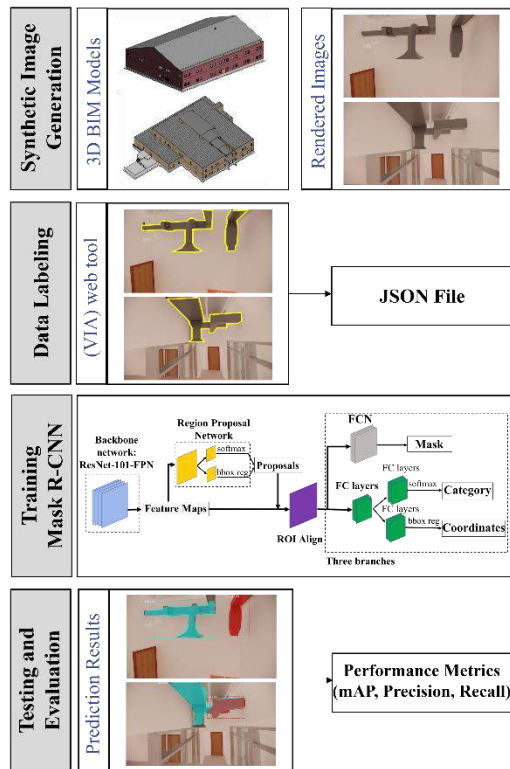

Figure 1. Overview of the proposed method

3.2 Instance Segmentation using Mask R-CNN

For our research we have employed the Mask R-CNN, an instance segmentation technique which is an extension of Faster R-CNN. In this method as compared to Faster R-CNN, a mask prediction branch is added in parallel with the existing classification and localization of candidate objects in the images.

The detailed Mask R-CNN architecture is depicted in

Figure 2. In the Mask R-CNN, convolutional backbone network including ResNet-101 and Feature Pyramid Network (FPN) extract feature maps from an image. Next, the feature maps are fed into Region Proposal Network (RPN) to propose the Regions of Interest (RoIs). Also, the Mask R-CNN is utilizing a quantization-free layer, called RoI Align for extracting predefined size feature maps from each RoI.

In the head network, fully connected layers perform object classification and bounding box regression in each RoI in parallel with a branch for predicting masks (by classifying each pixel into a predefined object class) using a fully convolutional network (FCN). Equation (1) is the multi-task loss function on each RoI referring to the sum of classification loss (L_{cls}), the bounding-box loss (L_{box}), and the mask loss (L_{mask}). Specifications of L_{cls} and L_{box} which have the same loss functions that are utilized in Faster R-CNN and demonstrate classification and detection error are described in [25] and details of L_{mask} are provided in [26], where

$$L = L_{cls} + L_{box} + L_{mask} \quad (1)$$

3.2.1 Training the model

Training the Mask R-CNN is based on the Matterport's implementation [27] using the open-source libraries Keras and Tensorflow. Feature Pyramid Network (FPN) and ResNet101 are applied as a backbone network and rather than training the model from scratch, it is initialized by utilizing pre-trained weights on the MS COCO dataset. After testing different epochs for training the Mask R-CNN, the best results are achieved with 90 Epochs and the batch size of 2, the weight decay of 0.0001, and the learning rate of 0.001. To minimize the overfitting problem and to improve the generalization of the model, different sets of image augmentation techniques such as the Horizontal Flip, the Vertical Flip, Rotation, the Gaussian Blur and Brightness are investigated to create modified copies of the existing data. Details of this investigation are provided in Table 1.

Table 1 The parameters of the augmentation techniques

Data Augmentation Technique	Parameters
Flip	Horizontal & Vertical
Rotation	One of $\Theta=90^\circ, 180^\circ, 270^\circ$
Brightness (Multiply)	(adding value) (0.8,1.5)
Image smoothing (Gaussian blur)	(σ value of Gaussian kernel) (0.0,5.0)

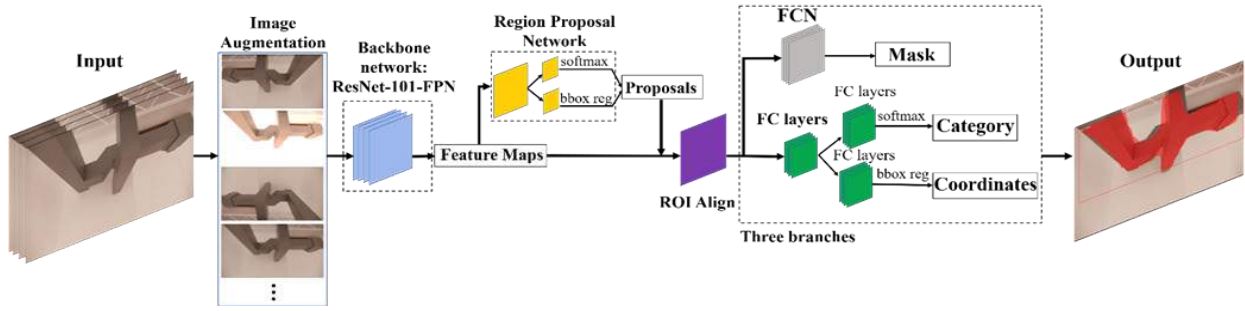

Figure 2. Mask R-CNN network architecture

3.3 Testing and Evaluation

The Mask R-CNN performance can be measured based on the test dataset. Precision and Recall are the selected evaluation metrics. Precision is defined as the ratio of the true predicted samples to the total samples and recall is defined as the ratio of true predicted samples to the total predicted samples, where TP is True Positive, FP is False Positive, and FN is False Negative, that is

$$Precision = \frac{TP}{TP + FP} \quad (2)$$

$$Recall = \frac{TP}{TP + FN} \quad (3)$$

The mean Average Precision (AP) is another commonly utilized metric for evaluation of the CNN object detectors which is defined as the mean of AP over all classes. Based on the Pascal VOC2010–2012 definition, for a pre-defined Intersection over Union value (IoU) as a threshold, AP represents as the area under the precision-recall curve, which is between 0 to 1 and is calculated as follows [28, 29].

$$AP_{all} = \sum_n (R_{n+1} - R_N) P_{interp}(R_{n+1}) \quad (4)$$

where the interpolated precision (P_{interp}) at a recall level (R_{n+1}) is equal to the maximum precision that is achieved for any recall level $\tilde{R} \geq R_{n+1}$, that is

$$P_{interp}(R_{n+1}) = \max_{\tilde{R}: \tilde{R} \geq R_{n+1}} P(\tilde{R}) \quad (5)$$

4 Results

In this section, the performance of the Mask R-CNN architecture is evaluated. The model is implemented in the Google Colaboratory (Pro) which is a cloud service based on Jupyter Notebooks with a Tesla P100-PCIE-16GBGPU (accessible up to 24 hours), and the Python3 runtime to overcome the limitations of computer hardware such as disk space for data storage or data processing speed. According to the provided information, the training of the model took 4-5 hours.

To assess effects of augmentation techniques on HVAC duct detection, two experiments are conducted on the training image dataset. In the first experiment, the images are used for training the model with no augmentation technique used (Experiment #1). In the second experiment (Experiment #2), the augmentation techniques that are described in Table 1. are applied for the model regularization and generalization,

The results of the experiment are summarized in Table 2. Moreover, the mAP score for entire images in the Experiment #1 and Experiment #2 is 88.69% and 90.6%, respectively. Figure 3. illustrates the downward trend of the loss function during the training process in the Experiment #2. It also shows the success of the model in preventing overfitting since there is a desired convergence of the training and validation errors. The output images from the HVAC duct detection extracted from the Experiment #2 by using the Mask R-CNN are depicted in Figure 4.

Table 2. HVAC duct detection results using two augmentation experiments.

Training dataset	TP	FP	FN	Precision (%)	Recall (%)
Experiment#1	223	74	32	75.08	87.45
Experiment#2	224	53	31	80.87	87.84

5 Discussion

Due to absence of an open image dataset from building elements in the construction job sites, this research has utilized synthetic images that are generated from 3D BIM models to train a deep learning model for HVAC ducts recognition. Since the dataset is not large, to increase the model performance during the training process, transfer learning based on the COCO dataset, and different data augmentation techniques are considered and applied.

It has been shown in Table 2 that the performance of Experiment #2 with a precision value of 80.87% and a mAP score of 90.6% is better than the Experiment#1 with a precision value of 75.08% and mAP value of 88.69%

and it can be stated that the effect of data augmentation on the model is meaningful and helpful.

According to the results obtained, the developed method provides a robust and accurate tool for recognition of installed HVAC ducts utilizing synthetic images. As such it addresses scarcity of available datasets of real images. It is suggested that performance of the developed method be evaluated using a larger training dataset that includes a mix of both the synthetic and real images and impact of various augmentation techniques be considered for further investigation. Moreover, the developed method can be extended to detect additional building elements such as piping, beams, among others to help progress reporting to be more efficient.

Figure 3. Loss value at each epoch in training and validation sets.

Figure 4. Results of the proposed method

6 Conclusion

This study has utilized a synthetic image dataset that is generated from 3D BIM models to overcome the requirement of having large real-image datasets for training deep learning algorithms. The dataset includes images from various viewpoints, lighting conditions and occlusions to evaluate the robustness of the model. Due to the special appearance of the HVAC ducts, a pixel-wise segmentation approach was selected to increase the accuracy of the detected HVAC ducts spatial locations in images as compared to other algorithms such as the Faster R-CNN where detection is limited to bounding boxes. The Mask R-CNN was also implemented to accurately recognize the HVAC ducts in construction sites with the training time between 4-5 hours. The model results that use transfer learning and data augmentation techniques have a mAP of 90.6%, a precision of 80.87%, and a recall of 87.84%. According to the obtained results, the Mask R-CNN model can accurately detect HVAC ducts with irregular shapes. The main contribution of this research is development of a solution and scheme that can automate HVAC ducts recognition, and its later use in automated progress reporting making use of as-planned and as-built stages via digital imaging taken from either 3D models or real construction jobsites. This will considerably reduce the manual effort and time in monitoring and reporting. To evaluate the performance of our proposed methodology in the construction phase with real HVAC ducts, it is planned to extend our work by utilizing real images. Also in future work, performance of other CNN architectures with more building classes will be fully explored.

Abstract –

Obtaining accurate information of defective areas of infrastructures helps to perform repair actions more efficiently. Recently, LiDAR scanners are used for the inspection of surface defects. Moreover, machine learning methods have attracted the attention of researchers for semantic segmentation and classification based on point cloud data. Although much work has been done in the area of computer vision based on images, research on machine learning methods for point cloud semantic segmentation is still in its early stages, and the current available deep learning methods for semantic segmentation of the concrete surface defects are based on converting point clouds to images or voxels. This paper proposes an approach for detecting concrete surface defects (i.e. cracks and spalls) using a Dynamic Graph Convolutional Neural Network (Dynamic Graph CNN) model. The proposed method is applied to a point cloud dataset from four concrete bridges in Montreal. The experimental results show the usefulness and robustness of the proposed method in detecting concrete surface defects from 3D point cloud data. Based on the sensitivity analysis of the model using three cases defined with different number of input points, the best test results show the detection recall for cracks and spalls are 55.20% and 89.77%, respectively.

1 Introduction

Many of the old infrastructures that are near the end of their service life are still in use, which increases the need for regular inspection of these structures [1, 2]. Advanced technologies (e.g. LiDAR scanners, sensors) have made the inspection process more accurate and reliable [3, 4]. These technologies, such as LiDAR scanning, are a promising alternative to traditional visual

inspection, which is unsafe, labor-intensive, costly, and subject to human errors [5]. Although much work has been done for processing images using computer vision, research on machine learning methods for point cloud semantic segmentation is still in its early stages [6]. Image-based methods have limitations, such as the need for appropriate lighting conditions and additional information to analyze images (such as focal length), and may also fail to analyze more complex geometric surfaces [7, 8, 9]. Furthermore, using the methods that are not applying raw point clouds as input will increase the dataset size by converting the point cloud to other data formats, resulting in missing information or causing heavy computing [6, 10]. Deep learning is one of the most effective machine learning techniques, which uses more than two hidden layers in order to acquire high-dimensional features from the training data [11, 12]. So far, deep learning with images has achieved acceptable results by learning complex structures. Currently, researchers are adapting these methods by using point cloud data as raw input.

In order to automate the inspection process, this paper proposes an approach using the 3D semantic segmentation technique by adapting a Dynamic Graph Convolutional Neural Network (Dynamic Graph CNN) model. The main purpose of the automated inspection process in this paper is to detect concrete surface defects, including cracks and spalls. The proposed method mainly consists of five steps: (1) data collection, (2) manual annotation, (3) data pre-processing, (4) training and evaluation, and (5) testing.

The rest of the paper is structured as follows: Section 2 contains the literature review. The methodology is explained in Section 3. Section 4 shows a case study and experimental results. Finally, the conclusions and future work are presented in Section 5.

2 Literature Review

2.1 LiDAR-based Defect Detection

LiDAR scanning is a non-contact measurement

technology that has proven its potential in capturing accurate and instant point cloud data from object surfaces [1, 13]. However, the resolution and noise level of point cloud data pose some challenges in detecting small cracks [14]. Therefore, to overcome this limitation, an additional feature, which is the RGB color, is considered in deep learning models [5, 6].

Laefer et al. [9] used fundamental mathematics to define the smallest width of unit-based masonry cracks, which can be detected with terrestrial laser scanner by considering the main parameters of depth and orientation of crack, orthogonal offset, and interval scan angle. Anil et al. [15] focused on the performance of laser scanners by using an automated algorithm on point cloud data from reinforced concrete surfaces and asserted the possibility of detecting 1 mm crack based on point cloud data. Xu and Yang [16] used the Gaussian filtering method and image-generated data from the point cloud to detect the cracks of a concrete tunnel structure. Teza et al. [17] proposed an automatic method for the inspection of damaged areas of concrete bridge surfaces using a laser scanner and Gaussian mean curvature computation. Makuch and Gawronek [18] proposed an automatic inspection system for reinforced concrete cooling tower shells using point cloud data and local surface curvature computation. Olsen et al. [19] proposed using cross sectional analysis to detect surface damage based on laser scanner data. Liu et al. [20] utilized the distance and gradient-based method to detect the defective area of bridge surfaces using laser scanner data. Valença et al. [21] proposed a method combining image processing and terrestrial laser scanning technology to automate the process of capturing the geometrical characteristics of cracks on concrete bridges. Kim et al. [22] proposed a technique to indicate the location and measure the quantity of concrete surface spalling defects larger than 3 mm using laser scanner data. Truong-Hong et al. [13] presented an approach to detect the bridge cracks using a terrestrial laser scanner and developed a tool to measure the length and width of cracks based on point cloud data and RGB color produced from an external camera. Tsai et al. [23] assessed the probability of using point cloud data to detect cracks with the dynamic-optimization-based segmentation method and assessing the crack segmentation performance using the linear-buffered Hausdorff scoring method. Cabaleiro et al. [24] developed an automatic crack detection algorithm using LiDAR data for timber beams inspection to identify the crack geometrical characteristics. Mizoguchi et al. [25] proposed a customized region-growing algorithm along with an iterative closest point algorithm to detect the surface defects of concrete structures based on laser scanner data. Nasrollahi et al. [26] proposed a method for detecting concrete surface defects based on collecting point cloud data from LiDAR scanners and using a Deep

Neural Network (DNN). Guldur and Hajjar [27] developed damage detection algorithms for automatic surface normal-based defect detection and quantification using LiDAR scanner data.

2.2 Dynamic Graph CNN

DNNs or deep feedforward networks utilize multiple deep layers along with highly optimized algorithms to learn from trained data sets without the process of manual feature extraction [28]. A CNN is a class of DNNs containing input, convolutional, subsampling, and output layers [29].

Dynamic Graph CNN, proposed by Wang et al. [30], is a new point-based CNN suitable for high-level tasks, such as object classification and semantic segmentation. Dynamic Graph CNN can improve capturing local geometric functions as it creates a local neighborhood graph and dynamically updates the graph with the nearest neighbors after each layer of the network. Rather than operating on individual points, the model iteratively performs convolution on edges associating the neighborhood point pairs. The operation layer for edge feature generation is called EdgeConv, which defines the relationships between a point and its neighbors. Figure 1 shows the mechanism of Dynamic Graph CNN edge feature generation. As shown in Figure 1(a), X_i and X_j are a point pair, and e_{ij} is $h_{\theta}(X_i, X_j)$, which is the edge feature function; h is the function parameterized by the set of learnable parameters θ . Figure 1(b) shows the channel-wise symmetric aggregation operation on the edge features associated with all the edges originating from each vertex, where X_i' is the EdgeConv operation, which is defined by applying asymmetric aggregation operation at the i -th vertex. The segmentation model of Dynamic Graph CNN involves a series of three EdgeConv layers and three fully connected layers. The parameter k in the model is the number of the edge features for each point, which is computed in each EdgeConv layer for the input of n points.

3 Methodology

Dynamic Graph CNN, originally designed to detect indoor building elements, is modified and adapted to automate the inspection process of concrete surface defects, including cracks and spalls. This model is selected because it considers the edge feature, which is the most valuable feature in concrete surface defects detection. Figure 2 shows the proposed method for 3D point cloud-based concrete surface defects detection.

The following five main steps are used to automate the inspection process of concrete surface defects:

(1) Data collection: The geometric features of defects, particularly the depth, play a significant role in extracting

important features and having practical results. Therefore, data collection is an important step and has to be done accurately. The scanner position and the scanning parameters, such as resolution, quality, Field of View (FOV), and the number of scanned points, are the factors that can affect the visibility of defects in the collected point cloud data.

(a) Computing an edge feature e_{ij} from a neighboring point pair X_i, X_j

(b) Channel-wise asymmetric aggregation operation on the edge features associated with all the edges originating from each vertex

Figure 1. Mechanism of Dynamic Graph CNN edge feature generation [30]

(2) Manual 3D point cloud annotation: After data collection, the selected parts need to be manually annotated based on the types of targeted surface defects. In this paper, two main types of surface defects, which are cracks and spalling, are considered. Each part of the dataset is annotated into three categories of crack, spalling, and non-defect.

(3) Data pre-processing: The annotated dataset is prepared and augmented by adding flipped data. The original dataset files are converted into data label files, which are 2D matrices with $XYZRGBL$ in each line. Then, each part is split into blocks, and for each block, normalized location values on the Y surface are added [30]. Each point is represented as a 7D vector of XYZ , RGB , and N_y . The normalized location values over X and Z directions are not considered as the depth of defects is in the direction of the Y -axis, and normalized location values over X and Z directions are not valuable and mislead the network's learning process. The sizes of blocks are defined based on the sizes of the structural defects in the dataset. Hence, the selected block sizes in the data pre-processing step are assumed to be less than $40\text{ cm} \times 40\text{ cm}$ on the XZ surface, with the depth of the defects as the third dimension, which is equal to the depth of the deepest defect in each segment. Moreover, in this step, the wrapped and normalized points inside the blocks are converted to Hierarchical Data Format (HDF) [31], and HDF5 files are used for the training process in the next step.

(4) Training and evaluation: As discussed in Section 2.2, a series of three EdgeConv layers followed by three fully-connected layers are included in the segmentation model of Dynamic Graph CNN, and the number of the k -nearest neighbors of a point for EdgeConv layers is specified for the input of n points in the model. In the adapted Dynamic Graph CNN, the input points variables are changed from a 9-dimensional vector to a 7-dimensional vector by removing the normalized location values of the x -axis and z -axis, and the network is fed by 7-dimensional input data. As the defect's numbers of points in this paper are less than the non-defect number of points, which is known as the issue of "imbalanced datasets", a weighted softmax loss function is utilized to adapt the model to our prepared dataset, and the corresponding weight vector is set based on the points distribution among the three classes.

(5) Testing: To validate the model accuracy, the unseen parts of the dataset, which are not used in Step 4, are used for the testing step. The confusion matrix is used to describe the model's performance using the equations presented in Table 1. In this paper, the term "overall accuracy" refers to the percentage of correct predictions for the test data. Furthermore, the recall is assumed to be more relevant than precision as the process of concrete surface inspection aims to minimize the chance of missing actual defect points, which can be achieved by minimizing the "False Negative" prediction of the model.

4 Case Study and Implementation

This paper used point cloud datasets from four reinforced concrete bridges in Montreal, scanned using a FARO

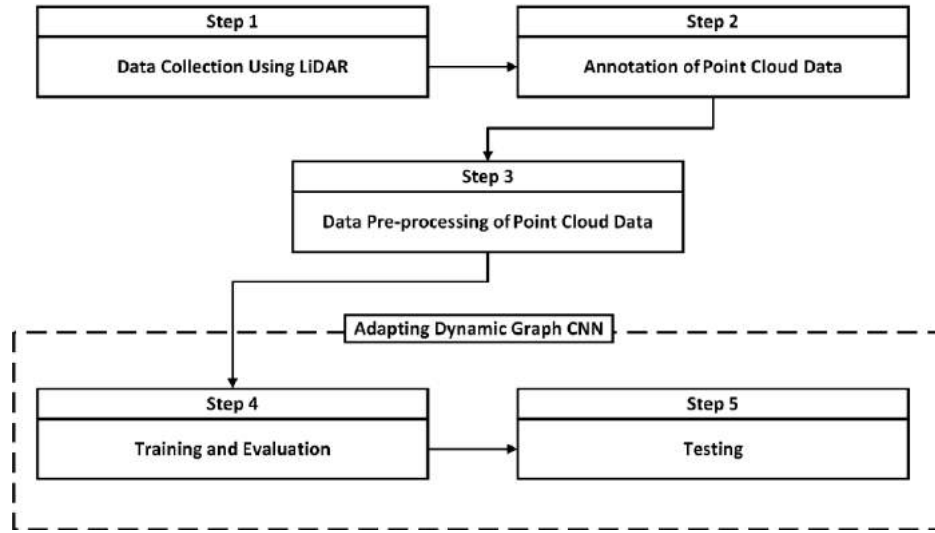

Figure 2. Proposed method for 3D point cloud-based defect detection

Table 1. Model Performance metrics

Performance metrics	Equation
Precision	$\frac{TP}{TP + FP}$
Recall	$\frac{TP}{TP + FN}$
F1 score	$2 \times \frac{Precision \times Recall}{Precision + Recall}$
Intersection over Union (IoU)	$\frac{TP}{FP + TP + FN}$
Overall accuracy	$\frac{TP_{Crack} + TP_{Spall} + TP_{crack}}{All\ perdiction\ of\ the\ points}$

Note: *TP* refers to true positives, *FP* refers to false positives, and *FN* refers to false negatives

Focus3D scanner [32]. Table 2 shows the scanning parameters. Furthermore, CloudCompare software [33] is used to register and eliminate the irrelevant points of the point cloud data. The scanning process in this step is affected by several factors, such as the battery capacity and performance limitations, especially in severe weather conditions, scanning time, and traffic constraints. For this reason, different settings, including different numbers of stations, were used to scan each of the bridges. In some scans, the FOV was reduced to avoid scanning irrelevant objects (e.g. moving vehicles).

The prepared dataset includes 102 selected segmented parts from the scanned bridges. The number of annotated cracks in the selected parts is 595, and the number of annotated spalls is 773. The annotation process is done

manually in CloudCompare software using the following rules based on experience: (1) a specific range of 150,000 pts to 400,000 pts is considered for the number of points of each selected part; (2) the scanned surfaces are classified into rectangular parts because of the box shape of the blocks in the model; and (3) the part size should consider the higher density of points in some parts and it should not contain more than the maximum defined number of points, which is 400,000 pts. The annotated datasets are split into five areas. Area 1 to 3 are used for training, Area 4 is used for evaluation, and Area 5 is dedicated to testing. The X-axis is set along the concrete surface, the Z-axis is set in the vertical direction of the canonical coordinate system, and the Y-axis is set perpendicular to the surface and in the direction of the depth of the defects. The depth of defects is set to have positive Y values. Furthermore, in this paper, to enlarge the size of the dataset, the augmenting method of flipping the point cloud data is used. In this regard, the annotated parts are flipped with respect to the YZ plane. The total number of segmented parts after adding the flipped data is 204 parts. The statistical information of the dataset, including the flipped data, is given in Table 3.

Wang et al. [30] used the block size of $1\text{ m} \times 1\text{ m}$ on the XY surface for rooms with a height of 3 m to detect indoor building elements. The number of points of 4,096 is used for their training process. This setting results in a very low density of points for detecting most types of defects in this paper (e.g. medium-sized spalls). In the adapted Dynamic Graph CNN, the block size of $40\text{ cm} \times 40\text{ cm}$ is set based on the sizes of the structural defects in the dataset. Moreover, the density of points in each block is increased by raising the number of points. This paper defines three cases with different number of input points of 8,192, 10,240, and 12,288, which are sampled for each block during the training process.

Table 2. Scanning parameters of four scanned bridges in Montréal

Scans		Number of Stations	Resolution	Quality	Horizontal FoV	Vertical FoV	Number of Points (Mpts)
Bridge 1	Scan 1	8	1/4	6x	23° to 259°	-42.5° to 71°	25.5
	Scan 2	4	1/4	6x	23° to 259°	-42.5° to 71°	25.5
Bridge 2	Scan 3	6	1/1	2x	0° to 360°	-60° to 90°	710.7
Bridge 3	Scan 5	4	1/2	4x	0° to 360°	-45° to 71°	134.5
Bridge 4	Scan 6	2	1/2	4x	0° to 360°	-60° to 90°	177.7

Table 3. The statistics of the prepared dataset

Dataset		Number of segmented parts	Number of points	Defects				Non-defects
				Crack		Spalling		Number of points
				Number of cracks	Number of points	Number of spalls	Number of points	
Training (59.5%)	Area 1	32	10,418,902	264	104,256	226	715,768	9,598,878
	Area 2	44	11,003,768	334	112,436	266	282,822	10,608,510
	Area 3	42	10,651,316	160	67,714	356	744,356	9,839,246
Evaluation (19.6%)	Area 4	44	10,552,584	192	80,454	328	762,156	9,709,974
Testing (20.9%)	Area 5	42	11,257,240	240	128,538	370	1,365,228	9,763,474
Total		204	53,883,810	1,190	493,398	1,546	3,870,330	49,520,082

The number of the k -nearest neighbors of a point for EdgeConv layers is set equal to 20 following the suggested value by Wang et al. [30].

The training and evaluation results, including the overall accuracy and mean loss of defined cases, are presented in Table 4. Precision, recall, F1 score, IoU, and overall accuracy are calculated to evaluate detection results for the defined cases. The test results from the three samples of 3D point cloud semantic segmentation of adapted Dynamic Graph CNN are shown in Figure 3. The test results (Table 5) show the detecting recall for cracks for spalls for Case A (8,192 points) are 55.20% and 89.77%, respectively. Increasing the number of points from 8,192 to 12,288 improved the crack detection recall from 55.20% to 58.67%. However, this increase resulted in decreasing the spall recall from 89.77% to 87.40%, and non-defect recall from 97.17% to 96.64%. This is because increasing the number of points sometimes can cause overfitting.

Furthermore, as the depth of each segmented part are different, and the learning process depends on the maximum depth of the part's defects, the recall result of the tests is categorized based on the depth of segmented parts used in the test. As shown in Table 6, the parts with more than 7 cm depth can increase recall up to 80.04% for crack and 93.33% for spall.

5 Conclusions and Future Work

This paper proposes an approach using the 3D semantic segmentation technique and a modified Dynamic Graph CNN model to automate the inspection process of concrete surface defects, including cracks and spalls. The prepared dataset includes 204 segmented parts from four scanned concrete bridges in Montreal. Three types of segments (i.e. crack, spall, and non-defect) are annotated in the training dataset. The performance of the network is improved by modifying the setting of the network (e.g. modifying the loss function) and by augmenting the dataset (i.e. by flipping the point cloud data).

The case study shows the usefulness and robustness of the proposed method in detecting concrete surface defects from 3D point cloud data. The best test results show the detection recall for cracks and spalls are 55.20% and 89.77%, respectively.

The small size of the dataset is one of the main limitations of this paper, and a larger dataset is expected to improve the learning process resulting in better performance and accuracy of the model. Moreover, due to computing resource limitation (i.e. memory and processors limitation), it was not possible to study the effect of increasing the number of input points of the model to more than 12,288 and increasing the density of sampled points in each block by reducing the size of each

Table 4. Training and evaluation results

Case	Number of sampled points for each block	Block size (cm)	Training		Evaluation		Training time
			Mean loss	Overall accuracy (%)	Mean loss	Overall accuracy (%)	
A	8,192	40×40	0.0022	97.54	0.0081	97.50	13h 44m
B	10,240	40×40	0.0024	97.39	0.0090	97.65	16h 35m
C	12,288	40×40	0.0030	97.04	0.0082	96.88	20h 18m

Table 5. Testing results (%)

Case	Overall accuracy	Crack				Spalling				Non-defect			
		Precision	Recall	F1 score	IOU	Precision	Recall	F1 score	IOU	Precision	Recall	F1	IOU
A	95.94	69.98	55.20	61.76	44.68	79.30	89.77	84.2	72.72	98.54	97.17	97.85	95.79

Deep Learning-Based Entity Recognition in Construction Regulatory Documents

Phillip Schönfelder and Markus König

Department of Civil and Environmental Engineering, Ruhr University Bochum, Germany

phillip.schoenfelder@rub.de, koenig@inf.bi.rub.de

Abstract -

In the construction industry, contractors require precise knowledge of design restrictions originating from regulatory documents and contract specifications. For the automatic compliance checking of the building design regarding these rules, they have to be converted from the representation in natural language to a machine-readable format. This task, if carried out by human experts, is quite laborious and error-prone, and thus its automation is anticipated. A building block of this information extraction process is to find the key terms which carry the semantic information in each design rule. Named entity recognition, a sub-task of information extraction in the field of natural language processing, aims towards finding these entities in unstructured text and assigning them a label according to predefined classes. This paper presents a method based on a supervised deep learning transformer model, which is used to extract relevant terms from a corpus of German regulatory documents. It requires few training data, no user interaction and achieves weighted performance scores of over 95% precision and 95% recall, given that 12 unbalanced classes are specified. Additionally, it is investigated how different tagging schemes and model variations affect the classifier's performance. For future extensions, the class labels are chosen such that they can be linked to concepts already defined by Industry Foundation Classes. As part of this study, a training data set is created consisting of 2500 sentences from construction law documents, annotated with named entity tags.

1 Introduction

Building information modeling (BIM) offers great potential for the automation of processes in the architecture, engineering and construction (AEC) industry. One of these processes is the checking of the building design against rules and specifications from law documents, technical guidelines and individual contract requirements. For example, the building design must ensure accessibility and

meet appropriate fire safety measures, according to the respective regulations.

Automatic compliance checking (ACC) requires a BIM model to be checked on the one hand, and rule specifications in machine-readable format on the other. Regulatory documents are however written in natural language, and thus the rules must be transformed into logical, structured expressions to be processed automatically. Obtaining such logical expressions from these unstructured text documents is however a quite complex task. If carried out manually by domain experts, it turns out to be error-prone and time-consuming. Hence, the objective is to develop automated systems that perform rule extraction with a minimum of human interaction.

An important building block in this process is the extraction of relevant terms from the clauses found in legal documents pertaining to buildings, building parts, documents, organizations, material types, and other engineering concepts. These terms are called *entities* in the realm of named entity recognition (NER), a sub-task of information extraction (IE) in the field of natural language processing (NLP). Subsequent processes, such as the extraction of relations between entities or finding semantic triplets rely on the priorly detected named entities. [1]

Previous approaches of NER in the construction domain include Li et al. [1], who used a Bi-LSTM architecture with a self-attention mechanism to detect entities as part of their relation extraction procedure. Zhang and El-Gohary [2], renowned researchers in ACC, proposed an unsupervised-learning approach to link terms in the legal text to IFC concepts based on semantic similarity. As a numerical measure, they used the cosine similarity of the word embeddings. Recently, Moon et al. [3] used an architecture consisting of a Bi-LSTM and an on-top conditional random field (CRF) layer for NER in a variety of English regulatory documents, mainly standard specifications of US states. For the proposed six distinct entity classes, their method achieved performance scores of 91.9% precision and 91.4% recall. A similar architecture was employed by Song et al. [4], who report precision and recall scores of 39% and 68%, respectively, for a dataset in Chinese language. Zhong et al. [5] propose an end-to-end neural architecture to extract temporal constraints from Chi-

nese building codes. One of their involved process steps is to identify processes, objects and interval times by a NER algorithm based on a Bi-LSTM + CRF architecture. While many of the stated approaches achieve high performance scores and allow for the integration into promising algorithms, none of them has taken advantage of state-of-the-art transformer model architectures. However, for the purpose of classifying near-miss safety reports of the construction industry, transformer models have already been employed successfully by Fang et al. [6]. In this paper, a method is presented to find entities in unstructured regulatory construction documents and classify them with regard to selected Industry Foundation Classes (IFC) and a handful of generic classes. To achieve this goal, a state-of-the-art deep learning transformer model is trained with an annotated training set consisting of German public construction law texts.

The remaining part of the paper proceeds as follows: Section 2 lays out some of the most important background information about the tools used for this paper. Section 3 is concerned with data processing and presents how the existing transformer model can be extended to suit the task at hand. Section 4 addresses the experimental setup and includes detailed information about the learning algorithm. The results of the conducted experiments are displayed in Section 5. The findings are wrapped up in Section 6.

2 Background

2.1 Transformer models in NLP

Natural language is a form of sequential data and thus its processing requires adequate handling of data series. A frequently used tool in this regard are recurrent neural networks (RNNs), which inherently have the ability to process input data sequentially. With the advent of transformer models [7] in 2017, RNNs are being superseded by this new model architecture in many applications. Transformer models have the distinct advantage of being efficiently parallelizable and thus they can make use of GPUs, which reduces training times. This makes training on huge amounts of data possible.

A prominent example of transformer models is BERT (Bidirectional Encoder Representations from Transformers) [8]. Roughly speaking, it adapts the encoder part of the transformer architecture and stacks a total of twelve encoders, each with a hidden dimension of $H = 768$ per input token. This makes up to a huge model with roughly 1.1×10^8 weights. A high-level view of the architecture is displayed in Figure 1. At first, the input sentence is tokenized with respect to a fixed vocabulary tailored for BERT which consists of about 30 000 word and word piece [9] tokens. Words which are not in the vocabulary can be represented as multi-token words with the help

of word piece tokens. Since the vocabulary includes even single letters, every possible input word has a valid tokenization. The input sentence is allowed to have a maximum length of 512 tokens. Second, the tokens are mapped to word embeddings, i.e. vectors $\mathbf{u}_i \in \mathbb{R}^H$, which represent the contextual meaning of each token. These vectors \mathbf{u}_i are then fed into the first of twelve encoders. Each encoder consists of a multi-headed self-attention mechanism and a feed forward layer (i.e. multi-layer perceptron (MLP)). For a more detailed explanation of the inner workings of BERT, incl. normalization layers, positional encoding etc., the reader is referred to [7].

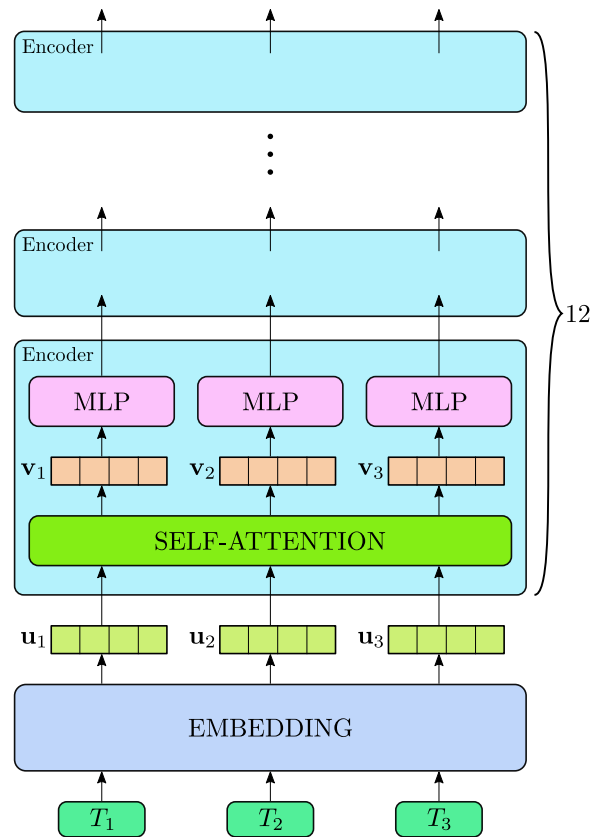

Figure 1. Simplified, high-level view of the BERT architecture [7, 8]. The word tokens are embedded and fed through twelve encoder blocks, each consisting mainly of a self-attention layer and a feed forward layer.

Since its release in 2019, BERT has gained great attention in the NLP community. There are two main reasons why BERT is chosen as a model for the conducted study: First, it shows superiority in performance compared to other model architectures in several NLP benchmark problems. It is particularly inspiring for this study that it outperforms the state-of-the-art NER models at the time

of its release. [8] Second, a large dataset is not necessarily needed in order to make use of BERT, since it is meant to be a model for transfer learning: pre-trained BERT models are already available for usage. They have been trained, in an unsupervised manner, with fake tasks such as next sentence prediction or masked language modeling. Large, plain-text corpora like Wikipedia or text books serve as a data source in this regard. These pre-trained language models require few additional training data if the task is only to fine-tune them with regard to a certain domain-specific language.

2.2 Industry Foundation Classes

Industry Foundation Classes (IFC) are a semantic standard [10] issued by the buildingSMART organization to aid in describing and exchanging building information in the AEC domain. Its purpose is to provide an interface for sharing data between different software tools. The IFC schema includes definitions of many construction related entities, as well as their properties and relations. These entities can be of varying nature: some describe physical parts of a building, e.g. IfcElements or IfcSpatialStructureElements, some describe more abstract things, e.g. IfcProcess, or even persons (IfcActor). An excerpt of the most general entities is shown in Figure 2.

3 Methodology

3.1 Data Preparation

In the conducted study, a text corpus is assembled from the public construction law texts of four of the 16 federated states in Germany. The documents are converted from PDF to plain text. Noise, such as page numbers, navigation links, etc., are removed manually where necessary. To subdivide the text according to sentence boundaries, the spaCy [12] sentence segmentation tool is used, which is based on sentence parsing. Since structural text elements such as headings or incomplete sentences do not carry any meaning, sentences with a word count below 15, including punctuation and special characters, are disregarded. All remaining clauses are full sentences and can be properly processed by the BERT model. The cleaned documents are annotated using the web-based annotation software INCEpTION [13].

3.2 Classification Scheme

The most typical entities to be detected by NER methods are generally terms like dates, documents, geopolitical entities (GPEs) and numerical values. For this study, in addition, some domain-specific entity labels are defined

as entities in accordance with IFC classes. With the purpose of providing a proof of concept, only some high-level classes are selected, e.g. IfcActor, IfcBuilding, IfcBuildingElement and IfcSite, since they occur most frequently in the text. Table 1 lists all of the selected class labels and gives a brief description of what is included in each class.

3.3 Preprocessing

Before a tokenized sentence is fed to the model, it requires adjustment to meet the expected input format. Unlike RNN-based models, BERT expects an input of fixed size which consists of exactly 512 tokens. Therefore, each sentence is tokenized with the specialized BERT tokenizer and surrounded by the special tokens [CLS] (indicates sentence beginning) and [SEP] (indicates sentence ending). Sentences exceeding the maximum input length of 512 tokens are truncated, shorter sentences are padded with [PAD] tokens.

