Hand Gesture Recognition; Wearable Sensor; Dataset Creation; Performance Comparison

1 Introduction

In the construction field, maintaining good communication is very important since it keeps the site safe and the project running smoothly and on schedule [1–3]. As one of the common ways to communicate, hand gestures are widely employed on construction sites due to their simple but effective nature [3–5]. They aid workers from different backgrounds and cultures to express their thoughts without difficulty [6]. Besides, consider that words may not be heard clearly on

construction sites due to the noisy environment. Hand gestures provide a standard mode for workers to receive correct directions without the need for complicated devices [7].

However, hand gestures may not always be captured or interpreted correctly in the fields, which easily leads to worker injuries/fatalities, work interruption, and stoppage, etc. For example, it was reported that when a crew chief entered an active work area on an All-Terrain Vehicle (ATV), he was asked to leave by a foreman using a hand gesture. However, the gesture was not captured by the crew chief. The result was that the ATV was hit by a bulldozer and the chief suffered a fractured leg [8]. Another accident was noted when a driver was driving a concrete truck. He misread the hand gestures given by an officer and hit a 27-year-old electrician, who was working on the replacement of traffic lights from the back of his truck [9].

These accidents indicate the necessities to automatically capture and interpret hand gestures in construction fields. So far, there are many research studies proposed for hand gesture recognition based on wearable sensors. The employed wearable sensors included Inertial Measurement Unit (IMU) [10], surface electromyography (sEMG) sensors [11], etc. The methods in these studies were employed to recognize sports referee gestures [10], promote human-computer interactions [11], understand sign languages [12], etc. They were based on either hand-crafted features [11] or deep neural networks [13]. The results illustrated the potential of using deep neural networks to capture and recognize hand gestures with excellent learning ability.

Although the performance of existing methods for hand gesture recognition is promising, it remains unclear whether they could be applied in the construction field to capture and interpret hand gestures made by construction workers. This paper presented a feasibility study on investigating whether hand gestures in the construction field could be recognized automatically with wearable sensors. A new dataset containing 8 classes of hand gestures for instructing tower crane operations was created. To measure the

recognition performance with the created dataset, two state-of-the-art deep neural networks, namely, Fully Convolutional Neural Network (FCN) and ResNet were employed to achieve hand gesture recognition. The recognition results demonstrated that a high classification accuracy (96.9%) could be achieved, which illustrated the feasibility and potential of wearable sensors to automate the hand gesture recognition in the construction field.

2 Related Work

Currently, various research studies have been developed to achieve hand gesture recognition. They could be classified into two categories, vision-based methods [14,15] and wearable sensors-based methods [16,17], depending on the type of data source they relied on.

2.1 Vision-Based Hand Gesture Recognition

So far, many efforts have been dedicated to hand gesture recognition based on the video data. They either relied on hand-crafted features or through deep learning. Traditional methods generally relied on hand-crafted features, such as Improved Dense Trajectories (iDT) [18] and Mix Features Around Sparse Keypoints (MFSK) [19]. Besides these features, many research studies were focused on deriving novel features to represent the appearance, shape, and motion changes of a gesture [20–22]. Currently, the use of deep learning technologies has become a mainstream in gesture recognition. For example, Miao et al. [23] proposed a multimodal gesture recognition method using a Res3D network. The extracted spatiotemporal features from the Res3D were combined through canonical correlation analysis and then the final recognition was made by a linear SVM classifier. Molchanov et al. [24] combined 3D Convolutional Neural Network (CNN) with recurrent layers to perform simultaneous detection and classification of dynamic hand gestures. The recurrent 3D-CNN enabled the gesture classification without requiring explicit pre-segmentation. Cao et al. [25] presented a framework of C3D+LSTM+RSTTM which augmented C3D with a recurrent spatiotemporal transform module. The presented framework could not only capture short-term spatiotemporal features but also model long-term dependencies. Köpüklü et al. [14] proposed a hierarchical CNN structure to realize the real-time hand signal recognition. The proposed architecture firstly employed a detector which was a lightweight 3D-CNN to detect the existence of hand gestures and then utilized deep 3D-CNNs to classify the detected gestures.

2.2 Wearable Sensors-Based Hand Gesture Recognition

Motion sensory data provide an alternative data source to achieve hand gesture recognition. They usually can be collected by various wearable sensors attached on human bodies or placed near hands, such as surface electromyography (sEMG) sensors, Inertial Measurement Units (IMU), etc. Currently, many methods have been developed to recognize hand gestures based on wearable sensors. For sEMG sensors, Su et al. [26] presented a robust hand gesture recognition framework based on random forests. The random forests were established using improved decision trees which included the pre-classifiers to avoid the misclassification of gestures with similar features. Allard et al. [27] applied CNNs on aggregated data from multiple users to identify hand gestures. In their work, CNNs were combined with transfer learning to decrease the data requirement of the training model. For IMU sensors, Fang et al. [16] designed a new CNN architecture named SLRNet to achieve dynamic gesture recognition. The CNN architecture extracted the features of two hands and fused the features into the fully connected layer. Jirak et al. [28] introduced an echo state network (ESN) framework for continuous gesture recognition. The framework included LSTM layers to achieve the automatic detection of the start and end phase of a gesture.

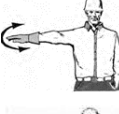

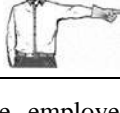

3 Methodology

3.1 Dataset Design

In this study, the accelerometer and gyroscope signals captured from wearable sensors are employed as raw data. The accelerometer signals are used to measure the vibration or acceleration of hand/finger movements while the gyroscope signals refer to the rotational motions of hand/finger. During data collection, the subject who makes hand gestures was requested to wear the sensor on his hand at first. To capture the characteristics of construction site environments, the way to make hand gestures is considered when creating the dataset. The subject was moving and making hand gestures synchronously.

The hand gestures made by the subject are those commonly seen on construction sites. For example, tower cranes are the most frequently shared resources [29,30], which are mainly used for lifting heavy things and transporting them to other places. 8 classes of hand gestures for directing tower crane operations were selected here, as indicated in Table 1.

Table 1. Hand gestures for instructing tower crane operations adapted from [4,5]

Hand gesture	Examples	Hand gesture	Examples
Hoist		Trolley travel left	
Lower		Stop	
Tower travel		Swing right	
Trolley travel right		Swing left	

In addition, several techniques are employed to preprocess the raw data. First, all the sensors are unified to sample at 5HZ for synchronization since the original sampling rates may be different for various sensors. Besides, the raw signals coming from sensors may be affected by external noise. To eliminate noise, the mean and standard deviation of raw signals are firstly subtracted from the data to obtain the offset of the signals. Then, Z score standardization (Eq. 1) is utilized to rescale the raw data, which allows all signals to be considered with equal importance.

$$z_i = \frac{x_i - \mu_i}{\sigma_i} \quad (1)$$

where z_i is the standard score for i -th signal channel, x_i refers to the raw data for i -th signal channel, μ_i and σ_i are the mean and standard deviation of i -th signal channel, separately.

3.2 Hand Gesture Recognition

Based on the findings from existing studies of recognition methods, deep learning networks illustrated an excellent learning ability among all the methods [13,31]. Thus, in this study, the recognition methods are selected from state-of-the-art deep learning networks which achieved high recognition accuracy. In previous studies, FCN and ResNet networks achieved better recognition performance compared to other deep learning networks [32,33]. Therefore, they are selected here to test the performance on the created dataset. The characteristics of the selected methods are summarized as below.

The architecture of FCN is first composed of three convolutional blocks where each block contains three

operations: a convolution followed by a batch normalization whose result is fed to a ReLU activation function. The result of the third convolutional block is averaged over the whole time dimension which corresponds to the Global Average Pooling (GAP) layer. Finally, a traditional softmax classifier is fully connected to the GAP layer's output. Figure 1 shows an overview of FCN architecture. More details of the network architecture could be found in the work of Wang et al. [33].

Figure 1. The architecture of FCN

In addition, ResNet is composed of three residual blocks followed by a GAP layer and a final softmax classifier whose number of neurons is equal to the number of classes in a dataset [34]. The main characteristic of ResNet is the shortcut residual connection between consecutive convolutional layers. Each residual block is first composed of three convolutions whose output is added to the residual block's input and then fed to the next layer. The number of filters for all convolutions is fixed to 64, with the ReLU activation function that is preceded by a batch normalization operation. In each residual block, the filter's length is set to 8, 5 and 3 respectively for the first, second and third convolution. The architecture of ResNet is indicated in Table 2.

Table 2. The architecture of ResNet

Layer name	Number of blocks
Conv1	192
Conv2	384
Conv3	384
Global pooling, fc layer with softmax	---

The recognition performance is evaluated in terms of gesture classification accuracy. The classification accuracy is defined as the percentage of correctly labeled gesture samples by the recognition method.

4 Results

4.1 Dataset Preparation

To create the dataset, Tap Strap 2 [35] is selected as the wearable sensor. As shown in Figure 2, it includes five 3-axis accelerometers and one IMU (3-axis accelerometer + 3-axis gyroscope). The five accelerometers are located at five fingers, separately, while IMU is placed on the thumb. There are totally 21 signal channels captured by the Tap sensor.

Figure 2. The structure of Tap Strap 2

During data collection, each class of gesture was performed 20 times by the subject, resulting in 160 (20×8) gestures in the dataset. The duration for each gesture is 10 s. Examples of the collected data for one gesture could be found in Figure 3. The details of the dataset after preprocessing are listed in Table 3. The average signal values for these 8 classes of gestures are -0.043, -0.873, 0.200, -0.069, 0.148, 0.042, 0.233 and 0.361, separately.

Figure 3. Examples of the data for one gesture

Table 3. Dataset description

Gesture class	Min	Mean	Max	Variance
Hoist	-4.287	-0.043	3.513	1.027
Lower	-4.876	-0.873	3.670	1.098
Tower travel	-3.760	0.200	4.126	1.008
Trolley travel right	-3.664	-0.069	4.056	1.061
Trolley travel left	-3.240	0.148	3.699	0.897
Stop	-4.531	0.042	4.294	1.143
Swing right	-3.381	0.233	2.759	0.498
Swing left	-3.306	0.361	2.970	0.470
Total	-4.876	0.000	4.294	1.000

4.2 Training for Recognition Methods

The recognition methods have been implemented on an Ubuntu Linux 64-bit operating system. The hardware configuration includes an Intel® Core™ i7-4820K CPU (Central Processing Unit) @ 3.70 GHz, a 32 GB memory, and an NVIDIA Titan Xp DDR5X @ 12.0 GB GPU (Graphics Processing Unit). For training, the dataset is randomly split into training (80%) and testing (20%) sets, resulting in 128 training and 32 testing gestures.