The experiments are carried out using three different tagging schemes, two of which require further pre-processing of the tokenized sentence. Simple, token-wise tagging of entities does not require further pre-processing, but it generally leads to a classifier with a vague understanding of where multi-token words start and end. To combat this impreciseness, the tagging scheme can be enriched by the IOB (I = inside, O = other, B = beginning) or BILOU (L = last, U = unit/single token) label-prefixes. [14] They can be derived directly from the already tokenized sentence by simple logic rules.

3.4 Model Architecture

The output matrix of BERT is of size $L \times H$, with sequence length L and hidden dimension H , i.e. it consists of one vector $\mathbf{z}_i \in \mathbb{R}^H$ for each input token T_i , with $0 \leq i < L$. A dropout layer with a dropout probability of $P_D = 0.3$ serves as a regularization measure, and is placed directly after the BERT model [15]. Each vector is fed forward through a single dense layer with output dimension N_C , which is the number of distinct classes. Note that for each position in the sentence, the weights of these dense layers are equal and thus they do not count as separate parameters. Thus, it only introduces 9216 additional weights to the model, if $N_C = 12$, i.e. it hardly increases model size. To predict the label for each token T_i , the arg max function that follows the dense layer selects the label with the highest score, per vector $\mathbf{x}_i \in \mathbb{R}^{N_C}$.

Since the corpus at hand consists solely of German text, the GBERT model presented in [16] is used, which has been pre-trained on various German corpora amounting to more than 160 GB of text data. The model architecture itself is identical to the one proposed in the original BERT

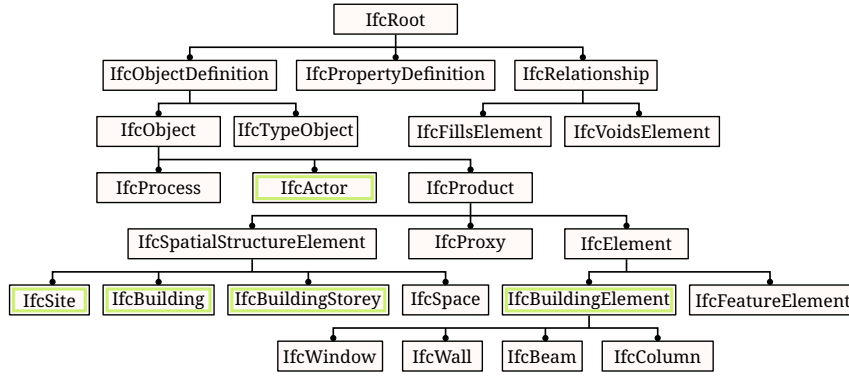

Figure 2. Partial view of the highest hierarchy levels of the IFC data model [11]. The highlighted classes are used for classification within this study.

Table 1. Performance scores of the model in the cross-validation experiment: model trained on all texts but one, and tested on the unseen model.

Class label	Key	Description, examples
IfcActor	ACT	organization, companies, persons
IfcBuilding	BUI	building types, e.g. schools, offices, or building definitions
IfcBuildingElement	BUE	building elements, such as doors, walls or windows
IfcBuildingStorey	STO	building story specification
IfcDate	DAT	temporal dates like "12.4.2013"
IfcSite	SIT	site of construction, dismantling etc.
IfcTransportElement	TRA	elevators, escalators, etc.
Document	DOC	certificates, assessments, official notices, etc.
Geopolitical Entity	GPE	countries, states, city states, etc.
Law Text	LAW	names of referenced law texts
Law Reference	REF	specifications of section/paragraph/clause in law text, e.g. "§ 70 Abs. 3"
Numerical Value	NUM	numerical value, possibly with unit, e.g. "7.5 m"

paper [8]. To investigate the influence of sheer model size, both GBERT_{BASE} and GBERT_{LARGE} are used as part of the model architecture in separate experiments and the test results are compared. This larger model's architecture is similar in concept, but more generous in terms of parameter count: it has 24 encoder blocks instead of 12, 16 attention heads per multi-headed attention block instead of 12, and has a hidden dimension of 1024.

4 Experimental Setup

To evaluate the performance of the proposed model, two experiments are conducted for this study:

1. **4-fold cross-validation:** To train a model on as much data as possible without compromising the amount of available test data, the model is N_D -fold cross-validated, where N_D is the number of documents. The sentence samples of $N_D - 1$ documents will be split up to parts of 90% training data and 10% validation data, while the sentences of the remaining document serve as test data.
2. **Training with little data:** To demonstrate the

model's performance in the case that only few sentences are annotated, it is trained on only one input text at a time and tested on all others. This emulates the situation of domain experts, who cannot spend many hours with the annotation of building design rules, but instead only annotate a small portion of the corpus. Each training document is split up in the ratio of 9:1 to form training and validation sets, respectively. The rest of the corpus serves as a test set.

For both experiments, all three tagging schemes mentioned in Section 3.3 are tested and the results are compared.

4.1 Error Measure

Assigning labels to tokens within a sequence of text is a multi-class classification problem for each of the tokens. As a suitable loss function, the cross entropy loss is selected. It is computed for each of the tokens T_i and summed up over the whole sentence. The model's outputs at those positions which have special tokens ([CLS],

Figure 3. Schematic illustration of the named entity recognition model architecture used in this study. The arg max layer is used for predicting the most likely label, while the vectors $\mathbf{x}_i \in \mathbb{R}^{N_C}$, $0 \leq i < L$ are used for loss computation.

[SEP] and [PAD]) as their input are not considered for loss computation.

Since only a small portion of words in the dataset are considered key terms, the number of unlabeled words is much higher than the number of actual named entities to detect. But even the classes themselves vary in size, which could lead to a biased classifier that favors more frequent class labels, especially the *no-entity* class. As addressed in [17], this class imbalance is a common problem in NLP and quite typical for NER tasks. As a remedy, a weighted cross entropy loss function is selected, and the loss is averaged with respect to each batch. For a given true class label C and the vector of logits $\mathbf{x} \in \mathbb{R}^{N_C}$, as predicted by the model, the loss is computed by

$$l_{CE}(\mathbf{x}, C) = w_C \left(-x_C + \ln \left(\sum_j e^{x_j} \right) \right) \quad (1)$$

where $\mathbf{w} \in \mathbb{R}^{N_C}$ is the vector of weight values assigned to each class label C . Since this loss function incorporates the negative log likelihood loss with the log softmax function, it expects raw output values from the model. Therefore, as shown in Figure 3, the model itself does not include any activation function. [18]

To calculate the weights w_C , the class label distribution in the respective training set is determined. Knowing the number of target labels occurrences per class t_C , the weights are computed by

$$\hat{w}_C = \sqrt{\frac{1}{t_C}} \quad (2)$$

and normalized by

$$w_C = \frac{\hat{w}_C}{\sum_{C=0}^{N_C} \hat{w}_C}. \quad (3)$$

This strategy introduces a higher penalty for the model whenever it predicts false-positives in the majority classes and a lower penalty for the model whenever it predicts false-positives in the minority classes, making up for the bias induced by the class-imbalance.

4.2 Learning schedule

In all training procedures of the described experiments, a constant learning rate of $l_r = 3 \times 10^{-6}$ is chosen. The batch sizes are $b_{\text{train}} = 16$, $b_{\text{val}} = 16$, $b_{\text{test}} = 16$ for training, validation and testing, respectively. The number of epochs has the upper limit of $E_{\text{max}} = 100$, however, to prevent overfitting, it advisable to follow an early-stopping strategy. In this regard, a good compromise between minimizing both the out-of-sample error and the training time is to stop training after three consecutive epochs with an increase in validation error. [19] The model with the best validation error up to this point is then selected as the trained model. This robust and efficient mechanism is used in all experiments.

5 Results

To account for the class label imbalance, all precision and recall values presented in this section, and consequently all F1 scores, are weighted with regard to class label occurrences. [20] Note that this can lead to an F1 score which is not between precision and recall. Table 2 summarizes the results of experiment 1. An averaged F1 score of 95.4% indicates the trained model's capability to be used for the task at hand. Even the lowest performance, if trained on a corpus of roughly 1900 sentences, was recorded to be 95.0% precision and 94.4%

Table 2. Performance scores of the model in the cross-validation experiment: model trained on all texts but one, and tested on the unseen text. Left column: ISO codes for the states of Germany whose building codes are included in the study.

Tested on	Precision	Recall	F1 score	Epochs
BE	0.958	0.953	0.955	18
BW	0.958	0.953	0.955	26
HB	0.950	0.944	0.946	36
HH	0.964	0.960	0.961	29
avg.	0.957	0.952	0.954	27

recall. Analogously, Table 3 shows the results of experiment 2. In comparison to experiment 1, the performance scores are, on average, slightly lower. This is plausible, as per training/test run, the model was trained on only one document instead of three. Nonetheless, even with such little training data, the model achieved averaged performance values of 93.5% precision and 92.6% recall.

In order to give a better insight into the incorrectly classified tokens, Table 5 displays the confusion matrix, created by accumulation of the confusion matrices of all token-wise labeling experiments listed in Table 2.

As it is of vital importance for the classifier to accurately detect entity beginnings and endings, its performance is examined for multiple tagging schemes. Table 4 shows some performance indicators obtained by experiment. As expected, the algorithm works best for the easiest of the addressed NER problems, i.e. without any tagging scheme. However, the results differ hardly if enhanced tagging schemes are used, as the average F1 score is 94.3% when using the IOB-scheme and also when using the BILOU-scheme. A greater discrepancy is the number of needed training epochs to achieve the stated performance scores: while training without any scheme is stopped, on average, after 27 epochs, it takes 31 epochs to train a model for the IOB scheme and 64 epochs for the BILOU scheme. In general, the learning curves are similar to the one displayed in Figure 5, which suggests that training for a few epochs might suffice to achieve almost saturated performance scores.

When using BERT_{LARGE}, the achieved F1 score is, on average, 0.2 percentage points lower in comparison to the results obtained with BERT_{BASE}. This shows, at least in this case and with the specified hyperparameters, the larger model is not worth the additional computational cost.

To give an idea of the produced output, an exemplary sentence with the detected entity labels is shown in Figure 4.

6 Conclusions

In this paper, a model architecture for NER mainly based on the pre-trained GBERT model is presented. When

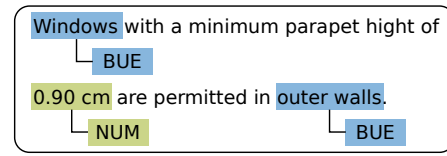

Figure 4. Example of analyzed sentence incl. the detected entity labels. Original sentence prior to translation: "Fenster sind in diesen Außenwänden ab einer Brüstungshöhe von 0,90 m zulässig".

Trained on	Precision	Recall	F1 score	Epochs
BE	0.919	0.910	0.913	34
BW	0.949	0.943	0.944	29
HB	0.938	0.927	0.930	41
HH	0.934	0.925	0.928	21
avg.	0.935	0.926	0.929	31

trained and tested on German public building code documents, average performance values of up to 95.7% precision and 95.2% recall are observed.

The main aspects of the conducted study are the following:

1. To the authors' knowledge, this is the first application of a transformer-based deep learning model to German text in the construction domain. The feasibility of the concept is proven and further development of processes based on the presented NER method is made possible.
2. In the course of the study, a data set is created which contains about 2500 sentences from German construction law documents. The clauses have been cleaned, processed for usage and have been manually annotated.

It is illustrated that the proposed model functions well, even with small amounts of training data. This makes it possible to use the model, with little annotation effort, as a building block in other processes. Possible applications could help with the automatic semantic enrichment of

Table 4. Average performance scores of the model with regard to the used tagging scheme.

Tagging scheme	Prec.	Recall	F1 score	Epochs

BIM models or with automatic rule extraction from legal documents in the construction domain.

A possible limitation of the method is that it might only work well within the given corpus of law texts, which are admittedly quite similar to each other. One could argue that the technical and legal terms in the construction codes are, by their nature, quite repetitive and that it is no surprise they are detected, since then the model basically acts as a string matcher. Therefore it remains to be examined if the model would indeed outperform such a rule-based approach.

Future works should include, first, a more fine-grained categorization of entities to fit more and also more specific entities in the IFC schema. This is necessary to produce an exhaustive mapping from terms in law clauses to IFC objects. Second, to extract information regarding the relations between those objects, the dataset needs to be extended by another layer of annotations and a second model has to be introduced to detect these relations. Third, a larger dataset should be created that contains all of the 16 federated state building codes, and also other

types of legal documents to examine the generalization of the trained model.

Abstract –

The construction site is prone to a considerable number of accidents due to its dense and complex nature. Accidents due to falling from opening at the construction site are leading reasons for severe injuries and sometimes fatalities. Openings and Holes are made on floors and roofs during the building construction or destruction. Despite being aware of the hazards associated with openings, gaps, and holes when working at heights, many workers fail to cover the openings or remove the covers for ease of work. The current inspection procedure relies on manual practices that are error-prone, time-consuming, expensive, and difficult for a site manager to monitor. Therefore, the authors propose a pull-reporting approach to resolve this issue by utilizing a computer vision detector model embedded in the android mobile to facilitate the safety manager. The proposed application uses YOLOv4 trained weights on a custom dataset obtained from the recorded videos at the Korean Scaffolding Institute with various view angles and various degrees of occlusion and data crawling techniques. The weights are then deployed on edge devices using TensorFlow API, Java programming, and maintain a real-time database of unsafe behavior. The developed system can identify, classify, and record the fully opened openings (FOO) and partially opened openings (POO) at the construction site along with geo-coordinates details in real-time.

Edge Computing; Worker Driven Approach; Construction Hazards; Trade Worker Safety; Safety Monitoring

1 Introduction

In recent decades, the construction industry has grown, resulting in higher firm profits, financial accessibility, and commodity demand. Despite its

prominence, it has long been recognized as one of the world's most dangerous industries due to its severe accident rate than other industries [1]. Falls from heights (FFH) are a severe construction industry issue [2]. According to research, FFH is responsible for around 48 percent of major injuries and 30 percent fatalities. Most FFH events occur due to the fully opened opening (FOO) and partially opened opening (POO) at the temporary supporting platforms, e.g., scaffolding and on-ground openings. There are several safety regulations and procedures in place to protect workers' falls from height; for instance, the gaps, holes, and openings should be covered so that the person working near the edges could be safe during his task.

Even though covering the openings and gaps is a legal requirement and employees are aware of their risk of falling, workers have shown a reluctance to utilize these regulations, as could be understood by many accidents that already happened in construction. Extra efforts besides their tasks and the constraints it imposes on mobility have been identified as the reasons for non-compliance.

The detection of wall openings is similar to the detection of slab holes. The location of the wall element must be considered in the special situation: whether it is an interior or exterior wall [3]. To avoid any fall, the wall opening should also be protected [3]. Construction and safety managers require realistic means to monitor and ensure that the openings, holes, and gaps are entirely covered with the desired strength material. On the other hand, the safety inspection procedure can be time-consuming and intermittently commenced because traditional practices rely on the push-inspection approach or manual inspection process where the safety managers enforce the safety rules through top to bottom monitoring style. Correspondingly, safety rule compliance about the hole, gap, and opening covering is challenging if done with the traditional practices, and the possibility of falls from height remains a severe hazard. Therefore, this paper presents an intuitive pull-reporting approach which means that the worker is involved in this process to report

to the safety manager by using an android-based application to automate the manual inspection process.

2 Literature Review

Construction sites have a distinct, dynamic, and complex working environment and non-standardized design and work processes that may expose employees to hazards. Researchers and experts in construction safety and health management have put a lot of effort into preventing falls from height[2].

Proactive and Passive strategies can be used to prevent and minimize the seriousness of injuries generated from FFH [4]. Preventative methods that focus on safety training and education are known as proactive methods. The creation of short-term training programs and implementation of specific fall protection training programs are two examples. Passive strategies are based on the analysis of fall accident data to build future preventive measures. For instance, using accident records and data from routine safety inspections to identify factors contributing to deadly occupational falls [4]. Fixed safety equipment (e.g., guardrails and opening covers), fall arrest systems (e.g., full-body harness), and travel restraint systems (e.g., belts); are FFH preventative measures generated from an examination of accident data. On the contrary, enforcing rules may boost the usage of safety protective equipment and is said to be a reactive strategy to address the safety issue.

Several researchers have been attracted to use computer vision in their fields, such as in the construction industry for worker safety monitoring, progress monitoring, and worker action recognition to automate the manual procedures at the construction site [4–9]. Therefore, computer vision-based methods have become widely used in project progress monitoring [8], productivity analysis [5, 6], and safety monitoring [10]. Recently researchers have been focusing on computer-vision-based safety monitoring of the worker. Khan et al. [1] proposed a Mask R-CNN-based detection algorithm to check the worker's safety while working on the mobile scaffolding and achieved an overall 86% accuracy on the testing dataset. Weili Fang et al. [10] used Mask R-CNN-based algorithm for the recognition of the unsafe behavior of construction workers traversing structural support during the construction. This approach first detects and segments the worker and support, and then an overlapping detection module is used to find a relationship between workers and structural support. [10] During the testing of the algorithm, they have achieved precision and recall of 75% and 90%, respectively.

Nath et al. [6] develop three Deep learning (DL) models on YOLO architecture for the detection of PPEs (hard hats and safety vests) from images. KNN search optimization technique was created by Heidari et al. [11]

to compute anchor positions that fulfill fall clearance and swing hazard.

Holes that pose a potential safety hazard(s) can be found inside buildings, on work platforms, on roofs, during roadway/bridge construction, in shops or warehouses, and other outdoor working environments. Roof ducts/drains, skylights, unfinished stairs or missing steps, unsupported ceilings/walkways, and manholes are some examples of holes/openings or gaps found on construction projects. Unprotected holes in the floor, deck, or roof have caused several serious injuries. However, falls through holes can be easily avoided with proper planning and the personal attention of the trade workers and safety manager.

3 System Development

This section presents the dataset preparation, model training, deployment on devices, and firebase database.

3.1 Dataset Preparation

A large amount of digital image data with various patterns is needed to train a vision intelligence-based detection model. As vision intelligence approaches emerge in the construction sector, obtaining labeling datasets from open-source websites remains difficult. Therefore, images of the hatch opening with enough variations were collected from three sources; (1) Google search engine, (2) random frames from YouTube videos, and (3) recorded videos in a Korean Scaffolding Institute. In this paper, different types of keywords for crawling techniques are used, such as "hole opening", "hatch opening", "partial opening on construction", "opening on construction site". As another source for image data collection, multiple videos have been recorded at the Korean Scaffolding Institute for FOO and POO in Seoul, Korea. Random frames were extracted using Fast Forward MPEG (Ffmpeg) tool in python. Data cleaning is an important step for the model's training; therefore, a two-step process is used for data cleaning to select the useful dataset to train, validate, and test the deep-learning model. The goal of the two-step process is to generate a useful dataset for the deep learning model. In the first step of data cleaning, unsuitable/unclear images such as incorrect exposure were removed.

There are eight simple techniques for avoiding overfitting, but two of them were used in this study: the Hold-Out and Data Augmentation [12]. The Roboflow platform was used to pre-process and label the 852 images. According to the Hold-out (data) technique, the total image data should be divided into train and test datasets. The common ratio is 80:20, but in this case, the Hold-out technique was used with a ratio of 87:8:5 for training, testing, and validation, respectively. Thus, image data from the training set of 1657 images, a test set

of 163, and a validation set of 80 images were retrieved. Data augmentation techniques such as crop, rotation, shear, hue, saturation, brightness, and exposure were applied to the training set to increase the dataset [12]. As a result of the augmentation process, the total number of image data after the augmentation is 1900 labeled images across the two classes (1) Opening, (2) partial opening. The dataset's labeling can be seen in the picture below:

Figure 1. Dataset Preparation

3.2 Model Training

Object detection with deep learning techniques has currently attracted many researchers worldwide, owing to its applications in our daily life. For example, business analytics, self-driving vehicles, face identification, and medical image analysis depend on object detection [13]. GPUs, CPUs, IoT devices, and embedded computers are needed to create these everyday applications. To detect FOO and POO on the construction site, the pre-trained YOLOv4 object detection algorithm is used. The blog [10] stated the rule of thumb is 1000 images for image

recognition, but this number can be reduced significantly in the pre-trained model. The YOLO is implemented in Darknet, an open-source framework written in C language, and Compute Unified Device Architecture (CUDA) is used for parallel computation. Darknet establishes the network's fundamental architecture and serves as the basis for YOLO training. This architecture is simple, fast to set up, and supports both Graphical Processing Unit (GPU) and Central Processing Unit (CPU) computation [14]. The YOLO (You Only Look Once) network is an algorithm that operates to detect an object in a single stage. It processes images with a single CNN and can measure classification results and object location coordinates directly. The detection speed has been significantly improved thanks to end-to-end object positioning and classification [15].

YOLOv4 network uses CSPDarknet53 for the image features extraction and network training. [16]. After that, Path Aggregation Network (PANet) was applied as a neck network to improve the extracted features fusion, and the head of YOLOv3 is utilized to realize object detection. Fig. 2 shows the architecture of YOLOv4. The key modules of the YOLOv4-based FOO and POO detection model are as follows:

- A convolution layer, a batch normalization layer, and a Leaky-ReLU activation function made up the CBL (Convolution, Batch Normalization, and Leaky-ReLU) module.
- Both the CBL and CBM (Convolution, Batch Normalization, and MISH) modules extracted the features. The difference was that the CBM's used MISH activation mechanisms instead of Leaky-ReLU [17].
- By splitting low-level features into two sections and then fusing cross-level features, the CSP (Center and Scale Prediction) module could improve CNN's learning ability [18].

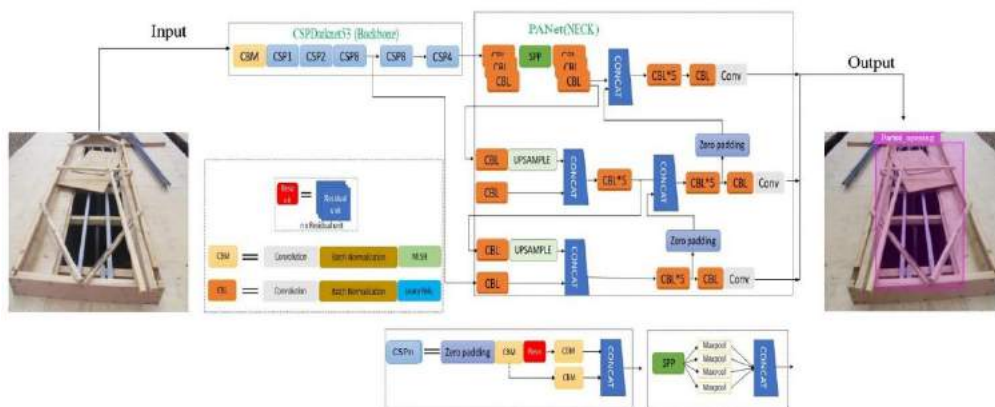

Figure 2. The architecture of YOLOv4 [19]

The POO and FOO detection based on YOLOv4; the main steps involved in the training are as follows:

- As mentioned above, this paper uses a dataset from three sources; (1) Google search engine, (2) random frames from YouTube videos, and (3) recorded videos in a Korean Scaffolding Institute. All the images are uploaded to the Roboflow platform to label the dataset into two classes, "opening" and "partial opening," with the ratio of 87:8:5.
- The batch size, learning rate, number of classes, mini-batch size, and the number of convolutional kernels in the previous layers are modified. For the detection of an object, the network input size was set to 416 pixels \times 416 pixels, the learning rate set to 0.00065, batch size to 64, mini-batch size to 16, the step size to 8000-9000, filters to 21, momentum and decay rate to 0.949 and 0.0005, respectively. The parameters used in the configuration file of the YOLOv4 are shown in Table 1. At every 10,000 steps, the training process produced several models; the best model fit was used in our testing and deployed on Android devices. The training, validation, and testing set were used for training, validation, and testing of the proposed model, respectively.

Table 1. Parameters of FOO and POO detection model

Parameters	Values
Input Size	416 x 416
Batch Size	64
Learning Rate	0.00065
Momentum	0.949
Decay	0.0005
Iterations	4000
Classes	2

The Loss curve during training is depicted in Fig. 3, and it can be seen that the model learning performance was higher, and the convergence speed of the training curve was faster at the beginning of the FOO and POO detection. The blue curve represents the training loss or error on the training dataset. The mean average precision at the 50% Intersection-over-Union threshold (mAP@0.5) is indicated by the red curve that determines if the model generalizes successfully on a previously unseen dataset or validation set. The graph shows that the model has the highest mean-average-precision score of 89 percent map (best model) during training at 3600th iteration, and the final map reported as 87.7% on the last iteration. The slope of the training curve steadily decreased after the 200 iterations in training. The number of training iterations and the training curve can be considered as

inversely proportional as training iterations increase, the training curve decreases.

Figure 3. Loss Curve

3.3 Deployment on Devices

This section describes the methodology for deploying the trained YOLOv4 model and converting the YOLOv4 object detection model to TensorFlow Lite for on-device inference. TensorFlow Lite consists of tools used for machine learning on edge devices such as smartphones and IoT. TensorFlow Lite is the TensorFlow framework designed to visualize inference on small devices, meant to avoid a round-trip data computation to and from the server capability of real-time detection and work without internet connection. [20]. Fig. 4 explains the process of FOO and POO object detection-based mobile applications. As we explained earlier about the dataset preparation and training, after that, the YOLOv4 based FOO and POO object detection model was deployed to an android application. There are two main steps to deploy a Deep Learning model on edge devices:

- The first one is converting the model into TensorFlow Lite format; For the conversion of YOLOv4 (TensorFlow model) into TensorFlow Lite, the TensorFlow Lite (TfLite) converter is used. TfLite converter takes the YOLOv4 (TensorFlow) model as input and generates the TfLite model (an optimized Flat Buffer format identified by .tflite file extension). During conversion, the quantization is applied to reduce the model size because the android studio cannot deploy a model that is larger than 250MB.
- The second essential step in the deployment is to Run inference. Inference refers to executing the model to make predictions based on input data, but

it requires Metadata. TensorFlow Lite metadata describes the model, including license words, input information (pre-processing), normalization, output information (post-processing), mapping labels. Normalization is a popular data pre-processing technique that converts values into a common scale without distorting differences in value ranges. As a result, the normalization parameter. In this case, the normalization parameters for each float model

though this is strengthened in a wall opening that should also be protected [3]. This information will then be uploaded to a database with the worker's current location (longitude and latitude)

The Geocoder API is used to determine the worker's current position using Geocoding process. The Geocoding process converts the addresses into latitude and longitude-based coordinates. These geocoded

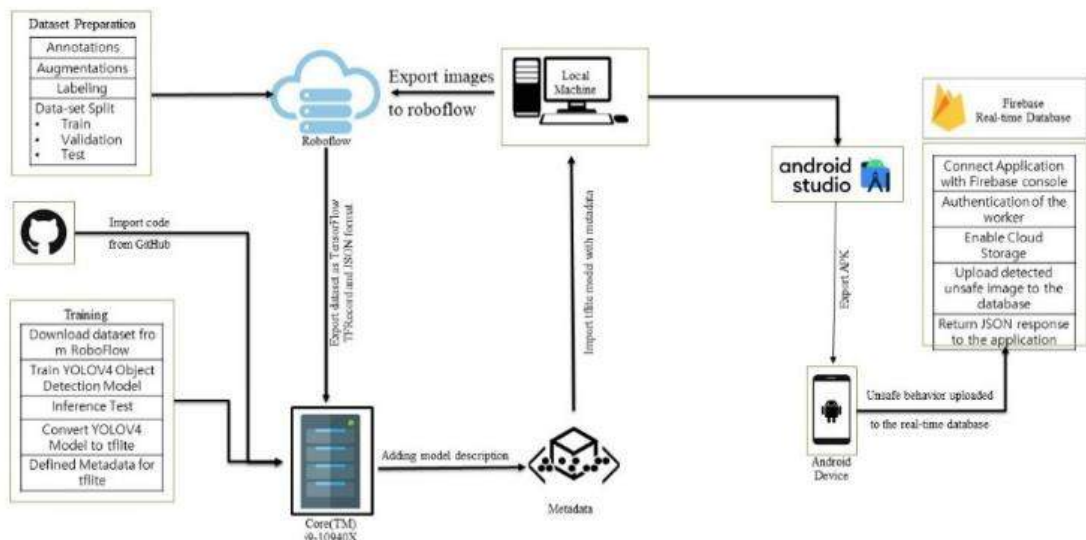

Fig. 4 Process flow of FOO and POO Detection

mean and standard deviation were 127.5. After that, the model is exported to an Android Studio[20].

-
- Now the quantized model is exported into an Android Studio Integrated Development Environment (IDE). The application is built on top of an open-source platform with a TensorFlow backend that was cloned from the GitHub repository. We have modified both the back end and the visual front end. In the backend, the real-time Firebase Database is used to record the unsafe behavior of FOO and POO on the construction site. This application encourages workers to be involved in this process, called a worker Driven approach or Pull-Reporting Approach. Supposing that the worker walks around the construction site, opens an application, and reports any unsafe activity associated with FOO and POO. The application may also recognize a vertical opening as a hole,

coordinates are further used for the placement of the markers on a map. The algorithmic component shows how the object identification and unsafe actions are uploaded to the Database using java language with android studio, as shown below:

Table 2. Algorithm

Title: Pseudo Code for FOO and POO detection

Input: Video Frames

Output: Detect Unsafe Behavior with current location.

1. Load the .tflite model and labels files from the assets folder.
2. Set Minimum Confidence = 0.5
3. Start Camera activity to get input.
4. Extract Frame from the video.

5. While (frame != 0):
 - Send frame to Detector class:
 - 1) If (Detected result != null and Detected result confidence >= Minimum Confidence):
 - i. Draw Rectangle on Detected frame
 - ii. Get the Current Location of the Worker using Geocoder API
 - iii. Get the Title of Detected Result
 - iv. If (Detected Result Title == "Opening"):
 - Upload Detected frame with the current location of the worker to the Opening folder in Database.
 - Return to step 4.
 - v. Else:
 - Upload Detected frame with the current location of the worker to the Partial Opening folder in Database.
 - Return to step 4.
 - 2) Else:
 - Return to step 4.
6. Close an application to stop the process.

First, to explain the algorithm, the TensorFlow Lite model is loaded, and the labels file from the assets folder

to perform object detection. The detected result confidence is compared with the minimum set confidence that is 0.5. The process of getting and passing frames to the Detector class operated continuously until the application close. The frames are being extracted from the video. An individual frame is passed to the Recognition function declared and defined in the Detector java class that returns the result. An algorithm compares the detected result confidence with the minimum confidence. The detector java class will process the frame if the detected result confidence is greater than the minimum confidence and will draw a rectangular box on the detected result. An application will get the worker's current location by using Geocoder API. Further, it checks whether the detected frame is labelled as "opening" or "partial opening" by comparing the label of the detected result. The detected result will be uploaded to the designated folder in the firebase database based on the mark, and this process will continue until the application is running.

Both options are provided in an application such as video detection as well as static image detection. Fig. 5 visualizes the four buttons, and if a worker clicks the gallery button, the gallery will open, and the user can pick an image; if the user clicks the camera button, the algorithm will identify the result and upload it to the designated folder with the current location of the Worker into Firebase database. Firebase notifies the worker that the data has been uploaded until the unsafe behavior has been registered.

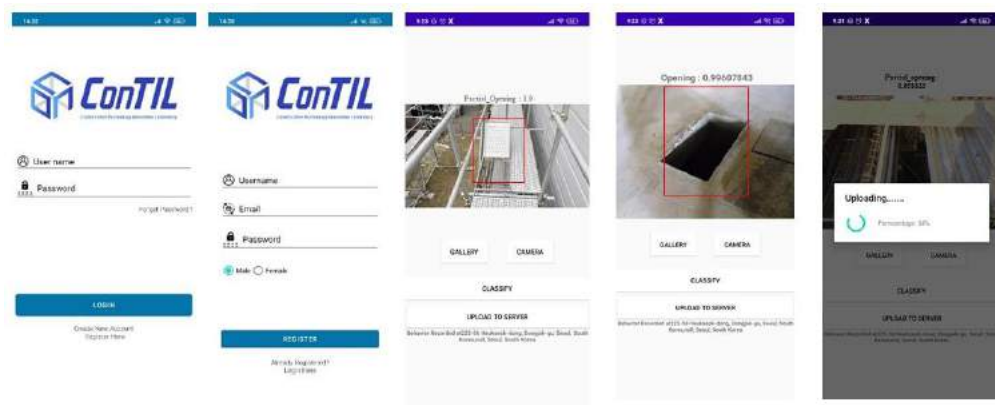

Figure 5. Android-based application

4 Results and Evaluation

To check the feasibility of the proposed model, the

validation set containing 80 images of fully opened openings (FOO) and partially opened openings (POO) were used. The results can be seen in Table 3 that presents the outcomes of the performance indicators used

to evaluate the proposed model. The qualified model has a recall of 82 percent and precision of 92.35 percent, with an overall mean average precision of 87.70 percent and an intersection over union of 76.40 percent (IoU). The test data produced promising results, and the model was chosen to detect data from actual construction sites. The results demonstrated that the model could achieve high precision on real-time data.

Table 3. Performance Matrices of trained model

Evaluation Indexes	Test Results
Precision	92%
Recall	82%
Average IOU	76.40%
mAP	87.70%
F1 Score	86%
Average Loss	0.86

5 Conclusion

In this paper, the authors propose a pull-up reporting approach based on an android operating system to detect FOO and POO on the construction site to overcome the manual inspection process. YOLOv4 detector is trained on our custom pre-processed dataset and then later converted to the TensorFlow lite model by using TensorFlow API to deploy and perform inference on the edge devices. The qualified model shows that our developed application can perform better and facilitate the automation process of construction site management. The trained model has an F1 score of 86% percent, which shows how accurately our model performs predictions on the custom dataset. Moreover, a rewarding functionality and more case scenarios such as missing planks and missing guardrails would be added to the application to reward the worker who facilitates the safety manager in identifying risk at the construction site.

Abstract –

Snowplowing is critical to winter road operation and maintenance since it can improve driver's safety and mobility. The goal of this study is to generate optimal routes for snowplowing that can reduce travel distance and improve efficiency by considering operational constraints. To achieve this goal, we first adopted the Chinese Postman Problem to generate initial routes to be Euler circuits, and then the shortest path was generated using Dijkstra's algorithm. For an optimization process, the tabu search algorithm as a meta-heuristic approach was applied to find near-optimal routes by optimizing the order of precedence of snowplow routes, and the minimum maintenance standards and turn directions were considered as a constraint of the defined objective function.

Through a simulation study, we compared routes generated by different approaches in terms of total travel distance, turning restriction, and road maintenance priority.

Keywords –

Snowplow optimization; Chinese Postman Problem; Tabu search algorithm; MMS; Dijkstra's algorithm

1 Introduction

In many Canadian municipalities, the snowfall is sufficiently heavy to require the use of large, costly snowplowing vehicles to remove it. A slight delay in the schedule can result in the formation of thick sheets of ice that worsen public travel safety. In extreme circumstances, storm drains become blocked, and transportation is brought to a halt. However, municipalities need to spend a considerable amount on annual expenditures to provide an acceptable level of snowplowing service. One of the promising solutions to deal with this problem is to identify optimal routes for snowplow trucks that can allow the desired level of

service quality to be maintained while improving efficiency and reducing costs.

Since snowplowing is a complex process, there are various factors to be considered that have a direct influence on formulating optimal routes to reduce operational costs. The representative examples of these factors include the number of trucks, deadhead, fuel consumption, and time travel [1].

To deal with this combinatorial optimization problem, mathematical optimization techniques can be a tool to design efficient and optimal routes for snowplowing [1, 2]. In the earlier studies on snowplow routing, Malandraki and Daskin formulated the maximum Chinese Postman Problem, which allowed each arc to be visited multiple times in order to derive a snowplow route [3]. The authors in [4] proposed a hierarchical optimization method in which the high-priority roads are served first.

Kinable et al. compared mixed-integer programming with constraint programming to evaluate the effectiveness of the heuristic algorithm that was used for the problem of optimizing the routes [5]. A heuristic approach based on network clustering and capacitated vehicle routing was proposed by [6], which deals with ice and snow control.

These studies have not included complex real-world constraints fully, so a more sophisticated approach is needed to optimize routes while accurately representing actual operational conditions. As an actual constraint that needs to be further considered, Minimum Maintenance Standards (MMS) [7] is the required service time that municipalities in Ontario must meet to remove ice and snow according to the defined roadway class. The number of ways (e.g., 1- or 2-way street) and turning direction are also key constraints that can restrict the generation of optimal routes and affect efficiency in snowplowing. Therefore, this project aims to propose an advanced and practical optimal routing strategy for residential snowplowing services that can identify optimal routes, and thus generate the least costs while considering various operational constraints that

have not been fully considered in the existent studies.

For this, Chinese Postman Problem (CPP) [8] and Dijkstra's algorithm were applied to generate initial routes and shortest paths, respectively. The tabu search algorithm [9] was used to find near-optimal routes by optimizing the order of precedence of snowplow routes that can satisfy the MMS and turn directions as a constraint for the optimization process.

This paper is divided into five sections. In Section 1, the complex process of snow plowing is described and existing studies are discussed. Section 2 discusses data gathering and processing for route generation. Section 3 elaborates on the applied methodologies, which include the defined objective function, CPP, and tabu search algorithm. The simulation results are presented in Section 4 along with a comparison between the generated routes. Section 5 includes a summary of the findings and recommendations for future research.

2 Data Gathering and Processing

This section describes the process of gathering and processing the geographic data necessary to generate the initial route for each truck.

For the data gathering, OpenStreetMap (OSM) [10] was selected, which is a free editable map of the world, created by a community of mappers. To begin gathering data, a map of the targeted municipality (Clarington) was extracted from OSM using the QGIS [11] software, as seen in Figure 1.

Figure 1. Map of the targeted municipality

Since trucks have designated areas, the next step is to extract the individual truck routes on Clarington's network using the map in Figure 1.

The routes for one of the operational trucks in the OSM and Clarington's network are shown below as an example.

Figure 2. Routes of a truck in OpenStreetMap (a) and corresponding ones in the Clarington's network (b)

The attributes from the city's network, including roadway class, number of ways, etc., were transferred to the OSM routes. Using a complete set of initial data (OSM routes) for each truck that is required for optimal routing, shapefiles were generated to apply the optimization algorithm.

3 Methodology

3.1 Problem Description and Objective Function

The route optimization problem considered in this study is a classical route inspection problem, which can be described using several parameters as follows.

Let $G(V, E)$ be a strongly connected multigraph where $V = \{v_0, v_1, \dots, v_n\}$ is a set of nodes including the depot location, v_0 and $E = \{(v_i, v_j) : v_i, v_j \in V, i < j\}$ is a set of directed edges. Nodes represent intersections in the road network, while edges represent road segments.

Each edge $e = (v_i, v_j) \in E$ has a non-negative travel cost, c_{ij} interpreted as the travel distance. t_{ij} is the travel time for each road segment.

Another variable introduced in this study is the accumulated time, $T_{ij} = \sum t_{ij}$ that sums up each t_{ij} . Each edge should be traversed at least once and deadheading (i.e., act of traversing an edge without service) should be minimized.

Each node contains the geographical information of longitude and latitude that is used to calculate the heading angle and the number of turns.

Each road segment is given the priority of road class, $X_{ij} \in P$ that is denoted by the range of $P = \{1, \dots, p\}$ where the roads in class 1 have a higher priority than the rest of the roads. Often, the priority class of a road is determined by its traffic volume. As a result, highways have a higher class than residential roads due to their higher traffic volume.

To meet the MMS, we defined an objective function that yields a higher value for servicing higher-class roads first as compared to servicing in reverse order. Figure 3 demonstrates how to calculate the values for the two opposite cases to deal with the MMS. Since a

higher value is desired to satisfy the MMS, our objective function for the optimization process was set to provide an optimal solution when it maximizes its output. In the objective function, we also penalize it whenever left-, U-, and sharp right turns occur since these types of turns need to be avoided for safety and efficiency. In this paper, the calculated value of the objective function is referred to as the fitness value. The finalized objective function is given in Eq. (1).

$$\max (\sum X_{ij} T_{ij} - a * \sum Left_{turns} - b * \sum U_{turns} - c * \sum SharpRight_{turns}) \quad (1)$$

where a, b, c are coefficients.

Figure 3. Comparison of routing sequence for the MMS: Routing sequence for higher class roads (a) and lower class roads (b)

In order to count the left-, U- and sharp right turns, we distinguish each type of turn by defining its angle range (Figure 4). This angle is calculated relative to a heading. When the truck reaches an intersection, the angle between this intersection and the next one can be calculated using cosine laws.

3.2 Chinese Postman Problem

After translating the snowplow problem into the language of graph theory and defining our objective function and constraints, the next step is to address the Chinese Postman Problem (CPP), a well-known problem in graph theory. When given a connected undirected weighted graph G , the CPP computes a minimum cost-closed path that contains all edges at least once.

Figure 4. The defined angle ranges for each type of turn

The pseudocodes for the CPP algorithm are presented in Figure 5 and each step will be explained with the results presented in Section 4.2.

Chinese Postman Problem - Pseudocodes
Input: An undirected connected graph $G = (V, E)$
Output: A (CPP) tour $T = (n_1, e_1, n_2, e_2, \dots, n_1, e_1, n_{i+1} = n)$
Step 1: Determine if G is Eulerian
Step 2: If G is Eulerian, obtain an Euler – tour T
Step 3: If G is not Eulerian, find a minimum – cost augmentation of G to construct an Eulerian multigraph G' , and let T be an Euler – tour of G'
Stop

Figure 5. A pseudo algorithm for the Chinese Postman Problem

An Eulerian graph is a closed path that uses every edge of a graph exactly once. Figure 6 shows a simple example of a conversion of a non-Eulerian graph to an Eulerian. Figure 6 (a) is a non-Eulerian graph while Figure 6 (b) is the minimum-weight expansion of the non-Eulerian graph to make Eulerian. In the figure, every double edge in the graph represents a backtrack. From the assumption that node 1 is the starting and ending node for the closed tour, a possible solution obtained by applying the CPP algorithm is $T = (1, 2, 4, 5, 6, 5, 7, 3, 4, 3, 2, 1)$ with a total length of 24 by summing up the length of edges (i.e., the distance between nodes) to travel.

Figure 6. Non-Eulerian graph (a) and minimum-weight expansion of the non-Eulerian graph (b).

3.3 Tabu Search Algorithm

Tabu search is a meta-heuristic optimization technique for optimizing model parameters. Similar to other metaheuristic algorithms, the tabu search algorithm starts with an initial solution and progresses iteratively by searching immediate neighborhoods. During the search process, a set of predefined local search schemes and unique memory structures are used to prevent a solution from getting stuck in a suboptimal trap. The pseudocodes of the tabu search algorithm implemented in this study are provided in Figure 7 [12].

The tabu search algorithm relies on three main factors, namely, short-term memory, long-term memory, and tabu list. The short-term memory prevents the algorithm from generating the previously generated solution and hence intensifies a search. The long-term memory performs diversification to search into new regions and prevent a solution from being stuck in a suboptimal dead-end. By containing all the previous solutions, the tabu list facilitates the short-term memory to track the previously visited solutions.

The next step was to generate efficient neighborhoods with the help of the permutation process after finding the initial route. Once an optimal solution is selected among the newly generated neighborhoods, it is verified whether the generated solution is better than the initial one. If a better solution is found, the permutation process is repeated to find another set of different neighborhoods; otherwise, a different combination of routes is searched through the procedure of merging and separating edges.

Algorithm 1 Tabu Search Algorithm

Input: An initial solution of truck routes, maximum iteration number, length of tabu

Output: The possible improved truck routes

Step 1: Initialization

Set

Current solution=Initial solution

Current value=Initial value

Best solution=Initial solution

Best value=a large number

Maximum number of iteration=a large number

then

 Best solution=Current solution

 Best value=Current value

 add current solution to tabu list

end if

end while

end for

Figure 7. The logic flow of the tabu search algorithm

3.4 Dijkstra's algorithm

To find the shortest path between the nodes (intersections), Dijkstra's algorithm was implemented [13]. Dijkstra's algorithm maintains a set of vertices whose final shortest-path weights from the source (depot location in our case) have already been determined. The algorithm repeatedly selects a vertex with the minimum shortest path estimate and relaxes all edges leaving the selected vertex. Since Dijkstra's algorithm is a single-source shortest-path problem on a weighted and directed graph, it matches exactly with the snowplowing routing problem described in this study.

4 Results and Discussions

This section provides an explanation of the results along with an analysis of them. Specifically, the generation of a network topology from initial routes will be discussed first, and then, the results obtained by applying the CPP algorithm are presented. Finally, the results obtained with the optimization algorithm are discussed.

4.1 Network Topology Generation

Using the NetworkX library [14], the initial routes generated with OSM and QGIS were converted into a network topology in Python.

A network topology of one of the service trucks is

shown in Figure 8 in the Python graphing format, where the nodes are labeled with their node IDs.

Figure 8. Network topology in the Python graphing format.

4.2 Results Obtained Using the CPP Algorithm

Following the generation of the network topology, the CPP algorithm was implemented to create Euler circuits for each truck. The CPP algorithm first identifies all odd degree nodes, then and adds backtracks (edges) to make them even nodes in order to generate an Eulerian graph (circuit).

To achieve an Eulerian graph, the CPP follows three steps. The first step is to compute all possible pairs of odd degree nodes as seen in Figure 9. The second step is to calculate the shortest path between nodes that can be achieved by applying Dijkstra's algorithm to minimize the distance for backtracking [15]. Hence, this step plays a critical role in achieving optimal routes. Figure 10 shows a complete graph connecting every node with the shortest path through the second step.

The final step in the CPP algorithm is to add backtracks to the original network. Once we have the information about the roads entailing backtracking, the original map is updated by including the backtracked edges that are highlighted in blue in Figure 11.

Figure 9. Pairs of odd degree nodes

Figure 10. The shortest path among pairs of odd degree nodes

Figure 11. Backtracks added to the original network

4.3 Results of Optimization Algorithms

Table 1 presents the values for major variables assumed during the optimization process. For the MMS, the roadway should be serviced within the required time set out in the table (i.e., original time in a parenthesis for each road's class). However, since the service area covered by only one truck was considered for simulations, the shortened time was applied instead of the original application time. For example, the original applicable time of 4 hours for road class 1 was assumed to be 1 hour instead.

To administer the optimization process, it is required to calculate the fitness value of each route. The routes with the highest fitness value qualify for the next iteration of optimization. The optimization was conducted for 10 iterations.

In Table 2 presenting simulation results, the route in the first column (Route 1) was obtained as a reference route by the application of the CPP and Dijkstra's algorithm. The route in the second column was generated using a combination of the CPP with Dijkstra's algorithm and the tabu search optimization.

The tabu search algorithm can generate optimal solutions by swapping the neighboring nodes in the permutation process. Therefore, for the second column

route (Route 2), neighboring nodes were swapped at nodes where at least three roads (edges) are connected.

Table 1. Assumptions for the optimization process

Matric	Assumed Value
Vehicle speed	35 km/h
Truck areas	Clarington
Number of trucks	1
Applicable time for road class 1	1 hour for simulation (original time: 4 hours)
Applicable time for road class 2	2 hours for simulation (original time: 6 hours)
Applicable time for road class 3	3 hours for simulation (original time: 12 hours)
Applicable time for road class 4	4 hours for simulation (original time: 16 hours)
Applicable time for road class 5	5 hours for simulation (original time: 24 hours)
Number of lanes	Both single and multi-lanes covered

The fitness value is affected by the number of left-, U-, and sharp right turns, and MMS (see Eq. (1)). If a route has the highest value of $\sum X_{ij} T_{ij}$ regarding MMS with the fewest number of these turns, this is considered the best optimal route.

In the table, while Route 2 has one more left turn than Route 1, there are fewer U-turns and roads failing to meet the MMS in Route 2 than in Route 1.

Therefore, Route 2 provides a safe and practical solution by minimizing undesirable turns and considering the required service time based on MMS. In addition, both the total travel time and distance of Route 2 are slightly shorter than those of Route 1.

The fitness values in Table 2 take into consideration of both the above operational constraints and traditional issues of travel distance and time. Hence, the highest fitness value of Route 2 implies that this is the optimal route by providing the best overall performance that eliminates unfavorable turning directions and achieves the shortest total travel time (i.e., the shortest distance for backtracking with Dijkstra's algorithm) simultaneously.

In Figure 12, the roads that are serviced within the designated service time are labeled as 1, and those that do not meet this requirement are labeled as 0.

In the optimal route, a starting node for service was selected based on the shortest distance from the depot location. This will allow a truck to travel the shortest

distance to reach its designated service area. Figure 13 indicates the location of a starting node for the truck considered in this study that guarantees the shortest distance to the depot.

Table 2. Comparison between the routes obtained from simulations

Routes	Route 1: CPP	Route 2: CPP + Optimization
Fitness	-20	60
Total travel Time	1h 17min	1h 15 min
Total travel distance (km)	63.4	62.9
Left Turns	21	22
U-turns	12	9
Sharp Right Turns	0	0
Number of roads (edges) failing to the MMS	4	3

Figure 12. The satisfaction of MMS is indicated on the map

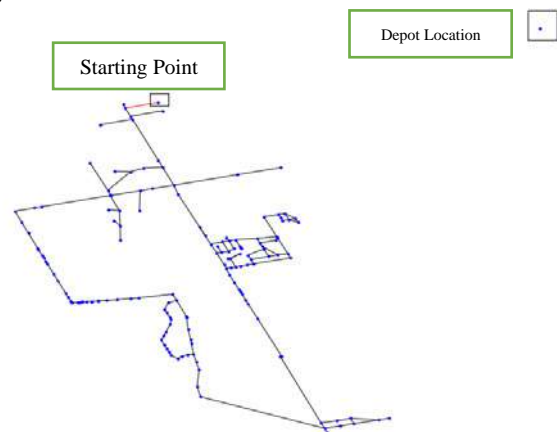

Figure 13. Locations of the starting node and depot for the truck under consideration

5 Conclusions

The main objective of this project is to optimize the routes of residential snowplowing services. For this, an initial network topology was generated using the GIS data from the OSM that includes the city network's attributes. Then, the CPP with Dijkstra's algorithm and the optimization process with the tabu search algorithm were applied to generate an optimal route.

In the defined objective function for the optimization process, the MMS and penalty for unwanted turning directions for safety and efficiency were considered. Therefore, the generated optimal solution represents the route that can satisfy the shortest travel time and the MMS requirement as well as minimize the number of deadheads and unpreferred turns.

Since our study was limited to simulation results, it is required to validate the proposed method through field tests by considering the real-time dynamic routing situations and on-site weather conditions.

The project focuses on the improvement of the current service efficiency by optimizing the route sequence. Therefore, as future work, we can create new routes by reassigning roads to further reduce the total travel distance in the entire service area and to balance the workload between truck drivers.

Abstract –

In civil infrastructures such as buildings, bridges, and tunnels, cracks are initial signs of degradation, which affect the structure's current and future performance adversely. Optimum maintenance plans in terms of cost and safety are important to evaluate the degree of deterioration of a structure. Manual inspection is usually performed, and cracks detected during inspections could help the inspectors to understand the damaged state of the concrete structures. However, these inspections are costly, laborious, and easily prone to human error. An automatic and fast crack detection at the earliest stage is crucial to avoid further degradation of the structure. In the past decades, various deep learning techniques have been introduced by researchers to automate the crack detection task. This paper introduces a deep learning-based multi-model ensemble approach for crack detection in concrete structures. The proposed architecture consists of five different customized convolutional neural networks (CNN) trained on data set created from two public datasets. The dataset consists of 8400 crack and non-crack images having a resolution of 224 * 224. Detailed experiments show that the majority voting ensemble technique shows better performance for crack detection in concrete structures. The accuracy of the individual CNN models 1, 2, 3, and 4 is recorded to be 95%, 96%, 95%, and 97%, respectively, while the accuracy of the ensemble techniques is recorded to be 98%.

1 Introduction

Cracks are one of the first signs of degradation in any

civil infrastructure, which requires proper attention and inspection in a timely manner. Traditionally, a team of experts carries out a visual inspection to check if there are any defects (cracking, spalling, defective joints, corrosion, potholes, etc.) in structures and report them for proper maintenance. Visual inspection is challenging and expensive, time-consuming, and laborious as it requires several trained professionals for the inspection. Moreover, visual inspection is not always reliable; failure to detect problems at the earliest stage can lead to disastrous effects. To overcome these limitations, a computer vision-based system is alternatively used to aid civil engineers during the inspection of concrete structures.

Normally, a vision-based crack detection system takes images as an input and gives them to the crack detection algorithm for classifying and localizing the cracks. The input images can be acquired using a digital camera, Unmanned Ariel Vehicle (UAV), or a smartphone. Most of the early crack detection systems are based on image processing methods such as thresholding [1], edge detection [2], filtering [3-6], fuzzy [7,8], percolation [9], and region growing [10]. However, the accuracy of these approaches heavily relies on the image focal length, quality, and capturing environment. Machine learning-based crack detection methods have improved the weaknesses of the rule-based approaches and can be categorized into traditional and deep learning approaches.

In traditional approaches, various features such as mean and variance [11], histogram [12,13], texture [14], Local Binary Patterns (LBP) [15] and multi-features [16] are extracted from the images. The obtained features are then given to various classifiers such as Support Vector Machine (SVM) [17,18], Decision Tree (DT), Genetic Algorithm [20], and various other classifiers for evaluation purposes. Feature extraction is a challenging task as it requires domain knowledge to extract the relevant information from the images which reflect the

actual cracks.

To overcome the limitation of traditional approaches, an automatic feature learning technique such as deep learning is used, which automatically extracts useful features from raw images. Deep learning models have shown enormous performance in solving various concrete crack detection problems [21-23][33]. Zhang et al. [24] proposed CNN architecture consisting of six layers for crack detection in pavement structures using one million image patches of size 99×99 . The patches are obtained from 500 images having a resolution of 3264×2448 collected by using a smartphone. Wang et al. [22] trained a five-layered CNN architecture for crack detection in pavement structure using 760 K image patches. Ali et al. [23] combined CNN architecture with a sliding window approach for crack detection and localization in pavement structure using 4k patches created from images acquired by using an unmanned aerial vehicle (UAV). Similarly, Cha et al. [25] performed CNN-based crack detection and sliding window-based crack localization in concrete structure using 40k images. Xu et al. [26] used 6k images and 28 layered end-to-end CNN architecture for crack detection in bridge structures. Pauly [27] investigate the effect of network depth on the performance of the pavement crack detection model and showed that network generalization ability could be enhanced by increasing the network depth. Zhang et al. [28] proposed CrackNet, a five-layered CNN architecture capable of detecting cracks in 3D asphalt surfaces at the pixel level. Due to the high computational time of the network and difficulty in detecting thin cracks, the authors improved the architecture by proposing CrackNet II [29], which can detect hairline cracks and has low processing time.

Transfer learning models make CNN more applicable with less computational cost. Transfer learning models make CNN more applicable without incurring high computational costs or necessitating knowledge of how CNNs work. Gopalakrishnan et al. [30] developed a pavement crack detection model using pre-trained VGG 16 architecture using a small amount of training data. The proposed transfer learning model outperformed previous CNN models in terms of reliability, speed, and ease of implementation. Zhang and Chang [31] developed a

pavement crack detection system using an Image-Net pre-trained model and 80k image patches. Wilson et al. [32] proposed a robust concrete crack detection model system based on the VGG-16 model using 3.5k images acquired by using UAV.

Although several deep learning algorithms are available for crack detection in concrete structures, however, none of them is completely accurate, and each method makes errors during prediction. It is still difficult to decide on the architecture and parameters of each model. Individual models may perform well for one classification task but not for another. Ensemble classifiers, on the other hand, aggregate the predictions of numerous independent models into a single prediction depending on criteria such as majority voting, unweighted and weighted average, and so on. Training multiple models and combining their predictions may result in better performance than individual models because the ensemble classifier explores a larger solution space from the set of individual classifier predictions. Therefore, this paper presents an ensemble classifier based on five different individual customized CNN models. The detailed experiments are evaluated on a dataset consisting of 8400 crack and non-crack images having a resolution of 224×224 . The results are validated on different performance metrics such as accuracy, precision, recall, and F-1 score.

2 System Model and Assumptions

The proposed system is comprised of the three modules listed below:

- (1) Database Creation
- (2) Ensemble CNN modeling
- (3) Classification Results.

In database creation, data is prepared and given as an input to CNN models built from scratch with varying parameters. The predictions obtained from the multi CNN models are combined by using ensemble methods such as Majority voting, weighted and unweighted average. Each module is discussed in detail below.

Figure 1: Overview of the proposed system

2.1 Database Creation

The dataset in the proposed system is created from publicly available datasets by Özgenel [34] and Dorafshan [35]. The main reason for combining the two datasets is to provide enough variance in the dataset's samples. The dataset consists of 16.8K image patches having a dimension of 224*224 pixels. As shown in Table 1, the patches were chosen at random from the datasets, with the split ratio for the training, validation, and testing sets being 60:20:20. Manual labeling was done for the crack and non-crack classes, each of which has an equal number of image patches.

Figure 2: Samples of crack and non-crack patches in the dataset

Table 1: Total number of samples used in Training, validation, and Testing

Data	Training data		Validation Data Testing Data	
	Crack	Non-Crack	Crack	Non- Crack
16.8k	5.6k	5.6k	1.4k	1.4k

2.2 Convolutional Neural Network (CNN)

CNN is the most widely used deep learning network. CNN mainly comprises convolutional, activation, and pooling layers. The main function of these layers is to introduce non-linearity, extract relevant information (features) from input images and reduce its dimensionality to enhance network generalization. The function of each layer is described in detail below.

2.2.1 Convolutional Layer

CNN's convolutional layer extracts useful information from images and preserves the spatial relationship between its pixels. The filter slides over the image pixels, add them together and add bias to it to obtain the output feature vector as shown in Equation 1.

$$O = \sum(I_{k \times k} + W_{k \times k}) + Bias \quad (1)$$

The convolution operation is performed on the input receptive field $I_{k \times k}$ where k represents the size of the kernel. $W_{k \times k}$ represent the filters weights which will be

convolved over the input image, and B represent the filter bias. The obtained feature map is given as an input to the activation layer.

2.2.2 Max-Pooling Layer

The max-pooling layer performs a down sampling operation on the input array to reduce its dimensionality. The max-pooling layer divides the input array into small non-overlapping blocks and considers the maximum value of each block which helps in the reduction of model parameters and computational time.

2.2.3 Activation Layer

The activation layer performs an elementwise operation on the features coming from the convolutional layer to set the non-negative values to zero. This layer also introduces non-linearity to the feature map to ensure its usability. The mathematical operation of the activation layer is depicted in Equation 2 below.

$$\sigma(I) = \max(0, I) \quad (2)$$

Where I represents the input feature vector.

2.2.4 Fully Connected Layer

The fully connected layer takes the results of the convolutional and max-pooling layer and performs logical inference on it. The input is flattening from 3D to 1D before giving as an input to the fully connected layer. The mathematical operation of a fully connected layer is shown in equation 3.

$$O_{V_o \times 1} = W_{V_o \times V_i} I_{V_i \times 1} \cdot B_{V_o \times 1} \quad (3)$$

Where O represents the output, V_i and V_o shows the size of the input and output vector. Additionally, the weight and matrix biased are represented by W and B .

2.2.5 Softmax Layer

The softmax layer is located at the end of the CNN architecture and is used for the prediction of classes. The softmax layer takes a vector of scores $x \in S^n$ and calculate probabilities $P \in S^n$ from the input scores. The mathematical operation is shown in Equation 4.

$$P = \begin{pmatrix} P_1 \\ \vdots \\ P_n \end{pmatrix} \text{ where } P = \frac{e^{x_i}}{\sum_{j=1}^n e^{x_j}} \quad (4)$$

Multiple models have been used in the proposed work. The summary of each model is shown in Table 2.

2.3 Ensemble Modelling

Ensemble CNN model consists of individually trained CNN models, which combines the prediction from multiple models to classify a new instance. In the proposed work, five different customized CNN models are used, and the predictions are aggregated to improve the system accuracy. Firstly, all the CNN models are trained individually on the same training data, and then the models are combined together for accurate prediction.

In the proposed work, three model different model combination techniques have been used: Majority voting, unweighted and weighted ensemble, as explained in detail below. The overall process of ensemble modeling is explained in Figure 3.

Figure 3: Representation of Ensemble Modeling process.

2.3.1 Majority Voting

In majority voting, the prediction of each model for a sample of data is known as a vote. The prediction having the majority votes from all the models is considered as the final prediction of the ensemble model. Suppose the prediction of CNN 1, 2, and 3 is label 0 while the prediction of CNN 4 and 5 is label 1. Then, the final prediction of the ensemble model is label 0 because of the majority votes. The mathematical representation of majority vote probabilities is shown in Equation (5) and (6) below.

$$\hat{P}_i = \frac{\sum_{j=1}^n M(P_{ij})}{n}, i = 1, 2, \dots, m \quad (5)$$

$$\text{Where } M(P_{ij}) = \begin{cases} 1 & \text{if } P_{ij} = \max(CNN(j)) \\ 0 & \text{Otherwise} \end{cases} \quad (6)$$

Equation (2) combines all the votes assigned by the CNN model to j . n represent the total number of voters and are used for normalization purposes. In the majority voting approach, each input image will be assigned a class, and the vote of every model is considered equally without looking at their individual accuracies.

2.3.2 Unweighted and Weighted Ensemble

In an unweighted ensemble, the final prediction of the model is the average of the outcomes of all the CNN models. Averaging outcomes of CNN models decrease variance between them and increase the generalization ability of the ensemble model. The averaging of the CNN models' output is shown in Equation (7) in detail.

$$P_i^k = \text{softmax}^k(O_i) = \frac{o_i^k}{\sum_{j=1}^n \exp(o_j^k)} \quad (7)$$

In the above equation, n represent the number of classes, P_i^k is the output probability for unit i in class k ,

O_i^k is the output of k^{th} CNN model for i^{th} unit. In a weighted ensemble, weights are assigned to voters. The model is considered based on weighted majority voting and the sum of weighted probabilities. The weights to the voters are adjusted either by looking at their accuracies or by considering them as parameters and performing the optimal adjustment.

3 Experiments and Results

The experiments were performed on the dataset explained in section 2.1. The ensemble model consists of five different CNN models having different architecture and parameters, as shown in Table 2. CNN models and their ensembles are evaluated based on their accuracy, precision, recall, and F score as shown in Equation (8), (9), (10), and (11), respectively.

$$\text{Accuracy} = \frac{TP+TN}{TP+FP+TN+FN} \quad (8)$$

$$\text{Precision} = \frac{TP}{TP+FP} \quad (9)$$

$$\text{Recall} = \frac{TP}{TP+FN} \quad (10)$$

$$F_{1\text{ score}} = 2 \times \frac{\text{Precision} \cdot \text{Recall}}{\text{Precision} + \text{Recall}} \quad (11)$$

TP (True Positive) and TN (True Negative) values show the correctly identified crack and non-crack samples, while FP (False Positive) and FN (False Negative) represent the incorrectly identified crack and non-crack samples. All the experiments were performed using python programming on an Alienware Arura R8 core i9-9900k CPU @3.60 GHz desktop system with 32 GB RAM and an NVIDIA GeForce RTX 2080 GPU. The number of epochs for all the models was chosen 20 as the loss of all the models reach a minimum level, and there was no further improvement in the model's accuracy. In the proposed work, five different CNN architectures were trained for 20 epochs which results in 100 trained networks. The best-performing trained network of each model was selected based on the evaluation metrics, as shown in Table 3.

In the proposed work, all the CNN architectures were built from scratch, and their various parameters were fine-tuned to achieve high performance. A comprehensive visual evaluation of all the CNN models was performed, the training and validation loss curves were plotted as shown in Figures 4, 5, 6, 7 and 8. The confusion matrices of all the models are summarized in Table 3.

In CNN model 1, the number of parameters is 1.19 million, and the number of convolutional layers and max-pooling layers are 3 and 3, respectively. The accuracy

and loss graph of the training and validation of CNN model 1 is shown in Figure 4. In the graph, both the training and validation curves show little divergence, which shows that the model is not subjected to overfitting. The testing accuracy, precision, recall, and F1 score of CNN model is 0.928, 0.982, 0.921, and 0.951, respectively, as shown in Table 3.

Similarly, CNN model 2 consists of 6 convolutional and 5 model max-pooling layer. The architecture has a total of 0.92 million papers. The accuracy and loss graph shows that the architecture has less tendency towards overfitting, as shown in Figure 5. The testing accuracy, precision, recall, and F1 score of the CNN model 2 is 0.970, 0.994, 0.971, and 0.983, respectively.

Figure 4: Training and Validation of CNN model 1 (Accuracy and loss graphs)

Figure 5: Training and Validation of CNN model 2 (Accuracy and loss graphs)

Figure 6 shows the accuracy and loss graph of training and validation of CNN model 3. The graph shows no signs of the model overfitting. The architecture of model 3 consists of 4 convolutional, 4 max-pooling, and 0.32 million parameters. The testing accuracy, precision, recall, and F1 score of the model is 0.953, 0.996, 0.950, and 0.973 respectively. Moreover, the number of parameters in CNN model 4 is 0.11 million. The architecture consists of 5 convolutional and 5 max-pooling layers.

Figure 6: Training and Validation of CNN model 3 (Accuracy and loss graphs)

The accuracy and loss graph of CNN model 4 shows no overfitting, as shown in Figure 7. The testing accuracy, precision-recall and F score of the model are 0.966, 0.995, 0.967, and 0.981, respectively.

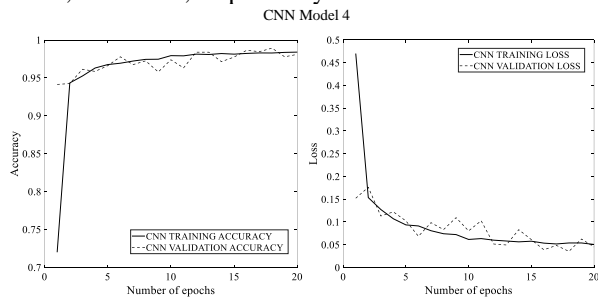

Figure 7: Training and Validation of CNN model 4 (Accuracy and loss graphs)

Moreover, the architecture of the CNN model 5 consists of 3 convolutional and 3 max-pooling layers and is having 0.83 million parameters. The accuracy and loss graph of the training and validation of the model is shown

in Figure 8. The testing accuracy, precision, recall, and F score of the model is 0.976, 0.981, 0.982, and 0.974, respectively.

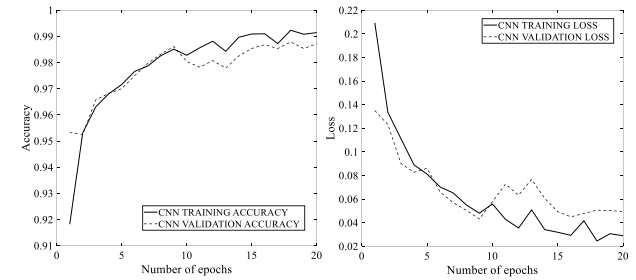

Figure 8: Training and Validation of CNN model 5 (Accuracy and loss graphs)

It can be seen from Table 3 that CNN model 2 and 4 outperform all the individual models in term of accuracy, precision, recall, and F1 score. The combined ROC curve of all the models is shown in Figure 6 below. To improve the accuracy further, ensemble modeling is used. In ensemble modeling, all the ensemble models i.e. the majority voting, unweighted average, and weighted average ensemble classifiers, achieved better results than individual models. The majority voting ensemble classifier achieved the highest testing accuracy of 0.991 with precision, recall, and F1 score of 0.996, 0.985, and 0.990, respectively. The testing accuracy, precision, recall, and F1 score of unweighted average ensemble classifiers are recorded 0.989, 0.995, 0.982, and 0.989, respectively. The testing accuracy of the weighted ensemble classifier is 0.990, which is slightly higher than the unweighted ensemble classifiers. Also, the value of precision-recall and F1 score of the weighted ensemble classifier is 0.997, 0.982, and 0.989, respectively.

4 Discussion

In the proposed work, a multi-model ensemble classifier is presented. The ensemble model combines the prediction of various customized CNN models by using various ensemble techniques such as the majority voting, unweighted average, and weighted average. The dataset is made from two publicly available datasets and contains 16.8k crack and non-crack patches. It can be seen in Table 3 that the ensemble models show better performance as compared to individual classifiers for crack and non-crack classification. The proposed models successfully achieved above 98% to classify between crack and Non-crack patches. It is found that all the proposed ensemble models achieve the best accuracy, precision, recall, and F1 score in comparison with the individual CNN models. The performance of individual CNN models (CNN Model 1, 2, 3, 4, and 5) are comparable with each other.

Table 3: Overall Experimental Results

Model	Confusion Matrices			Testing Accuracy	Precision	Recall	F score

Figure 7: ROC curve (receiver operating characteristic curve) of all CNN individual models

The proposed model has the capability to enhance the performance of individual deep learning models and is very useful in the automatic detection of concrete cracks. The proposed framework is designed from a combination of less computational CNN architectures. The proposed system can be modified by adding more damage types of concrete structures in the dataset. The proposed framework can be easily used for a real-time robotic video inspection system. One of the drawbacks of the proposed system is its dependance on the base CNN models. If the accuracy of one of the models is degraded the overall accuracy will be affected.

5 Conclusion

In the proposed work, a new deep learning-based ensemble classifier is proposed by combining the predictions of various CNN models. The performance of the proposed Ensemble classifier is compared with individual CNN architectures in terms of testing accuracy, precision, recall, and F1 score. For the dataset creation, two publicly available datasets are selected and combined to provide variance between data samples. Extensive experiments were conducted by training individual CNN models to investigate their performance. The prediction from these models are then combine or ensemble to improve the performance of Concrete Crack Detection Model. From the experiments and above discussion, it can be concluded that the proposed multi-model ensemble classifier can be used for crack detection in concrete structures. As the current study was based on crack detection in static images, therefore, in the future, we are planning to explore crack detection in video streams of concrete structures using end to end deep learning techniques.

Abstract –

As construction projects resume worldwide and workers return to the job site, the possibility of transmitting the Covid-19 could be added to the extensive list of risks confronting workers in the construction sites; thus, the workers need to work alone in an assigned activity. Many workers are already working alone in the construction sites, such as utility workers, repair technicians, teleworkers, operators, and drivers. Lone workers in construction are subjected to greater safety risks compared with those working alongside others. Considering the accidents faced by lone workers, it's less likely that another person would be there to aid them - and if they don't get treatment quickly enough, serious injuries might prove deadly. Currently, the construction sites depend on physical inspections to the construction sites and manual observation of video streams generated through close circuit television (CCTV). To solve this issue, this research work presents an automated deep learning-based fall detection system of a lone worker to provide information of severe situations and help the workers in their golden time. A diverse dataset of multiple scenarios having workers with the excavator, forklift, ladder, and mobile scaffold is established, and a deep learning algorithm has been trained to validate the concept. The developed system is expected to reduce the efforts being made in manual inspection, enhance the timely access of the due aid from co-workers and supervisors, which is more easily obtainable in non-lone working situations.

Keywords –

Deep Learning; Covid-19; Construction Hazards; Worker Safety; Lone Person Fall

1 Introduction

Despite limited access to timely assistance, lone workers independently cope with potentially risky

situations such as extreme weather conditions, tools, and equipment failure. If alone the injured worker receives aid promptly, the injuries could turn out to be fatal, among other accidents in a construction job site. Fall accidents are common and severe accidents that can happen anywhere on a construction site. Even if workers fall from a low height (1m or 2m), it frequently results in significant mishaps, probably death.

Substantial efforts are being made to significantly reduce fall accidents in Korean construction job sites and enhance construction safety management. The extensive efforts include quality safety education, advanced safety training, high-elevation work management rules, and the use of fall prevention protective equipment. As per the Korea Occupational Safety and Health Agency (KOSHA)'s industrial accidents and analysis (2009 to 2017), fall accidents in the construction industry represent a considerable share of 47.7% to 52.1% [1]. This tendency was also observed in various countries, including the United States [2], Singapore [3], Norway [4], and Hong Kong [5].

Consequently, falls from great heights have received extensive research attention and have become an essential topic in the construction industry. Construction workers are prone to weariness, drowsiness, and loss of balance, increasing safety risks and fall accidents due to their severe physical needs and irregular lifestyle (e.g., alcohol, misuse, night shifts, and insufficient rest interval). However, most of the studies focused on safety facilities and PPE inspection; this only helps reduce the severity of damages rather than providing quick aid and timely assistance when a fall accident happens. Therefore, this research work presents the inevitable approach to detecting a person in falling conditions, which will ultimately help employers automatically monitor lone workers and respond timely to any falling accidents.

The current stage of computer vision application in the construction industry is covered in Section 2. Section-3 describes the dataset and model development. Section-4 includes evaluating the developed model using the

performance indicators to validate the feasibility and practicality of the proposed system's for actual implementation. A conclusion is included at the end of the work.

2 Literature Review

Despite the efforts of researchers, safety specialists, and strict enforcement of safety rules, construction accidents, and fatalities have not appreciably decreased. Falls are a significant public health concern worldwide and one of the leading causes of severe and fatal injuries among construction workers. Researchers and experts in construction safety and health management have devoted tremendous efforts to prevent falls [6]. Proactive and passive strategies such as safety training education and preventive measures on safety accident analysis are developed to prevent and minimize the severe injuries generated from FFH [7]. For instance, using accident records and data from routine safety inspections to identify factors contributing to deadly occupational falls [7]. Fixed safety equipment (e.g., guardrails and opening covers), fall arrest systems (e.g., full-body harness), and travel restraint systems (e.g., belts); are FFH preventative measures generated from an examination of accident data. However, the social distancing regulations imposed by governments worldwide lead many workers to deal with assigned activity solely, and the construction workers already working alone are comparatively facing a greater risk of injuries. Considering the accidents faced by lone workers, it's less likely that another person would be there to aid them - and if they don't get treatment quickly enough, serious injuries could become a fatality.

Researchers have leveraged recent technological advancements to automate safety management procedures. Until yet, very little attention has been devoted to protecting the lone worker accidents generated through FFH. Sensor-based technology has garnered a lot of attention in recent decades for monitoring PPEs worn by construction workers [8,9], such as activity recognition [10,11] and safety of the construction workers [9,12–16]. In particular, most FFH prevention studies used sensors to detect risky behaviour to avoid FFH accidents by analyzing workers' motions, body positions, and walking patterns [17–19]. Furthermore, many researchers have developed methods to detect workers' actions and body postures using wearable sensors' signals [10,20]. Yang et al. [10] Yang et al. [10] investigated workers' behavior patterns from three angles: while conducting the lab experiment, they attached the sensor to the workers' waist and recorded acceleration and angular velocity.

The system's accuracy in predicting unsafe behavior, was 98.6% and 60.9 percent, respectively. Owing to construction site complexity, the prediction model had a hard time distinguishing behaviors related to moves that

weren't in the training data. Furthermore, most sensor-based monitoring devices possess issues concerning noise, precision, loss, and errors in the data they acquire.

Apart, In the recent decade, several researchers have been attracted to use computer vision in their fields, such as the construction industry for worker safety monitoring, progress monitoring, and worker action recognition to automate the manual procedures at the construction site. Recently researchers have been focusing on computer-vision-based safety monitoring of the worker [6,21–25]. A growing number of recent studies in the construction industry have focused on using CNN-based methods, such as Faster R-CNN, R-FCN, SSD, Retinanet, YOLOv3 for detecting workers, faces to recognize non-certified persons, non-hardhat-use, equipment for activity recognition, guardrails, PPE for steeplejacks [6,24–26]. Fang et al. [27] developed a deep learning-based approach to detect non-hardhat users in a construction site. Fang et al. [6] developed an automated approach to detect safety harnesses to prevent heights falling using double-layer CNN. Likewise, Ding et al. [28] presented convolution neural networks (CNN) and long short-term memory (LSTM) that automatically identify unsafe behavior by detecting humans climbing on a ladder. Khan et al. [23] proposed Mask R-CNN-based algorithm to monitor the worker's safety while working on the mobile scaffolding. Weili Fang et al. [29] used Mask R-CNN-based algorithm to recognize the unsafe behavior of construction workers traversing structural support during the construction. Nath et al. [30] developed three Deep learning (DL) models on YOLO architecture to detect PPEs.

Despite these efforts being made to integrate the computer vision for an intelligent construction site, considerable efforts are required to extend the computer vision application in the construction industry. Currently, the construction sites around the globe is recommencing again, and the workers are joining back the construction job site. The possibility of transmitting the Covid-19 could be another risk confronting by the workers in the construction sites; thus, the workers need to work solely or on a distance from another worker to complete the given tasks. Moreover, many workers are already working solely in the construction sites, such as utility workers, repair technicians, teleworkers, operators, and drivers. As we all know, lone workers in construction are subjected to greater safety risks than those working alongside others. Contemplating the lone worker's mishaps or severe accidents, the probability of helping another person would be less in that situation - and if they don't get first-aid quick enough in their golden times, these serious injuries might result in death. Currently, the construction sites depend on physical inspections to the construction sites and manual observation of video streams generated through close circuit television

(CCTV). Correspondingly, this research study has tried to put efforts on the appropriate and exceptional use of the provided rich information generated through digital data. Thus, this research proposed a deep learning-based worker's fall detection system, enhancing timely access to due aid from co-workers and supervisors.

3 System Development

This section includes a comprehensive discussion on dataset Preparation, deep learning model selection, and Model Training. The dataset preparation part focuses on establishing scenarios, digital data collection, cleaning, and finalizing the data for ultimate deep learning. The appropriateness and feasibility of the deep learning model specific to lone person detection are stated under the subsection (deep learning model selection). The model training section stipulates the specification adopted during the training process of the deep learning model.

3.1 Dataset Preparation

A considerable amount of digital image data with diverse patterns is needed to train a vision intelligence-based detection algorithm. As vision intelligence technologies emerged recently in the construction industries, collecting labeled datasets from open-source websites remains problematic. Therefore, images and multiple videos for lone person detection with enough variations considering scenarios with ladder, forklift, Excavator, and Mobile Scaffolding have been recorded at the Korean scaffolding institute in Seoul, Korea. Random frames were extracted using Fast Forward MPEG (FFmpeg) tool in python. FFmpeg is an open-source software package that comprises many libraries dealing with audio, video, and other multimedia files. The inappropriate images such as (irrelevant) and duplicate images from the same scenes were removed from the dataset during the dataset cleaning process.