As for training details, the learning rate and the batch size are set as large as possible. When the loss is steady, the learning rate is reduced with a fixed decay factor which is set to 10. Stochastic gradient descent (SGD) is employed as the optimizer. Specifically, the learning rate of FCN and ResNet is set as 0.0001 while the batch sizes of these two methods are 16 and 64, separately. Figure 4 shows the loss reduction along with the training progress.

Figure 4. The loss reduction along with the training progress

4.3 The Recognition Performance

Table 4 presented the recognition performance of FCN and ResNet. For both FCN and ResNet, the networks achieve the training accuracy of 100% and the validation accuracy of 96.9%. The training losses of FCN and ResNet are 0.000 and 0.001, separately, while the validation losses of these two networks are 0.030 and 0.015, respectively. Both of them achieve satisfying recognition performance.

Table 4. The Recognition performance of best models

Indexes	FCN	ResNet
Training loss	0.000	0.001
Validation loss	0.030	0.015
Training accuracy	100%	100%
Validation accuracy	96.9%	96.9%

4.4 Pilot Study

Further, a pilot study was conducted in a laboratory environment to test whether the methods used in this study could serve as an interface to help workers control and/or interact with construction machines. Specifically, the subject was asked to perform hand gestures, which were captured by a Tap sensor connecting to a computer. The motion data captured by the Tap sensor were input into the deep learning networks in real time. Based on the recognition results, the corresponding instructions would be sent to a remote controller, where the control signals would be transmitted to operate the truck model remotely.

Figure 5 showed an example of using the deep learning networks to remotely control a toy truck to move and lift its dump box. The subject firstly made the hand gesture of “swing right” to request the truck model to turn right. The gesture was captured by the framework and the corresponding instruction was sent to the truck model through the remote controller. Following the instruction, the truck model drove towards the right gradually. After a short pause, the subject then performed the gesture of “hoist” to request the truck model to lift its dump box. The truck model received the corresponding instruction and then lifted its dump box.

Figure 5. Examples of the test results in the pilot study

5 Conclusions and Future Work

In construction fields, it is common for workers to rely on hand gestures to communicate and express thoughts because of their simple but effective nature. However, the meaning of these hand gestures was not always captured precisely. As a result, it would lead to construction errors and even accidents. This paper investigated whether the recognition of hand gestures could be automated based on wearable sensors in construction. A new dataset with 8 classes of hand gestures in construction is introduced and employed to

evaluate two state-of-the-art recognition networks, FCN and ResNet. The results indicated a high classification accuracy (e.g. 96.9%) could be achieved. Further, a pilot study was conducted in a laboratory environment to test whether the methods used in this study could serve as an interface to help workers control and/or interact with construction machines.

Future work will focus on including more classes of construction gestures into the dataset to make the training and testing of hand gesture classifiers more robust. Besides, it will investigate how to use the gesture detection and classification to control construction machines.

Abstract –

Construction environments are often densely populated with multiple resources (e.g., workers, equipment, and materials). As an increasing number of mobile robots are expected to coexist and interact with humans at close proximity, it is necessary that these robots are capable of not only avoiding collisions with people but also not disturbing human work and deteriorating human comfort. Failing to maintain a proper social space can lead to fatal accidents and inefficiency. To accommodate this need, this study aims to develop a social navigation model that enables robots to navigate in a contextually compliant manner. We created a simulation environment where robot agents can learn socially and contextually aware policies using reinforcement learning. The results showed that the agent was able to secure the respective minimum separation distance for different types of workers while achieving similar overall performance in contrast to baseline models which often violated the work-related proxemic considerations. This finding will contribute to building future construction mobile robots with social intelligence which are capable of understanding the context of the workplace and adapting to appropriate behaviors accordingly.

Construction mobile robots; Social Navigation, Human-Robot Interaction, Reinforcement Learning

1 Introduction

Construction environments are often densely populated with a variety of resources such as workers, equipment, and materials, and they are usually operated in close proximity. As a result of the environment's congested and dynamic nature, the construction industry suffers from contact collisions between workers and equipment [1]. To prevent high traffic accidents, it has

been essential to maintain a certain distance from one another.

As a growing number of mobile robotics engaging in non-permanent construction tasks such as reality capture [2,3], safety surveillance [4], and environment monitor (e.g., illuminance measurement) [5] are developed and expected to be deployed in near future, the introduction of mobile robots will bring new safety risks to workers who are in vicinity to the robot trajectory. During operations, robots will encounter a number of workers in different situations, and their movement and the resulting interaction with people can create discomfort and safety threats, causing rejection [6].

Thus, to deploy autonomous mobile robots in construction sites, safe and efficient navigation that produces socially acceptable robot behaviors in the context of construction sites is a vital precondition. This means that these robots are capable of moving through crowds of people while preserving a minimum distance from the co-existing people. This brings the notion of social navigation, which accounts for social conventions such as comfort, naturalness, and sociability, in addition to traditional navigation objectives such as obstacle avoidance and task completion. Due to its importance, robot mobility in a socially compliant manner has been an active area of research in various domains [7,8].

However, one limitation of the existing socially aware navigation models is the lack of understanding of individuals' different proxemic requirement based on their work context. Previous research studies treated each individual equally in their models, assuming no difference in proxemic requirements or preferences among different groups of pedestrians [9–11]. In construction environment, nevertheless, individual pedestrian workers possess unique proxemic considerations based on their work-related contexts. Each worker requires different personal spaces depending on his operational status and space constraints. For example, if a worker is carrying heavy materials where various safety hazards are presented, he needs a

larger separation distance from others to feel safe and uninterrupted. To this end, robots should exhibit appropriate proxemic behaviors with respect to these different needs of workers in order to be seamlessly integrated into the construction environment.

Our study aims to develop a context-appropriate social navigation (CASN) algorithm sensitive to different types of pedestrian workers' proxemic needs in construction sites. We used different reinforcement learning (RL) algorithms on the CASN model and evaluated them against baseline models. The preliminary results demonstrated that the proposed model can navigate in crowds with appropriate social etiquette comparable to state-of-the-art methods with some limitations. This finding will contribute to building future construction mobile robots with social intelligence capable of understanding the workplace context and taking socially and contextually appropriate behaviors accordingly.

2 Background

2.1 Social Spaces and Proximity Considerations in Construction

For navigation tasks in a human-populated environment, mobile robots' behaviors must be acceptable by the humans who share the same space with robots. One paramount aspect of such spatial behaviors is that it does not intrude on people's social space, including personal space and activity space as humans perceive [12].

The notion of personal space is first introduced and delineated in the proxemic theory by Hall [13]. Proxemics is the study of spatial distances that individuals maintain in various social and interpersonal situations, and it is used to define interaction strategies. According to Hall, people can perceive and manage their personal space from others and respect others' space in a similar manner. Similar to personal space, actions performed by humans constitute activity space. Other people maintain this space to avoid disturbing the activity.

These social spaces, such as personal or activity spaces, often depend on environmental or cultural factors. Thus, the preferred social space distance is subject to be changed based on the context [14]. For example, if the potential threat is high, personal space distance tends to get larger. Understanding and respecting this personal space is vital in terms of safety assurance. When personal space interferes, people feel discomfort, and it increases physical safety risks.

In the construction domain, which are often characterized as unstructured and cluttered, respecting proxemics, or the minimum distance from other workers is even more critical. Various construction activities are

concurrently operated in proximity, and both workers and equipment constantly change their positions in the construction job sites. Consequently, there are many direct and indirect safety risks of shared spaces with unmanned vehicles in proximity [15–17]. Maintaining the relevant separation distance from workers, therefore, is critical for mobile robots to assure both physical and psychological safety.

For example, when autonomous robots are integrated into the construction sites, any robot behavior that impinges on workers' personal space will be perceived as not only unsafe but also unpleasant. In particular, if activity spaces are threatened while they are performing construction activities, they will lose comfort and sense of safety. Some may even feel disrupted and demotivated because the impact of autonomous navigation behaviors on workers varies depending on the context. For example, workers will perceive smaller personal space for those who are just walking compared to those walking during task operations (e.g., transporting materials from one place to another). Similarly, workers will perceive a larger personal space for those in a safety-critical situation than those in less dangerous situations.

Thus, to avoid interrupting the activities and decreasing productivity in construction, it is critical for robots to understand the status of workers and maintain a corresponding separation distance from the workers. In other words, while the primary personal space needs to be respected in the construction domain, it is also essential to preserve context-specific activity spaces in certain work-related situations.

To this end, construction mobile robots should understand these contextual proxemic considerations and constraints safely and effectively navigate the construction site where robots encounter various workers and work situations. The detailed proxemic considerations are further discussed in Section 3.1.

2.2 Socially-aware Navigation Algorithms

Socially-aware navigation refers to the strategy in robot motion planning which accounts for social norms and conventions regarding space management [8]. It is based on the belief that humans interact with robots similarly to human-human interaction; thus, robots can learn from the social norms observed by humans to acquire more acceptable social behaviors and interactions with humans [18]. Socially compliant robots have the ability to perceive and understand crowd behavior to plan their future trajectory to reach their target destination while maintaining an appropriate distance from other pedestrians [7].

There are two approaches in the socially aware navigation literature. A first approach is a model-based approach, which describes the spatial behaviors in terms of a set of rules (e.g., distance, velocity, acceleration,

direction) [19]. Using hand-crafted functions to ensure collision avoidance, it performed well in an austere environment; however, it did not generalize well and lacked the capacity to adapt to various situations and lead to oscillatory paths.

To address these limitations, recent works have focused on learning-based approaches such as deep reinforcement learning [11] and imitation learning [20]. In the Inverse Reinforcement Learning (IRL), or imitation learning framework, agents can learn the underlying reward function from human demonstrations. Deep reinforcement learning (DRL) methods such as Deep Q-Network (DQN), Double DQN (DDQN), Trust Region Policy Optimization (TRPO), and Proximal Policy Optimization (PPO), can learn how to behave by interacting with an environment through a sequence of observation, actions, and rewards. Recent work in robot navigation research, DQN, and TPPO showed state-of-the-art performances [21]. To this end, this study leverages the state-of-the-art RL algorithms, namely DQN and TRPO, to develop CASN social navigation model that accounts for various contextual proxemic needs.