The decisive image data of 799 images were uploaded to the roboflow platform for pre-processing and labelling. A total of 2037 annotations were labelled across the six classes in the dataset (1) Person Falling, (2) Worker, (3) Ladder, (4) Forklift, (5) Excavator, and (6) Mobile Scaffolding. The dataset was separated in the following ratio: 91:4:5. As a result, 1857 images from the training set, 80 images from the validation set, and 100 images from the test set were gathered for further experiment.

As mentioned in the literature section, the deep learning models required large enough data for training to correctly identify and recognize the interested objects. The data augmentation techniques have been utilized to increase the image data. Apart from dataset maximization, data augmentation techniques increase the accuracy of deep learning models. According to a conducted

experiment [31], a deep learning-based model with image augmentation outperforms a deep learning model without image augmentation in terms of training loss and accuracy and validation loss and accuracy for image classification tasks. In the augmentation process, we have performed flip (Horizontal), shear (15°), hue (between -25 to +25), and brightness (between -19 to +19) on the training set to increase the dataset. After the augmentation process, the total number of image data is increased to 2037 images. The process of labeling the dataset is exhibited in the below figure (see Figure 1).

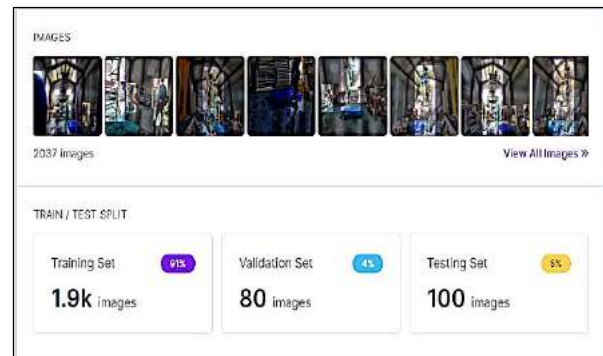

Figure 1. Dataset establishment in Roboflow platform

3.2 Deep learning Model Selection

In recent years, cutting-edge technology has been used in computer vision applications to detect resources. The previous efforts reported two primary categories of object detectors: single-stage object detectors and double-stage object detectors. Depending on the problem to be solved, one could choose among them (single-stage or double-stage object detector). The main difference between a single-stage and a two-stage object detector is that a single-stage object detector's output can be acquired after the first CNN (Convolution Neural Network) operation. The high-score area proposals obtained from the first-stage CNN are typically passed to the second-stage CNN for the final prediction in the case of the double-stage object detector.

The inference times of single-stage and double-stage detectors could be defined as:

$$T_{\text{one}} = T_1^{\text{st}} \text{ and } T_{\text{two}} = T_1^{\text{st}} + mT_2^{\text{nd}}$$

The above equation defines m as the number of area recommendations with a confidence score greater than a threshold. In the case of real-time object detection, the single-stage object detectors are preferred to use because the inference time of the single-stage detectors is constant but for the double-stage object detectors are variable [32]. Consequently, in our case, a real-time object detection of the lone falling person on the construction site is significant to report and assist them as soon as convenient.

Therefore, this research work adopted a recently emerged single-stage object detector type named as Scaled-YOLOv4 algorithm. The model scaling technique is an important approach for effectively detecting objects with significant accuracy and real-time recognition on numerous kinds of devices, such as embed devices, while minimizing computing resources. The most common model scaling techniques are the depth (convolutional layers' numbers in a CNN) and width (convolutional filters' numbers in a convolutional layer) of the architecture's backbone. A deep learning-based algorithm (scaled YOLOV4) for object detection was recently published as an addition to the pool of detection techniques integrating scaling techniques. This scaling technique showed significance in terms of performance on small and large networks without compromising the

and YOLOv4-P7 [32]. The structure of YOLOv4-P5, YOLOv4-P6, and YOLOv4-P7 is depicted in Figure 2. The authors of the Scaled YOLOv4 have performed the compound scaling of the architecture backbone on size input, stage, and width scaling. The inference time is used as a constraint for the additional width scaling of the architecture backbone. The authors conducted experiments on the MSCOCO-2017 dataset to validate the proposed scaled-YOLOv4-large, and the results show that the YOLOv4-P6 can achieve real-time performance at 30 frames per second (when the width scaling factor is set to 1) and the YOLOv4-P7 can achieve the real-time performance of 16 frames per second (When scaling factor of the width is 1.25) [32]. As a Result, scaled YOLOv4-large is selected to detect lone person falls on a construction.

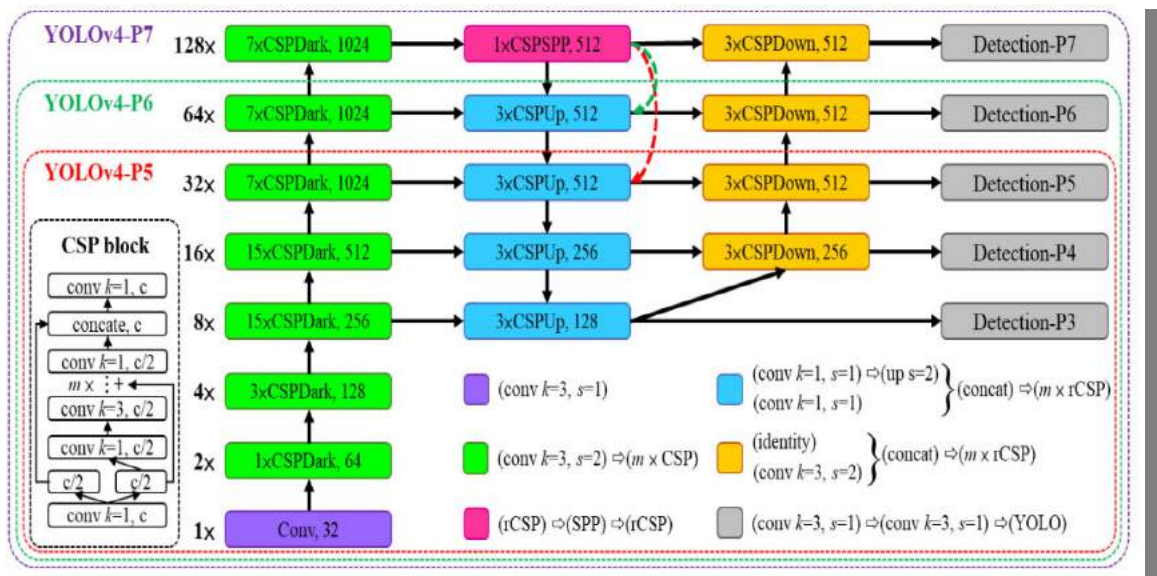

Figure 2 System architecture of YOLOv4-large, with YOLOv4-P5, YOLOv4-P6, and YOLOv4-P7 [32]

model's performance [32].

The authors of the Scaled YOLOv4 manuscript have designed a different version of the Scaled YOLOv4 for low-end GPU, and high-end GPU, and the general GPU. The YOLOv4-CSP is re-designed of the original YOLOv4 for the general GPUs with high performance and accuracy. The authors designed YOLOv4-tiny with a simpler structure and reduced parameters to make it feasible for the development on mobile and other edge devices (Andriod, etc.). YOLOv4-large is designed for the high-end GPUs such as cloud servers, the main goal of proposing this is to achieve high accuracy while minimizing training time and achieving efficient performance. A fully CSP-ized model has been created named as YOLOv4-P5 and scaled it up to YOLOv4-P6

3.3 Model Training

The experiment was conducted using an open-source Scaled YOLOv4 GitHub repository. The required repository of YOLOv4 was clone to the colab environment, all the dependencies, such as the torch mish activation function for Cuda, were imported. The training of the model is performed using Intel Core i7 9th generation with NVIDIA GeForce RTX 2080Ti. The hyper-parameters of the Scaled YOLOv4-large can be seen in the given Table1. To perform detection, we have modified hyper-parameters in the configuration file so that the step size is set to 9600,10800, the learning rate to 0.0026. The momentum and the weight decay were set 0.949 and 0.0005, respectively. Maximum batches were

set to 12000, and the epochs were set to 1000. An iteration indicates a specific change to a model's weights, while an epoch, on the other hand, determines one iteration across the whole dataset.

Table 1. Parameters of Scaled YOLOV4

Parameters	Values
Input Size	416 x 416
Batch Size	16
Learning Rate	0.00261
Momentum	0.949
Decay	0.0005
Iterations	1000
Classes	6

4 Results and Evaluation

The feasibility of the trained lone person fall detection model is tested with the different performance indicators. The model test and evaluation are performed on test and validation dataset. The Figure 3 reveals the correctly detected results of the lone person falls. The developed model successfully detected all the objects in a given testing and validation dataset. The efficacy of the trained model is quantified using mean average precision (mAP), a single numerical number that indicates the effectiveness of the entire system in object identification (and information retrieval). Other evaluation matrices such as Precision, Recall, are also used to check the performance of the developed system.

Figure 3. Detected Results of the Trained Model

4.1 Precision

The number of true positives (Tp) divided by the number of false positives (Fp) plus the number of true positives (Tp) makes precision (P) value of the model. False positives (Fp) are instances where the model mistakenly identifies something as positive when it is truly negative. Precision actually measures how many of the predicted positives were truly positive. It is mathematically denoted as follows:

$$P = \frac{Tp}{Fp + Tp} \quad (1)$$

The below figure (see Figure 4.) shows the precision (48.5%) of our proposed model. As we detect the person falling, the precision and recall could be adjusted by selecting an optimum point on the precision-recall curve.

Figure 4. Graphical representation of precision matrix

4.2 Recall

A recall expresses the capacity to discover all relevant instances in a test dataset. Recall (R) measures how many true positives were successfully found. Simply, the number of true positives (Tp) is divided by the number of false negatives (F_N) plus true positives (Tp). The mathematical form of recall can be written as:

$$R = \frac{Tp}{F_N + Tp} \quad (2)$$

Recall (83%) of our proposed scaled-YOLOV4 based model is depicted in the Figure 5.

4.3 F1-Score

The F1-score is a metric for how accurate a model performs on a given test data. It is commonly applied to examine binary classification algorithms that categorize examples as either "negative," or "positive". The F-score, which is defined as the

harmonic mean of the model's recall and accuracy, is an average of combining the recall and precision of the model.

$$F1 - Score = 2 \cdot \frac{(Precision) \cdot (Recall)}{(Precision) + (Recall)}$$

The F1-score observed during the experiment was 60.82%.

Figure 5. Graphical representation of recall

4.4 Mean Average Precision

The average of Average Precision (AP) is called mAP (mean average precision); mAP allows you to demonstrate the overall system's usefulness as a single numerical value. The following Figure 6 shows the mAP calculated when the Intersection of Union IoU was set to 0.5 and the mean average precision (mAP) obtained in this case was 72.5%.

Figure 6. Graphical representation of mAP at 0.5

The following picture shows the mAP calculated on the different IoU thresholds ranging between 0.5 to 0.95

and achieved 37% mAP (see Figure 7.).

Figure 7. Graphical representation of mAP at 0.5 to 0.95

5 Conclusion

This research work introduced, developed, and evaluated a deep learning-based system for lone person detection on scaled-YOLOv4 architecture. For instance, if an alone worker faces any fall accidents on the construction site, the system will automatically recognize the falling person. To develop the proposed system, diverse digital image data has been gathered with different scenarios. The designed deep learning-based lone person fall detection system was successfully implemented on the test dataset. The detection model's quantitative data indicated a mean average precision (mAP) of 72.50 percent, precision of 47.5 percent, recall of 83 percent, and F1-score of 60.82 percent. According to the findings, the presented system had good accuracy in detecting person falling conditions. As a result, it is expected that this technique will have a major impact on the automated detection of a lone person fall among construction workers. It is also anticipated that the construction industry could take advantage of the system, particularly in the current scenario of COVID-19.

Abstract –

Buildings consume a large amount of energy and a plenty of methods to mine into energy consumption data to aid intelligent management are proposed. However, the data quality issues are inevitable and the influence is lack of discussion. This paper proposed a data cleaning method combing threshold and cluster method. This paper also proposed an index to evaluate the accuracy improvement on big data prediction. A case study is conducted and it is found that the accuracy of data filling is not sure to agree with the improvement of prediction after filling.

Keywords –

Data Cleaning; Building Energy; Prediction

1 Introduction

Building consume 40% of global primary energy [1] and researchers have found that systematic building energy management can help reduce energy usage by 5% to 30% [2]. Building energy management data contains a lot of useful information and energy consumption prediction is one of the core issues of building energy management, because it can realize pre-reservation and deployment of energy, find abnormal energy usage and assist intelligent decision-making [3]. However, due to the limitations of the hardware conditions of sensors and network transmission environment, the data quality issues is inevitable. According to our investigations of existing building energy monitoring platform, a large amount of data appears quality issues such as missing and anomaly. Although there are plenty of prediction models, the process of data cleaning actually requires considerable efforts [4].

Any prediction algorithm relies on reliable data input, otherwise it will be ‘garbage in, garbage out’. Therefore, it is always necessary to clean the data before prediction. However, traditional manual data cleaning methods have problems such as heavy workload and incomplete inspection. Many scholars believe that based

on the big data perspective, the quality of big data is different from traditional one. The goal of big data is the analysis or application, so the quality of big data should be to what extend do the data meets the requirements of big data analysis applications [5-7].

However, the current methods for building energy consumption data cleaning mostly are based on the data itself, which fails to make full use of the relationship between energy and the property of the building. The methods for data quality evaluation mostly are based on in-sample evaluation methods, which is not consistent with the application scenario [8].

In response to the problems above, this paper first points out the data quality issues in building energy management platforms. Aiming at data missing and anomalies, this paper then propose the methodology of semi-automatic anomaly recognition and data filling. Based on the application of energy consumption, this paper then proposes an evaluation indicator to show how the data cleaning promotes the accuracy of the prediction. A case study is finally provided to demonstrate the method in this paper and verify its feasibility.

2 Methodology

According to investigation into real data collected by sensors and stored in energy monitoring platforms, two major kinds of data faults are missing and sudden change. A sudden change occurs due to an overpass on the survey range of the sensor. Data missing may occur due to loss of internet connection. Based on investigation of existing building energy monitoring platform, we recognized data missing and anomaly as two major data quality issues to be solved in this paper.

The overall methodology for data cleaning and its evaluation for prediction of building energy consumption is shown in Fig 1.

In the data cleaning process, abnormal data are first recognized using methods based on threshold and clustering and the faulty data are eliminated from the data set. Then missing data are filled using methods

based on interpolation, regression and clustering.

In the data prediction process, three commonly used method: multivariable regression, time series analysis and artificial network are chosen and compared. RNN (recursive neural network) model is finally selected to compare the quality of data cleaning.

In the evaluation process, we tested the accuracy elevation using different data cleaning method when data missing rate ranges. And an evaluation indicator is proposed to compare between different data cleaning methods.

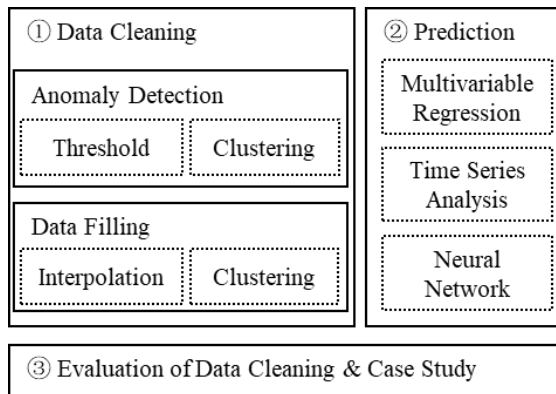

Figure 1. Overall Methodology

3 Data Cleaning

3.1 Anomaly Detection

According to literature review, anomaly detection for building energy data mainly consists of methods based on threshold and clustering. Our research combines these two methods hoping to get a more precise result.

3.1.1 Threshold Method

A threshold can be selected in advance and used to eliminate all data that exceeds the threshold. This method can be used as preliminary screening. Threshold could come from meaning of the data, for instance, energy consumption cannot be negative, so zero is a lower bound of the data. Threshold can also come from experience or standard, i.e. if the data far surpasses the daily consumption, it is probably an anomaly. According to statistics, we also chose 3 times of standard deviation as a threshold, where 99.7% of the normally distributed data should fall into the range.

3.1.2 Clustering Method

Energy consumption actually may show a mix of different consumption mode. Workdays show a high consumption and weekends show a low consumption. Figure 2 shows a disassemble of energy consumption

mode using Gaussian mixture model, and the data shows a composition of two normal distributions. This indicates that we may need to first cluster the data into different groups and detect anomaly in each group, rather than regard the data set as a whole.

Figure 2 Disassemble of energy consumption mode

In this research, k-means algorithm is applied to perform data clustering, and threshold method is again used to detect anomaly data. Although the principle of k-means algorithm is simple, the hyper parameters are subjective and influences the final result. We implemented a process to automatically perform the detection and the workflow is shown in Figure 3.

Elbow point is used to determine the amount of clusters. For a cluster consisting of n sample data, loss function is defined as the sum of square of distance between data and the center. Different k values are selected and loss function decreases as k increases. We choose the k value which brings the most improvement as the final hyper parameter.

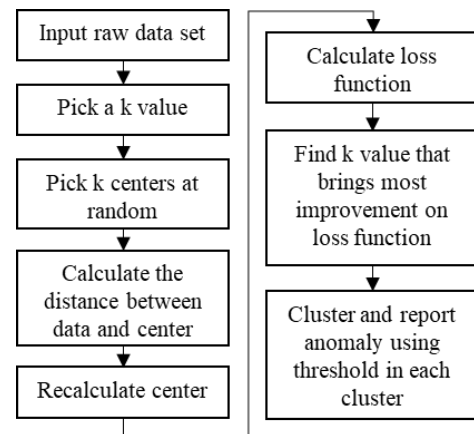

Figure 3. Workflow of data cleaning

3.2 Data Filling

After identifying anomaly data, some prediction algorithms can directly remove the missing data, but this method may make it difficult to make full use of some correctly recorded data, and some prediction algorithms require data recording to be continuous. In this regard, after removing anomaly data, we should

also try to fill in these data.

The clustering method uses the knn (k nearest neighbors) algorithm, and the core idea is that in the sample space, the category of a sample is directly determined by the k nearest samples. K nearest neighbors of a missing sample are found and the weighted average of these samples is used as the final filling result. The regression method uses multiple linear regression methods to construct the relationship equations between the monitoring data of different meters, and then calculates and fills in the missing data.

For dealing with missing data, most of the existing processing methods use historical data as a reference data set. For example, interpolation is a commonly used method. This method is simple to calculate, and results can be obtained quickly when there are not many missing values. Another example is the pattern analysis method, which analyzes the pattern of energy consumption data for the same period in the history of each year, and compares it with the energy consumption data before and after the missing value, finds the historical data with the same energy consumption pattern, and uses the weighted average method to fill in. This method also highly requires historical data. Moreover, these methods do not consider the actual meaning of the data, and cannot reflect the true situation when there are too many missing values.

Taking into account the relationship between BIM and monitoring data in the energy management platform, it is possible to identify the data of other functional areas that are similar in function, orientation, area, and energy use mode to the monitored functional area at this point, and different areas at the same time. There should be a certain relevance in the energy use rules. If the area, location, function, orientation and other characteristics of the space are similar, the monitoring values of other spaces can be used to calculate the missing value of this point. Using the association relationship shown by the data model in the energy management data platform, if the data at a certain point is missing, you can make full use of other associated data to estimate it.

4 Data Prediction

Energy consumption prediction generally refers to the prediction of energy consumption in the future through the monitoring of historical data, in order to estimate the energy consumption that may occur in the future. Currently commonly used methods include

multiple linear regression, time series analysis, and artificial intelligence prediction methods. A summary of comparison between these methods is shown in Table 1.

Multiple linear regression is to use of regression analysis to establish the relationship between a number of explanatory variables and the explained variables, so as to achieve the purpose of prediction. The explained variable is the future energy consumption monitoring value of the predicted point, and the explanatory variable usually has four main sources: (1) the historical energy consumption monitoring value; (2) data from other sensors related to the predicted sensor; (3) the physical attributes of the monitored space itself, such as area, function, orientation, etc.; (4) the time attribute, such as seasons, weeks, and holidays. The advantage of multiple linear regression is that it is easy to calculate, saves computing resources, and can quickly obtain an estimate of the predicted value, but the disadvantage is that the predicted result depends on the form of the artificially set regression equation, and the ability to handle the nonlinear relationship between variables is limited. Under the condition of abnormal or missing data, since the historical energy consumption monitoring value will appear as the explained variable, all samples containing abnormal or missing values cannot be used as learning samples to train the model, which may reduce the number of samples.

Time series analysis method is to use autoregressive, moving average and other methods to split the components of the time series into trend items, periodic fluctuation items and residual items, which can be used to analyze the nature of the data itself. The advantage of this method is that it can fully mine the laws of the data itself, decompose the components of the data, and obtain more information that can be understood. The disadvantage is that the time series analysis method has strict requirements for data integrity. Missing data will make the model unable to work. All vacant data must be filled in to make predictions. Therefore, for building energy consumption monitoring data with abnormal or missing data, this method needs to be used with extreme care, and attention must be paid to the sensitivity of the prediction results to the filling data.

Artificial intelligence prediction usually uses the artificial neural network that has developed rapidly in recent years to predict energy consumption. This prediction method has a good generalization ability and can be applied to various prediction problems. The prediction results of these methods are more accurate.

Table 1 Comparison between energy consumption prediction methods

Method	Advantage	Disadvantage	Influence of missing data
Multi-variable regression	Simple model, easy to train	Only deal with linear relationship	Reduce sample volume
Time series analysis	Pattern is comprehensible	Strict requirement on data completion	Missing data have to be filled
Artificial intelligence	Most accurate	Complex model, time consuming	Reduce sample volume

However, the disadvantage is that the complexity of the model is relatively high, so the computing resource requirements are relatively large, and the number of samples is also relatively high. Similar to the multiple regression method, the abnormality and lack of data will also make the samples with these data unable to be used as training samples, which will affect the training effect of the model.

5 Evaluation for Data Cleaning

5.1 Influence of Data Cleaning on Prediction

Although the prediction of building energy consumption monitoring data is a hot research topic, most studies use relatively complete and high-quality data sets. In fact, it is not reasonable to regard filled data to be the same as the original data. However, these studies did not explore how the filled data will affect the prediction results. Some literature points out that although data filling improves the integrity of the data set, it does not necessarily improve the effect of data prediction. When a small rate of data is missing, the data integrity has little impact on the prediction results, and data filling does not greatly improve the prediction results. When the data missing rate is moderate, data integrity has a great influence on the prediction results. At this time, data filling will greatly improve the accuracy of the prediction results. When the data missing rate is high, both data prediction and data filling lack corresponding training sets, so it is difficult to achieve better results, and it is difficult to improve the data prediction effect after data filling.

Although both the accuracy of data prediction and the accuracy of data filling decrease with the increase of the data missing rate, when the data missing rate is moderate, the improvement of the data prediction effect by data filling is the most significant. In the context of big data applications, the purpose of data filling is not to faithfully restore the original data of the data set, but to improve the data prediction effect through data filling. Therefore, simply comparing the accuracy of the data filling algorithm with original data sets is not the final goal. The data cleaning quality evaluation for data prediction should emphasize on the improvement of the prediction effect. The effect of data cleaning should be evaluated by comparing the prediction effect before and after the data cleaning, the effect of the data cleaning is improved [9].

5.2 Evaluation of Prediction

Methods of relative error and absolute error can be used to evaluate the prediction effect. In order to compare various algorithms between different samples,

the relative error is often used to evaluate the prediction effect. Commonly used evaluation indicators are Mean Absolute Percentage Error (MAPE), R-squared [10] and Theil Inequality Coefficient (TIC) [11]. Among them, the value range of the MAPE is 0 to infinite, where 0 means a perfect model, and more than 100% means an inferior model. The value range of R-squared is 0 to 1, where 1 indicates a perfect model. The value range of TIC is 0 to 1 and the smaller the value, the smaller the difference between the fitted value and the true value.

Since the value range of the TIC is a limited interval, this research adopts the TIC as the evaluation index of the model's prediction effect. Since the evaluation of data cleaning quality for data prediction should start with the improvement of prediction effect, the effect of data cleaning should be evaluated by comparing the prediction effect before and after data cleaning. Therefore, on a certain data set, the difference in the TIC before and after data cleaning represents the improvement of the data cleaning effect on data prediction.

$$\begin{aligned} \text{Prediction Accuracy Improvement} \\ = \text{TIC}_{\text{befroe}} - \text{TIC}_{\text{after}} \end{aligned} \quad (1)$$

5.3 Evaluation Index for Data Cleaning

If we plot the prediction accuracy before and after data filling under different data missing rates, as shown in Figure 4, it can be seen from the figure that when the data missing rate is small, the loss of the TIC is not large. However, when the data missing rate is medium, the TIC increases rapidly, which indicates the rapid attenuation of the prediction effect. When the data missing rate is very large, the prediction accuracy remains at a very low level. The effect of data filling is to postpone the missing rate at the inflection point of the prediction effect attenuation, i.e., when the missing rate is medium, the data filling increases the number of samples available, it can also restore or maintain the data characteristics, so the prediction accuracy can be maintained at a high level at the same time. However, in the case of a high data missing rate, the characteristics of the data itself cannot be reflected, and there are not enough available samples to fill in, and the filling and prediction results are close to random.

To compare the improvement of the prediction effect of different data filling methods, we can compare the difference of the TIC under the condition of different data missing rates, and comprehensively consider the quality improvement under various data quality. Therefore, the area between the two curves can be used to characterize the improvement of the prediction result by the data preprocessing operation, and the calculation formula is as follows. The larger the area in the figure, it means that the data filling method can achieve better

data prediction effect improvement under various data missing rates. Therefore, the data cleaning effect evaluation index for data prediction can be defined as the following formula.

$$\begin{aligned} & \text{Evaluation Index for Data Cleaning} \\ & = \int_{0\%}^{100\%} (TIC_{after} - TIC_{before}) d(\text{missing rate}) \end{aligned} \quad (2)$$

6 Case Study

This research takes an office building Creative Plaza located in Dalian China as a case study. This building has a building height of 85 meters, with 16 floors above ground and 2 floors underground, and has a total building area of 36,500 square meters. Each floor and each zone has a set of sensors to collect electricity consumption every 15 minutes since 2018. We take the electricity consumption of Zone A on the 11th floors from March to July 2020 as an example.

Figure 4 Creative Plaza building

6.1 Anomaly Detection

The raw data of 11th floor is shown in Figure 5(a) and we can see an obvious sudden change. The average of the data set is 494.57 and standard deviation is 7368.94. These two anomalies are eliminated using threshold method as in Figure 5(b). After removing the outliers, the data showed a stable fluctuating trend, but there was still a suspicious data anomaly.

Figure 5. Electricity consumption data (unit: kWh) before (a) and after (b) threshold method

After the elimination of sudden change, we use k-means algorithm to implement the clustering method to detect abnormal data. The number of clusters k is iterated and the loss function under different k values is

as shown in Figure 6(a). We can see that when $k=3$, the decrease in loss function is the maximum using elbow point method.

Figure 6 (a) Relationship between loss function and number of clusters (k); (b) Result of clustering

The clustering result divides the original data into 3 categories: high/ medium/ low energy consumption patterns. Anomaly detection is carried out for each type of monitoring data utilization principle. It can be seen that the two highest and lowest data points that deviate from the main trend are abnormal data. It is also caused by the jump of the monitoring meter and should be eliminated. The data after removing all abnormal data is shown in Figure 7, and the whole process is completed automatically.

Figure 7. Data after data cleaning

6.2 Data Filling

To compare the accuracy of different data filling methods, some of the original data of the electricity consumption of the 11th floor was randomly removed to simulate the lack of data, and the remaining data sets were used for data filling. The error between the filling value and the monitored value is compared in the cases of different missing rates, and the accuracy of different repair methods is compared. There may be two typical cases of missing data. (1) missing at random: this situation often occurs when abnormalities such as the jump of the measurement meter are abnormal, and the missing data is at random. (2) continuous loss: this situation often occurs in abnormal situations such as power failure or stoppage of the measuring meter, or network transmission. Generally speaking, adjacent data

with random missing time can characterize the missing data to a certain extent, and the data law can still be retained. Continuous deletion may make data difficult to recover, and the laws hidden in the data are more difficult to analyze. The accuracy of data filling in these two scenarios are summarized in Table 2 and Table 3.

Table 2 Data Filling Accuracy (Missing at Random)

Missing Rate	Filling Accuracy		
	Interpolation	Regression	Clustering
10%	90.29%	95.09%	94.03%
20%	86.25%	94.64%	92.84%
30%	85.88%	94.24%	92.67%
40%	84.25%	93.77%	92.55%
50%	79.06%	92.99%	91.59%

Table 3 Data Filling Accuracy (Continuous Missing)

Missing Rate	Filling Accuracy		
	Interpolation	Regression	Clustering
10%	85.19%	95.76%	93.86%
20%	83.02%	93.60%	92.71%
30%	81.20%	93.98%	92.31%
40%	79.83%	92.63%	91.45%
50%	75.78%	94.32%	89.60%

As can be seen in the tables, the accuracy of regression outperforms interpolation and clustering. In all three methods, the accuracy in continuous missing scenario is lower than missing at random and the influence is more obvious in interpolation method.

6.3 Data Prediction

In order to test the accuracy of the building energy consumption prediction algorithm, the 126 data sample are divided into two parts using in-sample test indicators. The first 112 sample points are the training set, and the last 14 sample points are the test set. The prediction result is compared with the last 14 sample points, and the TIC value as an index of prediction accuracy is calculated.

In this case study, considering the data availability, the input to the model consists of three parts. The first part is the daily historical data of power consumption in Area A on the 11th floor. Since the data exhibits obvious weekly fluctuations, the historical data of 7 previous days are used as training data, and the data of the following day is used as output data. The second part is the daily historical data of the power

consumption of the 9th and 10th floor of area A. These two areas are related to the predicted power consumption of the 11th floor area A. The functions and energy use scenarios of these areas are similar. The third part is the properties of the space, including the area, floor, orientation and other information that can be obtained from BIM model. In time series analysis, ARMA model is applied. And for artificial network, RNN model with a hidden layer of 10 neurons is applied.

The prediction results of the three models using multiple regression model, time series analysis, and artificial neural network are shown in the figure below. The TIC values are 7.37%, 6.76%, and 6.32%, respectively. The prediction accuracies of the three models are all acceptable. Among them, the artificial neural network can handle the nonlinear relationship between variables, so the prediction The effect is best, as shown in Figure 8.

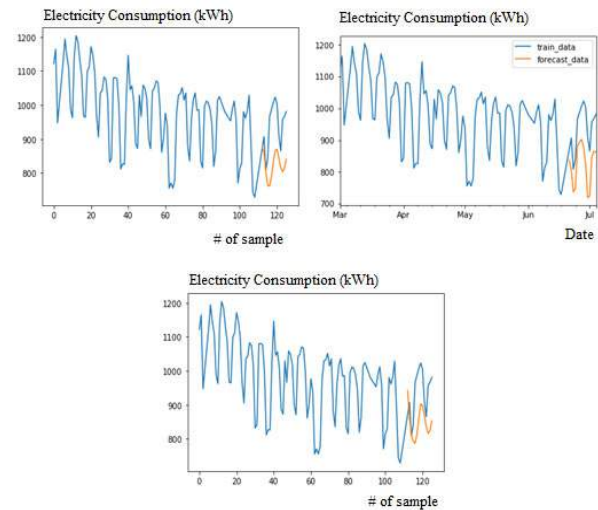

Figure 8. Prediction result of (a) multi-variable regression, (b) time series analysis, (c) artificial network (blue: real data, orange: prediction)

6.4 Data Cleaning Evaluation

In order to compare the influence of data filling on prediction, we eliminate different proportions of data and perform neural network on the remaining data after data filling with three different methods: interpolation, regression and clustering as is introduced above. We tested these methods in two data missing scenarios: missing at random and continuous missing. Two evaluation indices are applied: TIC of prediction and accuracy of filled data compared with real data. The results are summarized in Table 4 and Table 5 and is shown in Figure 9 and Figure 10.

Table 4 Evaluation of Data Cleaning (Missing at Random, TIC=6.32% when no data missing)

Missing Rate	No filling	Interpolation		Regression		Clustering	
	TIC	Accuracy	TIC	Accuracy	TIC	Accuracy	TIC
10%	7.61%	90.29%	6.79%	95.09%	7.47%	94.03%	6.92%
20%	9.91%	86.25%	7.02%	94.64%	7.56%	92.84%	7.22%
30%	12.23%	85.88%	7.24%	94.24%	7.90%	92.67%	7.56%
40%	13.09%	84.25%	7.30%	93.77%	8.43%	92.55%	7.62%
50%	16.58%	79.06%	7.76%	92.99%	8.72%	91.59%	7.97%

Table 5 Evaluation of Data Cleaning (Continuous Missing, TIC=6.32% when no data missing)

Missing Rate	No filling	Interpolation		Regression		Clustering	
	TIC	Accuracy	TIC	Accuracy	TIC	Accuracy	TIC
10%	9.11%	85.19%	7.31%	95.76%	7.31%	93.86%	7.30%
20%	11.82%	83.02%	7.44%	93.60%	7.66%	92.71%	7.44%
30%	13.73%	81.20%	9.38%	93.98%	8.51%	92.31%	7.63%
40%	16.65%	79.83%	10.36%	92.63%	9.22%	91.45%	8.31%
50%	19.93%	75.78%	12.33%	94.32%	9.63%	89.60%	8.97%

In this case, if we compare the accuracy of filled data, the accuracy of regression is the highest. However, using the data filled with clustering method, the prediction is more accurate, as is summarized in Table 6. Therefore in this case, the in-sample evaluation method does not agree with the prediction result, while the latter one is the real target of big data application.

Table 6 Data Filling Evaluation (Missing at Random)

Filling Method	Average Accuracy of Data Filling	TIC Improvement after Data Filling
Interpolation	66.96%	12.28%
Regression	82.66%	23.15%
Cluster	79.77%	23.88%

Figure 9 Accuracy of data filling in different data

Figure 9 TIC of prediction after data filling in different data missing rates

7 Conclusion

Building consume a large amount of energy and a plenty of researchers have proposed methods to mine into energy consumption data to aid intelligent management, however, the data quality issues are inevitable and the influence is lack of discussion. This paper proposed a data cleaning method combing threshold and cluster method. This paper also proposed an index to evaluate the accuracy improvement on big data prediction. A case study is conducted and we found the accuracy of data filling is not sure to agree with the improvement of prediction after filling.

This research is a tentative discussion for the relationship between data cleaning and prediction for building energy consumption and there are several

issues for future work. For example, more data sources from BIM could be taken into consideration so that the relationship between these data could be recognized to improve the data cleaning. More data filling methods and prediction algorithms could be conducted to get a more comprehensive comparison.

E-mail: daniel.napps@ruhr-uni-bochum.de, dennis.pawlowski@ruhr-uni-bochum.de, markus.koenig@ruhr-uni-bochum.de

Abstract

Architects today still very often create traditional 2d plans in the early planning phase, which form the basis for discussions with investors, clients and engineers. The designs are often difficult to understand for non-experts and design variants can only be compared with great effort. The use of BIM models simplifies both communication and the actual creation through the use of parametric modeling approaches. Even though a building project always has very individual characteristics, it makes sense to take experience from other projects as a basis for the design. Therefore, it may be that suitable floor plans of similar buildings already exist, which are a good basis for variant studies in early design phases. A challenge is to be able to access the experience of other architects. Currently, this information is not available and is difficult to transfer from one project to the next. This paper outlines a solution for a BIM-based variant retrieval of a building design in early design phases using Case Based Reasoning (CBR) and Pattern Matching (PM). On the one hand, this offers the possibility to learn from old mistakes, and on the other hand, it enables the quick selection of suitable variants for a building from a diverse pool of variants.

Keywords –

Building information Modeling (BIM), case-based reasoning (CBR), Early Design Phases, Industry Foundation Classes (IFC), Pattern Matching (PM), Variant Retrieval, Similarity

1 Introduction

In the planning phase, referencing building concepts is a common practice, for example to find and evaluate similar building concepts and use them for a new project. Such manual search can take an unacceptable amount of time. An automatic generation of suitable designs or variants promises a faster workflow and at the same time serves as a transparent assessment of the building project and various analytical parameters, which is not

insignificant for the consideration of the variants themselves [14]. Variant matching always allows a suitable thematic and technical view (construction costs, sustainability, etc.) due to the attributes stored in the Industry Foundation Class (IFC) interfaces, as the effects of the change in parameters and components are directly visible in the efficiency of the building. In order to find variants, the case-based reasoning method can be useful [7]. This approach starts with a problem (search query) that correlates with the specific ideas about the building project and the concepts of the planners. This paper presents a solution for finding suitable variants in the early design phases of buildings, using the case-based reasoning (CBR) approach based on the IFC standard. For this purpose, specific case studies are provided to explain the similarity calculation used, which is essential for the first phase of the CBR cycle. Building on the basic idea of CBR (similarity recognition) the method of pattern matching (graphical pattern recognition) is used to illustrate the selection of suitable variants with given framework conditions (search queries).

In previous research, a concept for modelling and managing design options was already created, which is connected to the BIM models. Three variant classes (structural, functional and product variants) were defined and implemented using the IFC [11]. This procedure avoids redundancy and offers a wide range of applications. Furthermore, a representation of variants in using graph theory was introduced [10].

The basic idea of finding suitable variants of floor plans already appeared in 1996 in a journal article by Gomez de Silva Garza and Maher [9]. At that time the technical possibilities regarding BIM models did not exist. Langenhan et al. [13], address this issue and attempt to match building floor plans using the fingerprint method and a database matching. BIM is not integrated here either. Similar to us, Althoff et al. [14] use the CBR approach with the help of exact and inexact graph matching to support the architect in finding similar 2d floor plans in the early design phases. The properties and consequences of components and structures cannot be identified. In the reviewed literature, there is no

evidence of the correlation between BIM models and variant decision-making.

This paper is dealing with the topic in order to offer a different and evolved solution that integrates BIM. This paper addresses the issue to provide an evolved solution that integrates BIM models and uses IFC for the implementation. These factors are essential for interdisciplinary collaboration during the early design phases of buildings and are neglected by the authors mentioned above.

2 Background and methodology

The following chapters briefly summarize the basic theoretical knowledge and methodology on which the paper is based on.

2.1 BIM in context of the research topic

The acronym BIM stands for Building Information Modeling, which has been increasingly influencing the construction industry for several years. In a digital building model, the exact geometry of the building and information on all the built-in components are stored within the model and recorded over the entire life cycle of the building. Thus, this information can be used for (facility) management, revitalization, expansion or demolition. Additionally, a loss-free exchange of files with investors, energy and construction engineers or facility management is possible over the entire life cycle of the building [3].

The exchange of this (open) BIM data is made possible by the Industry Foundation Classes (IFC), an international open standard (ISO 16739) developed by buildingSMART [6]. The IFC is continuously being further developed since 2013 and is available in the latest version of the IFC standard as IFC4 [12].

BIM is compatible with our research work because the IFC interface can be used to define the information range of individual elements, directly show the changes of parameters and thus allow a comparison of parameters among themselves and thematically, regarding the whole design. Therefore, structure, function and product variants can be assigned to the respective level of detail (LOD). Three variant types have already been defined [11]. The structure variant offers options to the structure of the building, for example the geometry of the building or the number of building storeys. The functional variant can be exemplified by the load-bearing structure of the building or objects that fulfil the same use or purpose. The product variant, as the smallest level of the variant types, includes individual objects (e.g. doors) that can be exchanged with similar objects or other property values, without affecting the structure and function.

Using BIM and IFC makes it possible to capture different variants with the entire geometry and all

properties. This means that they are available to everyone as explicit knowledge. For the research in this topic, a graph-based representation of the data structure is chosen [10]. In this, the BIM model is represented based on the IFC standard with the different entities, attributes and, consequently, the geometry. This continues the previous considerations in the research context and is suitable for the methodological approach of CBR and pattern match (PM). For this purpose, patterns must be defined, which in turn are linked to the similarity definitions and afterwards they can be shown as several options in a graph database.

2.2 Current problems

Currently, individual BIM models are being developed from scratch for each construction project. In this process, the planners are guided by the wishes of the client. The planner therefore designs a great many different floor plan variants for a wide variety of building types and uses during his professional career. This experience is used when a planner encounters similar boundary conditions and construction requirements. However, since this procedure is related to the implicit knowledge of the planner, the number of variants is limited. With the presented solution the knowledge of each planner is available by storing different variants of building designs in a database and generating automated solutions.

2.3 Methodology and process

2.3.1 CBR

CBR is a methodical way of problem solving, using problems that have already been solved and proven to be successful. In the context of this research, it is useful to adapt a suitable solution from a case base, as a 1:1 transfer of the solution turns out to be difficult, because buildings are mostly heterogeneous. Thus there are almost never exact matches, since the external or internal circumstances are not the same even though the appearance may be the same. That is why it is necessary to determine a degree of similarity. The usefulness of a solution is consequently an optimization phase that is based on the similarity determination of the components and adapted to their specific weighting [7].

The process of case-based reasoning can be represented as a cycle, which Aamodt and Plaza [1] divide into four steps: retrieve, reuse, revise and retain. In this paper the retrieval process is dealt with and the problem is defined as finding a suitable variant. The procedure is demonstrated by own case studies and differs from MetisCBR [14] in that it includes both, a graph structure and geometry to make the search results more accurate.

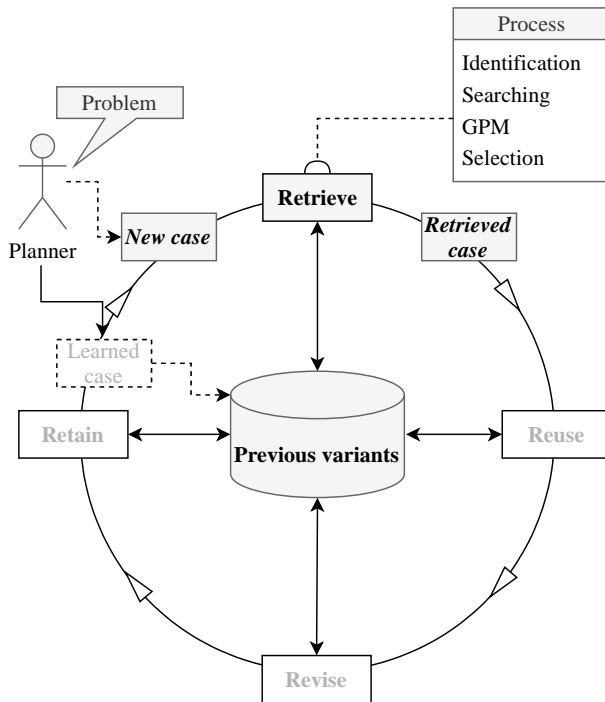

Figure 1. CBR cycle according to Aamodt & Plaza [14]

2.3.2 GPM

The method of graph pattern matching (GPM) is a possibility to find (suitable) variants from a graph database. Based on a pattern query, matching graphs are selected from a case base that provide an answer to the existing request (problem). This approach can also be extended to subgraphs if more specific requirements are being searched for. Similarity definition and weights are of great importance for the pattern matching in order to limit the results and have them target-oriented [15]. Furthermore, a categorization is made between two types of pattern matching (PM), which are called exact PM and inexact PM [14].

An exact PM is characterized by one-to-one isomorphism, i.e. the same number of nodes are contained in both graphs and both graphs have the same manner of connections (number of edges). If the graphs are not isomorph, subgraphs can be examined for isomorphism in the next step [14].

The inexact PM is a different approach that is more suitable to the heterogeneous field of the building sector, because building structures and room uses differ from each other. The search query is decomposed into different IFC data or building components and these are evaluated and normalized with a similarity score [14].

In addition, specific weights are added, which allows the similarities to be determined and the relevance for the comparison of variants to be specified. A variant is a match if the graph of the variant is a subgraph of the

database entry. In contrast to the exact pattern match, so-called replacement rules are applicable to the inexact PM [14]. These replacement rules are important, because they extend the inexact pattern match similarity. For example, instead of a load-bearing wall, the user is able to choose a load-bearing column. or instead of a connection between two rooms with a door, a breakthrough is possible. These replacement rules must be individually adapted by the user.

2.3.3 Similarity

In the following, the similarity calculation according to Richard Hemming is determined, which is often used in the retrieval process of the CBR. The concept of generalized similarity determines the similarity of two cases for any number of attribute values, which can be weighted and normalized (1). According to Hemming, a qualitative and quantitative similarity determination is possible. Generalized similarity allows a comparison of normalized real attributes, as well as a comparison based on classifications [2].

$$\text{sim}(p, v) = \frac{\sum_{i=1}^n \omega_i \text{sim}_i(p_i, v_i)}{\sum_{i=1}^n \omega_i} \quad (1)$$

Using this formula, the similarity between a problem p and a possible variant v , with non-negative weights, is a value between zero and one. The more similar the variants, the higher the value of sim [12]. According to this approach, the similarities are used for all entities stored in the IFC data structure. Depending on the type of entities, similarity measures can be defined for both IFC quantities and property definitions.

2.3.4 Retrieval

In a database (case base), n variant graphs are defined, which differ from the simple consideration of the building graphs in that they contain option points. These variant graphs were defined as part of other projects and include structural, functional and product variants. Following the top-down design, the new user specifies the various parameters for the current project (problem) for which he wants to find a variant (e.g. use of the building floor, sizes, number and functions of the rooms). The process also allows searching for required connections (e.g. between the rooms). It is up to the user to decide whether this is necessary for the problem or not.

After that, the individual entities are weighted by the user, which results in priorities being selected depending on individual preferences and the use cases, generating different solutions in the end. The database is searched for graphs that are either an exact match or an inexact match of the graph of the problem. These matches are presented to the user and sorted by the magnitude of the

calculated similarity. If the result still has a need for optimization, fine-tuning can be done. This is helpful to show possible further structure, function or product variants for a selected area if a match is identified. This might be the case if a room contains windows or doors as a result, which in turn can be replaced by other product variants. Another case could be chosen other wall structures, for example, to improve the energy properties of the building (structure variant) (Fig. 2).

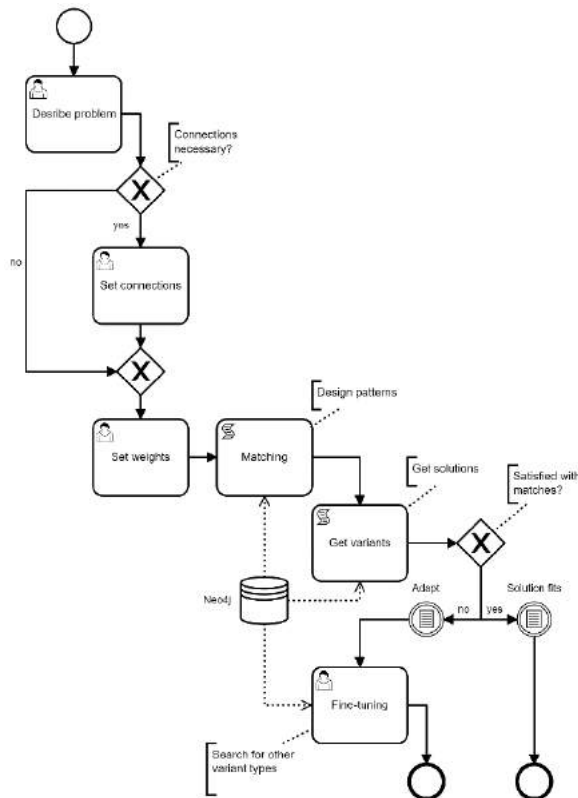

Figure 2. BPMN (Retrieve)

3 Case study

With the help of a simplified case study, the BIM-based variant retrieval is presented. In determining the weights, planners and architects usually act subjectively, stick to their experience, are oriented to the sustainability or adapt the wishes of the clients [4]. In this paper the authors assume the role of the user, which is why the problem description and weights are determined by them.

A variant is to be found for a ground floor with office use, an area of 290 m² and with at least two offices. Other criteria set by the user are, offices with windows, a connection of the offices with a corridor, the wall thicknesses and other attributes. According to this problem description, the floor plan could possibly look

like the following which captures the problem visually, but is not part of the data base (Fig. 3).

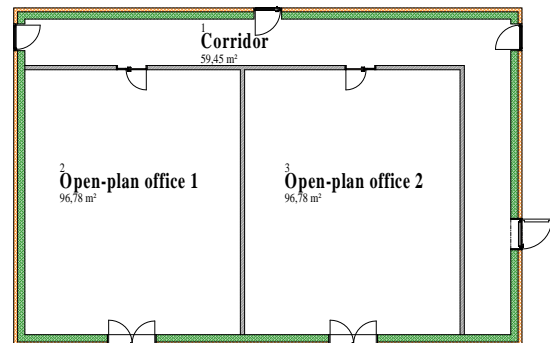

Figure 3. Exemplary floor plan according to problem description of the use

The comparison of the problem with different variants from a case base is based on the different attributes, stored in the BIM model. Table 1 lists the attributes essential for the case study, together with their defined specifications. Based on these attributes, the most similar problems in the current case base are determined for the defined issue.

Table 1. Attributes and specifications

Entities	IfcObject-Quantities	Property definitions
IfcBuilding-Storey	GrossFloorArea GrossVolume	-
IfcColumn	AverageHeight GrossFloorArea GrossVolume	LoadBearing
IfcDoor	OverallHeight OverallWidth	IsExternal FireBearing
IfcRelConnects	-	-
IfcSpace	GrossFloorArea GrossVolume	Category
IfcWall	NormalWidth	LoadBearing
IfcWindow	OverallHeight OverallWidth	IsExternal

The calculation of the similarity measure must be defined for each property. For this purpose, the individual properties are mapped to integers in order to be able to calculate normalized differences. The properties are given values to make strings and deviations measurable and to be able to measure the differences. At the end of the table there is a normalization factor (NF) to normalize the differences and receive a number between zero and one. A difference of zero corresponds to the similarity measure one, that means, that the attributes are equal to each other. A difference of one equates to the similarity measure zero, that means that the properties are not similar to each other.

Table 2-6. Values for similarity determination

Boolean	Value
True	0
False	1

Deviation area & volume	Value
0%	0
< 5%	1
5% up to < 10%	2
10% up to < 15%	3
15% up to < 20%	4
20% and above	5
Normalization factor (NF)	1/6

Deviation height & width	Value
0cm	0
< 5cm	1
5cm up to < 10cm	2
10cm up to < 20cm	3
20cm up to < 30cm	4
30cm and above	5
NF	1/6

Deviation NominalWidth	Value
0cm	0
< 1cm	1
1cm up to < 2cm	2
2cm up to < 3cm	3
3cm up to < 5cm	4
5cm up to < 7cm	5
7cm up to < 10cm	6
10cm up to < 20cm	7
20cm and above	8
NF	1/9

Category (DIN 277)	Value
NUF 1	0
NUF 2	1
NUF 3	2
NUF 4	3
NUF 5	4
NUF 6	5
NF	1/6

Weights must be added to the selected properties to capture the relevance of the properties and solve the problem. The list of weights and the calculation of the corresponding values are subjective estimations of the designer. These weights are selected in this example as follows (Tab. 7).

Table 7. Entity weighting

IfcData	Weights
IfcBuildingStorey	1,0
IfcColumn	0,2
IfcDoor	0,3
IfcRelConnects	0,5
IfcSpace	0,6
IfcWall	0,7
IfcWindow	0,3

After these steps, the similarity measure between the problem and two possible variants can be calculated. The example mentioned at the beginning is the problem (p) for which a solution is to be found that corresponds to the weights (ω) with the specific attributes (a) of the variants (v). The values of the attributes are calculated according to the following formula [2]:

$$\begin{aligned} \text{sim}(p(a_1), v(a_1)) &= \omega_1(1 - (NF_1(p(a_1) - v(a_1)))) \\ \text{sim}(p(a_1), v_1(a_1)) &= 1(1 - (\frac{1}{6}(0 - 0))) \\ \text{sim}(p(a_1), v_1(a_1)) &= 1 \end{aligned} \quad (2)$$

In this example (2), the similarity of the IfcBuildingStorey between the problem and variant one is shown. The calculation is made for each quantity and property of the entities (Tab. 1).

The similarities of the entities are calculated, with regards to the problem, and compared in the following table (Tab. 8), with the characteristics of the individual attributes. In this process, the inputs requested by the user are compared on the basis of their IFC data with already solved problems from the case base.

Table 8. Similarity

Entities	Variant 1	Variant 2
IfcBuildingStorey	1	1
IfcColumn	0,2	0
IfcDoor	0,1	0,3
IfcRelConnects	0,5	0,4
IfcSpace	0,3	0,6
IfcWall	0,25	0,5
IfcWindow	0,15	0,3

The floor plans of the two variants are compared pictorially in order to show the differences to the problem

(Fig. 4 and 5).

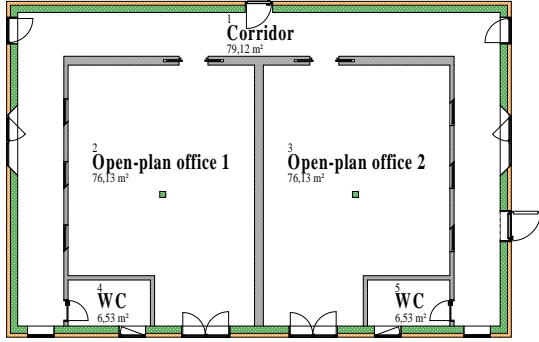

Figure 4. Building floor plan representation variant one

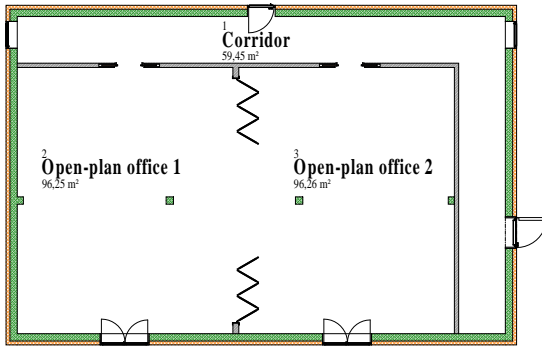

Figure 5. Building floor plan representation variant two

Compared to figure 3, the two possible solutions have differences that are more or less significant.

However, instead of the image representation, the actual process matches the IFC data structure of different projects from the case base with the existing problem. The graph of the variants one and two are inexact pattern matches out of the IFC structure of the problem definition. The representation of the floor plans is thus only representative in order to have a better look at the differences, which is more difficult to see in the graphical representation.

In figure 6, a simplified representation has been chosen to show the graphical structure of the problem. The individual properties of the data are stored in the nodes and edges.

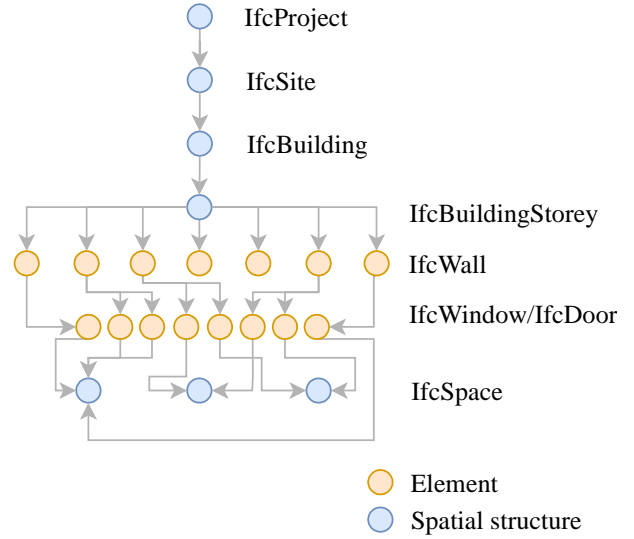

Figure 6. IFC structure of the problem definition

According to the similarity calculation, a similarity of variant one (x) to the problem (p) is calculated as follows:

$$\begin{aligned} \text{sim}(p, x) &= \frac{1 + 0,2 + 0,1 + 0,5 + 0,3 + 0,25 + ,015}{1 + 0,2 + 0,3 + 0,5 + 0,6 + 0,7 + 0,3} \\ \text{sim}(p, x) &= 0,694 \end{aligned} \quad (3)$$

For variant two (y), the similarity is calculated in the same way.

$$\begin{aligned} \text{sim}(p, y) &= \frac{1 + 0 + 0,3 + 0,4 + 0,6 + 0,5 + 0,3}{1 + 0,2 + 0,3 + 0,5 + 0,6 + 0,7 + 0,3} \\ \text{sim}(p, y) &= 0,86 \end{aligned} \quad (4)$$

In this case, it indicates that variant two has a greater similarity to the problem and thus results as the more suitable solution regarding this issue.

If the user is not completely satisfied with this solution, he or she can search for possible alternatives to the variant types in the fine-tuning section. An example of a procedure in this area is illustrated in figure 7.

```

MATCH (c:IfcElement)-->(d:IfcElement)-->(e:IfcSpatialStructureElement),(d:IfcElement)-->(f:IfcSpatialStructureElement)
WHERE c.Entity='IfcOpeningElement' AND 0.19<=c.Depth<=0.21 AND 0.8<=c.Height<=0.9 AND 1.8<=c.Width<=2.3
AND d.Entity='IfcDoor' AND d.OperationType='SINGLE_SWING_RIGHT' AND d.IsExternal=false
AND e.Entity='IfcSpace' AND e.RoomKeyUsageType='1 Living'
AND f.Entity='IfcSpace' AND f.RoomKeyUsageType='2 Office work'
AND size((c)-f,IfcRelSpaceBoundary)-1 >= 2
RETURN c,d,e,f,Id(d)

```

Figure 7. Optional product variant (PM)

In the given case the user is able to find an optional product variant (door) out of Neo4j based on specific deviations. By using the given cypher query, the database is searched for a door that fits into a given wall opening (depth, height, width). The object is an interior swinging door that opens to the right and connects an office use with a living use. Exact or inexact pattern matches are searched in the database that match the selected variant for which there is an option for the variant type.

Matching alternative variants are returned and the user can choose a suitable option or expand the search. This process can be adapted for each product variant and extended to functional and structural variants if required.

4 Conclusion and future work

With the help of CBR, existing knowledge can be used to find solutions for similar problems. The similarity measures can be flexibly adapted to the individual requirements of the user.

In this paper, a BIM-based solution for the retrieval process in the early design phase of a building is identified. This makes it possible to include all the information stored in a BIM model in the similarity measurement using IFC. The paper points out optimization tendencies for the current research, which will be identified and dealt with in the current research. Based on this, the other processes of the CBR move into the focus of the upcoming research.

CBR is based on the fact that there are enough variants in the graph data pool. In the presented example the number of variants is quite limited, but sufficient to show the retrieval process of finding a suitable variant for a simplified given problem. Machine learning can be used in the future research to fill up the variant pool and generate a higher number of possible matches.

Following on this the increase in complexity of buildings and their structures will be addressed in the next phase. Studies indicate that a high number of nodes, relationships and properties does not cause any difficulties for the graph database and thus the utilisation

of the CPU and query speeds are only dependent on the implemented hardware [5]. Therefore, CPU utilisation must be tested under various complex conditions. Complementary Grossniklaus et al. [8] highlight the advantages of a graph database (e.g. Neo4j) in relation to a large amount of data, as it allows high data correlation between entities, an efficient query performance and powerful graph-based algorithm.

The exemplary weights of the entities can be extended to the individual quantities and properties in further studies in order to be able to provide even more targeted results. In addition to that, extensions can be made according to the value, based on other parameters, such as fire protection, u-value or energy efficiency.

In addition to this, the similarity calculation can also be extended to provide more accurate results and needs to be implemented so that an automated similarity matching algorithm can be used. The shown calculation can possibly be supplemented by other established similarity calculations.

Abstract -

Computer vision technologies, including 2D/3D perceptions, have grasped more and more attentions in construction industry, which can provide effective support in many industry tasks, including autonomous digging and safety protection. However, dusts and mists always exist in many industry jobsites, which heavily affects the applications of computer vision technologies in industry operations, such as stone and truck detection and segmentation. To relief these problems, we propose a dedusting approach that utilizes deep convolutional network based closed-loop framework to remove the influence of dust and mist in construction sites. Taking an image with dust as input, the proposed framework can effectively remove the dust component, thus clean image can be obtained.

To achieve this, we divide the image with dust into three components, including clean image component, atmospheric light component and transmission (dust) component, and a U-Net structure that contains an encoder and three decoders is used, where the encoder is for effective feature extraction, and the three decoders are for the recovery of the three image components, thus clean image, atmospheric light and transmission (dust) components can be obtained. To guarantee that the network can be convergent, two supervisions are utilized, one for the clean image, and the sum of the three image components should be same with the input. Experiments demonstrate the effectiveness of the proposed approach.

1 Introduction

Computer vision technologies have drawn more and more attentions in construction industry, because complementary and effective information can be provided to improve the efficiency and safety in many industry jobsites, such as obstacle detection [1], segmentation [2] and depth enhancement [3][4][5], *etc.* However, bad weather events such as fog, mist and haze may exist in the construction industry, besides, dust also commonly occurs in the process of industry job, which dramatically reduce the visibility of many scenery and constitute significant obstacles. While images captured from hazy and dust fields usually preserve most of their major context, they require some visibility enhancement as a pre-processing before feeding them into computer vision algorithms. This pre-processing is generally called as image dehazing/dedusting, and image dehazing/dedusting techniques aim to generate haze and dust free images purified from the bad weather and dust

Figure 1. Example images captured in hazy and dust environment. (a) Hazy images and (b) Dust images.

environment events.

Sample hazy and dust images are illustrated in Fig. 1 (a) and (b), respectively. These images are captured under heavy hazy and dust conditions, where the objects, such as trees, excavators and roads are hard to identify, and the performances of computer vision technologies are limited under such conditions. To relief the influence of hazy and dust, single image dehazing methods have been proposed which dehaze an input image without requiring any extra information. Single image dehazing approaches are divided into prior information-based methods and learning based methods. Prior information-based methods are mainly based on the parameter estimation of atmospheric scattering model by utilizing the priors, such as dark channel priors, color attenuation prior and haze-line prior. Meanwhile, except the network structures, the performance of deep learning based approaches also rely on training data, and researchers tend to create synthetic dehazing datasets, which have a more practical creation process than real dehazing datasets.

According to previous approaches [6], hazy and dust

images contains three components, including transmission map, clean image and atmospheric light. The transmission map means the hazy/dust component, the atmospheric light means the atmosphere of the sky and the clean image is the target image that aims to recover. Most of current deep learning based approaches usually takes hazy and dust images as input and directly regress the clean images with direct supervision. In this paper, we propose a novel network which utilizes a closed-loop framework to effectively recover clean images using hazy/dust images as input. In specific, the proposed framework employs a U-Net structure which contains an encoder and three decoders, where the encoder aims to extract effective features, and the three decoders aim to recover the three image components of the hazy/dust images. Meanwhile, to guarantee that the network can be convergent, two losses are utilized. Firstly, clean loss: the recovered clean image should be same with groundtruth, which is the first loss. Secondly, reconstruction loss: the recovered transmission map, clean image and atmospheric light should reconstruct the hazy/dust images (input images) if the network works well, which means the closed-loop. The contributions of this paper can be summarized as:

- We propose a novel framework which contains a closed-loop structure and can recover the transmission map, clean image and atmospheric light of the hazy/dust images, simultaneously.
- Two losses, named clean and reconstruction loss, are utilized, which guarantees that the proposed framework can be convergent.
- Experiments demonstrate that hazy/dust images can be well tackled which prove the effectiveness of the proposed approach.

The remainder of this paper is organized as follows: related works are reviewed in Section 2, the proposed method is introduced in Section 3, the experiments and results at the actual site are described in Section 4, and the conclusions are presented in Section 5.

2 Related work

Currently approaches are mainly focus on image dehazing, which is divided into hand-crafted prior based and learning-based data-driven solutions.

2.1 Handcrafted Prior based Image Dehazing

Single image dehazing is an ill-posed problem in computer vision, and prior based approaches have been proposed to relief the problem. [7] proposes the dark channel prior (DCP) based approach, which is based on the observation that local regions in natural non-hazy scenes have

very low intensity in at least one of their color channels. The pixel values in the dark channel increases with haze increases. Thus, the value in the dark channel can be used to measure haze component and transmission map. Several techniques refined the DCP for halo free transmission map estimation using different edge-preserving smoothing filters. Except the dark channel prior, color-lines, color attenuation prior, color ellipsoidal prior, gamma correction prior, haze-lines also commonly used in image dehazing.

Meanwhile, previous approaches have proven that hazy images are prone to color cast issues in the presence of different atmospheric conditions like the sandstorm. Based on the observation, haze density weight along with white balancing for haze aware is utilized in image dehazing [8]. Besides, saturation correction that handles color cast is also proposed in image dehazing [9]. Furthermore, [10] proposes saturation-based transmission map estimation for dehazing which performs color correction using white balancing approach.

2.2 Learning based Image Dehazing

Deep learning based approaches have also proven the effectiveness in image dehazing. DehazeNet [11] proposes effective strategy to estimate the transmission map for image dehazing. Meanwhile, DCPDN [12] proposes a dense encoder-decoder model to effectively estimate the transmission map and atmospheric light, thus clean images can be obtained. Considering the image-to-image translation over the atmospheric model expression for image dehazing, [13] proposes a generative adversarial network (GAN) based Pix2pix network to recover clean images. Besides, [14] proposes GAN based model for dehazed texture-aware image dehazing, which comprises of CycleGAN and conditional GAN. In [15], the effectiveness of patch size is analysed in DCP based image dehazing approaches, and an efficient patch map selection mechanism is utilized through CNN for clean image recovery. Meanwhile, a gradient prior is utilized in [16] which combines the idea of DCP with a semi-supervised deep model to obtain clean images. GridDNet [17] introduces an end-to-end deep learning architecture with pre- and post-processing blocks to obtain clean images with hazing image as input. Multi-scale CNNs is also employed in [18] for image dehazing, and [19] produces haze-free images using multi-scale gated fusion network using encoder-decoder architecture. What's more, in RYF-Net [20], RNet, YNet and FNet are utilized for transmission map estimation in RGB and YCbCr space, respectively, thus clean images can be obtained with the estimated transmission maps. To well perform image dehazing, FAMED-Net [21] proposes a fast multi-scale dehazing model to fuse the response from a three scale encoder. [22] proposes to learn different levels of haze and develop an integration strategy to get the

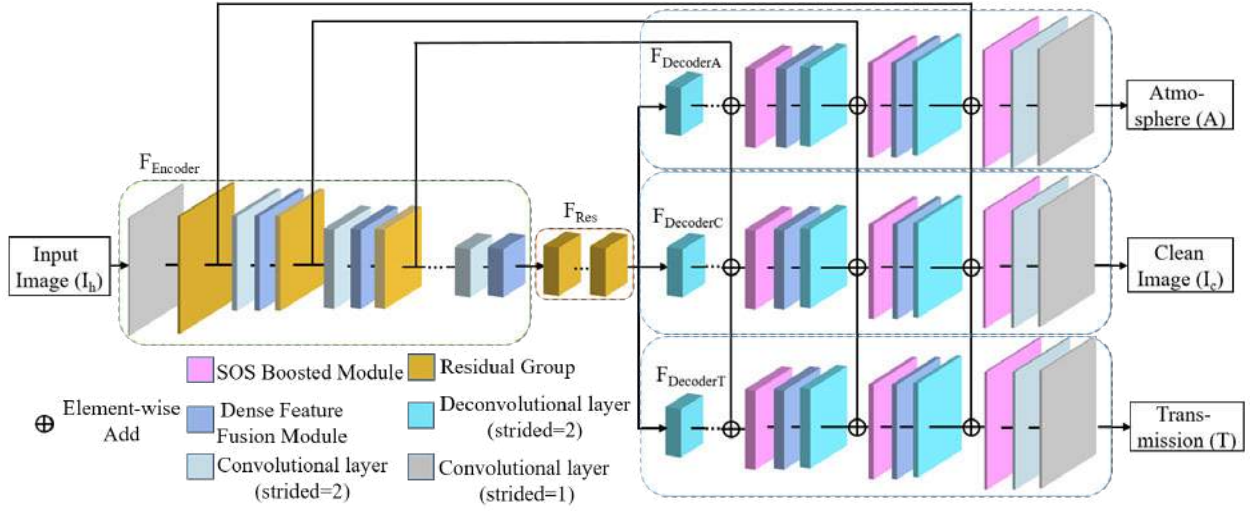

Figure 2. The figure demonstrates the network architecture of our approach. Using hazy/dust image as input, an encoder module and three decoders are used to recover atmospheric light (A), clean image (I_c) and transmission map (T) of the input image, respectively. $F_{Encoder}$ is first used to extract features, where Dense Feature Fusion strategy and Residual Group (F_{Res}) are utilized in the encoder process to obtain better features. In the decoder process ($F_{DecoderA}$, $F_{DecoderC}$ and $F_{DecoderT}$), deconvolutional layers are first used to up-sample the features, then SOS Boosted strategy is employed to enhance the obtained features. To obtain better results, the Dense Feature Fusion strategy are also used in the decoder process.

final dehazed images. Besides, [6] proposes a multi-scale based deep network which works on strengthen-operate-subtract-boosting strategy for image dehazing.

3 Our Approach

According to existing approaches [6], a hazy image I_h can be modeled as following:

$$I_h(x) = T(x)I_c(x) + (1 - T(x))A \quad (1)$$

where I_c denotes a haze-free clean image, A describes the global atmospheric light indicating the intensity of ambient light, T is the transmission map, and x represents the pixel position. Then, Eq. 1 can be reformulated as:

$$I_c(x) = \frac{I_h(x) - (1 - T(x))A}{T(x)} \quad (2)$$

Hence, the $I_c(x)$ can be obtained if transmission map T and atmospheric light A can be estimated. Besides, if I_c , T and A can be well recovered, the hazy image I_h can also be reconstructed. Based on Eq. 1 and Eq. 2, we propose an effective framework for image dehazing and dedusting.

In specific, the proposed network is based on the U-Net architecture, and the multi-scale boosted decoder (SOS boosting strategy) proposed in [6] is also utilized here. As shown in Fig. 2, the network includes three components, an encoder module ($F_{Encoder}$), a boosted decoder module ($F_{Decoder}$), and a feature restoration mod-

ule (F_{Res}). The boosted decoder module ($F_{Decoder}$) contains three decoders, including $F_{DecoderA}$, $F_{DecoderC}$ and $F_{DecoderT}$, which are designed for the estimation of Atmospheric light, clean image and Transmission map, respectively. Using a hazing/dusting image as input, the proposed framework can obtain the Atmospheric light, clean image and Transmission map, simultaneously. Specifically, SOS boosting strategy, dense feature fusion and residual group are used in the encoder and decoder processes.

3.1 Residual Group

Following [6], the residual structure is used in this paper, which aims to intensify the features using a residual mechanism. A residual block contains a Conv-ReLu-Conv structure and a addition operation, and the residual group contains K residual blocks. In this paper, we set $K = 3$.

3.2 Boosting Strategy

The effectiveness of boosting strategy has been proven in image denoising. Using the previously estimated image, [6] uses SOS boosting algorithm as a refinement process to obtain the strengthened image. The algorithm works positively to improve the Signal-to-Noise Ratio (SNR) under the axiom, and the denoising method with boosting strategy obtains better results in terms of SNR with less noise. For image dehazing, the SOS boosting

strategy can be formulated similarly as:

$$\hat{J}^b = g(I + \hat{J}) - \hat{J} \quad (3)$$

where \hat{J}^b denotes the estimated image after boosting strategy, and $g(\cdot)$ is the dehazing approach, and $I + \hat{J}$ represents the strengthened image using the hazy input I . Following [6] and as shown in Fig. 2, we also utilize boosting strategy to obtain better dehazing/dedusting image results in this paper, and please see [6] for more details.

3.3 Dense Feature Fusion Module

The U-Net architecture is commonly used, and several drawbacks exist, including: (1) the spatial information is missed in the process of the encoder block, and (2) the connections between the features from non-adjacent levels are insufficient. In this paper, to remedy the missing spatial information and exploit the features from non-adjacent levels, the Dense Feature Fusion Module (DFF) is used here. Following [6], the DFF aims to intensify the boosted features using an error feedback mechanism, which is used in both the encoder and the decoder blocks. As shown in Fig. 2, two DFF modules are utilized in both the encoding and decoding processes. In specific, one of the DFF module is used before the residual group in the encoder and another DFF module is used after the SOS boosted module in the decoder. Besides, feature fusion is also employed by connecting the enhanced DFF output in the encoder/decoder to obtain more representative features.

3.4 Loss

As discussed above, using the hazing/dusting image I_h as input, the proposed framework can obtain the Atmospheric light (A), clean image (I_c) and Transmission map (T), simultaneously, and the estimated A , I_c and T can be used to reconstruct the input hazing/dusting image, which means the closed-loop. Hence, two losses, including clean loss ($loss_c$) and reconstruction loss ($loss_r$) with L1 are utilized, which can be formulated as:

$$loss_c = \sum ||I_{gt} - I_c|| \quad (4)$$

where I_{gt} means the groundtruth clean image, I_c means the estimated dehazing/dedusting images obtained by our approach.

$$loss_r = \sum ||I_h - \hat{I}_h|| \quad (5)$$

I_h means the input image and \hat{I}_h means the reconstructed input image using estimated A , I_c and T with $\hat{I}_h = TI_c + (1 - T)A$.

The final loss is defined as:

$$loss = \alpha loss_c + \beta loss_r \quad (6)$$

where α and β are weight parameters and we set $\alpha = 0.5$, $\beta = 0.5$ empirically in this paper.

3.5 Implementations

In this section, we provide more implementation details of our approach. In specific, as shown in Fig. 2, in each decoder module ($F_{DecoderA}$, $F_{DecoderC}$ and $F_{DecoderT}$), convolutional and deconvolutional layers are used in this paper. And after each convolutional and deconvolutional layer, the Leaky Rectified Linear Unit (LReLU) with a negative slope of 0.2 is used. For the residual group [23], it consists of three residual blocks in (F_{Res}). In the encoder module, the kernel size of the first layer is set as 11×11 pixels, and kernel size with 3×3 is set in all the other convolutional and deconvolutional layers. The proposed framework is jointly trained and the Mean Squared Error (MSE) is utilized as the loss function to constrain the network output and ground truth. ADAM solver [24] is employed and the entire training process contains 100 epochs. We set $\beta_1 = 0.9$ and $\beta_2 = 0.999$ with a batch size of 16. The initial learning rate is set as 10^{-4} with a decay rate of 0.75 after every 10 epochs.

3.6 Evaluation metrics

To effectively demonstrate the effectiveness of our approach, following [6], two kinds of evaluation metrics are employed here, including PSNR and SSIM.

Given two images I_x and I_y with pixel values from 0 to 255, the formulation of PSNR is defined as:

$$MSE = \frac{1}{MN} \sum_{i=0}^{M-1} \sum_{j=0}^{N-1} (I_x(i, j) - I_y(i, j))^2 \quad (7)$$

$$PSNR = 10 \log_{10} \left(\frac{255^2}{MSE} \right)$$

where M and N are the height and width of I_x and I_y .

The structural similarity index measure (SSIM) is used for measuring the similarity between two images (I_x and I_y). And the formulation of SSIM is defined as:

$$SSIM = \frac{(2\mu_x\mu_y + c_1)(2\delta_{xy} + c_2)}{(\mu_x^2 + \mu_y^2 + c_1)(\delta_x^2 + \delta_y^2 + c_2)} \quad (8)$$

where μ_x and μ_y are the averages of I_x and I_y , δ_x and δ_y are variances of I_x and I_y , δ_{xy} is the covariance of I_x and I_y , c_1 and c_2 are two variables to stabilize the division with weak denominator.

4 Experiment

To prove the effectiveness of our approach, we provide the experiment results of our proposed dehazing/dedusting approaches in both qualitative and quantitative levels.

Figure 3. Visualization of dedusting results of real-world captured dusting images. The first rows are the input dust images and the second rows are the results obtained by our approach. As shown in this figure, the input images are suffered from heavy dust and our approach can remove the dust effectively.

Figure 4. Visualization of dehazing results of hazy images generated in traffic scenarios. GT means ground truth images. The first row shows the input images, the second row shows the results obtained by our approach and the third row shows the ground truth images.

Following [6], the RESIDE dataset [25] is used as the training data for image dehazing. The RESIDE dataset [25] contains both synthesized and real-world hazy/clean image pairs for both indoor and outdoor scenes. Hence, to obtain a dehazing model with better generalization ability, 9000 outdoor hazy/clean image pairs from the RESIDE training dataset [25] are selected as the training set. Note that the redundant images from the same scenes are removed to avoid over-fitting the training process. To augment the training data, the images of each pair are re-sized with three random scales within the scale range from 0.5 to 1.0. Besides, to further augment the training images, the hazy images are randomly cropped with resolution of (256×256) patches and flip operation with horizontally and vertically directions are utilized here.

Meanwhile, for image dedusting, we use real-world captured dust/dust-free image pairs as the training dataset, and these images are captured under real-world industry operation scenarios. The training data for image dedusting model contains 1000 image pairs.

4.1 Dehazing/dedusting results

Fig. 3 and Fig. 4 illustrate the visualization results of image dedusting/dehazing, respectively.

Fig. 3 demonstrates a digging and truck loading process of a excavator, which is captured in a real-world industrial operation scenario. As shown in Fig. 3 (input), the digging and truck loading process is suffered with heavy dust, and the working areas and the excavator are blurry. In such process, the machine, such as excavator, is difficult to detect for human eyes due to the existed dust, and it is even harder to detect for computer vision technologies. Besides, the operation areas, such as the rock areas, are also difficult to localize, even for humans, which heavily impede the automation of such process. As shown in Fig. 3 (results), our approach can remove the influence of dust effectively, and the areas of excavator and rocks are be easily found after the dedusting process.

Fig. 4 illustrates the dehazing results using hazy images captured in city scenes. As shown in Fig. 4 (input), hazy conditions are always exist in city and traffic scenes, which also heavily affect the detection and identification of buildings, cars and humans, etc. Besides, as shown in Fig. 4 (results), our approach can effectively remove the influence of hazy, and clean images can be obtained, which can help to detect and identify buildings, cars and humans, etc.