3 Methodology

3.1 Context-appropriate Social Navigation

The social space is highly relevant to the context. Construction workers keep a shared convention of construction workspace in construction sites when they interact/work with other workers, and the relevant social space is determined by the activity or task a worker is taking. Thus, the robot's spatial movement should reflect the construction work context to select the appropriate proxemic requirement for different pedestrian workers. This study defined three levels of proxemic considerations and assigned low, medium, and high proxemic requirements for different worker types, as illustrated in Figure 2.

The low proxemic requirement includes normal pedestrian workers who are not conducting construction activities; thus, they are the most flexible in their spatial movement. The medium proxemic requirement group includes load-carrying pedestrian workers. Because these workers have some physical constraints due to their material, they require a larger space than the regular group. Lastly, the high proxemic requirement groups are those who are actively conducting construction activities. Intruding their activity spaces will lead to inefficiency. Thus, priority was placed on this group with the most significant space.

Based on the principles of proxemic theory, we created the corresponding work zone as concentric boundaries and assigned three levels of work zone radius

based on the pedestrian worker type. The small work zone indicates that there are less safety risks and activity disturbance compared to the large work zone. We define the work zone distances specific to the work status as $d_{w,s}$, $d_{w,m}$, $d_{w,l}$ for normal pedestrian, load-carrying pedestrian, and operational activity groups, respectively.

Table 1 Work Zone

Pedestrian Worker Type	Work Zone Size	
Normal Pedestrian	Small	0.2
Load-carrying Pedestrian	Medium	0.3
In-Activity	Large	0.4

Figure 2. Examples of Different Work Zone based on the Working Status

Acknowledging the need for different workers, this study aims to incorporate these different proxemic considerations into social navigation models. We leveraged DQN and TRPO as the base algorithms of the proposed model. Within the RL framework, we formulated this problem as a sequential problem that the robot agent interacts with the environment, observes the states of other humans, and makes a sequence of decisions to maximize the expected return.

DQN is a value-based DRL method that solves the problem by approximating the optimal value function. The optimal policy is to maximize the expected return. It leverages experience replay which stores past experiences and randomly use a subset of them to update the Q-network.

$$V^*(s) = \sum_{t'=t}^T \gamma^{t'-t} v_{pref} R_{t'}(s_t, \pi^*(s_t)) \quad (1)$$

TPPO, on the other hand, is a policy-based DRL method which becomes very powerful in recent DRL research [22]. Formulating as a hard constraint problem, it aims to maximize the objective function, $J(\theta)$, subject to trust-region constraint, which enforces the distance between old and new policies measured by KL-divergence to be small enough with guaranteed monotonic improvement.

$$J(\theta) = E_{s \sim p_{\pi_{\theta old}}, a \sim \pi_{\theta old}} \left[\frac{\pi_{\theta}(a_t | s_t)}{\pi_{\theta old}(a_t | s_t)} \hat{A}_{\theta old}(s | a) \right] \quad (2)$$

In our model, the radius of the robot is r , and the radius of the human be r_h . The center to center distance between robot and human is defined as d_c . Then, the minimum separation distance between robot and human, d_{min} , is given by

$$d_{min} = d_c - r - r_h \quad (3)$$

To provide feedback to the robot to learn the desired navigation behaviors, the reward function, R_t at timestep t , at state s , and after action a are defined in such a way that the overall navigation goal was fulfilled by achieving a balanced outcome for both success rate and securing the corresponding minimum distance. It implemented different reward functions for different worker groups with corresponding values of work zone spaces based on the operational status. This was designed to be enforced greatly when violating the work zones of worker groups compared to those in regular conditions.

We tried different reward factors for the new reward function, and each reward function calculation is done in the following sequence.

$$R_t(s, a) = \begin{cases} 1, & \text{if success} \\ (d_{min} - d_{w,s})f, & \text{if } d_{min} < d_{w,s} \\ (d_{min} - d_{w,m})f, & \text{if } d_{min} < d_{w,m} \\ (d_{min} - d_{w,l})f, & \text{if } d_{min} < d_{w,l} \\ 0, & \text{otherwise} \end{cases} \quad (4)$$

In addition to negative rewards for collision, we added another set of penalties for invading the assigned personal space for each group. The penalty factor f , is defined for intruding the work zone. This ensures better integrity of the algorithm in the sense that those who are working and situated in safety-critical environments are given higher priority over regular workers.

3.2 Simulation Environment

Because training robots in actual physical environments can be expensive and dangerous, much RL research is done in simulation environments and transfer the learning outcome to the physical environment. In our study, all experiments were carried out using a 2D navigation simulation environment, RVO2 [23]. RVO2 simulates human movements by Optimal Reciprocal Collision Avoidance (ORCA) policy [24]. ORCA uses the optimal reciprocal assumption to generate a path in a shared space while avoiding other agents and preventing collisions with the local observation of the environment, as illustrated in Figure 1.

Figure 1. Simulation Environment w/ Reciprocal Collision Avoidance

Our simulation environment is composed of n human and a robot, and the robot task is to navigate toward a given goal in a crowd setting of n pedestrian workers. We assumed that humans could avoid collision with other humans based on ORCA. However, we assumed that humans do not change their paths based on the robot.

The robot, on the other hand, observes the states of the environment, {distance to the goal position}, and adapts its actions to avoid collisions. The robot action space is given {direction, velocity}. It was assumed that the robot knows the goal position, and it can identify the category that a human belongs to in real-time with the vision data it obtains through navigation. The reward function is defined by {Reaching Goal Reward, Collision Reward}.

When the minimum separation distance between robot and human is smaller than the radius value, it would be considered a collision.

The episode will terminate when it reaches the goal in the duration of 25 secs or fails the task by colliding with people or by timeout.

3.3 Experiment

We incorporated the proposed CASN model into DQN and TRPO, and compared them with baseline models. We implemented the ORCA and Socially Attentive Reinforcement Learning (SARL) algorithm as the baseline models. SARL [25] also adopts DQN with an attentive pooling mechanism to learn the importance of neighboring humans with respect to their future trajectories. As it considers various factors like speed and directions of humans as opposed to the previous work assuming the closest neighbors had the most crucial effect on the robot, it improved the performance (e.g., time efficiency) compared to other state-of-the-art benchmark models. These models are used to delineate how the robot would behave without the knowledge of different proxemic considerations.

In addition, we experimented with these algorithms in various density environments. Because robots would encounter a varying density of dynamic obstacles and crowds while moving through the construction sites (e.g., a narrow corridor and/or open space), it is imperative to explore how the density of the crowd would influence the

performance of our model. Thus, we compared the results of our models in the same environment with different densities: robot navigating among five people versus ten people to understand how each algorithm would perform differently in various density environments.

For the experiments, we implemented the algorithms in PyTorch. Adopting from the framework of [26] in each set of training experiment, 10,000 training episodes were run with a batch size of 100. We used the learning rate of 0.001 and the discount factor of 0.9. We adopted the ϵ -greedy policy, where the exploration rate decays linearly from 0.5 to 0.1 in the first 5000 episodes and stays 0.1 for the remaining 5000 episodes.

3.4 Evaluation

As it is challenging to quantify the social conformity of robot behaviors, we used the following five evaluation metrics: success rate, collision rate, navigation duration time, violation of social space, and the minimum distance between human and robot while violation to evaluate social behaviors of the navigation algorithms. Firstly, the success rate is defined as the rate of the robot reaching the target goal within a time limit of 25 seconds, and it is considered as a failure when the robot collides with humans or the total navigation time is over 25 seconds. The collision rate is defined as the rate of robots colliding with humans, which means that the distance between the robot and a human is zero. Violation of social space is defined as the rate at which the minimum distance between the robot and a human is less than the designated work zone size. The minimum distance during violation is defined as the distance between the robot and a human when the robot intruded on the work zone of different workers. We assumed that a larger minimum distance during violation is more socially acceptable.

4 Results

This section compared our context-appropriate social navigation model against the baseline model and showed significant improvements in terms of social conformity. We also describe the performances of proposed models – DQN and TRPO in different density scenarios: high and low density of pedestrian workers.

4.1 Low Density

Our preliminary results showed that the context-appropriate navigation algorithms successfully learned the social norms relative to different workers' proxemic requirements in the low-density simulation environment. Figure 1 show the cumulative discounted rewards of the robot with respect to the number of episodes.

Figure 2. Cumulative discounted rewards for 5 human density

The summarized result is described in Table 2. Except for the ORCA baseline model, most algorithms successfully learned to navigate to the target position. The DQN baseline model showed a relatively similar total navigation duration time. However, in terms of social norm compliance, it suffered from a higher rate of personal space violations and the shorter minimum separation distance during the violation. On the other hand, our CASN models could maintain proper distance for different worker groups, ensuring their physical and psychological safety. It also showed increased minimum distance in case of violation.

In comparing different RL algorithms, the policy gradient algorithm TRPO did not significantly outperform the SARL algorithm in the low-density setting. We observed that all algorithms that we experimented with did not have significant differences in outcomes regarding the success rate, the total navigation time, and frequency of the violation.

Table 2 Comparison of Context-Appropriate Social Navigation model in low density environment

Model	Avg. Duration (s)	Success Rate (Suc no / Total no)	Collision Rate (Col no / Total no)	Frequency of Violation (Violation no. / Total no.)			Avg. Distance during Violation		
				Small	Medium	Large	Small	Medium	Large
ORCA	10.86	0.43	0.57	0.09	0.17	0.10	0.08	0.12	0.17
DQN	10.67	1	0	0.01	0.02	0.03	0.15	0.24	0.34
CASN-DQN	10.55	1	0	0.01	0.01	0.01	0.17	0.25	0.36
CASN-TRPO	10.75	1	0	0.01	0.01	0.01	0.17	0.27	0.38

4.2 High-Density

Similar to those in the low-density scenarios, the preliminary results in the high-density simulation environment also showed that the context-appropriate navigation algorithms successfully learned the social norms relative to different workers' proxemic requirements. However, the overall performance of the CASN models in the high-density environment slightly decreased in terms of total navigation duration, frequency of violation, and the average separation distance during the violation. They tend to converge slowly compared to those in the low-density environment, as illustrated in Figure 2. This tendency of decreased performance was most apparent in the baseline models. They suffered from a higher number of failures and violations, demonstrating the lack of the capacity to handle such high-density situations.

In comparing different RL algorithms, the policy gradient algorithm TRPO outperformed the SARL algorithm in the crowded environment setting, as

summarized in Table 3. It reduced the total navigation duration. However, these models were not able to maintain the proper distance from the group with a large personal space requirement.