As shown in Fig. 3 and Fig. 4, our approach can effectively remove the dust and hazy components of dusting and hazing images, which can support the construction process in human working.

Table. 1 and Table. 2 demonstrate the quantitative results of PSNR and SSIM of the inputs and results obtained

Table 1. PSNR results of images shown in Fig. 4. The better results are shown in bold. "e-1d" mean results using one encoder and one decoder to recover clean images.

Eval	Test1	Test2	Test3	Test4
input	15.029	18.549	15.778	12.387
e-1d[6]	19.591	21.021	16.254	27.007
Our	20.035	21.411	16.620	27.501

Table 2. SSIM results of images shown in Fig. 4. The better results are shown in bold. "e-1d" mean results using one encoder and one decoder to recover clean images.

Eval	Test1	Test2	Test3	Test4
input	0.8041	0.8956	0.7845	0.7489
e-1d[6]	0.9207	0.9356	0.8525	0.9534
Our	0.9527	0.9603	0.8862	0.9707

by our approach. Test 1, Test 2, Test 3 and Test 4 in Table. 1 and Table. 2 mean the figures in Fig. 4. The PSNR and SSIM can be calculated with the formulation of Eq. 7 and Eq. 8. "e-1d" mean results obtained using one encoder-decoder structure [6], and "Our" mean results obtained using one encoder and three decoders with clean and reconstruction loss.

As shown in Table. 1, the PSNR results of our approach outperform the input images and "e-1d", which also prove that our approach can effectively remove the influence of hazy and recover better images that are close to the groundtruth. SSIM can be used for measuring the structure similarity between the recovered image and groundtruth. In Table. 2, better SSIM results can also be obtained by our approach, which prove that images with better structures can be obtained that are much more similar with the groundtruth.

5 Conclusion

In this study, we propose a closed-loop framework to remove the influence of dust and hazy in construction sites, which contains one encoder and three decoders. Taking a image with dust as input, the proposed framework can effectively remove the dust component, thus clean image can be obtained. To achieve this, we divide the image with dust into three components, including clean image component, atmospheric light component and transmission component, and a U-Net structure that contains a encoder and three decoders is used, where the encoder is for effective feature extraction, and the three decoders are for the recovery of the three image components, thus clean image, atmospheric light and transmission components can be obtained. Clean and reconstruction losses are utilized to guarantee that the network can be convergent. Experiments demonstrate the effectiveness of the proposed approach.

Abstract –

The use of robotics in construction improves safety and productivity in construction sites. However, there are limitations for construction managers to monitor robotic construction processes. This is due to the lack of well-developed human-robot collaboration interfaces. Digital Twin (DT) and Mixed Reality (MR) are two emerging technologies that can help to address these limitations by enhancing human-robot interaction, for on-site construction processes. However, DT in MR for human-robot interactions in robotic construction processes has not yet been widely studied in research or in practice.

This work explores effective human-robot collaboration for automated construction processes using on-site real-time DT of robotic process in a MR construction environment. First, a DT prototype of a robotic construction process establishes a two-way communication between the physical and virtual models of the robot arm. Next, real-time process data is collected from the robot and sent to the visualisation and database platforms. This work describes the workflow in order to send the real-time data to the MR headset for direct visual feedback and direct interaction with the robot arm. The prototype is validated using a case study demonstration of a robotic masonry construction process.

By demonstrating this proof of concept for real-time DT of robotic construction processes in MR, this work contributes to construction management for digital fabrication through human-robot collaboration. This work concludes with potential future research directions including data access and manipulation for digital processes in construction sites.

Keywords –

Robotics; Mixed Reality; Digital Twin; Human-Robot Collaboration; Real-time visualisation; Digital Fabrication, Augmented Fabrication

1 Introduction

The construction sector ranks almost the lowest in digitalisation amongst many other industries [1]. Research in digitalisation of the industry is needed to improve the current process of construction. One such digitalisation approach is the use of robotic technology. Recent research explores robotic technology to integrate design and construction processes and their adoption in the scale of industrialised construction [2].

Robots can be used for various repetitive and dangerous tasks [3]. The use of robots requires a better feedback loop between humans and robots for collaboration in design and construction processes [4]. Digital twin is an emerging technology to improve human-robot interaction for collaboration in construction [5]. The state-of-the-art digital twin concept in construction is described by Sacks et al. [6] as the “construction twin,” or in other words the twinning of the construction process. In the case of digital fabrication, when the construction process is undertaken by robots, the digital twin of robotic construction refers to the twinning of the robotic process.

Conventional robotic processes in the construction industry follow the workflow as shown in Figure 1. For the execution of a robotic process, first a code is written. The required data and the code are then sent to the robot for execution. The robot follows the commands as written in the code. Finally, the physical robotic task is completed. After the execution, a user inspects the commands procedure and creates a feedback loop by editing the code and sending it to the robot again.

Figure 1: Conventional feedback loop

However, this conventional feedback loop is relatively sequential and real-time feedback is not supported during the robotic construction process. This can be improved by a cyber-physical real time DT throughout the process [4]. DT enhances computational abilities and provides a collaborative system [5], [7]. Although DT can improve the collaboration, construction workers require the feedback to be in a visual format to better understand and respond efficiently [8]. This work proposes an alternative feedback loop that integrates information throughout the processes, while augmenting virtual feedback using DT and immersive visualisation in MR. The data produced in the process is stored in a database to use for future purposes such as progress monitoring or process automation. The proposed feedback loop is shown in Figure 2. It allows users to communicate with the robot in a much more efficient way. The proposed DT allows a two-way communication between the robot and the human to improve the effectiveness of the collaboration during the process.

Figure 2: Proposed feedback loop with DT in MR

2 Literature Review

This section explains the following four topics in recent research:

- Robotic construction
- Digital Twin (DT)
- Spatial Computing in Mixed Reality (MR)
- Data Management

2.1 Robotic construction

In construction, it is often challenging to use robots on site because many construction sites are unstructured and dynamic [9]. On one hand, robotic construction can save time, improve geometrical accuracy, reduce construction cost and improve site safety and human well-being [10]. On the other hand, it requires specific robotic expertise and information integration to operate robots on-site [11]. This can be improved by the use of dedicated sensing devices to improve the feedback loop [12].

Robotic technology has been adopted in the construction industry for many applications, such as

drywall installation, painting, welding, bolting, drilling, pouring concrete, masonry, façade installation, 3D printed formwork and external walls, timber structure assembly and autonomous anchoring [10], [13]–[17]. Construction robots often involve discrete interaction between human and robot during the robotic construction processes. For example, the feedback of scanned data has been used for robotic design and construction of timber architecture [19]. This can lead to safety issues, especially in a dynamic environment on the construction site [18]. The industry requires a more interactive and immersive feedback loop such as using sensing devices for humans to interact in real-time with robots [12].

2.2 Digital Twin (DT)

DT was first proposed by NASA to a novel "paring technology" to connect the real world and cyber world. It can increase the cognitive abilities towards intelligent and autonomous systems. DT has been used in various contexts by many researchers and industries.

DT for construction follows the twin of the building rather than the process. The DT as used in construction is described by Tao et al. [21] as a representation of three main elements: the physical element, the digital counterpart and the connecting link [6], [21]. It is referred to the Building Information Modelling (BIM) model as well as the data generated in the operational phase [22]. However, its foundational concept has not yet been well defined for construction processes.

Different from DT, the digital shadow represents a one-way communication to the physical representation; whereas, DT represents automatic two-way communication between the physical and digital environments. DT can be classified into two types - Product DT and Process DT [23], [24].

2.2.1 Product Digital Twin (DT)

Product DT refers to the twin of a physical asset, where the asset's properties and behaviour can be represented in digital form through modelling, analysis and simulation [25]. The difference between the digital model and the digital twin is the connection between the physical and digital models [26]. In the construction industry, product DT is often referred to as the digital asset of the building in the operational phase. It consists of the BIM model of the building together with live integrated data modelled with semantic relationships [27].

2.2.2 Process Digital Twin (DT)

Process DT refers to the dynamic behavior of the operation conducted with the physical counterparts to achieve real time synchronisation between the digital and physical environments. In a process environment, such as manufacturing, a digital twin would be used for monitoring, control, diagnostics and prediction [28]–[30].

Such a real time synchronisation of data can lead to efficient human-robot collaboration with virtual and physical objects. This facilitates innovative approaches for design, validation and control of the robotic processes [31]. DT can also be used for product life cycle management [21]. The process DT twin in the manufacturing industry is used to improve the human-robot collaboration using head mounting devices. Process DT includes the following properties [26]:

- Simulation of robotic process
 - Two-way communication with robot
 - Real time monitoring of sensed data
 - Data storage for future
- However, to date, there are few examples of process digital DT for construction robotics.

2.3 Spatial Computing in Mixed Reality (MR)

MR is the augmentation of virtual objects in the real world that can be visualised with a head mounted device. This allows users to see the real world as well as the virtual objects that are embedded in the real world. Within the concept of MR, spatial computing creates an environment for communicating and visualising the spatial relationships of the real world [32]. This enables real time interaction between the virtual objects and the physical environment. Spatial computing can be used to make the virtual object interact with the real world. MR can be used to control the robots [33]. In the construction industry, MR can be used for safety collaboration, site survey, prefabrication, remote design, training for workers and facility management [34]–[36]. However, there is no defined application of MR in robotic construction processes.

2.4 Data Management

Huge amounts of data are created in digital processes. Data in the DT of construction processes can be used for process tracking and project monitoring purposes [6]. The data here refers to the live data obtained from the DT, which can include any sensor data that is obtained in real time.

Available databases for data storage can be relational or non-relational. A relational database is often in table format. These are commonly used by Civil Engineers in .csv format so that it can be imported to Autodesk® Revit for scheduling or quantity takeoff purposes [37]. Relational databases are not highly scalable; often this data structure gives rise to high complexity as data cannot be easily encapsulated in a table [38]. The creation of a DT for construction robotics requires multiple sources of data from various sensing technologies. Thus, there is need to explore of non-relational databases in construction DT to accommodate

data from multiple sources.

Data obtained from DT can be used for various purposes such as optimising the process that is being executed by making the robots process aware. This can be achieved by creating semantic data relationships to open up intelligent semantic platforms (referred to as Generation 2) and agent driven socio-technical platforms (Generation 3) of a Construction Digital Twin [27]. Furthermore, an ontology-based communication can be used in a standardised way for data transfer [39].

3 Workflow

Figure 3 shows the proposed workflow for the DT of robotic construction process in MR.

Figure 3: Workflow of the DT of the robotic construction process in MR

This workflow represents the procedure that is required to be followed for any robotic construction process. The process includes design, robotic operation, visualisation in MR and data storage.

Design is the first step in a conventional construction process. The required data from the design is filtered and sent to the robot, depending on the task that the robot would perform. The level of detail of data sent to the robot depends on the geometrical information required for path planning, to define the robotic process. Path planning represents the local navigation of a robotic system. The robotic process can be simulated and visualised in MR prior to sending it for operation to the robot. Any change in design can be altered during the robotic process and visualised in MR. Further, the data during the DT process is stored in a database, which acts as a log that can be used for process monitoring purposes.

4 Validation and Findings

To verify and validate the proposed workflow in Figure 3, a prototype of a robotic masonry construction process for a robotically fabricated wall is conducted as a case study.

4.1 Masonry Construction

4.1.1 Modelling

First, the masonry wall is modelled using computational design as shown in Figure 4. The bricks are modelled as mesh objects in Rhinoceros 3D (Rhino)[®], along with the information of the plane at the midpoint of each block. A reduced scale of 1:2.5 of the standard brick size is used. The width of the brick must lie in the tolerance value of the robotic pickup tool. The data extracted from modelling for robotic execution are the midpoints of each brick along with the plane of orientation and the width of each brick. In the Grasshopper script, each plane representing the midpoint of the block is stored in the plane component. This component is connected to robotic execution for the “Place location” of the brick

Figure 4: Wall model in 3D

4.1.2 Robotic process

Figure 5: Robotic path planning

The robotic process involves path planning of a robot for the masonry work. The Universal Robot 5 (UR5) was used for the prototype. The robot can be seen in Figure 6. The path of the robot follows repetition of the picking and placing of the bricks. The path is visually coded using the Robots plugin in Grasshopper. **Error! Reference source not found.** shows the points of placing the brick along with the pickup point. Once the path is simulated and is ready for execution, data can be sent to the robot through LAN connection to pick up bricks at a dedicated location. The execution follows the path shown in Figure 6. The following steps are shown as follows:

1. Unobstructed point above pick up location
2. Pick up location
3. Unobstructed point above pick up location
4. Unobstructed point neat place-location
5. Place point – obtained from model
6. 30mm above place point
7. Unobstructed point neat place location

Figure 6: Robotic Positions

4.1.3 Visualisation

The simulation and the live data obtained from the Rhino Grasshopper are visualised in the MR. The mesh data is sent as a game object from Grasshopper to Unity® using Rhino®. Inside Unity and visualised with the MR headset using Zero Iteration. In this work, Magic Leap headset is used for visualisation. It allows users to monitor the entire process of simulation and the robotic operation. Visualisation of the simulation in MR is a step for *Virtual Commissioning*, which is used to simulate the expected manufacturing systems and control programs prior to execution of the physical system. This simulation visualises both the robot and the robotic process in the real place on-site [33]. After sending the robotic commands, the live position of the robot is obtained for visualisation. This visualisation allows the user to live monitor the process. Figure 7 **Error! Reference source not found.** shows the live position of the robot as well as the mixed reality parallel to each other. Also, the robotic process can also be monitored and controlled remotely using Magic Leap® MR control tools.

Figure 7: Real and Virtual display

4.1.4 Data Storage

The live positions of the robot are recorded each second from Grasshopper and sent to Dynamodb using Amazon Web Services. The current data includes the angle of each joint of the UR5. In future, if more sensors are added for monitoring in the construction process, the items can be added directly to the Dynamodb database for storage. Each element would be represented in a well-defined format as explained below. This format can be used for all future projects.

```
{
  "Time": "05/09/2021 16:54:06",
  "Type": "Robot",
  "Robot": {
    "FkInput": "3.699685| -1.825343| -1.045692| -1.842495|1.57278|3.701816"
  }
}
```

The "Time" attribute represents the time of the sensor data received. It also acts as the primary key to the database, which means all the values are unique. The "Type" attribute represents the information of the type of

sensor that is being used. Here, the sensor is directly from the robot and thus has the value of "Robot". The technology is represented by "Robot" attribute. The value corresponds to the data obtained from the robot. In this the value represents the angle of each joint of the robot at an instance of time. The robotic configuration of UR5 can be reconstructed using this value. For other sensors, the attribute changes to the corresponding sensor information retrieved.

4.2 Discussion

4.2.1 Potential Applications

1. Process Monitoring

Figure 8: Process monitoring

Construction managers can use the proposed workflow for process monitoring as proposed by Sacks [6]. The project intent and status information can be obtained from the visual information seen in mixed reality. This information can be used directly by the users to monitor, control and update the real-time progress of construction in DT. Reality capture can also be added as one of the sensor inputs to be used for progress monitoring management [20].

Furthermore, digital fabrication engineers can use process monitoring to compare the intended information to the actual completed process. This can help when material behavior is not well known. For example, the application of materials such as concrete, fabric etc. where the material properties are not rigid and are not easy for simulation.

2. Remote Monitoring

Construction managers or project owners can use the proposed workflow to monitor the process from a remote location, away from the construction site, as shown in Figure 9 **Error! Reference source not found.** Managers can simultaneously monitor different zones or locations of the construction site enabling them to multitask more efficiently. For project owners, the progress of the construction can be monitored completely remotely. It gives the owners an opportunity to know the status of construction while remaining in an office far away from the construction site.

Figure 9: Remote monitoring

3. On-site virtual commissioning

Digital fabrication engineer can use real place virtual commissioning as a pre-check in the construction site, before the execution of the robotic process [40]. The robotic process can be checked on the site using MR. This can help to avoid collisions within an unstructured construction site as well as avoid the bottleneck of activities due to uncertainty in execution. This virtual commissioning can also facilitate coordination amongst the project teams – in particular the digital fabrication design coordinator – to comprehend and incorporate digital fabrication requirements during design development of the design process [41].

The proposed use cases for various project roles are summarized in Table 1.

Use Case	User	Application
Process monitoring	Construction manager	Live status update
Process monitoring	Digital fabrication engineer	Live monitoring of intended and executed details
Remote monitoring	Construction manager; owner	Remote monitoring of multiple projects
Real-place virtual commissioning	Digital fabrication engineer	Precheck of the process before execution
Real-place virtual commissioning	Digital fabrication Design coordinator	Incorporate digital fabrication requirements in design development

Table 1: Potential applications

4.2.2 Limitations and future research

The digital fabrication process is dependent on the type of task done by the robot. Each process requires specific input and process development. The validation of the workflow was done using the masonry wall construction. In brick masonry, the geometry of the wall

with the mid-point and plane data of each brick is necessary and sufficient data for robotic construction. The robotic execution is a process-orientated setup. Each type of function would require basic understanding of the function to be performed by a human. This will help in creating a better human-robot collaborative environment. The details in each robotic process are unique to its application. More research is required to study the process as well as consider what technology would be required to sense the monitoring process, with the potential future development of a holistic framework for real-time DT of on-site robotic construction processes to be visualised in MR.

The currently used MR headset had a least count of 100mm, whereas the robot has a least count of 1mm. This means any value between 51mm and 150mm for the robot would correspond to 100mm if measured using MR. Thus, the spatial information from the MR in this workflow cannot be sent to the robot for execution of the process. Future research can be done to improve the sensor accuracy of the MR device. If required, an external sensor can be added to the DT to measure distance more accurately.

The data used in the DT process is directly extracted from the robot. In future research, more sensors can help in better feedback of the robotic process. The database created in this research allows the addition of data from multiple sensors of any type. More research is needed to determine which sensors should be added and the relevant data required for the process.

The data is stored using the Amazon DynamoDB database. The database needs to be filtered and queried according to the use case. The current approach lacks semantic relation to the entities. With the addition of more sensors, the structure of data should be supported by the creation of ontology to show the execution of the process.

5 Conclusion

This work combines state-of-the-art research on robotic construction, DT, spatial computing in MR, and data management to propose a workflow for a DT of

robotic construction. The DT is visualized in a MR prototype using multiple computational design platforms. The workflow is validated using a brick-laying construction process that uses a UR5 robot arm. The prototype demonstrates how the workflow enables a real-time DT of robotic processes for on-site construction. This work discusses three potential use cases of the prototype – process monitoring, remote monitoring, and real-place virtual commissioning – in construction including potential users and their applications. Moreover, this work illustrates the limitation of this research and the potential lines of future research.

Overall, this work contributes to the body of knowledge in construction twins and construction management using MR technology. Based on the findings, DT helps to improve collaboration for human-robot interaction and enable remote control, monitoring and real-time updates of the robotic processes using MR technology. Also, BIM-based DT of robotic construction in MR facilitates information integration and data management for digital fabrication adoption in design. Furthermore, the DT allows users to give the feedback to the robotic process in a more efficient way with an immersive environment for visualisation and human-robot interaction.

6 Acknowledgement

The authors would like to thank Magic Leap® Zurich for their support and collaboration of this research.

Abstract

Mechanical, Electrical, and Plumbing (MEP) play a crucial role in civil construction projects. MEP is characterized by various interdisciplinary and interconnected activities of multiple trades. Traditionally, not updated design information and communication problems are very common in this industry. Thus, schedule delays and cost overruns are frequent in MEP construction projects. Furthermore, relatively low penetration of digitization and very few applications of new technologies can be mentioned as main inhibitors for performance improvements in this industry. Augmented Reality (AR) in combination with Building Information Modeling (BIM) are some of the emerging technologies that support providing information in real-time, on-demand and location-based. By using as case study, a multistorey apartment building we compared the performance of conventionally MEP practices and the support with an AR head-mounted display. The study results showed measurable benefits in terms of significant reductions in execution time. However, also potential negative effects like increased work accident risks were recognized. The results are further discussed in a SWOT analysis that examines the AR application in terms of performance inhibitors and enhancers in both internal and external settings. Future research activities should consist of developing a standardized implementation model to best exploit the benefits of AR also within other construction trades.

Keywords –

Augmented Reality; MEP; Construction; SWOT; Performance; BIM

1 Introduction

Mechanical, Electrical and Plumbing (MEP) works are characterized by different skilled labours requiring

high coordination efforts. Generally, MEP covers air conditioning, heating and ventilation systems (HVAC), water supply and drainage systems, firefighting and fire protection systems, as well as electrical power and lighting systems. Traditionally, MEP works can be considered as an important construction trade, generally making up from 40 to 60% of total project costs [1].

Further, MEP works on-site are characterized by budget and time constraints as well as complex management of multiple simultaneous processes and stakeholders [2,3]. Conventional MEP works constitute lengthy processes using 2D drawings of different MEP systems to find possible conflicts or coordinate various tasks amongst different trades on-site. Often the drawings and documents are not up-to-date, incomplete, and not digitized making it hard to search for useful information. Digitization of information is very important to reduce non-value-adding activities in MEP systems [4].

Emerging technologies such as Building Information Modeling (BIM) and Augmented Reality (AR) have high potential to improve the previously mentioned issues [5]. BIM is a digital representation of a physical building that serves as a shared information database and supports decision-making throughout its life cycle [6]. AR places the user in a real environment augmented with additional information generated by a computer creating a new form of a context-aware interface [7].

It has been shown that AR systems increase productivity in areas such as maintenance [8,9], logistics [10], and training of complex tasks [11] by supporting these works with step-by-step guidance [11,12] or through supervisory control to find i.e. installation errors [13]. Due to the complex structure in building and MEP projects and the client-contractor dynamics, as well as the inherent image of being expensive and immature, AR has not been widely applied in the construction industry so far [14]. In addition, the slow adoption of new technology makes construction one of the least automated and digitized industries [15].

The rarity of skilled MEP workers, the increase in labour and material costs, the pressure from owners to

deliver a project faster and with lower costs, as well as the heightened complexity of MEP systems pose major challenges for companies in this sector [16,17].

This paper aims to show that AR technology applied in a case study of MEP installation in a multi-story apartment building helps increasing efficiency compared to traditional working methods. The main results of the case study application are summarized in a Strengths, Weaknesses, Opportunities, and Threats (SWOT) analysis.

2 Literature review

In section 2.1 BIM and the integration of AR are described. Section 2.2 presents the general application of AR and section 2.3 describes the state of the art of AR applications in construction.

2.1 BIM and AR integration in construction

AR integration with BIM consists of displaying digital models and other correlated data in real-time by augmenting them to the physical context of construction [12]. Generally, the research on BIM-AR integration is still ongoing and limited to only a few successful implementations [18]. Although several construction management software products are available on the market that integrate AR/VR technology to visualize interactive 3D models on-site, they lack the ability to display tasks and task related information as well as construction progress and performance [19].

2.2 AR in other sectors

AR is applied in various industries and fields as a tool to effectively deliver information to workers with the aim to increase productivity. Examples include automotive maintenance [8], aeronautical maintenance [9], logistics [10], control cabinet production [20], hospitals [21], manufacturing [22], as well as training of complex skills [11]. In these studies, tasks supported by AR could be substantially improved compared to traditional information systems such as paper-based manuals, drawings, or photographs. Further, AR accelerated the training process of assembly routines as well as increased the work memory retention. Literature reports that especially users with more work experience [8,9] or with less cognitive skills [23] could benefit the most from AR support. The analysed studies show that AR supports training and it reduces errors as well as the number of decisions to be made by the operators, and the time needed to finish tasks [8–11,20].

In addition, users of AR benefit from reduced cognitive workload, uninterrupted work via the guided

work instructions, and hands-free work in case of an AR head-mounted display (HMD) [8,9,11].

Table 1. General AR applications

Authors	Area/Industry	Results
Jetter, Eimeck, and Reese 2018 [8]	Automotive maintenance	Time and errors reduction with AR support
Loizeau et al. 2019 [9]	Aeronautical maintenance	Time and errors reduction, as well as less cognitive load with AR support
Remondino 2020 [10]	Logistics	Faster training and execution of storage operation, transport optimization
Khokhovsky et al. 2019 [20]	Control Cabinet Manufacturing	Reduced decision making and less errors with AR for assembly
Yoon et al. 2018 [21]	Hospital; Surgery	AR HMD enhances surgeons' operating experience regarding attention, procedure planning and time savings
Baroroh, Chu, and Wang 2020 [22]	Manufacturing	AR supports assembly operations, reduces human's mental workload, facilitates information exchange between operators and machines in real-time
Hou et al. 2017 [11]	Maintenance training in oil & gas industry	Decreased time and errors; faster learning with AR

2.3 AR applications in construction

Wang et al. [12] present the application of an AR HMD to provide design information in real-time resulting in significant time reductions for cognitive tasks (e.g. reading of drawings and work instructions). Hou et al. [11] developed a training framework for AR systems to teach complex procedures and increase skill levels in the oil and gas industries that allowed to decrease time and errors for completing maintenance tasks. Similar results were achieved by Chalhoub and Ayer [24] who compared the performance of Mixed Reality (MR) with the traditional paper-based method of providing design information for the assembly of prefabricated electrical conduits. Faster assembly times, less time needed to understand the given tasks, and less errors were the results. In this direction, Kwiatak et al. [23] found that the support of AR in the pre-assembly of pipe spools led to a considerable reduction of assembly task durations.

Participants with low spatial skills benefited the most from the AR application, deeming it suitable for training purposes. Considering the area of facility management, El Ammari and Hammad [25] developed a BIM-based MR approach to allow remote collaboration and visual communication between the office and on-site field workers. By using an Immersive Augmented Virtuality application, the office had the same view as the operator on-site that allowed to save time in data retrieval and approvals, and at the same time making less errors on-site. In this direction, Chen, Lai, and Lin [26] developed a fire safety equipment (FSE) inspection and maintenance system based on AR to provide information to the inspectors and engineers while doing maintenance and repair works. Compared to the traditional paper-based method, considerably time savings and fewer errors could be reached.

While some works regarding AR applications in construction to support training, assembly, or maintenance tasks could be identified, the literature indicates that guidelines, best cases and standardized implementation models are missing for a successful roll-out of AR in construction.

Table 2. AR applications in construction

Authors	Area/Industry	Results
Wang, Love et al. 2013 [12]	Architecture, Engineering, Construction and Facilities Management (AEC/FM)	BIM+AR support on-site helped in retrieving needed information, reduced errors, and tracked material flow
Hou et al. 2017 [11]	Oil and Gas facility operation and maintenance	AR helped to train complex skills faster, increased productivity, reduced rework, improved work safety
Chalhoub and Ayer 2018 [24]	Construction industry (electrical construction)	The use of MR led to higher productivity, reduced time to understand tasks, produced fewer errors, and increased accuracy
Kwiatek et al. 2019 [23]	Construction industry (assembly tasks)	AR helped to save time, provided strong cognitive support
El Ammari and Hammad 2019 [25]	Facility Management (FM)	AR improved field task efficiency via minimized data entry and errors, and reduced task time
Chen, Lai, and Lin 2020 [26]	Fire safety equipment (FSE) inspection and maintenance	Less maintenance duration, less errors, and paper-less work was achieved with AR support

3 Research methodology

The case study research method is based on the works of Hale [27], Kothari [28], and Zainal [29]. Specifically, our research follows three main steps: i) study design, ii) data gathering (observation), and iii) data analysis [28].

Step 1: Study Design

A multi-apartment building was selected for the case study to compare the performance of the carried-out tasks with and without AR support. This project case was identified because the design of the apartments of the ground floor was very similar with the one on the first floor. The project duration was around six months.

At the beginning, an analysis of the tasks that were suitable to support with AR was conducted. The tasks selected to be supported with AR were marking works for the installation of heating, ventilation, and sanitation as well as electrical tubes.

For the AR HMD, the Trimble XR10 safety helmet that incorporates the Microsoft HoloLens II was selected. We selected the application BIM Holoview (<http://www.bimholoview.com/>) because of the following reasons: i) user-friendly interface and very clear commands to execute, ii) possibility to colour the different assets and elements and iii) possibility to use it also without internet connection. The results were analysed and summarized in a SWOT analysis.

Step 2: Data gathering

Four foremen and the MEP company's BIM coordinator formed the case study's participants. The BIM coordinator is qualified as a mechanical engineering technician with eleven years of working experience. All foremen are certified installers with eight to twenty years of work experience, either for heating, ventilation, and sanitary (HVS) works, electrical installation, or underfloor heating (UFH) systems.

While the participants performed the given tasks, performance data such as time and accuracy were gathered by direct observations. To assure transparency and traceability of the data, the marking works with the AR HMD support were videorecorded. Time was measured by deducting the start of the operation from the end of the operation (cycle time).

The accuracy of the marking works was checked with the dimensions in the BIM model design and the corresponding deviations were noted in X and Y axis with positive values. The accuracy of the Z-axis was not controlled because the height of the objects in the BIM model was not modelled correctly.

Step 3: Data analysis

The analysis of the cycle time was recorded by mapping the relative time efforts compared to the traditional method for each main activity (e.g. marking of

underfloor heating) and construction location (e.g. kitchen apartment 1). Considering the accuracy levels, the average accuracy per task and per location was calculated. To give an indication of the reliability of the calculated average values we also inserted the number of values per task and construction location.

Finally, the case study results were summarized and discussed by using a SWOT analysis. Here, the AR support for marking works was analysed considering the strengths, shortcomings, opportunities, and threats for a daily use in practice. Thus, the analysis serves to establish initial guidelines for applying AR in construction.

4 Case study application

4.1 Case study description

The case study company is of medium-size and specialized in Mechanical, Electrical and Plumbing (MEP) works. As case study project, a medium-sized multi-apartment building in Northern Italy with five apartments on three levels was chosen. It was selected according to the following criteria: i) manageable size, which is not too complex and not too big for the tests on-site; ii) identical apartments on the ground and first floor being able to compare the work processes with and without AR support. An initial analysis was carried out to identify suitable work processes for the AR support. As a result, the MEP company decided to use AR to support the marking works for the installation of heating and sanitation tubes (HVS) as well as the underfloor heating (UFH) in the apartments and electrical pipes. The traditional way for doing the marking works consists of using 2D-drawings, a measuring tape and a spray can needed to indicate where the tubes should be placed on-site. Consequently, the marking activities with and without AR were compared.

The test started in June 2020 and finished in September 2020. Four foremen and the company's BIM coordinator participated in the tests. One foreman was responsible for the HVS works, another for the electrical installation, and two for the UFH installations.

The marking of the wall trenches for the HVS and electrical lines, as well as for the UFH were carried out with conventional means on the first floor, while on the ground floor they were supported by the AR HMD. This allowed a direct comparison between the two.

The shell construction was surveyed by means of a laser scanner and afterwards a so-called As-Built BIM model was elaborated. This served as basis for the AR support. The BIM model was georeferenced in the AR HMD by using two QR-markers.

The marking works supported with the AR HMD for the wall trenches are shown in Figure 1. The picture on

the left displays the view through the AR HMD, while the picture on the right shows the marking works done with spray cans.

The carried out marking works were recorded via video and afterwards the times of the works were analysed and compared.

Figure 1. Marking works with the AR HMD (Trimble XR10 - Microsoft HoloLens II)

4.2 Results

Figure 2 presents the relative time recordings for the marking of HVS, UFH and electrical works with the AR HMD compared to the traditional working method.

The AR supported marking works for HVS took around 23.3% longer in the eat-in-kitchens than with the conventional method (Figure 2). Conversely, the marking works for the UFH were 39.3% faster with the AR HMD in the eat-in-kitchens (Figure 2). Similarly, the AR-supported marking works in the bathrooms for HVS and UFH were 44.1% and 76.7% faster, respectively (Figure 2). Considering the HVS marking works in the toilet, 52.6% less time was used and a reduction of 84% for the marking works for electrical lines in the kitchen could be achieved with the AR support (Figure 2).

Summing up, between 39.3% and 84%-time savings could be reached by supporting the MEP marking works with the AR HMD.

The average accuracy of the MEP marking works with the AR HMD compared to design is presented in Figure 3. Here, the accuracy was measured by comparing the actual measurements on-site with the As-Built BIM model. The deviation is on average 8.03 cm for the accuracy of the markings for HVS in the eat-in-kitchens with 3 measurements (Figure 3). Similarly, the accuracy of the marking works for the UFH in the eat-in-kitchens is on average 4.56 cm with 18 measurements (Figure 3). The marking works for HVS in the bathrooms and toilets had average deviations of 3.75 cm with 8 measurements and an average of 10.25 cm with only 2 measurements, respectively (Figure 3). For the UFH marking works the average deviations from design are 2.8 cm with 3 measurements (Figure 3). Marking works for the electrical installations had a deviation of around 2.67 cm with 6 measurements.

Figure 2. Relative time efforts compared to traditional method for marking of HVS, UFH, and electrical works (negative values represent time savings and positive values additional time expenditures)

Figure 3. Average accuracy of marking MEP compared to design (bars in dark grey show average accuracy X-Y and bars with scattered grey visualize the number of measures)

In summary, it seems that the accuracy level increases with the number of measurements for the carried-out markings. The greatest accuracy was achieved with AR in complex areas where the operator traditionally needs

to seek out plans and drawings and take numerous measurements.

The average accuracy of the marking works with the AR HMD amounts to 3.68 cm for the UFH, 7.34 cm for the HVS, and 2.67 cm for the electric works. Therefore, it can be concluded that the AR HMD reached an accuracy level in X and Y axis between 2 and 8 cm.

5 Discussion

A SWOT analysis was chosen to discuss the performance inhibitors and enhancers of using AR by the MEP company in both internal and external environments. Therefore, general conclusions are drawn from this study for the use of AR in construction.

5.1 SWOT analysis

The SWOT analysis summarizes the strengths, weaknesses, opportunities, and threats of using the AR HMD to support marking works of MEP installations (Table 3). As a strategic planning tool, it compares the own activities (inside) to the competition (outside) and helps to set the right strategy, resources, and budgets as well as initiate projects and take related measures. Strengths (enhancers of performance) and weaknesses (inhibitors of performance) lay within the control of an organization, while opportunities (enhancers of performance) and threats (inhibitors of performance) are considered outside of an organization.

Typically, a SWOT analysis helps to expose the optimal combination between the internal strengths and weaknesses of a company and the environmental trends (opportunities and threats) that the company must face in the marketplace.

The identified strengths regarding AR can be seen as a resource or approach to achieve defined goals (e.g., AR can reduce training or assembly times). The weaknesses reveal the limitations or defects that AR brings towards achieving defined goals (e.g., AR could reduce work safety on-site due to impaired view). The opportunities refer to internal or external drivers in the industry, such as a trend that increases demand for the company to provide more effectively (e.g., reduced workload and faster task execution on-site). A threat can be any adverse situation in the company's environment that interferes with its strategy by presenting a barrier or constraint that restricts the accomplishment of defined goals (e.g., AR is believed by the management to be too expensive to incorporate into mainstream practice).

Table 3 shows the detailed SWOT analysis that was performed to analyse and discuss the case study results.

Table 3. SWOT analysis

Strengths
Time savings on-site via MS HoloLens II
Fast and intuitive training of new employees
Hands-free work
Easy detection of design and execution errors
Facilitates decision making regarding potential customer changes
Higher work safety since helmet is worn inside the building
Decreased cognitive load
Affordable initial purchase of AR HMD
Georeferencing directly on-site via markers
Weaknesses
Need for technology savvy employees
Required accuracy may be not enough to support construction activities
Uncomfortable to wear for long time
Software application costs are not negligible
Work safety risk during concentrated work
Georeferencing/Calibration on-site is difficult without markers
AR glasses cannot be removed without helmet
Opportunities
Higher efficiency and faster on-site execution
Reduced workload for employees on-site
Early use of technologies with high future potential
Digitization of the entire value chain
Collision checks during on-site project meetings
Threats
Required know-how to set up the AR HMD
High risk of damaging the AR HMD during construction works on-site
Technology change through scaling could make early investments in AR redundant
Technology currently not ergonomic and easy to use that may change in the near future

MEP practices supported by the AR HMD on-site can save significantly more time compared to the conventional working approaches. Further, the decreased perceived workload of the users led to better concentration on task execution with higher productivity. The users perceived the AR HMD as easy to learn and use. This resulted in reduced training efforts due to the immersive and interactive interface of the Microsoft HoloLens II. This is especially useful for novice operators or apprentices who are yet unfamiliar with certain tasks. Fifteen minutes were needed for training the participants and the training content could be easily applied into practice.

Considering the weaknesses of the AR HMD the following points were mentioned. The customer required an accuracy level of 0.5 cm in the bathrooms which could not be achieved in our case study. The desired accuracy depends on the AR HMD device, the used AR software, the georeferencing functionality, and the user himself. In the view of ergonomics, increased use of the AR HMD could lead to strains and pains which affect the user. Further, due to the slightly impaired field of view the work safety of the user could be impacted. An increased attention from the users is needed to prevent overseeing trip hazards on-site. However, according to the

participants the AR HMD would not have a major negative impact on work safety. Finding tech savvy employees and providing sufficient training is needed to successfully implement the AR technology in practice. Concerns were raised regarding the price-performance ratio of the AR HMD and the BIM software as well as the AR application used in the HMD.

The following section summarizes the main opportunities of the AR HMD to support construction processes. According to the case study results, higher efficiency levels and thus faster on-site executions can be reached. An employee on-site could be supported by experts or managers in the office and thus facilitating decisions making, faster on-site execution, as well as reducing the workload for the employee on-site. AR is a technology with high potential in future digitization of the entire value chain in construction.

Considering the main threats, in order to properly set-up and use AR in construction, specific knowledge and competencies are required. Recruiting high qualified staff may be especially difficult for small and medium-sized enterprises. Another potential risk in early investments is that the technology could potentially change or in other words improve in the short or mid-term. This could make early investments redundant. An investment in AR could be cheaper in the future through progress and scaling of the technology.

5.2 Practical insights

The following section describes practical insights that were recorded during the use of the Microsoft HoloLens II with the BIM Holoview application to support marking works on-site. At the beginning, the AR HMD needs a solid-warm-up time for a correct and stabilized projection of the hologram. This because the system needs to find its orientation in the room and therefore the user should move the AR HMD inside the room. In order to not losing accuracy, the user should be positioned with an angle of 90° to the hologram. Currently, the AR application allows only for a maximum of two QR-markers per location for its calibration. To avoid potential deviations caused by georeferencing, the two QR-markers should be positioned on a straight connected wall and not on two different walls facing an angle.

According to the literature, guidelines, best cases, and standardized implementation models are needed for a systematic and sustainable implementation of AR in the construction environment. Thus, the results of the paper can be used to guide AR implementations in other contexts and project scenarios of the construction industry.

6 Conclusion and outlook

Mechanical Electrical and Plumbing (MEP) play an important role in civil construction projects. MEP works are characterized by an increasing level of complexity as well as by various interdisciplinary and interconnected activities of multiple trades. Thus, schedule delays and cost overruns are frequent in MEP construction projects. Emerging technologies like Augmented Reality (AR) in combination with Building Information Modeling (BIM) support construction works by providing information on-demand, location based and in real-time. However, AR has been mainly applied in sectors like logistics, aeronautics, and automotive and scientific literature reveals a limited application in construction.

In the case study we empirically validated the use of an AR head-mounted display (HMD) to support marking works for MEP installations. The case study results revealed a drastic reduction of execution times on-site. At the same time, a high acceptance level and perceived usefulness of the AR HMD was recognized by the construction operators. Moreover, thanks to the very intuitive interaction functionalities of the AR HMD (Microsoft HoloLens II) a reduced training effort needed to understand the usage of the equipment was registered. However, also potential negative effects like higher work accident risks were recognized. The results were further discussed in a SWOT analysis by examining the AR application in terms of performance inhibitors and enhancers in both internal and external settings.

Although, our research faces some limitations. Firstly, the limited number of participants and the size of the case study restricted the amount of the gathered data. The accuracy was only measured in X and Y axis but not in Z axis. Moreover, deviations caused by the technology, or the human operator were not specifically measured and extrapolated. Further, the AR HMD was applied just to support marking works for MEP installations on-site.

Future research directions should distinguish deviations induced by human operators as well as the technology when measuring accuracy levels of the AR HMD. The integration of technologies such as RFID, GPS, Artificial Intelligence (AI), or motion detectors in AR could shape context-aware learning and execution experiences for the users. This could lead to more proper response and decision awareness in real functional settings. ‘Digital Twins’, a concept from manufacturing in which data is visualized in real-time and a bi-directional communication between the physical and virtual realm, could also aid in better decision making. The SWOT analysis highlighted that AR already has some useful applications in construction when compared to traditional working methods. However, there are still opportunities for improvement and further applications of AR should be initiated in the construction domain.

Abstract –

On-demand and real-time building information is of great value to support facility management. Such information can be easily retrieved from an up-to-date building information model (BIM), and then intuitively presented to facility managers or inspectors by augmented reality (AR). However, effective spatial registration into BIM so as to align the virtual and real content still remains an unresolved challenge. Leveraging recent development in the field of generative networks, this paper proposes a markerless registration approach that can automatically align BIM with the real view captured by a mobile device without any manual operation. A mobile AR application is developed based on the proposed registration approach. Our field experiments demonstrate the effectiveness of the proposed approach for automated BIM registration. The successful registration thus allows users to access the rich building information, especially invisible utility such as the mechanical, electrical and plumbing (MEP) system, in the real-life context for better facility management practice.

Keywords –

Augmented reality; Facility management; Markerless spatial registration; Building information model (BIM); Generative adversarial network (GAN).

1 Introduction

The importance of facility management (FM) can

never be overstated for built environments such as buildings and civil infrastructure [1, 2]. Without periodical inspection and maintenance, undesired defects or safety issues can continuously deteriorate, eventually leading to disastrous consequences in terms of economics, life, and social impacts [3]. During FM, inspectors or facility managers rely on relevant building information (e.g., equipment specifications, building materials, and spatial layout) to support decision making and condition assessment. This is especially true for utilities such as the mechanical, electrical and plumbing (MEP) system as they are normally invisible to humans and thus requires information on their layout and geometry to assist maintenance. In traditional FM practice, such information is manually retrieved from an archive of paper-based documents or materials such as drawings. The practice is laborious, time-consuming and cumbersome, calling for a more effective solution.

The rapid development of building information model (BIM) and its wide adoption provide a unified source where rich building information can be easily retrieved. Driven by the development, many mobile applications based on tablets and smart phones have been developed to bring the abundant information to the field for assisting decision-making [4, 5]. Although these applications have significantly streamlined the information retrieval process, they still suffer from the several limitations: a) require manual search of relevant information from the mobile device; b) insufficient intuitiveness due to a lack of connection between the virtual content and the real-life context. The limitations can be addressed by the application of augmented reality (AR), which aims at connecting the cyber space with the

physical world by superimposing virtual content onto the videos or photos of the real world [6-10].

A core component of AR is spatial registration that can align the virtual and real world according to their relative positions [1]. Most of existing AR solutions used 2D fiducial markers, or 3D objects with certain patterns as a target for registration. Such solutions require significant efforts in deploying and maintaining the markers in the building of interest [11]. Another stream of AR registration approaches seeks to utilize the global navigation satellite system (GNSS), Bluetooth, ultra-wideband (UWB), or other radio signals to estimate the position and orientation of an AR device in the coordinate frame of the virtual model. The estimated posture is then used to align the model with the real-world view. Such systems rely on external signal emission/receival infrastructure, which may not always be available (e.g., GNSS is not applicable in buildings), and require additional time and efforts for installation and maintenance as well.

BIM, as a readily available asset, shares similar visual appearance to its physical counterpart in the real world. Leveraging the similarity, there is potential to directly register a real-life photo into BIM for subsequent AR facility management applications, avoiding the reliance on markers or external infrastructure [12]. This study presents a markerless image-to-BIM registration approach that does not require manual initialization or pre-calibration. It does so by innovatively leveraging a style transfer model based on generative adversarial networks (GAN) to address the cross-domain gap between the virtual and real contents. A prototype mobile application has been developed to demonstrate the effectiveness of the registration approach to enable AR-based FM. The field experiments show that actional information can be easily retrieved from BIM with our AR application to support instant decision-making.

2 Literature review

2.1 Spatial registration for AR application

To align the virtual contents in BIM with the real-world view, spatial registration is an indispensable module for AR systems. According to the differences of registration principles, existing approaches can be divided into two major categories, i.e., marker-based and markerless registration [1]. The markers used in the former approaches are usually 2D images composed of distinctive visual features, which are referred to as fiducial markers [13-15]. In some cases, 3D objects with distinctive features can be pre-mapped to serve as registration markers as well [16]. Although marker-based approaches can generally achieve precise and robust registration, they require manual efforts to install and

maintain the markers [17, 18]. In addition, the approaches are subject to the drifting issue as users go farther away from the markers [1]. For many markerless solutions, an AR device's location in the virtual world is determined by calculating its relative position to external radio signal emission/receival infrastructure, e.g., GNSS [19], Wi-Fi [8], and UWB [20]. Orientation of the AR device is estimated with data collected by its onboard sensors such as gyroscope, electrical compass and accelerometer. Combining the calculated location and orientation, registration can then be realized. These solutions rely on an external radio signal system, which is usually expensive to deploy and maintain. In some cases, such systems can be even inaccessible (e.g., GNSS in indoor environments).

Research efforts have been made to develop registration techniques without the need of deploying markers or infrastructure. A line of major endeavors attempts to utilize computer vision and photogrammetry to recover the camera pose based on data retrieved from pre-mapped visual assets of the building of interests [18, 21]. However, significant efforts are still required to pre-map the environments. BIM shares similar visual appearance to its real-life counterpart, which can serve as a potential database of both the spatial and visual information of the environments to be registered, thus eliminating the requirements of pre-mapping. However, due to distinctive differences between the visual representations of BIM (plain texture) and real photos (abundant texture and details), there is a perception gap across the two domains. In [11, 22], manual initialization is required to designate a rough location, and then precise alignment was achieved by iterative closest point or perspective alignment. To overcome the cross-domain gap, Ha et al. [12] and Baek et al. [6] proposed an image retrieval algorithm for indoor localization based on deep learning features. However, camera localization based on image retrieval is subject to the issue of viewpoint change, which can undermine the performance of registration [23]. The limitations of existing research call for a vision-based markerless approach that can automatically and precisely register into BIM across domains.

2.2 AR-assisted facility management

Facility management is important to ensure the operation of buildings and infrastructure. As a knowledge-intensive activity, relevant building information is required to support FM decision-making. Traditionally, such information is retrieved from paper-based design documents such as drawings. The cumbersome practice has been alleviated with the proliferation of BIM, from which rich building information can be easily accessed via mobile devices such as tablets and smart phones [4, 5]. The practice can be further improved by aligning the virtual objects and

their relevant information in BIM with the real scenario captured by cameras through the use of AR [6-10].

In the area of civil and infrastructure engineering, many research attempts have been made to incorporate AR in FM for better efficiency and productivity. Kamat and El-Tawil [24] investigated the feasibility and potential of AR in evaluating structural damages. Chen et al. [8] devised a location aware AR framework for facility maintenance, which integrated Wi-Fi fingerprinting and room identification to achieve location awareness and can stream the site situation and inspection video back to remote control center. Chen et al. [9] integrated AR and BIM to facilitate the maintenance of fire safety equipment using mobile devices. Baek et al. [6] developed an AR system to assist FM based on the indoor localization algorithm proposed by [12]. The system used a client/server structure, and can visualize hidden pipelines in the field of view of Microsoft HoloLens.

Despite the significant progress made by previous studies, the BIM registration of existing systems either relies on external signal infrastructure for localization [8, 9, 24] or requires certain extent of manual operation for location initialization [11, 22]. In this study, we will explore how a markerless vision-based camera pose estimation approach proposed by [25] can be integrated in AR application to support FM.

3 Cross-domain spatial registration to style-transfer BIM

A cross-domain gap between textureless virtual models and real-life scenarios hinders the direct registration into BIM. As shown by Figure 1, a prior research by [25] indicates that style transfer based on generative adversarial networks (GAN) such as CycleGAN can bridge the cross-domain gap to enable meter-level indoor localization. Based on the findings, this study proposes an automated image-to-BIM registration method without the need of manual initialization.

(1) Style transfer based on generative adversarial networks

CycleGAN, a powerful unpair image-to-image translation GAN model [26], is used to train a deep learning model to realize style transfer between the BIM domain and the Real domain. To train the model, images from both domains need to be collected. In this study, images from 7 locations (around 2800 images for each domain) were taken in an indoor space of 112.8 m². After training, one of the generators is then used to convert the BIM-rendered images in the same indoor environments to photorealistic ones with vivid texture. The generator has a near real-time performance, which can convert a given image in less than 1 s. Hence, processing the entire

dataset (~2800 images) consumes no more than one hour. For more details on how the GAN model was trained, readers are suggested to refer to our previous work [25].

Figure 1. The effects of style transfer in addressing cross-domain gap

(2) Construction of a visual-spatial database

In the second step, a database of both visual and spatial information of the indoor environment is constructed based on the BIM images after style transfer. The visual information includes global and local visual features extracted from the BIM images. Chen et al. [25] demonstrates the superiority of edge histogram descriptor (EHD) over other global features in retrieving the style-transfer images; thus it will be used in our study. The local features used by us is scale invariant feature transform (SIFT). Spatial information refers to the real-world coordinates of SIFT keypoints detected from the BIM images. Such spatial coordinates can be extracted from BIM, as geometry layout of the environment is known priori in BIM. We developed a tool based on the application programming interface (API) provided by Autodesk Forge Viewer to automatically retrieve real-world coordinates corresponding to the keypoints from BIM in batch. Note that all the works mentioned in this step are implemented in an offline manner, which means they do not occur in the BIM registration process. Rather, its purpose is to prepare a database for registration in the subsequent step.

(3) BIM registration based on similarity comparison and photogrammetry

A newly captured photo (referred to as a query photo) in an indoor environment can be registered into the corresponding BIM by the following steps. First, the most similar style-transfer image to the query photo is retrieved from the database based on the cosine similarity between their EHD. Then, SIFT keypoint correspondences will be detected between the query photo and the retrieved BIM images after style transfer. As the 3D world coordinates of the keypoints have been extracted in last step, several pairs of 2D-3D

correspondences with known pixel and world coordinates can be obtained. Based on these correspondences, the query photo's camera position and orientation will then be calculated by solving a classical perspective-n-points (PnP) problem in photogrammetry theory. Finally, the estimated camera posture can be used by the AR device to align BIM and the real world.

4 Development of the markerless AR application

4.1 Overall development framework

Figure 2 shows the overall development framework of the markerless AR mobile application (APP) for facility management. Unity is used as the core development platform, under which the Android Studio needs to be installed to provide environment support for building and running the APP. We use Visual Studio to write and edit C# script for the realization of required functionalities such as taking photos and spatial registration. For model preparation, third-party software, SimLab Composer, is used as a middleware to ensure the BIM created by Revit can be safely imported to Unity without losing texture. To use image processing and CV related algorithms (e.g., SIFT detection and matching) in Unity environment, an external package called "OpenCV for Unity" also needs to import. After properly setting up the scenario and coding, the project can be built to release an APP that can run on any Android devices.

4.2 Model preparation and importing

Revit files cannot be directly imported into Unity. Instead, they need to be first converted to formats compatible for Unity, e.g., .fbx and .obj. It seems viable to first export a Revit model to a FBX format, and then re-import it to Unity. However, doing so will lead to undesired loss of materials and textures, as shown by Figure 3 (a). To solve the problem, we adopt the following solution. First, the model is exported as a .dwfx file from Revit, which is then processed in SimLab

Composer to generate a pack of files with both FBX and relevant materials extracted. Finally, the FBX model can be imported into Unity with proper texture and materials attached, as shown in Figure 3 (b).

Figure 2. Overall technical framework for the application development

During the above process, it is important to ensure the consistency of unit and up axis among different model processing platforms. It should be noted that Unity uses a left-handed coordinate system with the y axis as the up vector. To place the model in the same position as it is in Revit (so as to ensure a consistent coordinate system), we follow the below procedure: (a) re-assign pivot point of the model to a point with known coordinates; (b) specify the "transform.position()" attribute of the model as the coordinates of the known point; (c) adjust the rotation of the model as appropriate (e.g., 180° around the y axis in our case).

4.3 Realization of image-to-BIM registration

Since we intend to develop a standalone application without using servers, the visual-spatial database extracted from the style-transfer BIM needs to be properly incorporated as part of the software. In Unity, the Resources class allow developers to load and access assets of various formats, e.g., images, and text document. The EHD, SIFT features, image ID, and 2D and 3D coordinates of the key points are stored in separate text files. Note that sometimes a file might be too large to be loaded by the software loader in a time. In such cases, we divided data in the file and saved it into multiple different files, and added an indexing file on the top to ensure the easy retrieval of these files.

Next step is to retrieve correspondences based on visual features of the input query photo. A C#

Figure 3. Results comparison between different model preparation approaches: (a) direct import of FBX file exported from Revit; (b) processed by third-party middleware before importing

implementation of EHD [27] is used to calculate EHD features of the query photo. The calculation and matching of SIFT descriptors are realized by a third-party package called “OpenCV for Unity”. Based on the 2D-3D coordinate correspondences retrieved by feature matching, the camera posture can be estimated with the `Calib3d.solvePnP` function from the OpenCV for Unity package. Finally, we can align the virtual model with the real view in the query image by passing the estimated camera posture to the `transform.position()` and `transform.eulerAngles()` function of the camera object in Unity.

4.4 Superimposing virtual objects onto real view

To superimpose the virtual BIM model onto real

camera view of a mobile device, two camera objects in Unity need to be designated cooperatively. One camera is to capture the current view of the BIM model, and the other is used to display the streaming image of the real-life scenario recorded by the mobile phone camera in real time. The two cameras are designated to be present on the same display (i.e., phone screen), and the camera background canvas is placed behind the model by assigning a larger value to its depth attribute, thus ensuring the virtual model are overlaid onto the real view.

4.5 Device posture tracking

After initial registration, the device posture will be continually tracked to update the virtual model view to ensure alignment. The estimated camera posture in section 4.3 is used as the initial camera state, to which the

Figure 4. Setup and results of registration evaluation experiments: (a) distribution of test points in the experiment site; (b)~(s) image pairs showing level of alignment between virtual and real content after registration at each test point

relative camera orientation is then accumulated based on the gyroscope and accelerometer information obtained from the mobile device. Note that at current stage, translational movement of the device is not considered, but will be incorporated in the future by integrating other robust tracking techniques such as simultaneous localization and mapping (SLAM) or visual odometry.

5 Field experiments

To validate the effectiveness of the proposed approach, a field test was implemented in the student union (SU) complex of the University of Tennessee, Knoxville (UTK). The experiment site is at the northwest corner of the third floor of the SU, which covers an area of 12.0 m × 9.4 m.

5.1 Evaluation of the markerless registration approach

The data collection scheme and training of the style transfer model followed the settings and parameters mentioned in [25]. After training, the style transfer model was used to generate synthetic photorealistic images based on the given BIM-rendered images, and the visual-spatial database was then constructed.

To evaluate the efficacy of the proposed registration approach, 18 test points were set up, scattering evenly inside the experiment area, as shown in Figure 4 (a). Figure 4 (b)~(s) compare the real-life camera view taken by the mobile device and the resulting BIM view after registration at each test point. As can be seen from the figure, a great majority of the images have been successfully registered, leading to alignments with the virtual BIM model. Table 1 quantitatively analyzes the registration performance, showing a successful registration rate of 77.8%. It took 4.3 s in average to register an image. The results demonstrated the efficacy

of the proposed markerless registration approach.

Table 1. Summary of the registration performance

Type	Quantity	Proportion
Success	14	77.8%
Failure	4	22.2%
Total	18	100%

5.2 Demonstration of the mobile AR application

Figure 5 demonstrates the general procedure of using our mobile AR application for facility management. The application can be installed on tablets or any other mobile devices that support the Android operating system. After opening the application, users can click the “Photo” button at the bottom of the initial interface to enter the photo shooting page. Then, a photo of the surrounding environment should be taken by clicking the “SHOOT” button. Based on the taken photo, our proposed markerless image-to-BIM registration algorithm is executed to retrieve BIM model corresponding to the current camera view. Finally, after hiding the building structures, the effect of virtual-real alignment can be realized. By the use of our APP, the invisible utility such as MEP can be intuitively visualized, thus assisting decision-making for facility inspection.

6 Conclusions

Augmented reality is a useful technique to assist facility management of buildings and civil infrastructure. However, the promise and potential of AR has not been fully fulfilled due to the challenging issue of spatial registration. To tackle the challenge, this study proposes an image-to-BIM registration approach that requires

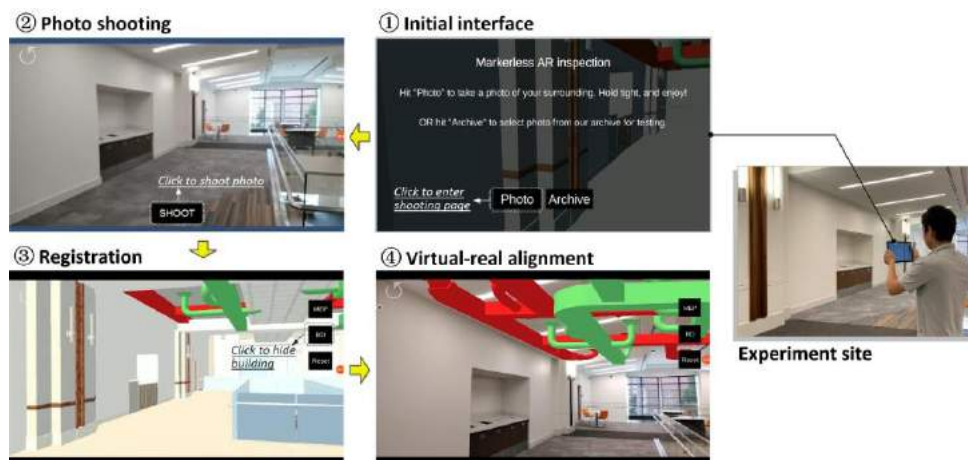

Figure 5. Workflow and corresponding interface of the developed mobile APP for facility management

neither fiducial markers nor external signal emission/receival infrastructure. The registration approach leverages CycleGAN style transfer to bridge the cross-domain gap between virtual and real content, and can estimate six degree-of-freedom camera pose by using classical photogrammetry theory. Based on the registration approach, a mobile AR application is developed to support facility management. The development used “Unity + Android studio” as the basic technical framework. Relevant development issues such as model preparation, realization of registration, virtual-real fusion, and device posture tracking were introduced subsequently. Experiments have been carried out to validate the effectiveness of the proposed approach and the AR application.

The proposed registration approach is challenged by several issues, e.g., illumination, deviation between BIM and real scenes, and architectural self-similarities. For the former two challenges, our previous research [25] has demonstrated the approach’s robustness against varying lighting conditions and certain changes of the physical environments (e.g., adding furniture that does not exist in BIM). For the last challenge, we acknowledge it as a downside commonly experienced by many computer vision applications. To overcome, it is suggested to integrate the approach with other sensors (e.g., barometers and gyroscope) to reduce the ambiguities among indoor spaces with similar designs or layout. Future research should also address the issue of motion tracking, and test out the approach’s generalizability to different types of indoor spaces, e.g., conference rooms and corridors.

Abstract –

The increased use of construction machinery in the industry poses challenges of safety and regulation for the site workers. A remote monitoring system for the construction machinery can help in avoiding fatal accidents whilst providing continuous sensor information to the user. The present remote controller has shortcomings of accessibility, less information transfer, longer training times, and sizeable delays in case of replacement. Smart glasses are already a booming trend in the industry in the domain of worker training and there is a need for simultaneously controlling and monitoring machinery using the portable device. A framework is proposed for using the smart glasses to provide network relay of the construction machinery with its digital counterpart by using the concepts of artificial reality and connectivity through the CPS to minimize the problems of safety and communication. The paper summarizes the solution by using a cyber-physical system along with the latest trend of AR (augmented reality) to control unmanned tower cranes on the location using smart glasses and digital twin technology. Future research can be oriented towards using this concept for other construction machinery.

Keywords –

Digital Twin, Smart Glasses, Cyber-Physical System, Augmented Reality, Construction Machinery, Tower Crane, Live Monitoring.

1 Introduction

The construction industry continues to expand expeditiously in the modern world. According to the report “Construction global market report 2021: COVID-19 impact and recovery by 2030” by the year 2025, the output volume of the construction will be around \$16614.18 billion, with a compound annual growth rate (CAGR) of 7%, with major stakeholders like China, India, and the US leading the growth [1]. The construction

industry still faces challenges like stunted technological growth, low productivity, and poor energy utilization as compared to the industrial sectors which are booming at a remarkable rate. [2] Further, due to the nature of the construction industry, accidents always tend to happen on a macroscale. One of the prominent reasons for accidents is construction machinery which is often not operated by well-experienced workers due to a lack of field training, safety awareness, and proper communication. [3]. One of the important machineries is the tower crane which is selected for this research. The tower cranes are however being continuously replaced by unmanned ones in recent years. The number of registered unmanned tower cranes was around 272 in 2015 and increased by 30% to 1826 at the end of the year 2019 according to the report by the Ministry of Land, Infrastructure and Transport, Korea. The increase in the number of such cranes is due to their faster job completion time and lesser costs.

The construction machinery like the tower crane can be controlled using a remote controller i.e., unmanned tower cranes. This requires a connection between the machine and a cyber-physical system which is a computer system mechanism monitored by computer-based algorithms. Abiola [4] has used the cyber-physical system for training workers on safety and postures while Cheng Zhou [5] proposed a cyber-physical monitoring system using the IoT parameters as a safety system for safely monitoring the constructions taking place underground and to increase crane safety. The remote controllers at present can communicate through both wireless and wired connections with the operating machines. The use of AR has also started in recent years and the digital twin is also paving its way in the construction industry. Table 1 provides a brief history of the number of automation approaches used in the past from using the cyber-physical systems connecting the real world to the internet; the use of digital twin copying natural behaviour in a virtual space; a safety system for monitoring and visualizing HMD system. A few papers have been listed along with the main purpose of their research and how they fit in with the construction machinery have been highlighted.

*CPS= Cyber-Physical System, DT= Digital Twin, SS= Safety System, SG= Smart Glasses

The approaches have mainly focused on either using the cyber-physical system or providing safety to the workers using some mobile or pad remote controller. There is no present technology that combines all the four concepts to give us a network that uses a cyber-physical system to provide safety while incorporating the concepts of digital twin using smart glasses. An approach to use the remote controller while providing a virtual model to assess the capabilities and monitoring of the model can be done by making a digital twin. The concept of the digital twin is to provide an exact twin model to its real counterpart which also copies all the functions. The use of digital twin (DT) has recently started in the construction industry. The DT technology provides the opportunity for the integration of the physical world with the digital world and has attracted much attention. Emergen Research estimates the digital twin market size to reach USD 106.26 billion with a steady CAGR of 54.7% in 2028 [6]. Hou [7] stressed the use of the digital twin in the safety of the workforce of construction using sensor and visualization technology. Alizadehsalehi [8] provided a generic framework to use DT through a monitoring system called DRX.

The framework comprising of the digital twin, the CPS, and the construction machinery need a communication process that does not have long durations, is easy to handle and can be accessed by all stakeholders. Communication in the construction industry still follows the conventional method of using phone calls and in some cases, video calls and emails. However, this does not address many problems as it is difficult to analyse without complete visual perception and spatial interaction. It is also not advisable that high-level staff be present on the construction site for every minor issue. This approach of using the construction machinery monitoring research has rarely been touched in the past.

The solution is to have a device and controller that can make communication easier without disrupting the workflow.

AR Smart glasses offer the technology to access both the digital twin and the construction machinery whilst leaving the hands free to focus on the tasks. While these glasses are continuously being used in other forms of industries like medicine, their demand in the construction field is yet to thrive. Wang S. provided a solution to using the smart glasses for the damage detection of the structures using deep learning and augmented reality techniques [9]. De Luca D. integrated the mixed reality platform and BIM with the help of smart glasses in the construction field [10]. Pierdicca R. has given the concept of using the augmented operator using the smart glasses to act as a guide system for the operator during the working process while the author has also given another concept of training on the job site using the AR glasses [11][12]. Although, in the past, the steps for the safety of workers have been provided using smart glasses; no solution exists for integrating the safety, sensor data, and communication elements into a single skeleton for the user. This paper, however, discusses a solution to combine the digital twin and cyber-physical systems for a construction machine using the augmented and mixed reality with the help of smart glasses.

2 Proposed Solution

Numerous solutions have been provided in the past for overcoming the problems of construction automation. Recently, pad controllers (using mobile phones or tablets) are being used to control the construction machinery. However, it is difficult to always carry the pad, does not provide the spatial view and for an unskilled worker is hard to control it. There is also no actual solution existing

for controlling a real prototype of a crane model or any other construction machinery using some sort of eyewear of head-mounted device wirelessly. It is possible to experience a less damaging and efficient functionality by using smart glasses which also provide accurate inspection of the structures and the ability to communicate with experienced personnel in real-time. With access to smart eyewear, it is easier to interact with the construction machinery and the digital twin. First, the use of the glasses is tested to see if they provide robust and fast access to the assembly of controlling the machinery. Second, the testing is done through the HMD to know the potential benefits of using it on the construction site. Figure 1 defines the workflow of the proposed method which follows 7 steps combining the cyber-physical system with the digital twin into the smart glasses for operation.

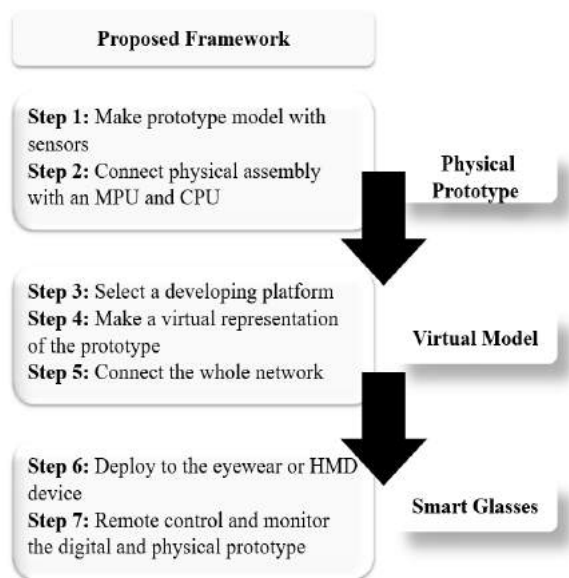

Figure 1: Workflow for the proposed method

3 Development of Remote-Control System

The digital twin framework for combining the virtual space with the physical space requires a prototype to test how the real model will work out in real-time. The development of the system encompasses four steps i.e., the creation of a cyber-physical prototype followed by the selection of a developing platform, making the virtual model, and lastly the incorporation of the smart glasses(eyewear and HMD) to the whole structure.

3.1 Cyber-Physical System

The physical model is the representation of a tower crane with the framework comprising of two servos, one

ultrasonic sensor, and the metal assembly. The model is connected further to an Arduino Uno Board using a breadboard which further gets connected to a laptop/PC. Figure 2 explains how the assembly relates to each other to mimic a visualization of the tower crane. Two servos have been used for the physical model. The specifications of the servo are Parallax Standard Servo which can hold any position over a 180-degree range controlling the crane arm and the Parallax Continuous Servo which is designed for continuous rotation and spins whole 360 degrees, so it controls the hook motion.

Figure 2: Physical Model for the prototype

The continuous servo is attached with a pulley which is again attached with a secondary pulley with a rubber band helping in the movement of the attached block which serves as our model weight to be lifted. An ultrasonic sensor HC-SR04+ is selected owing to its accurate range, ability to provide continuous distance readings, and performance is not affected by weather conditions. The accuracy provided is up to 3mm and it can detect the distance from 2-400mm. The wires are first attached to the components i.e., standard servo, continuous-servo, and ultrasonic sensor and goes into the breadboard which serves as a connection hub, and then only the relative voltage, ground, and sensor pins are attached with the Arduino Uno board. The microcontrollers are the heart of any robotic device and help to make seamless communication between the user and the related device. Arduino is a prototyping platform

that is used for making electronic objects. The platform provides an open-source software known as Arduino IDE, which makes it possible to communicate the microcontrollers such as Arduino Uno with Windows, Linux, or the Mac OS. Arduino IDE version v1.8.13 is used for connecting the physical model with the computer to send the commands between said devices. The board selected is Arduino Uno.

3.2 Developing Platform

A list of the top application and game engines that can help in making the software for the required purpose is presented in table 2.

Table 2. Platforms available for Development

Application Platform	Android	iOS	PC, Mac, and Linux	Universal Windows Platform
Unity	✓	✓	✓	✓
UE4	✓	✓	✓	✓
Godot	✓	✓	✓	○
CryEngine	○	○	✓	○
Gdevelop	✓	✓	✓	○
Corona SDK	✓	✓	✓	○
Construct 3	✓	✓	✓	✓

The best alternatives to use include Unity, Unreal Engine 4, and Construct 3 considering we need to deploy to the HMDs. Construct 3 is not free, between the Unreal Engine and Unity the latter provides better ease of access, developer support, wide assets store, and a vast range of tutorials so Unity is the most suitable option as most of the eyewear have the official support with Unity. Unity is a real-time development program used for creating interactive and real-time content incorporating the concepts of artificial and virtual reality. The engine has found its way into the architecture, engineering, and construction(AEP) industries helping in connecting the BIM data with the major stakeholders of the construction phase. The software provides the user to develop a scene with all the elements required and then deploy it to the necessary hardware device. Unity version 20.2.6f1 is used for this research as it has all the necessary plugins and continuous support from the developers. The noteworthy features include the Vuforia which is used for the development of augmented reality applications and the MRTK toolkit for the development of mixed reality applications. Recently, only two open-source platforms are available for development on the HMD.

3.3 Virtual Model

The digital twin of the model is made using Blender

v2.92 as the open-source software gives the ease of access as well as the ability to directly export the file to our simulation software i.e., Unity. The dimensions of the original model are replicated in the digital twin and a conjugate image of the model is made using the creation software blender. The base of the crane is modeled along with the frame, rope, weight, and pulleys. Although the software supports animation for the model, yet the animating part is done on Unity. The model serves as a digital twin i.e., providing identical movements with the corresponding changes in the physical model. Figure 3 gives a demonstrative look at the digital twin. The model is a direct replication of the physical twin to provide more conformity with the original model to see the output clearly as opposed to a conventional tower crane model.

Figure 3: The digital twin model for the prototype

3.4 Smart Glasses Integration

An application is developed, and the two different computer setups are done for the connection of the physical prototype with the virtual model. Consideration of how the eyewear operates and their functionality, the two setups differ in the interface and input methods:

3.4.1 Eyewear

The eyewear glasses provide display in only one eye and the three physical buttons with a touchpad are the only form of inputs available to the glasses. Using the Unity working environment, the interface is created in such a way that provides the relay between the server and client easily. Figure 4 shows the multi-way communication between the main three elements. The server can send commands to both the glasses and the

physical model whereby the glasses can also do the same vice-versa. The physical model moves according to both the server and client and gives the value of the sensor i.e., the ultrasonic sensor reading back to both devices.

Figure 4: Multi-Way Communication Between Physical Model, Smart Glasses, and PC Server

The interface consists of the distance from the ultrasonic readings as well as the angle for both servos. When the connection is made between the device and server by providing the I.P address and using the correct Wi-Fi, the data can be transferred from the physical model to the server and then from the server to the client i.e., the eyewear. Upon the successful connection, the sensor data gets updated continuously and the button “Camera” can be clicked to open the live interface. Vuforia is integrated into the assembly to provide the marker for the digital twin. The digital twin then gets updated with the respective input commands that are given to it. Figure 5 shows the interface of the application working on the glasses. The interface consists of buttons for controlling the crane arm and the hook as well as the output areas for the sensor readings. The ‘Move Up’ and ‘Move Down’ commands control the hook of the model while the ‘Move Left’ and ‘Move Right’ Commands control the crane arm. The distance from the sensor is calculated by first getting duration from the ECHOPIN reading when it is set as HIGH, then it is multiplied by the speed of sound and changing the cycle distance to only one side distance. The network IP address must be inputted manually using the physical buttons and the trackpad for seamless communication that helps the user to control the construction site while a construction manager can also check the sensor data while sitting in the office. Since the eyewear just sits on the eye and there is no need to hold it continuously, it provides a comfortable user experience. The control is present between the PC server and smart glasses meaning both can specify commands individually while the visualization occurs on both the crane model and the smart glasses to see what is going on with the prototype. Sensor data is transferred from the prototype to the glasses and the pc server to and forth so that it is possible to make multi-way communication possible.

The values in front of the distance i.e., the ultrasonic value readings are to assess the distance from the ground to the hook. So, when the value reaches an undesired value, the worker operating the eyewear can assess if any unconditional hazard is to occur. Lowering the sensor will lower the distance value shown on the screen and appropriate height can be assessed as to not hit anyone working on the site.

The interface made using the Unity platform provides a simple controller for the machinery with scripts attached to buttons. Clicking buttons send a command to the Arduino which is also programmed to know what to do when the button is pressed and then after processing the data request, it sends the output back to the user.

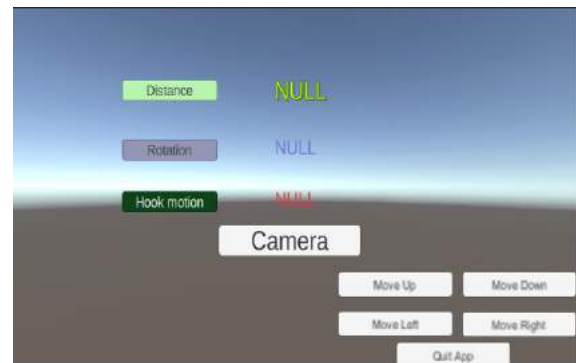

Figure 5: Interface of the application for Eyewear

3.4.2 Head-Mounted Device

The HMD provides a fully immersive experience for the user. The input can be done through eye and hand gestures. The Unity working environment with the help of the Mixed Reality Toolkit is used for making the interface for the assembly. The change here is the use of movement sliders to control the crane arm and the hook of the model. The model is placed using the spatial awareness feature of the HMD through marker-less AR technology.

Figure 6: Interface of the application for HMD

The data from the ultrasonic sensor now appears on a hologram and there is a separate user interface for controlling the animations of the model. The networking adopted for this is Photon Networking allowing access between the user and server competently. The hand gestures make it possible to interact with digital twins easily. Using the HMD, the input commands can be sent to the server which then communicates with the physical model whilst also the digital twin appearing as a Mixed Reality object can be controlled using the HMD. The separate hologram showing the distance can be moved and adjusted anywhere using the HMD technology called the “Near Object Interaction” and the “Box Collider”. Availability to resize the digital twin is also available with the use of the ‘Bound Control’ option. Like the eyewear, the sensor data is relayed from the physical model to the server first, and then with the help of proper networking, it is transferred to the HMD. From Arduino, functions like servo are used to send commands to the Arduino for movement, and Serial is used for getting the read and write data for the sensor. The data is converted into a string and then it is displayed. Using the serial command, the data is first fed from the Arduino to the Unity where it is then visualized properly. The scripts are attached to each button for moving the digital twin model and displaying the results.

A sample script for the servo is shown in figure 7. Two servos are used as described earlier so the movement sliders are set in such a way that when the horizontal slider is moved the servo pin automatically changes to the corresponding up/down motion pin and the prototype moves. Similar is the case with the hook motion, where controlling the slider on either the screen or in the head-mounted device makes it possible to send a number to change the pin to the Arduino, and then it sends to the prototype.

```
using System.Collections;
using System.Collections.Generic;
using UnityEngine;
using UnityEngine.UI;
using TMPro;

public class setValue : MonoBehaviour
{
    public TextMesh ServoPin;
    // Start is called before the first frame update
    void Start()
    {
        ServoPin = (TextMesh)GameObject.Find("servoPin").GetComponent<TextMesh>();
    }

    // Update is called once per frame
    void Update()
    {
    }

    public void setToX()
    {
        ServoPin.text = 2.ToString();
        //servoPin = 2;
    }

    public void setToY()
    {
        // Menu.pinMode(7, PinMode.Servo);
        ServoPin.text = 7.ToString();
        // servoPin = 7;
    }
}
```

Figure 7: Sample script for controlling movement

4 Results

The application for the smart glasses consists of the sensor distance reading, the rotation angle, and the movement of the hook up and down. It is possible to use the three physical buttons available on the glasses to send commands to operate both the 3D model as well as the prototype of the tower crane. There is also the option to use the trackpad to control the cursor and click on the “Move Left” and other commands. The exact ultrasonic readings in cm and servo’s angle in degrees appearing on the server appear on the client i.e., Eyewear, and the multi-way communication between three devices is working.

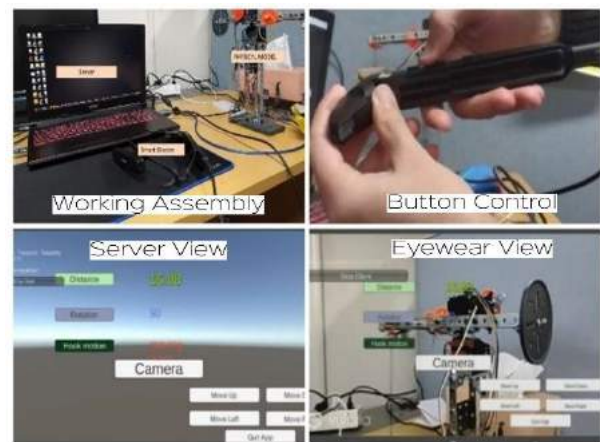

Figure 8: Working process for Eyewear

Figure 8 shows the working process of the eyewear where first has the assembly set up where the prototype is connected to a laptop which also acts as a server. Using the Wifi connection, the eyewear is connected to the laptop also. The application is then started on both the server(laptop) and the eyewear(client). The button control tells that when the application starts, we either have the trackpad to control the movement and interface or we can also use the side buttons for this purpose. Server view illustrates the actual graphical user interface present when the application is turned on in the laptop or server while the eyewear view shows what the user visualizes when he wears the hardware. The distance is shown in figure 8 which tells the measurement from the weight object on the hook of the machinery to the ultrasonic sensor. The rotation angle specifies the angle from the original position while the hook motion shows whether the hook is moving up or down. A network connection is made possible for the eyewear using a Unity plugin ‘Mirror Networking’. The distance reading showing the figure is the ultrasonic sensor and the rotation angle as well as if the hook is moving up or down is also being monitored continuously through both the

server and multiple clients. The animations for the digital twin are made in synchronization with the actual model to mimic the real behavior and the control buttons especially the hardware keys are assigned the controls for moving both the digital twin and the cyber-physical model at the same time. The communication takes place as soon as there is a connection on all the devices and there is smooth communication between the transferring of data between the devices.