Figure 2. Cumulative discounted rewards for 10 human density

Table 3 Comparison of Context-Appropriate Social Navigation model in high density environment

Model	Avg. Duration (s)	Success Rate (Suc no / Total no)	Collision Rate (Col no / Total no)	Frequency of Violation (Violation no. / Total no.)			Avg. Distance during Violation		
				Small	Medium	Large	Small	Medium	Large
ORCA	12.49	0.21	0.79	0.10	0.14	0.26	0.07	0.13	0.17
DQN	13.25	0.67	0.24	0.07	0.11	0.20	0.13	0.24	0.33
CASN-DQN	12.89	1	0	0.01	0.01	0.02	0.14	0.25	0.35
CASN-TRPO	12.51	1	0	0.01	0.01	0.02	0.15	0.25	0.36

5 Discussion

Our results demonstrated the potentials of the context-appropriate navigation model in making the robot aware of and responsive to varying types of pedestrian workers. Regardless of the RL algorithms, both value-based and policy-based methods showed acceptable outcomes. On the contrary, the baseline models without the proxemic considerations were not able to conform to the varied proxemic requirements, especially for the activity group with large personal space requirement. This suggests that social navigation algorithms without taking consideration of different proximity requirements would cause discomfort particularly to those who are in the most significant need of social norm conformity and in the most serious safety risks.

Although context-appropriate navigation model accounting for proxemics performed well in low to moderate density environments, the performance tends to degrade as the density of the human increase. It showed

underperformance in highly dense environments, causing the violation of social spaces and reduced minimum separation distance. This finding is similar to the prevalent limitation of the existing socially-aware navigation models [11]. Trautman et al. [27] showed that it is difficult to avoid freezing robot problem, which refers to a situation where robot halts or oscillates and results in either in a collision or no progress toward the goal, beyond a certain density environment. This finding implies that it will be even more challenging to learn and adhere to the different proxemic needs of workers in situations where workers and moving equipment are densely populated although the consequences of violation in highly dense areas can be more severe and dangerous. These results imply that the current proxemic-based reactive planner may not be effective or safe in the high-density situations. Instead, an interactive and cooperative planner which understands and incorporates context-specific rules or human preferences can be more effective and can enable effective maneuvers for fluent human-robot co-navigation.

6 Conclusion

For mobile robots to be safely and efficiently deployed in construction environments, they should be endowed with a certain level of social intelligence to avoid the risk of collisions as well as interruption of construction activities. Our work defined proxemic characteristics relative to work context and incorporated such proxemic requirements into the existing social navigation algorithms so that robots can adapt to the context. We compared the performance of our CASN models against the baseline models. Our preliminary study results showed that the current RL-based socially navigation models can handle low to medium density environments, but they struggled in a high-density environment. This indicates that proxemic-based social navigation algorithms have limitations in the high-density environment, and it is imperative to develop advanced and intricate human-robot interactions to handle such cases. Implicit or explicit human-robot interface can be incorporated to allow robots to more efficiently learn the social norm from human preferences. These findings will help develop and implement mobile robots with social intelligence capable of understanding the workplace context and taking socially and contextually appropriate behaviors accordingly in the construction domain. Such incorporation of the social norm will ensure the psychological and physical safety of workers and support successful integration of mobile robots in the construction sites.

The limitation of our model is that they were performed in a simple simulation environment. It only considers the pedestrian workers, excluding static workers and obstacles. Our model, thereby, may not work well in the real-world environment, which tends to be much complicated. Thus, in future work, we will include both stationary and moving obstacles in addition to different geometric spatial layouts to better represent the characteristics of the real world, and in turn, improve the performance for real-world implementation. Another limitation of our work is that the robot does not infer the social space of the encountering pedestrian workers. Instead, the predetermined values of proxemic requirement were provided to the robot. However, it is unlikely that this value will be fixed or that this knowledge will be provided to robots in real-world scenarios. In our future study, we will make the robot agent capable of inferring the dynamic social space of different workers without explicitly informing them by leveraging vision data collected from robot sensors.

Abstract

Highway construction and maintenance projects have been witnessing a significant expansion across the United States. This expansion, coupled with the ongoing problem of labor shortages, adds pressure on state Departments of Transportation (DOTs) to complete more complex projects under more strict cost and schedule constraints. In recent years, construction inspection has been particularly impacted by DOT labor shortage, creating a major need to understand inspection staffing in highway projects. This paper fills the literature gap through evaluating the staffing needs for highway construction inspectors. Data for 266 highway construction projects from 15 different DOTs were collected to identify factors that affect highway inspection staffing for Junior, Intermediate, and Senior inspectors. The analysis showed that inspection staffing depends on project type, level of complexity, and project size. The results also suggested that projects that experience cost or schedule overrun tend to hire more inspectors than projects that are completed within budget or on time. The identification of such factors can assist DOTs in quantitatively modelling and predicting the full-time equivalents (FTE) needs of highway construction inspectors on future projects.

1 Introduction and Background

Highway projects in the United States (U.S.) are among the most visible assets of infrastructure, stretching out over five million miles across the country [1]. The U.S. public sector spent nearly \$92.5 billion U.S. dollars on highway construction projects in 2018. With the ongoing U.S. economic expansion, the demand for highway construction projects continues to increase.

Highway and road construction put in place in the U.S. is forecast to grow to 107.74 billion in 2024 [2]. This significant expansion along with the increased complexity of highway projects has placed more pressure on state Departments of Transportation (DOTs) to ensure adequate staffing on their highway projects [3].

Staffing is an important resource to construction projects, and a shortage in the staffing needs of any activity during the construction process can lead to cost and schedule overruns as well as decreased safety performance [4]. Highway staffing into three construction categories [5]: (1) administration where construction staff handles administrative tasks such as planning, scheduling, change orders and budget management, (2) engineering where construction staff deals with tasks such as design, estimation, traffic control and conflict resolution, and (3) inspection where construction staff oversees the ongoing operations to ensure the work is performed as required in the contract.

Highway staffing, whether administrative, engineering or inspection, need proper planning for productivity, scheduling, and estimating manpower requirements to economically match the requirements for each activity. This is especially important in a time where DOTs are managing increased lane miles with reduced staff [5]. Between 2000 and 2010, state-managed lane-miles increased by an average of 4.10%, whereas the number of full-time equivalents (FTEs) decreased by 9.68% [5]. When FTEs are normalized across the managed road system, the responding transportation agency's FTEs per millions of U.S. dollars of disbursement on capital outlay decreased by an average of 37.26% [5].

Proper planning with staffing can thus be a major challenge for the construction industry. This is especially true in the current climate where workers are not attracted to the construction industry; the dynamic nature of construction, work settings, attire, technology, job hazards, and environmental conditions play an important role in creating a labour shortage problem for the construction industry [6]. State DOTs are no exception to the above problems, especially that the current evolution

in their projects comes at a time when they face high staffing turnover [5].

1.1 Factors Affecting Construction Staffing

With the increasing demand for highway projects and the declining level of in-state staff, one solution developed by DOTs to solve staffing shortage is forecasting tools. Forecasting tools allow DOT personnel to estimate staffing levels needed for a construction project, facilitate the management of this project, and protect the related firms from the damage caused by efforts to undertake projects when labour resources are not available [7]. The South Carolina Department of Transportation (SCDOT) investigated different projects to determine manpower requirements for construction project management [8]. Using data from 130 completed highway construction projects and over 11,000 employee payroll entries, regression analysis models were generated to predict overall manpower requirements for projects of a given type and cost. These overall requirements were then adjusted to predict manpower requirements for individual employee classifications using typical task allocation percentages obtained from questionnaire data [8]. The Texas Department of Transportation (TxDOT) performed a similar study in 2016 [9]. The primary purpose of the study was to assess the staffing requirements for transportation construction projects done by TxDOT to estimate staff needs for future work. Project completed between 2001 and 2011 were examined to study the impact of project characteristics and location and a regression model for CE staff hours was developed. Results of the model indicated that construction cost increase the demand by a power factor of 0.66, project type is a key factor in increasing or decreasing the demand, so does the degree of urbanization or the location of the project where metropolitan areas need more CE staff hours than those in urban and rural areas [9]. Another study [10] developed a protocol to provide Indiana Department of Transportation (INDOT) with a risk assessment framework to guide the inspection process and prioritize the allocation of limited inspection resources. The proposed novel risk-based prioritization approach for construction inspection assessed the risk associated with 90 critical inspection activities while considering quality, safety, cost, and time [10].

In addition to the research conducted in the highway sector, various studies were performed worldwide to analyse and forecast labour in construction projects. A study done in Hong Kong developed a simple regression relationship from 123 construction projects which were completed between 1995 and 2001, in which it estimates the labour demand from the cost of the contract [11]. Another study went even further by developing a multivariate regression analysis based on data collected

from 54 projects [12]. The models developed by the authors predicted labour demand based on project type, contract amount, construction methods, degree of mechanization, management attributes, expenditure on electrical and mechanical services, project complexity, and the physical site location [12]. A third study [13] analysed the impact of 12 different factors to develop a future model that predicts workforce demand in Poland using fuzzy analysis. They concluded that the deadlines set for the implementation of various works, the contractual deadline for completion of construction, the amount of work, and the construction technology used are the four factors that significantly impact the planned workforce. They also concluded that availability of workers, degree of cooperation between the designer and the contractor, and contract value are three factors with the least impact on planning workforce [13].

1.2 Gap and Objective

DOTs are facing significant challenges when it comes to staffing of administrative, engineering, and inspection, leading them to hire Construction and Engineering Inspection (CEI) consultants [14][15]. While previous research endeavours have evaluated and forecast construction staffing requirements for highway projects, no research has yet focused on understanding and examining the factors that impact highway construction inspection staffing needs. This paper contributes to the existing body of knowledge by filling a gap in the extant literature by investigating the factors that impact the staffing of highway construction inspectors. The identification of such factors can assist DOTs in quantitatively modelling and predicting the FTE needs of highway construction inspectors on future projects.

2 Methodology

To achieve the objective of the paper, a literature review was first conducted to identify the factors that affect the staffing of highway construction inspectors. A data-collection survey was then developed to collect project and staffing data from DOTs. Next, bivariate analysis was utilized to understand the effect of single independent variable (i.e. factors that can impact the staffing of highway construction inspectors) on the FTE needs of highway construction inspectors.

2.1 Level of Inspectors

To maximize the value of the data, analysis was performed for three levels of inspectors: Junior, Intermediate, and Senior [15]:

- **Junior** level inspectors hold a high school diploma, general education development (GED) or high

school equivalence test (HiSET) and less than 2 years of experience. Sample duties include performing on site measurements and computations, preparing final plans, change orders and estimating contract payments and engineering costs.