Figure 9: Working Process for HMD

The working assembly is like the eyewear except that the eyewear is now replaced with the head-mounted device. Here gesture control means that with the use of gestures, it can control the movement and work. The server view shows what happens on the server during the simulation while the HMD view shows what the user can see, and which objects can he interact with. Likewise, results for the HMD are obtained and illustrated in figure 9 which shows the hologram displaying the value of ultrasonic sensor data reading and it is continuously being updated as the crane model changes in real-time. The HMD has a different operating system and the application working for the solution is distinct from its counterpart. The readings from the ultrasonic sensor in cm appear in a hologram now, there is the option to control the digital twin only, and sliders can help in the movement of the crane vertically and horizontally. The holograms and the model can also be pinned and move anywhere owing to the spatial interaction provided by the HMD.

Table 3. Comparison with existing hardware

Functionality	Existing	Eyewear	HMD
Input	Touchscreen	Trackpad	Gestures
Live touch	○	○	✓
Portability	○	✓	✓
Multiple users	8	64	64

Table 3 provides a comparison of the existing devices with the eyewear and HMD. The HMD provides the most functionality to use while supporting features like spatial interaction where a person can interact with the environment and 3D objects intuitively.

The results show that it can coordinate the multi-way communication between the devices and simultaneous data transfer and monitoring can be done with a wireless connection. The need for controlling construction machinery with the help of smart glasses i.e., the eyewear and the head-mounted device, is achieved, and the digital twin functions well with the cyber-physical system to provide the required framework of a true wireless communication helping to monitor, control, and visualize making communication process adequate. Table 1 highlighted some of the approaches used in the past for remote control operations. The construction industry is using smart glasses for environment monitoring [13] and object recognition [14].

BIM data is also being monitored using the safety smart glasses to visualize the actual site condition as well as to compare the BIM model remotely [15]. Finally, a framework is proposed to combine the digital twin (DT) and cyber-physical systems (CPS) into smart glasses (SG) for operating construction machinery. Based on the physical prototype model of a tower crane with sensors, its virtual model was made, and smart glasses were deployed to remote control and monitor the digital and physical prototype. Portable smart glasses showed sensor distance, rotation angle, and movement information, implying that monitoring in the construction sites can be done with a wireless connection. By allowing both servers and glasses to control and monitor, the system facilitates collaboration and supervision on construction sites.

5 Conclusions and Future Work

The construction site always suffers from accidents and safety considerations need to be monitored continuously to avoid damage. The purpose of this research is to provide an integrated framework where it can wirelessly control the construction machinery using some eyewear and head-mounted devices. There is no more need to continuously hold the remote controller when it can be always worn providing better feedback and safety aspects. One thing to note while designing the interface and the algorithm is to worry about the safety aspect like how to ensure that collision does not occur with the nearby objects and workers. The work for safety is still under development and right now the focus is monitoring and controlling the models together. The idea is by using the spatial awareness system on the HMDs, it is possible to devise the collision system for the construction machinery so that nearby workers and

objects are protected. On the construction site, the idea can be implemented where the safety worker wears it on the site whilst the major stakeholders can monitor the activities from the office. The tablet is good for indoor use considering its size, the Eyewear is growing as an accomplished device in the construction field and can be used for both indoors and outdoors while the HMD is easier to use and provides the best performance in a spacious environment. The HMD also provides the option for Iris detection for security purposes, and it can be incorporated in the interface to allow for a more real-life situation of only letting the experienced staff whose iris is stored in the database be able to access the application. This is under consideration for future work. Moreover, construction machinery like excavators, bulldozers, and loaders can be consolidated with this idea to make a more intuitive yet powerful application to control all sorts of devices used in the construction site. The basic functionality to control the cyber-physical model using the smart devices are successfully tested and if more focus is given to the concept, a lot of different functionalities can be explored. Further, the cross-platform option is also under consideration where devices operating on the different O.S could also interact.

6 Acknowledgments

The research is the extension of the work “Augmented Reality and Digital Twin system for interaction with construction machinery” [16]. The work was financially supported by the Korea Ministry of Land, Infrastructure, and Transport(MOLIT) as Innovative Talent Education Program for Smart City. This work was supported by the National Research Foundation of Korea (NRF) grant funded by the Korean Government (MSIP No. NRF-2019R1A2C2005540). The initial work was done using a tablet device but that is not discussed here and only this research goes further into using the Eyeglasses Eyewear and the HMD remotely.

Abstract –

Energy-efficient buildings have gained an increasing attention in the construction industry due to their significant contribution to the world's energy consumption. Life Cycle Assessment (LCA) provides an opportunity to improve the energy performance of buildings through a holistic assessment of their life cycle. Previous studies have mainly applied Building Information Modeling (BIM) to export buildings' data into other LCA tools. This process is considerably time-consuming and error-prone, especially when matching and importing BIM data into the LCA software are conducted manually. This paper aims to develop a framework to quantify the embodied energy (EE) of modular buildings through BIM-LCA approach. Despite current practices, this model can contribute to facilitate changes during early design stages, delivering more energy-efficient buildings. To do so, the EE of modular residential building is estimated based on the boundaries defined by EN15978 Standard. An integration scheme of BIM and LCA is established in Autodesk Revit as a platform to evaluate the contribution of different building materials and stages in EE consumption. The proposed framework is validated and verified by conducting a real case study on an under construction modular project. This study can be used as a base platform to quantify EE and reduce the environmental impacts of the modular buildings by guiding architects and designers to come up with more sustainable building plans.

Life Cycle Assessment; Building Information Modeling; Energy Efficiency; Modular Construction; Embodied Energy

1 Introduction

Growing concerns about energy consumption and its environmental impacts around the world are pushing the construction industry to adopt sustainable approaches by

introducing stricter policies and regulations [1, 2]. Building sustainability refers to all activities and processes throughout the building life cycle which have the least harmful environmental and social impacts [2]. Energy consumption during a building life cycle plays a critical role in the environmental and economic aspects of its sustainability as it utilizes a considerable amount of natural resources and investments [3]. Construction industry has become a significant contributor to the world's energy usage, and its environmental impact is still increasing [4]. It has been reported that this sector accounts for up to 40% of energy consumption globally [5], raising the need to apply innovative methods to reduce energy consumption in order to achieve sustainability standards. In addition to poor environmental performance for which the construction industry has been criticized, this sector is also far behind other industries in terms of productivity and employment of new technologies [6, 7]. Modular construction has been promoted as a promising way moving towards modernization and greener buildings [8]. Modular construction has been gaining an important status in recent years as it is predicted to be the future application for the construction field; therefore, assessing and improving its energy performance has become a critical issue [9].

Buildings consume energy throughout their life cycle from raw material extraction to final disposal of demolished wastes [10]. Life Cycle Assessment (LCA) method has been widely utilized as an appropriate approach to evaluate buildings' energy performance during their lifetime. Applying LCA in construction projects at the early design stage simplifies making possible changes associated with different stages of a construction project to improve its energy efficiency and sustainability [11, 12]. Until recently, the main attention had been placed on the operational energy (OE) as operation phase is the longest phase in a building life cycle. However, this focus has been shifted from OE to embodied energy (EE) since significant enhancement has been achieved in reducing OE in recent years [13]. Despite current comprehensive research in the field of buildings LCA modeling, there are still significant gaps

and limitations in the quantification of EE specially in modular construction which needs further studies.

This paper aims to develop a conceptual framework for estimating the EE usage in modular residential buildings based on the system boundary introduced by EN 15978 Standard. This study integrates Building Information Modeling (BIM) with LCA to reduce the time and effort required to gather all data needed for the energy evaluation of different stages of a building during its lifetime. Furthermore, despite previous studies in which energy consumption in transportation, plant, and construction phases of the project were ignored in EE evaluation, this research contributes to quantification of these phases as well.

This paper will continue with a comprehensive literature review on the current LCA assessment methods of the residential projects. It then focuses on the development of an integrated framework to conceptualize and model the EE of modular residential projects based on EN 15978 phase boundaries. To verify the applicability of the framework and validate the developed model, a case study is conducted on a real under construction project, and EE used for this modular residential project is estimated.

2 Literature Review

Different types of classifications have been developed to refer to the energy consumption during the building life cycle, in which the EE and OE have been widely used in previous studies [14]. Demolition energy (DE) also has been introduced in a few studies which refers to the deconstruction of the building and the transportation of the waste material to the recycling plants or landfill centers. However, because DE includes a small portion of a building life cycle, it could be included in EE, rather than being separately classified [14]. Thus, in some studies, EE refers to all the energy utilized in material production, transportation, site activities, and final deconstruction phases. OE is the energy consumed while the building is in its operation phase including all activities which provide comfortable conditions for the occupants such as heating, cooling, lighting, and operating equipment [15].

2.1 BIM-LCA Integration

Due to the long duration, various resources, and risks and uncertainties, construction projects require more integrated energy evaluation approaches to be able to measure the consumed energies in different phases more accurately [14]. LCA has been established as a method to predict the buildings' impact on the environment throughout all stages of their life cycle [14, 16]. However, the complexity of LCA process makes it cumbersome and time-consuming for designers to employ it. BIM can

reduce this complexity and can assist the design team in making LCA more practical and more user friendly [17]. BIM is a platform representing physical and functional characteristics of buildings which can be shared with different stakeholders [18].

Shadram and Mukkavarra [4] used a BIM-LCA approach based on a multi-objective optimization method to balance between EE and OE in a building during its design process by considering the impact of various types of materials and their quantities on different stages of a building lifetime. Najjar et al. [12] integrated BIM and LCA to evaluate the negative endpoint impacts of building material and their related energy consumption on the environment at the early design stage. Cavalliere et al. [17] developed several LCA databases for different stages of the design process and linked them to the BIM model according to the level of development. Their framework can facilitate LCA in the design stage and ensure that reliable data is used throughout the whole process of building design. In an effort for evaluating EE, Rock et al. [13] proposed a BIM-LCA model to visualize the impacts of various types of building elements including structural parts including walls and floors on the environment. The EE was calculated using the Ecoinvent database and processed in Autodesk Dynamo. However, only the effect of different building materials on the EE was considered, and the energies used in transportation, plant, and construction site were not measured.

2.2 Energy Modeling Approaches

Different approaches have been adopted for EE evaluation while conducting BIM-LCA integration. These energy modeling approaches have been classified into four main categories [2]. In the first energy modeling scheme, researchers have not developed a comprehensive framework to be applied to other projects. Instead, they have mainly focused on the project-based outcomes. In the second energy modeling group, BIM software is used as a platform to export material quantities to other LCA tools. In the third modeling plan, transportation, and construction phases in a building life cycle have been excluded from LCA system boundary. In the fourth energy modeling scheme, either not adequate details have been provided in the framework process due to simplification, or the proposed methodology is too complex and cumbersome, making it impractical to be adopted in further studies [2].

3 Methodology

The proposed methodology in this study is based on the integration between BIM and LCA and aims to formalize the EE consumption of modular residential buildings including material production energy,

transportation energy, and off-site and on-site construction energy. In this study, LCA has been conducted according to ISO 14040 and ISO 14044 guidelines. The first step of conducting LCA based on these guidelines is that the main goal and intention of carrying out LCA should be clearly stated, and then the system boundary should be specified. At the next stage, which is considered as the most time-consuming stage, all the required data within the system boundary should be collected. Life Cycle Inventory (LCI) analysis mainly includes gathering all the building information defined in the system boundary and calculating the related inputs and outputs which have been set during defining the LCA scope and goal stage. The proposed methodology comprises several steps that have been depicted in Figure 1.

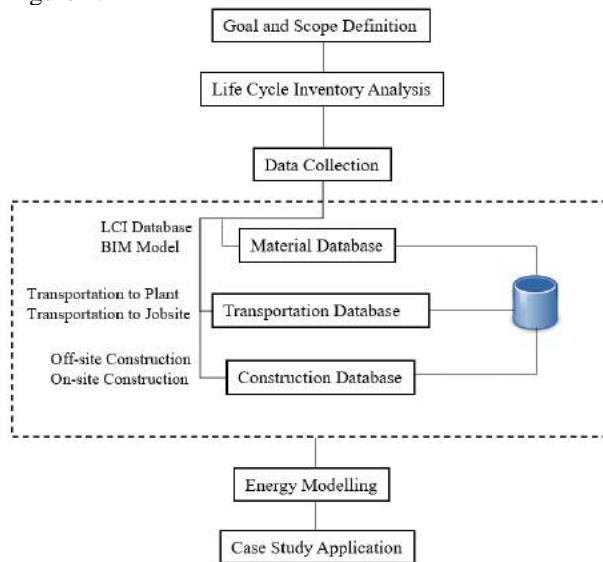

Figure 1. Proposed research framework on BIM-LCA integration.

3.1 Definition of Goal and Scope

The goal of performing LCA study in this paper is to formulate and quantify the EE consumption of modular buildings using BIM tools. This energy modeling will have different applications and can promote design decisions and schemes in order to reduce the EE consumption of a building. The system boundary selected in this study and different considered stages in a building lifetime are based on EN 15978 Standard. The system boundary defined in this standard consists of several stages, including product stage, construction stage, use stage, and end of life stage. The subcategories of each stage can be found in Figure 2. The system boundary in this study encompasses modules A1 to A5.

3.2 LCI Analysis

This step focuses on LCI analysis based on the boundaries defined in EN 15978 Standard. As this study intends to measure the EE of modular residential buildings, only product stage (A1 to A3) and construction stage (A4 and A5) will be investigated.

3.2.1 Data Collection

As one of the main steps of LCI analysis, different sources of data should be provided. In this paper, Bath Inventory of Carbon and Energy (ICE) was used to obtain the energy that is embodied in raw construction materials. This LCI database was selected because it solely focuses on the construction materials and does not include EE of other products in different industrial sectors. ICE is a cradle-to-gate database that includes all the energy usage during raw material extraction, transportation, and production stages of the construction materials. Further, Autodesk Revit software was used to access BIM models of modular buildings as it is a common tool for designing and visualizing both architectural and structural plans and also widely utilized as a technical communication platform amongst different phases throughout buildings life cycles. A custom script was developed in Autodesk Dynamo visual to create a database of material quantities and properties. Dynamo is an open-source visual programming plug-in for Autodesk Revit that consists of nodes to create algorithms in order to perform various tasks within Revit.

3.2.2 EE Formulation

The objective of this section is to quantify the EE of modular residential building and formulate the energies used in different phases of A1 to A5 defined in EN 15978 Standard. As per this guideline, EE is the total energy consumed during material production (E_M) (A1-A3), transportation energy (E_T) (A4), and processing (E_p) and construction energy (E_C) (A5). It should be noted that, unlike conventional buildings, EE of modular buildings in stage A5 has two stages of processing (off-site construction) and construction (installation and assembly). In modular approach, construction materials need be transported to another plant to be processed for modules and panels preparation which is known as off-site construction. The energy consumption of this processing stage on raw construction material is missing in LCI databases and should be separately calculated as an extra EE item in modular buildings. As previously discussed, ICE only covers EE in raw natural material extraction, transportation of these raw material to the factory, and production of construction materials. As per discussions above, the total EE consumption in modular buildings can be calculated based on Equation (1).

$$E_{Total} = E_M + E_T + E_p + E_C \quad (1)$$

Product Stage (A1-A3)			Construction Stage (A4-A5)	Use (B1-B7)					End of Life (C1-C4)				
A1: Raw Materials Extraction	A2: Transport	A3: Manufacturing	A4: Transport	A5: Construction & Installation	B1: Use	B2: Maintenance	B3: Repair	B4: Replacement	B5: Refurbishment	C1: De-construction\ Demolition	C2: Transport	C3: Waste processing	C4: Disposal
					B6: Operational Energy								
B7: Operational Water													

Figure 2. Buildings' system boundary defined by EN 15978 Standard.

Material production stage is one of the main contributors to EE. It is noted that the functional unit defined in ICE is one kilogram of the material, thus the embodied energy of the materials is presented in (MJ/kg). To have the total weight of each specific construction material, its volume (V) needs to be extracted from Revit Autodesk software to be multiplied by its density (ρ). E_M can be quantified based on Equation (2) by simply multiplying all the materials' quantities to their related energy coefficients (C_e) derived from ICE database.

$$E_M = \sum_i^n E_{mi} = \sum_i^n V_i \rho_i C_{ei} \quad (2)$$

E_T is all the energy used to transport the construction materials from the material production factory to the construction site. For modular buildings, transportation is typically conducted in two different steps of material transportation from construction material factory to processing plant for module production and then module transportation from plant to construction site. Energy consumption for transportation stage of a modular constructions can be calculated using Equation (3).

$$E_T = E_{TP} + E_{TS} = \sum_i^n E_{TPi} + \sum_i^n E_{TSi} = \sum_i^n \frac{D_i E S_i E L_i F_i L_{hvi}}{V_i} \quad (3)$$

In which, E_{TP} refers to material transportation to the plant for modular fabrication and E_{TS} refers to modules' transportation from plant to the jobsite. D is distance of transportation, and ES , EL , F , and V are engine size, engine load, fuel consumption, and average speed of the equipment, respectively. L_{hv} is lower heating value of the fuel.

As discussed, the construction stage (A5) of modular

projects is conducted in two steps of material processing (E_P) for modules production and on-site installation and assembly of modules (E_C). The construction energy can be quantified by summing of all the energy used by different equipment in both plant and jobsite to perform various tasks toward constructing and installing modules and panels. Knowing activities and their related equipment, the construction energy in both module production and module installation can be calculated by multiplying the amount of estimated time takes that the equipment performs the activity (h), its engine size, and its engine load. The Kilo-Watt hour (KW.h) unit should be converted to Mega-Joule (MJ), thus a factor of 3.6 would be used for this conversion. It is noteworthy that the embodied energy of modules' manufacturing is not a simple task to be quantified. This is due to the reason that the process of manufacturing modules does not necessarily belong to a single project, and a particular plant is producing the modules of several projects at the same time. In Equation (4), E_P and E_C refer to the energy consumption of equipment used for module preparation in the plant and modules installation in the jobsite, respectively.

$$E_C = E_P = \sum_i^n E_{Ci/Pi} = \sum_i^n 3.6 h_i E S_i E L_i \quad (4)$$

4 Case Study

The proposed framework is implemented on a real case study to verify the applicability of the methodology to quantify the EE of a modular building. An under construction modular building in Sydney, NSW Australia, was selected for the case study. The total building area of this building is 493 m². Figure 3 shows a BIM model of the building as designed in Autodesk Revit.

Figure 3. A BIM model of the case project.

Different sources of data have been used in this study. As the first step, all the geometrical data, the bill quantity of materials, and their relevant properties were obtained from the BIM model in Dynamo platform, and the material database was then created. Table 1 presents the materials inventory and their corresponding EE.

As previously explained, the EE data regarding material production in ICE database (stages A1 to A3) only includes raw construction material production, and extra energy consumption for transportation and

production of modular elements are not considered in the database. To acquire relevant information for transportation and construction phases, numerous interviews were conducted with the project management teams. Transportation has two stages of transporting materials from raw construction material production factory to the processing plant to make the modules and then transporting modules to the jobsite for installation. The relevant database was created by having the weight of raw materials and modules, and also the distance between factory, plant, and the jobsite. The transportation energy for this case project has been quantified in Table 2 and Table 3, respectively.

In modular construction approach, construction is conducted in two off-site and on-site phases. Off-site construction refers to the processing of material and producing the modules and panels. On the other hand, on-site construction is related to the installation of the modules in the jobsite. The quantification of off-site and on-site construction phases including the used equipment and machinery have been presented in Table 4 and Table 5, respectively.

Table 1. Material production energy

Element	Type of Material	Volume V (m ³)	Density ρ (kg/m ³)	Mass m (kg)	Energy Coefficient C (MJ/kg)	Material Energy E_M (MJ)

Electricity Supply	Generator	550	2	1	3960.0
Total					140713.2

As achieved results of this case project showed in Figure 4, 87.37% of total EE is associated with the construction material production showing the high contribution of this stage in energy usage. A significant 9.43% of the total EE energy for this case study has been used for transportation including the transportation between factory and plant (5.21%), and also between plant and jobsite (4.22%). Eventually, minor 2.01% and 2.19% of total EE content were consumed in off-site and on-site construction, respectively in this selected project.

It should be noted that though the amount of energy in transportation and construction phases has significantly less contribution to the total EE in the building life cycle compared with material production stage, they should not be ignored in buildings energy evaluation as they are still huge energy consumers.

The main objective of conducting this case study is to demonstrate the applicability and practicality of the developed research framework in EE measurement. This case project is to be investigated further in the future

studies to include all other elements of the building including the internal parts, fittings, and facades.

Figure 4. The proportion of energy used in different phases of the studied case project.

5 Conclusions

This paper proposed a framework to evaluate the EE for the life cycle of modular construction projects. The system boundary of the framework breaks down the EE in material production, transportation, and construction stage according to EN 15978 Standard. Further energy consumption regarding modular construction, namely transportation to processing plant and off-site construction, was also included in the EE quantification. LCI was conducted through BIM software for material take-off and numerous interviews were performed with project management teams for transportation and construction data collection. After formulization of the EE based on the selected system boundary, the methodology was implemented in a modular case project to test its applicability. As shown in the case study, the total amount of EE in a modular building's life cycle and the contribution of each construction stage can be quantified. As this framework can provide a detailed EE analysis, it can be practically used by architects to take into consideration the EE in their designs which results in a more sustainable construction.

This study can be further extended to include the EE of the other construction elements such as internal parts, decorations, facades, and fittings to yield a more accurate and more reliable EE consumption of construction projects. Further, a trade-off between EE and OE of the buildings can be conducted by the researchers in the early development phases to achieve more energy-efficient projects.

Abstract –

As robots are envisioned to be deployed in construction job sites to work with humans, there is an increasing need for developing intuitive and natural communication between robots and humans. In particular, spatial information exchange is critical to navigating or delegating tasks to collaborative robots. However, such deictic gestures are inherently imprecise and ambiguous. Thus, it is challenging for robots to reason about the exact region of interest, especially in a cluttered large-scale construction environment. To address this limitation, this study evaluates the performance of spatial information exchange through the experiments based on pointing targets on the wall and ceiling, which are the most common workspaces in construction. We observed that the current deictic gesture-based method can estimate the pointed position on the wall and ceiling with a mean distance error of 0.767m, while the error tends to increase by 0.715m in the ceiling and 0.115m in the side panels. Our experimental results indicate that the deictic gesture-based method has some challenges in ceiling and side panel conditions, while the overall panel recognition shows acceptable performance. The findings of this study will help novice construction workers naturally and effectively communicate with robots by delivering spatial information on specific objects or regions in the shared workspace.

Keywords –

Deictic Gestures; Spatial Referencing; Human-Robot Interaction

1 Introduction

As robotic technologies have advanced, the focus of robot adoption has shifted from large-scale robotic platforms to small-scaled task robots [1]. These robots are designed for various applications and have shown possibilities of the collaboration of robots and humans in construction sites. As they interact with people during

task execution, there is a growing need for a more intuitive and natural human-robot communication interface. In particular, spatial information exchange (e.g., target objects or regions of interest) is critical to navigating or delegating tasks to collaborative robots. Potential human-robot collaborative applications, for example, include controlling a robot to change its position [2], referring to a target object [3], and indicating target ceiling panel for installation [4] or target wall area for painting [5]. In human-human interactions, people often utilize deictic gestures to deliver spatial information, which are effective means to develop a mutual understanding of a referent with others [6]. Deictic gestures are especially beneficial for construction applications because they require no additional devices, and therefore are intuitive for novice users.

However, deictic gestures are known to be inherently imprecise and ambiguous for both humans and robots. It is especially challenging for a robot to reason about the exact region of interest in an unstructured and cluttered construction environment. Construction tasks are carried out in a large-scale 3-dimensional (3D) environment; thus, it is necessary to share various dimensional and scaled spatial information (e.g., floor vs. wall vs. ceiling, centered vs. angled). Although several previous works showed the performance of gesture-based spatial information exchange for short-distance applications (e.g., table, wall, and floor [7]), it has not been evaluated in a comparatively large environment. Thus, this study aims to identify the challenges associated with the deictic gesture-based spatial referencing in a large-scale environment. This was done by evaluating the performance of spatial information exchange through the experiments based on pointing targets on the wall and ceiling, which are the most common workspaces in construction. The findings can guide and inform our approaches to developing collaborative construction robots supported with a natural human-robot interface.

2 Background

2.1 Deictic Gesture-Based Spatial Referencing

Deictic gestures are often referred to as “pointing gestures”, typically performed by extending the arm and the index finger [8,9]. In general, people often use pointing gestures to deliver spatial information to others. In other words, deictic gestures are fundamental to direct others’ attention to objects and help develop a mutual understanding of objects in space [10,11].

Deictic gesture-based spatial referencing has been explored substantially in previous works for developing and evaluating various spatial referencing models according to task requirements. This large body of work shares the same purpose: to solve the problem of interpreting deictic gestures in order to map the referent in the environment that the user wants to indicate [2]. Tölgyessy et al. [12] presented a spatial referencing method navigating a mobile robot to an endpoint marker on the ground floor defined by a pointing gesture of a human operator. The suggested method shows the precise positioning of all the entities included in the interaction in 3D space. Jevtić et al. [13] employed pointing recognition for selecting shoes placed on the platform in front of the user. Furthermore, they exploited the concept of multi-modality to develop personalized interaction with a robot assistant for assisted dressing. Mayer et al. [14] evaluated humans’ referencing accuracy when interpreting deictic gestures for pointing the targets positioned horizontally on the wall. However, they only measured the performance in a collaborative virtual environment (CVE).

While previous works showed acceptable performance of the deictic gesture-based spatial referencing for short-distance applications, limited applications in large-scale environments need to be further evaluated.

2.2 Deictic Gesture Recognition

Deictic gesture-based spatial referencing aims to exchange accurate spatial information through deictic gestures. Therefore, deictic gesture recognition has a significant impact on the final referencing results.

Two main approaches for deictic gesture recognition have been proposed in the literature. One is a wearable sensor-based approach. This approach attempts to recognize deictic gesture by analyzing the electrical muscle stimulation (EMS) from electromyography (EMG) generated during the muscle activity [15,16], the change in measures from inertial measurement units (IMUs) [2,17], and the posture and motion data from data gloves [18]. However, although wearable sensors have the benefit of direct acquisition of the spatial posture of the pointing arm, they often require connection to a data

acquisition (DAQ) device, thus restricting the applicability of this method outside of a controlled environment [19,20].

Meanwhile, recent advances in computer vision technologies have brought vision-based approaches to mainstream deictic gesture recognition. Vision-based deictic gesture recognition does not require users any additional devices and only employs their pointing arms within the camera angle. Earlier approaches detected gestures through the visual features (i.e., skin-color blobs) collected from monocular cameras (e.g., RGB or infrared camera) [21] and binocular cameras [22].

Recent works on vision-based approaches have focused on the implementation of RGB-D cameras. Owing to the ability to augment the RGB image with depth information, RGB-D cameras are frequently being adopted in vision-based approaches.

In a vision-based approach, the deictic gesture is defined based on the relationships among the body joints. Three main models for estimating the pointing direction were developed [12,23]:

- *Elbow-wrist model* assumes that the pointing direction is defined by a vector connecting the elbow and the wrist (hand) of the pointing arm.
- *Head-wrist model* assumes that the pointing direction is defined by a vector connecting the head and the wrist (hand) of the pointing arm.
- *Shoulder-wrist model* assumes that the pointing direction is defined by a vector connecting the shoulder and the wrist (hand) of the pointing arm.

The choice of a particular model mainly depends on the task and on the technology available for sensing the subject’s posture [2]. This work evaluates the performance of the spatial referencing method using a shoulder-wrist model, because the elbow-wrist model gives lower accuracy in large-scale environments and the head-wrist model has potential problems associated with the occlusion in pose estimation (i.e., safety helmets) [24].

3 Methodology

3.1 Deictic Gesture Detection

The detection of the deictic gesture is performed based on the 3D human skeletal data extracted from the RGB and depth images. To estimate the human skeletal data, we employ OpenPose [25] library, a real-time human pose estimation system. The library (BODY-25 model) detects 25 human body joints from each RGB image frame in 2D coordinates. The 2D coordinates are then projected to corresponding 3D points using the depth information [26].

In particular, we focus on the position of the shoulder $\mathbf{p}_s = (x_s, y_s, z_s)$, elbow $\mathbf{p}_e = (x_e, y_e, z_e)$, and the wrist

$\mathbf{p}_w = (x_w, y_w, z_w)$ joints for deictic gesture detection, which is required for the selected shoulder-wrist model. We use wrist position instead of fingers, considering the computation efficiency for further on-site applications. Given the position of the three body joints, the elbow joint angle θ is defined by:

$$\cos \theta = \frac{\mathbf{v}_{se} \cdot \mathbf{v}_{sw}}{|\mathbf{v}_{se}| |\mathbf{v}_{sw}|} \quad (1)$$

where $\mathbf{v}_{se} = \mathbf{p}_e - \mathbf{p}_s$ is the vector from the shoulder to the elbow joint and $\mathbf{v}_{sw} = \mathbf{p}_w - \mathbf{p}_s$ is the vector from the shoulder to the wrist joint. If θ is below a predefined angle, the system assumes that the person is stretching their arm for “pointing” and performs the panel estimation.

3.2 Pointed Panel Estimation

To estimate the pointed panel, we first compute the pointed position. The pointing direction is defined by a straight line starting from the shoulder to the wrist joint:

$$\mathbf{s} = \mathbf{p}_s + \lambda(\mathbf{p}_w - \mathbf{p}_s), \lambda \in \mathbb{R} \quad (2)$$

For a ceiling pointing task, panels are parallel to floor at a constant height of the ceiling h . Therefore, the pointed position $\mathbf{p}_p = (x_p, y_p, z_p)$ is calculated as follows:

$$x_p = x_s + \frac{h - z_s}{z_w - z_s} (x_w - x_s) \quad (3)$$

$$y_p = y_s + \frac{h - z_s}{z_w - z_s} (y_w - y_s) \quad (4)$$

$$z_p = h \quad (5)$$

In a wall pointing task, panels are parallel to wall at a constant distance d . Thus, akin to ceiling, the pointed position in this case is computed as:

$$x_p = d \quad (6)$$

$$y_p = y_s + \frac{d - x_s}{x_w - x_s} (y_w - y_s) \quad (7)$$

$$z_p = z_s + \frac{d - x_s}{x_w - x_s} (z_w - z_s) \quad (8)$$

The pointed target is then estimated using the pointed position. Let $\mathbf{p}_{t,i}$ be the center point of the target panel index $i \in \{1, 2, 3, \dots, n\}$, where $n \in \mathbb{N}$. A panel with the closest Euclidean distance from the center point is selected as a pointed panel i_p .

$$i_p = \arg \min_i (|\mathbf{p}_p - \mathbf{p}_{t,i}|) \quad (9)$$

4 Experiment

4.1 Experimental Setup

The experimental setup is depicted in Figure 1. The RGB and depth images are simultaneously captured by Intel RealSense™ Depth Camera D435 at a frame rate of up to 30 fps and with an image resolution of 640 x 480 pixels and 840 x 480 pixels, respectively. The camera has an operating range of 0.11-10m. It is installed at position \mathbf{p}_c facing participants, at the height of 0.7m and the pointing subject is located at position \mathbf{p}_h , 3.0m away from the camera. Five target panels with an equal size of 0.7 x 0.7m are located side by side on both ceiling and wall.

Four participants (two males and two females) were recruited to perform the pointing tasks. Each participant performed two experiments, 15 iterations for each experiment. A single iteration consists of 10 pointing trials: five ceiling panels (from C1 to C5) and five wall panels (from W1 to W5), in sequential order. In sum, we obtained $2 \times 15 \times 10 = 300$ trials for each participant. A single experiment took approximately 10 minutes per participant.

Figure 1. Illustration of the experimental environment.

4.2 Performance Metrics

We use the following metrics to evaluate the performance of the deictic gesture-based spatial referencing.

Distance error. Euclidean distance between the pointed position \mathbf{p}_p and the center point of the target panel \mathbf{p}_t .

$$\varepsilon = |\mathbf{p}_p - \mathbf{p}_t|. \quad (10)$$

F1 score. We also refer to this measure as panel recognition rate (see Section 5.2). F1 score is defined by:

$$F1 \text{ score} = \frac{2 \times \text{Precision} \times \text{Recall}}{\text{Precision} + \text{Recall}} \quad (11)$$

$$Precision = \frac{TP}{TP + FP} \quad (12)$$

$$Recall = \frac{TP}{TP + FN} \quad (13)$$

For each pointed position, we consider it as true positive (TP) if it is classified as a correct target panel, false negative (FN) if it is classified as other target panels, false positive (FP) if the subject is pointing at other target panels, and true negative (TN) if the subject is pointing at other target panels but classified correctly.

5 Results

A total of 1,200 pointing trials of four pointing subjects were evaluated in an offline setting in order to validate the performance of the spatial referencing method. The main results are shown in Table 1 and Table 2.

5.1 Distance Error

The distance error by the pointing subject is shown in Figure 2. We observed a similar tendency between all four participants: on average, the ceiling pointing task yielded a higher mean distance error and standard deviation ($1.125 \pm 0.263\text{m}$) compared to the wall pointing task ($0.410 \pm 0.174\text{m}$).

Among the subjects, Subject 3 reached the highest mean distance error for the ceiling pointing task with 0.482m of distance gap between the lowest, Subject 1. For the wall, Subject 2 showed the highest distance error with 0.207m of distance gap between the lowest, Subject 1.

Moreover, the mean distance error was higher when pointing the side panels (0.836 ± 0.241 for C1/C5 and

W1/W5) than the panels near the center (0.721 ± 0.210 for C2-C4 and W2-W4). This phenomenon will be expanded up in Section 5.

5.2 Panel Recognition Rate

We found that the ceiling pointing task shows a lower panel recognition rate. The mean F1 score of the ceiling pointing task was 0.815, while the wall pointing task was 0.896.

Higher error distance increases the probability of inferring the wrong panels located nearby, which in turn lowers the panel recognition rate. Therefore, the F1 score tends to follow the reverse order of the distance error. This tendency is especially salient in the panels near the center.

Figure 2. Distance error by the pointing subject. (C1-C5 and W1-W5 refers to target ceiling and wall panels from left to right, respectively.)

Table 1. Evaluation results of the ceiling pointing task: Distance error (Mean \pm SD) and F1 score.

Metrics	C1	C2	C3	C4	C5
Distance Error (m)	1.118 ± 0.243	1.159 ± 0.197	1.121 ± 0.216	1.090 ± 0.319	1.135 ± 0.316
F1 Score	0.849	0.826	0.837	0.756	0.808

Table 2. Evaluation results of the wall pointing task: Distance error (Mean \pm SD) and F1 score.

Metrics	W1	W2	W3	W4	W5
Distance Error (m)	0.561 ± 0.204	0.325 ± 0.134	0.282 ± 0.196	0.352 ± 0.145	0.530 ± 0.180
F1 Score	0.948	0.802	0.946	0.861	0.921

6 Discussion

Our experimental results present that the current deictic gesture-based method can estimate the pointed position on the wall and ceiling with a mean distance error of 0.767m . We observed worse performance in the ceiling with a mean distance error of 1.125m , which was

0.715m higher than the mean distance error of the wall. In the estimation of the panel, the mean F1 score dropped at a rate of 8.98% compared to the wall. These measures indicate that variation in plane causes a performance gap in the dimensional information exchange regarding the perception accuracy and target recognition rate.

Furthermore, the mean distance error tends to increase by 15.91% when the target changes from the

center to side panels. In this situation, a subject mainly delivers the scaled spatial information to a robot.

In general, these results can be explained by the pinhole projection model (Figure 3). Human eyes see the world via pinhole projection. The 3D world (on the world coordinate system) is projected onto a flat projection plane: this plane is focal length d away from the projective center along the Z_h axis (on the human coordinate system), the gaze direction [27]. Thus, a 3D point $\mathbf{p} = (x_h, y_h, z_h)$ in the human coordinate system is projected to 2D coordinates on the projection plane at a rate of d/z_h : $\mathbf{p}' = (x_h, y_h)d/z_h$. Therefore, the area of the target panel is also projected to the projection plane, affecting the visible area of the panel with respect to the rate of d/z_h .

Figure 3. Pinhole projection model [27].

The top and side views of the experiment setup are depicted in Figure 4. \mathbf{A}_0 and \mathbf{A}_1 refers to the visible area of the panels projected on the projection plane, perpendicular to the gaze direction Z_0 and Z_1 (Here, we assume a person gazes at the center of the target panels

when pointing). In both situations, \mathbf{A}_0 is larger than \mathbf{A}_1 due to the difference in between the angles θ_0 and θ_1 , as well as the position of the panels. A smaller visible area hinders the subjects from pointing precisely while maintaining consistency. Thus, compared to the targets with comparatively large visible areas (wall and center panels), the performance degrades in the targets with small visible areas (ceiling and side panels). Overall, it can be noted that the visible area of the target is a crucial factor for human's ability of deictic gesture-based spatial referencing for both wall and ceiling conditions. Therefore, in practice, one can expect lower performance in referencing a distanced and angled regions of interest in overhead operations (e.g., electrical wiring, plumbing, and interior finishing work). In such situations, collaborative robots need mobility for estimation of the workspace geometry through navigating themselves closer to the target.

Considering the results mentioned above, we see three ways to improve the current spatial referencing method for application in collaborative construction robots. First, we could give the robot dimensional and scaled spatial information with interaction modalities (i.e., speech). This allows the robot to reason about the region of interest with additional criteria, thus enhancing perception accuracy. Presenting the spatial information with a form of region could be considered as well. Deictics are often thought of as referring to an object but can also be used to refer to a region of space [8]. This method provides interpretability and predictability to the user intent and has a collateral benefit of correction. Lastly, as suggested by Medeiros et al. [20], visual feedback makes a difference in the accuracy of the pointing task. In particular, we could enhance human's ability to indicate the target with a smaller visible area by receiving visual feedback from robots.

Figure 4. The top (left) and side (right) views of the experimental environment. The panels were spaced for a better understanding.

7 Conclusion

This work explored the challenges of the current spatial referencing method based on deictic gestures. It is challenging for a robot to reason about the exact region of interest in a large-scale 3D construction environment, cluttered in many situations. In this context, we selectively overviewed the performance of deictic gesture-based spatial information exchange in wall and ceiling with various angle conditions and discussed some solutions. Evaluation results show that the performance degrades in exchanging spatial information on the ceiling and side panels pertaining to the perception accuracy and the target recognition rate. The results also imply that the target's visible area is a crucial factor for human's ability of deictic gesture-based spatial information exchange for both wall and ceiling conditions. These findings can guide and inform our approaches to developing collaborative construction robots supported with an intuitive and natural human-robot interface.

In this work, we limited our focus on the performance evaluation to the robot's interpretation ability. Future work will include performance evaluation on the human's interpretation ability in a large-scale environment for a higher level of the collaborative environment such as shared autonomy. Furthermore, while we performed data processing and evaluation offline, we intend to further our research on on-site application of this method.