- **Intermediate** level inspectors hold a high school diploma, GED or HiSET, and have worked between two and four years. Their duties include inspecting construction materials such as asphalt or Portland cement, grading and bases, etc. These inspectors handle projects such as small to medium scaled bridges, roadside development and erosion control measures.
- **Senior** level inspectors hold a high school diploma, GED or HiSET, and have at least four years of experience. Hired in large scaled highway projects and critical structures, these inspectors are responsible for duties such as supervising the routine layout and staking, serving as party chief, technical expert and can perform duties of resident engineer's during their absence.

3 Data Collection

An online survey was distributed to different DOTs across the U.S. A total of 266 responses were recorded from 241 project managers and resident engineers across 15 different states highlighted in Figure 1. Respondents provided information about the type of the project, size of project, level of complexity, cost and schedule performance, and whether the project was fully staffed or not. They also provided the FTE of Junior, Intermediate, and Senior inspectors of the corresponding projects.

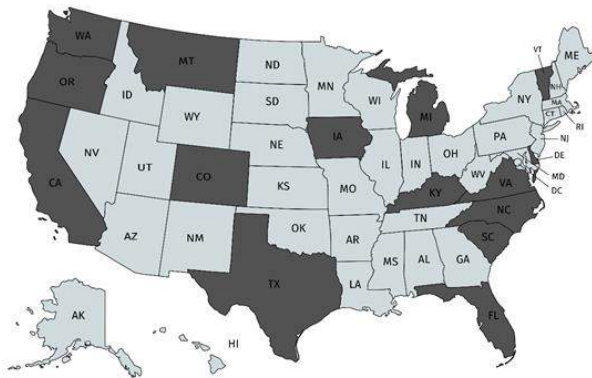

Figure 1. States that participated in the study (generated by MapChart.net)

The survey questions discussed different aspects of a specified projects, all of which are discussed in the following sections.

3.1 Type of Projects

The projects were distributed among four distinctive types (Figure 2):

- **Bridges** including all projects that involved constructing new bridges, and replacing or performing rehabilitation works on existing ones
- **Roadside (R.S.) Safety** including all project regarding guardrails, lights, signals, stripes, signs, and landscape
- **Roadside (R.S.) Enhancements** including all projects regarding ramps, curbs, shoulders, sidewalks, drainage, and retaining walls
- **Roads** including all projects that involved constructing new roads, and expanding, resurfacing or performing rehabilitation works on existing roads

Figure 2. Distribution of projects by type

3.2 Size of Projects

The size of project varied based on the contract cost of the project (Figure 3):

- **500k & Less** for a cost of \$500,000 or less
- **500k – 1M** for a cost between \$500,000 and \$1,000,000
- **1M – 5M** for a cost between \$1,000,000 and \$5,000,000
- **5M – 10M** for a cost between \$5,000,000 and \$10,000,000
- **10M & More** for a cost of \$10,000,000 or more

Figure 3. Distribution of projects by size

3.3 Complexity of Projects

The level of complexity of each project varies between minor, moderate and major based on a description adopted from (Li et al. 2019):

- **Minor Projects** include maintenance betterment projects, overlay projects, simple widening without or with slight right-of-way (or very minimum right-of-way) take; non-complex enhancement projects without new bridges (e.g., bike trails), categorical exclusion.
- **Moderate Projects** include no added capacity, minor roadway relocations, non-complex bridge replacements with minor roadway approach work, non-complex environmental assessment required.
- **Major Projects** include new highways; major relocations, new interchanges, capacity adding, major widening, major reconstruction, congestion management and/or complex environmental assessment required.

Figure 4. Distribution of project complexity

3.4 Cost and Schedule Performance

Data for the cost and schedule performance were collected as percentage overruns. For cost performance (Figure 5), negative percentages indicated that the project was under budget, a value of zero indicated on-budget, and a positive percentage indicated over budget. These terms were changed to binary values during analysis. For cost performance, projects that were on-budget or under budget were considered “within contract amounts” and assigned a binary integer of 0, while projects over budget were considered “above contract amounts” and assigned a binary value of 1.

Figure 5. Distribution of cost performance

As for schedule performance (Figure 6), negative percentages indicated that the project was ahead of schedule, a value of zero indicated as scheduled or on-time, and a negative percentage indicated behind

schedule. These terms were also changed to binary values during analysis. Projects that were on-time or ahead of schedule were considered “within schedule” and assigned a binary value of 0, while projects “behind schedule” were assigned a binary value 1.

Figure 6. Distribution of schedule performance

4 Data Analysis

Bivariate analysis was used to describe, explore, and summarize the factors that impact the FTE of highway construction inspectors. Different research questions were tested to further analyze the status of Junior, Intermediate and Senior inspectors across the different projects under study:

1. What is the impact of project types on the FTE of junior, intermediate, and senior inspectors?
2. What is the impact of project sizes on the FTE of junior, intermediate, and senior inspectors?
3. What is the impact of project complexity on the FTE of junior, intermediate, and senior inspectors?
4. What is the impact of cost performance on the FTE of junior, intermediate, and senior inspectors?
5. What is the impact of schedule performance on the FTE of junior, intermediate, and senior inspectors?

Due to the qualitative nature of the data, non-parametric tests were used.

Kruskal – Wallis Test: Known as the nonparametric version of the one-way ANOVA, Kruskal-Wallis is used to compare groups of equal or different sizes and indicate that at least one sample stochastically dominates one other sample. A significant p-value indicates that there at least two groups that were significant different than each other.

Conover – Iman Test: When the results of the Kruskal-Wallis test are significant, the Conover-Iman non-parametric post-hoc test is used to compare all possible pairs and identify which pairs are statistically significant. The pairwise comparisons between the studied groups indicate whether the difference is significant or not depending on the p-value.

Kendall’s tau-b Test: A non-parametric test that measures the correspondence between the ranking of the dependent and independent variables to test whether the dependent variable significantly increases or decreases as the independent variable changes. Kendall’s tau-b hypothesis test produces two statistical metrics: The first

metric is a p-value which can be thought of as the probability of having no statistical correlation between the two variables that are being studied. The smaller the p-value, the stronger the evidence of statistically significant correlation between the two variables. The second metric is the correlation coefficient, tau-b (τ_b). This coefficient measures the association between the two variables and ranges from -1 (100% negative association, or perfect inversion) to $+1$ (100% positive association, or perfect agreement); a value of zero indicates the absence of association.

4.1 Impact of the Types of Project

For every level of inspectors (i.e. Junior, Intermediate, and Senior inspectors), the FTE was measured across the four different types of projects. Figure 7 shows the FTE variation for Junior inspectors with roads being the highest (0.78), followed by bridges (0.63), roadside safety (0.44), then roadside enhancements (0.27). A similar graph was also developed for Intermediate and Senior inspectors. For Intermediate inspectors, the average FTE was highest for bridges (1.43), followed by roads (1.17), roadside enhancements (0.67), then roadside safety (0.54). As for Senior inspectors, the average FTE was also highest for bridges (1.43), followed by roads (1.03), roadside safety (0.76), then roadside enhancements (0.69).

The difference in the FTE of each inspector level across the various types of projects was statically tested using the Kruskal-Wallis test. The results from the Kruskal-Wallis resultant in a significant p-value for all three inspector levels: Junior (p-value = 0.0135), Intermediate (p-value = 0.0159), and Senior (p-value = 0.0316), indicating that there is a statistical significance across all three inspector levels. This implies that the FTE distributions of Junior, Intermediate, and Senior inspectors were not the same across the different types of projects.

Figure 7. Boxplots showing the variation of the FTE of Junior inspectors with respect to the level of complexity of the project and the correlation between both variables

When the results from Kruskal-Wallis showed statistical significance, the Conover-Iman test was employed to perform pairwise comparisons. The results of the pairwise comparisons for Junior, Intermediate, and Senior inspectors are shown in Table 1.

Table 1. Results of pairwise comparisons on project types for Junior inspectors

Project Types (Average)		p-value	Significance
<i>Conover-Iman Test for Junior Inspectors</i>			
Safety (0.44)	Bridges (0.63)	0.9345	Not Significant
Enhancements (0.27)	Bridges (0.63)	0.1904	Not Significant
Roads (0.78)	Bridges (0.63)	0.0653	Significant*
Enhancements (0.27)	Safety (0.44)	0.2318	Not Significant
Enhancements (0.27)	Safety (0.44)	0.0673	Significant*
Enhancements (0.27)	Roads (0.78)	0.0031	Significant**
<i>Conover-Iman Test for Intermediate Inspectors</i>			
Safety (0.54)	Bridges (1.43)	0.0311	Significant**
Enhancements (0.67)	Bridges (1.43)	0.2069	Not Significant
Roads (1.17)	Bridges (1.43)	0.6119	Not Significant
Enhancements (0.67)	Safety (0.54)	0.5141	Not Significant
Roads (1.17)	Safety (0.54)	0.0031	Significant**
Enhancements (0.67)	Roads (1.17)	0.0681	Significant*
<i>Conover-Iman Test for Senior Inspectors</i>			
Safety (0.76)	Bridges (1.13)	0.0154	Significant**
Enhancements (0.7)	Bridges (1.13)	0.0127	Significant**
Roads (1.04)	Bridges (1.13)	0.1575	Not Significant
Enhancements (0.7)	Safety (0.76)	0.7540	Not Significant
Roads (1.04)	Safety (0.76)	0.1376	Not Significant
Enhancements (0.7)	Roads (1.04)	0.0992	Significant*

*Significant at 90% confidence

**Significant at 95% confidence

The ad-hoc Conover-Iman test showed that roads, on average, needed significantly more Junior inspectors when compared to bridges (p-value = 0.0653), roadside safety (p-value=0.0673), and roadside enhancements (p-

value=0.0031).

For intermediate inspectors (Table 1), roads, on average, needed significantly more Intermediate inspectors when compared to roadside safety (p-value = 0.0031) and roadside enhancements (p-value = 0.0681), and roadside safety, on average, needed significantly fewer Intermediate inspectors when compared to bridges (p-value=0.0311).

As for Senior level inspectors (Table 1), bridges, on average, needed significantly more Senior level inspectors than roadside safety and roadside enhancements projects (p-value = 0.0154 and 0.0127 respectively).

4.2 Impact of the Size of Projects

The FTE of every inspector level was measured across the five different sizes of projects. Figure 8 shows the FTE variation for Junior inspectors, where the average FTE was 0.29, 0.38, 0.53, 1, and 1.69 for “500k & Less”, “500k-1M”, “1M-5M”, “5M-10M”, and “10M & more” project sizes respectively. For Intermediate inspectors, the average FTE was 0.56, 0.6, 0.92, 1.67, and 3.21 for “500k & Less”, “500k-1M”, “1M-5M”, “5M-10M”, and “10M & more” project sizes respectively. As for Senior inspectors, the average FTE was 0.79, 0.61, 0.94, 1.14, and 1.86 for “500k & Less”, “500k-1M”, “1M-5M”, “5M-10M”, and “10M & more” project sizes respectively. Correlation tests were also performed to test any correlation between the FTE variation and the increase in the cost of the project.

Figure 8 indicates that there is a positive relationship between the FTE of Junior inspectors and the size of the project. Similar positive relationships were witnessed in the boxplots for both Intermediate and Senior inspectors.

Figure 8. Boxplots showing the FTE of Junior inspectors with respect to the size (or total cost) of the project and the correlation between both variables

The boxplots of all three types of inspectors also showed that projects with 10 million dollars or more needed the highest average of Junior, Intermediate and Senior inspectors with an average of 1.69, 3.21 and 1.86

respectively.

The relationship between the FTE of staffing of all three inspector types and the size of the project was then statistically tested using Kendall Tau-b test, and the results are shown in Table 2. The results of Table 2 provide sufficient evidence to conclude that the FTE of each inspector level and the size of the project are directly correlated. The staffing of Junior, Intermediate, and Senior FTE inspectors increased as the size of the project increased.

Table 2. Results of Kendall Tau-b Correlation tests when analysing inspector FTE and size of project

Inspector Level	Tau-b	p-value	Significance
Junior	0.2742	0.00	Significant*
Intermediate	0.4125	0.00	Significant*
Senior	0.2304	0.00	Significant*

*Significant at 95% confidence

4.3 Impact of the Complexities of Projects

The FTE of every inspector level was measured across the three different levels of complexity. For Junior inspectors, the average FTE varied between 0.52, 0.49, and 1.44 for minor, moderate, and major complex projects respectively. Figure 9 shows the FTE variation for Intermediate inspectors, where the average FTE varied between 0.72, 0.99, and 2.97 for minor, moderate, and major complex projects respectively. As for Senior inspectors, the average FTE varied between 0.79, 0.98, and 1.9 for minor, moderate, and major complex projects respectively.

Figure 9. Boxplots showing the variation of the FTE of Intermediate inspectors with respect to the level of complexity of the project and the correlation between both variables

Figure 9 indicates that there is a positive relationship between the FTE of Intermediate inspectors and the level of project complexity, with projects of major complexity having, on average, a higher level of FTE Intermediate inspectors than projects of minor and moderate complexity. A similar positive relationship was

witnessed in the boxplots for Senior inspectors, but not for Junior ones.

The boxplots of all three types of inspectors also showed that projects with a major complexity level utilized the highest average of Junior, Intermediate and Senior inspectors with an average of 1.44, 2.97 and 1.9 respectively.

To confirm this positive trend, the relationship between the FTE of staffing of all three inspector types and the level of project complexity was then statistically tested using Kendall Tau-b test, and the results are shown in Table 3.

Table 3. Results of Kendall Tau-b Correlation tests when analysing inspector FTE and complexity of project

Inspector Level	Tau-b	p-value	Significance
Junior	0.0878	0.198	Not Significant
Intermediate	0.2614	0.00	Significant*
Senior	0.2481	0.00	Significant*

*Significant at 95% confidence

The results of Table 3 show that as projects become more complex, more Intermediate and Senior inspectors were needed. This can be attributed to the role of the Intermediate and Senior inspectors as described by [15]. These inspectors have several years of experience and are mostly hired for middle and large-scale projects, which are usually more complex than smaller projects. Moreover, more complex projects call for more experienced personnel especially Senior inspectors who can serve as party chief and are technical experts that can perform duties of resident engineers, making them eligible and important in higher level complex projects.

4.4 Impact of Cost Performance

Every level of inspector FTE was measured across the cost performance groups as shown in Figure 10 for Junior inspectors, where the average FTE was 0.45 for projects within contract amount, and 0.8 for projects above contract amounts. For Intermediate inspectors, the average FTE was 0.78 for projects within contract amount, and 1.35 for projects above contract amounts. As for Senior inspectors, the average FTE was the same regardless of whether the projects were within budget or exceeded it (an average FTE of 1 in each case).

The significance of the pairwise comparison between both cost performance types in terms of inspector FTE average was done using Wilcox test, with results shown in Table 4. The results show that projects that exceeded their budgets needed significantly more Junior and Intermediate inspectors than projects that were completed within contract amounts.

Figure 10. Boxplots showing the variation of the FTE of Junior inspectors with respect to cost performance

Table 4. Results of the Wilcoxon test for cost performance

Inspector Level	p-value	Significance
Junior	0.0073	Significant**
Intermediate	0.0432	Significant**
Senior	0.8322	Not Significant

4.5 Impact of Schedule Performance

Every level of inspector FTE was measured across the schedule performance groups as shown in Figure 11 for Junior inspectors, where the average FTE was 0.56 for projects on time, and 0.72 for projects over time. For Intermediate inspectors, the average FTE was 0.9 for projects on time, and 1.36 for projects over time. As for Senior inspectors, the average FTE was 0.89 for projects within contract amount, and 1.14 for projects over time.

Figure 11. Boxplots showing the variation of the FTE of Junior inspectors with respect to schedule performance

The significance of the pairwise comparison between both schedule performance types in terms of inspector FTE average was done using Wilcox test, with the results shown in Table 5. The results show that projects that exceeded their planned time durations needed

significantly more Intermediate and Senior inspectors than projects that finished within contract time. This was similar to what was seen in Table 4.

Table 5. Results of the Wilcoxon test for schedule performance

Inspector Level	p-value	Significance
Junior	0.9042	Not Significant
Intermediate	0.04779	Significant**
Senior	0.02101	Significant**

5 Conclusions, Limitations, and Further Studies

With the current evolution in highway construction projects, DOTs are often under pressure to complete projects as in as short a time as possible. However, the staffing shortage facing these agencies makes it more challenging to finish projects on time and within budget. Inspection is no exception to the problem, and this paper investigated the factors that affect and predict the staffing needs of inspectors. The analysis of the historical data from 266 highway construction projects from 15 different DOTs yielded the following results:

The FTE distribution of Junior, Intermediate, and Senior level inspectors were not the same across the four project types. Some types significantly needed more inspectors than others.

Projects with the highest level of complexity needed the highest FTE of Junior, Intermediate, and Senior inspectors. There was also evidence of a significant correlation between the level of complexity and the FTE of Intermediate and Senior inspectors: as the project became more complex, more Intermediate and Senior inspectors were needed.

As project size increase, more Junior, Intermediate and Senior inspectors were needed.

Projects that exceeded their budget needed significantly more Junior and Intermediate inspectors. Senior inspectors were on average the same regardless of the cost performance. As for projects that exceeded their time, they needed significantly more Junior and Intermediate inspectors.

The findings of the analysis are limited to the data points collected from the surveyed projects, and the use of bivariate analysis. Further studies will perform further multivariate analysis between factors and utilize the information to develop forecasting models to predict staffing for highway construction inspection.

Abstract –

Spatial conflicts affect crews' productivity and workers' safety. The idea of considering workspaces as a limited resource has brought a remarkable contribution to the effectiveness of traditional scheduling techniques that generally do not consider the spatial-temporal dimension of construction activities. In previous studies, the detection of spatial interferences among main workspaces has proven to be an effective way to track down spatial issues inherent to the works schedule.

In light of recent events, this research considers spatial interferences among workspaces as occasions of COVID-19 transmission, which must be avoided. The number of spatial issues detected in previous studies must be extended by also including spatial conflicts affecting crews moving to and from main workspaces in transfer spaces (i.e., the support workspaces). A BIM-based spatial conflict simulator, integrated within the work planning process and developed using a serious game engine, is presented in this study and tested on a real work scenario. The possibility of simulating working operations in gaming environments enables investigating on how behavioral constraints, such as social distancing, can be considered during work planning. The first research outcome is that the developed prototype can read the work plan and the BIM model to provide spatial interferences due not only to the main but also to the support workspaces. The second research outcome, emerged from our preliminary simulations, is that even in a short time span (e.g., 2 days and 3 activities), interferences involving support workspaces account for 33% of the complete list of detected conflicts.

Keywords –

Construction Management; Workspace Scheduling; Spatial Conflicts; BIM; Game Engine; COVID-19.

1 Introduction

During construction projects, spatial interferences are commonly recognized as one of the main issues that can severely affect the productivity and safety of crews who share the same workspace [1]. Hence, the need to enhance traditional scheduling techniques (e.g., PERT and CPM), generally based on activities' durations and precedence relationships, by considering the space usage for each task has emerged. Since the early 1990s, a new range of planning techniques based on the management of construction site spaces has been developed [2]. Considering space as a resource, similarly to workers, equipment, and materials, the construction site layout can offer limited but renewable workspaces. Once an activity is completed, the occupied space will be released and reused by other operations [3]. On this basis, existing studies have demonstrated that detecting spatial interferences between main workspaces (i.e., associated with value-added activities) can be an effective way to tracking down spatial issues, otherwise not identifiable from the works schedule [4].

This paper contextualizes the results from existing researches in light of the coronavirus outbreak, being spatial issues a possible cause of COVID-19 transmission in constructions sites. From this perspective, spatial interferences between different crews, even occurring for a limited time within support workspaces (e.g., transfer space of workers, equipment, materials, material storage space, equipment space, temporary structure space, etc.), can be seriously dangerous. An example is a spatial issue generated by a crew that moves between two main workspaces within a transfer space and passes through the space assigned to another crew. In order to detect the biggest set of such risky scenarios, behavioral constraints

(e.g., social distancing measures) must be considered regarding main workspaces and support workspaces. To this purpose, a BIM-based spatial conflict simulator has been developed using a serious game engine to validate the assumed construction work plan.

The remainder of this paper is organized as follows. In Section 2, the state-of-the-art regarding the management of the space resource in the construction field and research gaps are identified. Section 3 reports the adopted methodology to address spatial issues and COVID-19 restrictions through serious game engines. Section **Error! Reference source not found.** describes the use case and the experiment design, whereas Section 5 discusses the results. Finally, Section 6 is devoted to conclusions.

2 Scientific Background

2.1 Workspaces Definition from Literature

The idea of space as a type of resource was first introduced in project management by [11]. Workspaces are defined as renewable resources that can be occupied for activities execution; on completion, spaces currently occupied will be released and reused by other operations [3]. The authors of existing studies have defined different workspaces taxonomies. The most recurrent workspaces categories in the literature include the spaces occupied by workers [1][3][12][13][14], building elements under construction [1][3][4][12][14][15], equipment [1][12][14][13][15], temporary works [4][12][14][15], and stored materials [1][4][12][13]. Some authors define specific workspaces to protect building elements from damaging [1][15] or workers from injuries [3][4][12][14][15]. Finally, the spaces reserved for transferring equipment and material [1][4][14] and for the crews' movement between workspaces [1][4] are also defined in literature. The taxonomy proposed in [4], which has an analogy with the classification of value-added and non-value-added activities adopted in the manufacturing sector [16], is one of the most complete. According to this, the workspace occupied by a crew that directly adds tangible value to the construction process (e.g., building a wall) is classified as a "main workspace". In other words, "main workspaces" activities physically produce building elements that occupy "object workspaces". The latter are free until the corresponding building elements have not been built yet. It must be noted that value-added activities cannot be finalized without activities that, although they do not directly add any tangible value, support the construction process (e.g., transfer materials, equipment or workers, storage materials, install temporary works, etc.). These activities occupy the so-called "support workspaces".

2.2 Spatial-Temporal Conflicts Taxonomies

Many studies have recently tried to classify spatial interferences between tasks that share the same workspace. In [15], the authors have formalized one of the first time-space conflict taxonomy in construction, differentiating design conflicts, safety hazards, damage conflicts, and congestions. The first category occurs when the geometry of a building component conflicts with another building component. Since existing commercially available applications (e.g., clash detection and coordination) already solve this issue [14], design clashes are outside the scope of this research. According to [15], the second category, namely safety hazards, occurs when the space required by a hazardous activity conflicts with the space allocated to a labor crew. The third category, i.e., damage conflicts, may occur when a space that should be left available to protect a building component from getting damaged is shared with a labor crew, equipment, or a hazardous space [15]. For example, a damage conflict can occur if workers (i.e., labor crew space) walk through an area where recent concrete work was done and still has a fresh concrete slab (i.e., protected space), leaving their footprints and/or damaging that work. Similarly, a damage conflict is identified if debris falls on a surface (i.e., hazardous space) with fresh concrete (i.e., protected space). The fourth category, namely the congestion, occurs when the mutual sharing of space between labor crews, equipment, and temporary structures implies that the workspace available for a given activity is either limited or smaller than the required one [4][15]. The bigger the shared space, the higher will be the congestion level. In [12], the authors consider two types of spatial interferences, namely labor congestion and constructability issue, corresponding respectively to acceptable (ASI) and unacceptable spatial interferences (USI), introduced in [17]. Finally, in [3], a time-space conflict taxonomy, including the three available combinations between the entity spaces (ES) and working spaces (WS), is presented. The overlapping of two different entity spaces (ES-ES), similarly to the design conflict seen in [15], may cause a breakage in the building elements. When an entity crashes into a working space (ES-WS), delays and, in some cases, accidents may occur. Finally, an interference between working spaces (WS-WS), occurring between parallel activities, corresponds to a particular scenario of congestion, discussed by the authors in [4][15]. The taxonomy presented in [15] has been extended, in [1], with the theoretical definition of path-related conflicts (e.g., access blockage and space obstruction).

2.3 Research Gaps and Contribution of the Paper

What emerges from the literature review reported above

is that many efforts have been spent in formalizing object-related workspaces and spatial conflicts, which are defined concerning the corresponding building elements under construction. An example is provided by [4], where the authors developed a 4D tool for instantiating main workspaces and detecting related spatial conflicts. Crews moving between consecutive main workspaces, since they may interfere with each other, may result in COVID-19 transmission. Spatial conflicts must be avoided in any case to limit safety threats and constructability issues. In a sanitary emergence, where even short spatial issues occurring between different crews represent a possible threat of transmission, detecting and managing them in advance appear even more relevant. For this reason, an important step forward can be done by also considering transfer spaces (i.e., included within the wider category of support workspaces) in the search for spatial conflicts. This insight is confirmed by social distancing measures adopted by all countries after the coronavirus outbreak.

To the authors' knowledge, any tool that supports construction managers in validating work plans (i.e., construction schedules), looking to the COVID-secure requirement, does not exist nowadays. For this reason, the authors propose a prototype of a spatial conflict simulator integrated into the work planning process that implements social distancing measures for a real construction site scenario. Given its built-in computational capacity and the possibility of simulating and displaying dynamic scenarios (e.g., related to construction operations), serious game engines technology has been adopted to develop the simulation tool.

3 Methodology

3.1 Requirements for COVID-Secure Workplaces

During the last year, the spread of the COVID-19 pandemic has led regulatory authorities worldwide to adopt specific guidelines for each field of interest. For example, sector-specific guidances adopted by European countries in the fight against COVID-19 are collected in [5]. In the construction sector, as in many others, social distancing has been recognized as the first barrier against the spread of coronavirus. Keeping workers apart can create safer working conditions during the COVID-19 pandemic. Different countries around the world adopted slightly different social distancing thresholds (e.g., 1 m in Italy [6], 6 ft (~1.8 m) in the USA [7], or 2 m in the UK [8][9] and the UAE [10]). Where it is not possible to follow the social distancing guidelines in full concerning a particular activity, a hierarchy of controls [5][9] suggests considering whether that activity needs to

continue, and, if so, to take all the possible mitigating actions to reduce the risk of transmission. For example, if an activity requires workers operating within the social distancing threshold, it is highly recommended to maintain the same crew composition over time and keep it far from other crews [6][8][9].

3.2 Serious Game Engine Technology

Serious game engines are promising tools to integrate semantically rich models that can be provided in BIM and simulation engines. The first application of gaming technology can be found in the aircraft industry, using Microsoft Flight Simulator for educational purposes [18]. Later, serious game engines also became widespread in the AEC industry, demonstrating that mere entertainment is not the only feasible nor the most promising application. The success of this approach is due to the difficulty in carrying out real field experiments in some research areas, such as construction management, which usually requires quite a huge budget and time efforts to set up an experimental study. The use of game engines facilitates the deployment of virtual testbeds and tests execution. Examples of serious game engine applications in the construction industry come from education and training [19][19][21], collaboration [22], and also simulation and analysis [4][23][24][25].

In this study, the gaming technology was chosen to develop a prototypal spatial conflict simulator for validating construction work plans and creating, at the same time, the conditions for COVID-secure workplaces. For this study, Unity3D™ was adopted as the serious game engine. 3D models (e.g., for buildings, equipment, etc.) can be easily imported in various formats (e.g., FBX, COLLADA, etc.) by a built-in function, recreating a virtual replica of the construction site layout. Relying on this virtual model, walkable surfaces within the construction site can be automatically detected in Unity3D™, exploiting one of its native functions, called NavMesh Baking [28]. This is the process of creating a NavMesh from the level geometry. Once Render Meshes and Terrains of all game objects are collected, they are processed to create a navigation mesh that approximates the walkable surfaces of the level. Path search algorithms, such as Dijkstra, A*, D* or Any-angle pathfinding ones, can be used to compute the best path between two given points in Unity3D™. It is beyond the scope of this study to compare different path search algorithms. In this study, the A*, that is formulated in terms of weighted graphs, was used. Starting from a specific node of a graph, it aims to find a path to the given goal node having the smallest cost (least distance traveled, shortest time, etc.) [29]. This algorithm was implemented using the A* Pathfinding Project Pro tool [30], including an advanced function for NavMesh generation, called Recast Graph. This technology stack has been tested in [23] to develop a

BIM-based holonic management system for real-time support during fire emergencies. Gaming environments, such as Unity3D™, integrate physics engines, ensuring that the objects correctly accelerate and respond to collisions, gravity, and various other forces, making simulations closer to reality [31]. In addition, serious game engines enable implementing human and artificial sensors, known as agents, using pre-installed components or defining customized C# scripts. The sense of sight, for example, can be implemented to give human avatars awareness about what is happening around them. This can be done in Unity3D™ by modeling the field of view (FOV) as a collider; a user can see an entity simply if her/his FOV collider intercepts with the entity itself. This feature has been tested by [24] to develop a twin model mock-up that implements Bayesian networks to compute collision probability during drilling operations. Finally, in [25], the authors developed C# scripts in Unity3D™ to define avatars' behaviors, such as random wandering, and sensors for impacts checking to anticipate fall hazards within the construction site.

3.3 Workspace Management Framework

In this study, a workspace management framework for validating construction work plans and ensuring COVID-secure workplaces has been defined. The framework is described by the Business Process Model (BPM) depicted in Figure 1. On its basis, a prototype of a spatial conflict simulator has been developed within Unity3D™. The main tasks of the BPM, reported on the top of the same figure, are listed as follows:

1. Load BIM model.
2. Read 4D model and instantiate main workspaces.
3. Compute A* paths between main workspaces and instantiate transfer spaces (i.e., included within the wider category of support workspaces).
4. Run intersection tests among all the possible pairs of workspaces (i.e., main and support workspaces).

It must be noted that, as mentioned in Section 2.3, the main tasks 1 and 2 represent the state-of-the-art in workspace management [4], while main tasks 3 and 4 represent the contribution to the body of knowledge given by the current research work. According to the proposed framework, the user must load the BIM model (e.g., in FBX format) within the Unity3D™ environment. It has been assumed that, once the BIM model (e.g., in RVT format) and the work schedule (e.g., in CSV format) are opened within a commercial software for scheduling (e.g., Navisworks), the 4D model can be defined by linking each activity to the corresponding building elements. Afterward, the data related to the association between activities and their products can be exported into a CSV-formatted file. It must be noted that these tasks are out of the scope of this research and have been assumed

as input.

Afterward, the tool, thanks to the C# scripts “ModelInput.cs” and “InstantiateMainWorkspaces.cs” (pseudocodes available at [26]), developed by the authors, can read the 4D model and instantiate the main workspace for each activity. In detail, the main workspace is obtained by merging the main workspace units, instantiated for each one of the building elements (e.g., pillars) associated with the considered activity (e.g., install an alignment of pillars). The dimensions of each main workspace unit can be set for the corresponding activity by inputting an offsets vector applied to the building elements' footprint. Using the installation of a pillar as an example, an offsets vector $(X, Y, Z) = (4, 0, 4)$ indicates that the main workspace unit is obtained by applying a 4 m offset in both the X and Z directions and a null offset in the Y one (i.e., the same height of the pillar).

The commercial A* pathfinding tool, namely A* Pathfinding Project Pro [30], enables the tool to compute the best path between each pair of main workspaces corresponding to activities scheduled in succession. The C# script “InstantiateSupportWorkspaces.cs” (pseudocodes available at [26]) accesses the best path's nodes and instantiates the corresponding transfer space (i.e., included within the wider category of support workspaces) in the same location. In this case, the user can set the support workspaces' dimensions by inputting two distinct offsets vectors. The first one specifies the space required for operational purposes, whereas the second one must be set accordingly to the COVID-19 social distancing threshold in force in the considered country. Assuming to adhere to the 2 m social distance, the last offsets vector must be set as $(X, Y, Z) = (2, 0, 2)$.

The last main task consists of detecting eventual spatial conflicts between the instantiated workspaces. To this purpose, the authors developed a C# script, called “IntersectionTest.cs” (pseudocodes available at [26]), which carries out an intersection test between all the instantiated workspaces colliders to find eventual spatial conflicts. The simulation results are provided visually, in the Unity3D's Scene window, and as loglines, in the Console window (Figure 2). At this point, the construction manager can adjust the work plan according to the detected spatial conflicts and, then, the refinement loop continues until no spatial conflicts are detected or judged as negligible.

The data model that summarizes the main entities involved in a spatial-temporal simulation and the relationships between them can be described by an Entity Relationship Diagram (ERD) (available as extra material in [32]). Here, entities are grouped in the following domains: scheduling, resources, products, workspaces, paths, and spatial conflicts. The ERD notation expresses the cardinality of relationships between each pair of

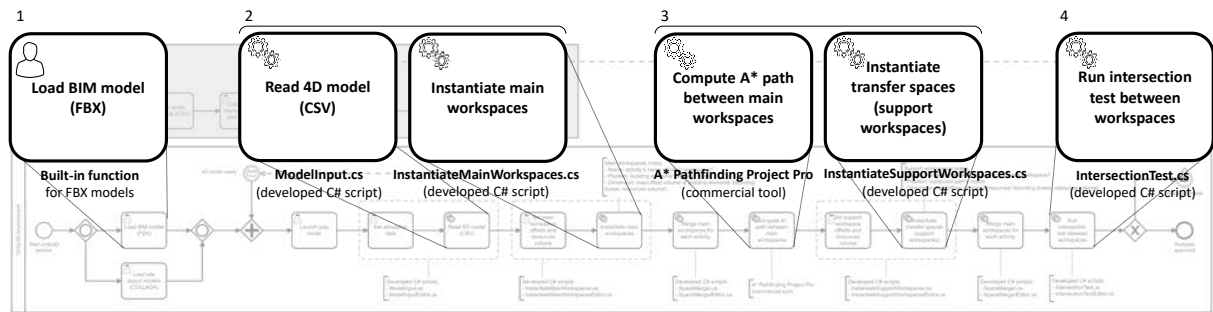

Figure 1. Business Process Model describing the logic behind the proposed workspace management framework for validating construction work plans (full-size figure available in [32]).

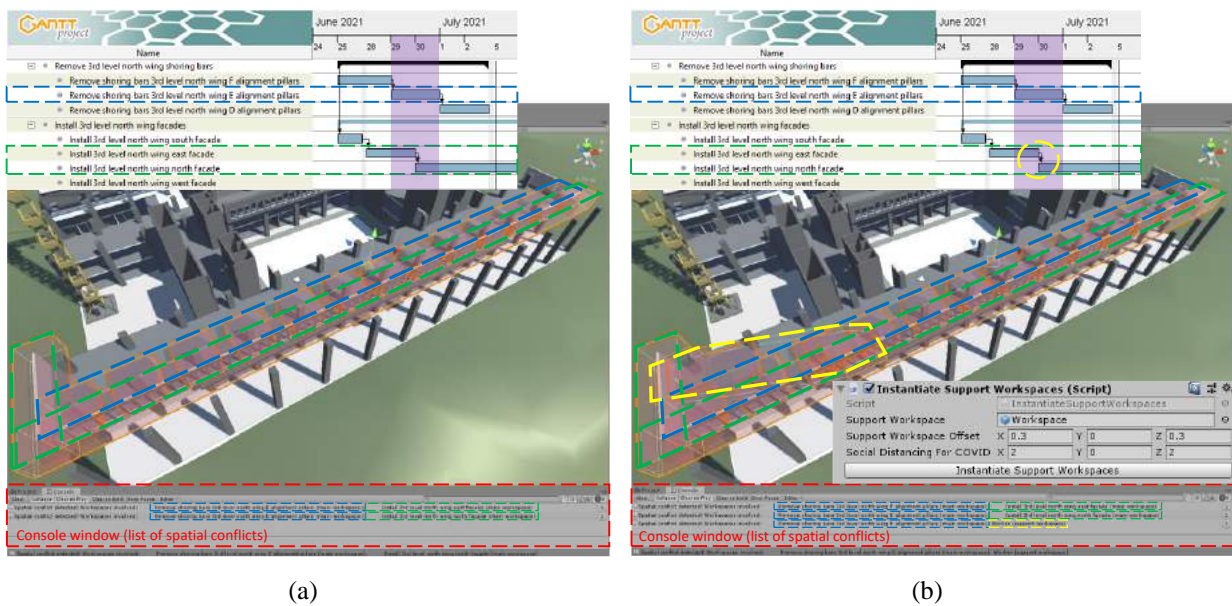

Figure 2. Application of the spatial conflict simulator respectively in the first (a) and second (b) scenarios for the same working days (i.e., June 29th and 30th) (full-size figure available in [27]).

entities by the symbols at the ends of the links. To cite a few examples, the link between the entities “Activity” and “Building element” is of type “1 to 0 or many”. In fact, an activity can produce no products (e.g., transfer pillars from the storage area to the installation area) or many (e.g., install an alignment of pillars). Instead, each link between the entities “Spatial conflict” and “Main/Support workspace” is of type “1 to 1” since each “Workspace ID” attribute in the first entity identifies a single main workspace.

4 Use Case and Experiment Design

The workspace management framework and the resulting prototypal spatial conflicts simulator, presented in Subsection 3.3, have been tested on the Eustachio building, a real construction project that currently houses

the Faculty of Medicine of the Polytechnic University of Marche in Ancona, Italy. A work schedule of the construction activities for this building is considered (available as extra material in [32]).

This study considered the installation of precast elements, specifically pillars and façades on the 3rd level of the north wing. As reported in [33] and [34], the installation steps for each element are putting it into position, installing shoring bars, and placing concrete within the element’s holes. Then, after having waited for concrete curing, the removal of shoring bars concludes the process. An excerpt of the work schedule related to removing the pillars’ shoring bars and installing the façades on the 3rd level of the north wing is displayed in Figure 2(a) and Figure 2(b). This Section aims to demonstrate:

1. How the proposed spatial conflicts simulator can effectively contribute to detecting COVID-

- spreading threats due to overlapping workspaces.
2. The relevance of transfer spaces and the wider category of support workspaces in detecting spatial conflicts and COVID-spreading threats.

To this purpose, the working days June 29th and 30th, highlighted in purple in Figure 2(a) and Figure 2(b), were considered for carrying out spatial conflicts simulations in two scenarios. In the first one, used as the benchmark, only main workspaces have been generated according to the state-of-the-art. Figure 2(a) displays the automatic instantiation of the main workspaces for the activities:

- “Remove shoring bars 3rd level north wing E alignment pillars”, which lasts for the working days considered and is executed by the pillars crew (see the blue dashed rectangle in Figure 2(a)).
- “Install 3rd level north wing east façade” and, in sequence, “Install 3rd level north wing north façade”, which is executed by the façades crew (see the green dashed rectangle in Figure 2(a)).

In the second scenario, both the main and support workspaces have been considered. In addition to the main workspaces for the activities listed above, the transfer spaces (i.e., included within the wider category of support workspaces) have been automatically instantiated. Since the activities “Install 3rd level north wing east façade” and “Install 3rd level north wing north façade” are in sequence, the assigned crew (i.e., façades crew) is asked to move from the first one’s main workspace to the second one. The corresponding transfer space (see the yellow dashed shape in Figure 2(b)) is automatically instantiated based on the best path between the two main workspaces and the offsets vectors. The front end of the C# script for instantiating support workspaces, reported in Figure 2(b), displays that $(X, Y, Z) = (0.3, 0, 0.3)$ and $(X, Y, Z) = (2, 0, 2)$ are the offsets vectors assigned, respectively, for operational purposes and COVID-19 social distancing. In both scenarios, the workspaces’ color, set as green as default, becomes red if the intersection test returns an overlapping (Figure 2(a) and Figure 2(b)). At the same time, the list of conflicting workspaces pairs is printed as an output (see the red dashed rectangles in Figure 2(a) and Figure 2(b)).

5 Results and Discussion

In this study, the installation process of precast elements on June 29th and 30th (highlighted in purple in Figure 2(a) and Figure 2(b)) was considered for testing the proposed spatial conflicts simulator. In the first scenario, only main workspaces were automatically generated, defining a benchmark according to the state-of-the-art. The potentialities of the proposed tool are fully tested in the second scenario by automatically generating both main and support workspaces.

In the first scenario, the intersection test between each pair of workspaces identifies the spatial conflicts between the following pairs of workspaces (Table 1):

- “Remove shoring bars 3rd level north wing E alignment pillars (main workspace)”, assigned to the pillars crew, and “Install 3rd level north wing east façade (main workspace)”, assigned to the façades crew.
- “Remove shoring bars 3rd level north wing E alignment pillars (main workspace)”, assigned to the pillars crew, and “Install 3rd level north wing north façade (main workspace)”, assigned to the façades crew.

In the second scenario, in addition to the spatial conflicts reported above for the first one, the one between “Remove shoring bars 3rd level north wing E alignment pillars (main workspace)”, assigned to the pillars crew, and “Worker (support workspace)”, assigned to the façades crew, is also detected (Table 1).

In both scenarios, the detected spatial conflicts are related to workspaces assigned to different crews (Table 1). Such interferences can cause not only productivity loss but also health and safety hazards, including COVID-spreading threats. Hence, the proposed spatial conflicts simulator can effectively support the construction manager in keeping different teams apart, as recommended by the COVID-19 guidances (Section 3.1). To sum up, the first main research outcome is an integrated spatial conflict simulator that reads the updated work plan and the BIM model of the site to provide as output the number of conflicts generated by interferences due not only to the main but also to the support workspaces. The second main outcome emerging from our preliminary simulations is that even in a short time span, limited to 2 days with 3 activities, interferences involving support workspaces account for 33% of the complete list of detected conflicts (Table 1). This demonstrates the relevance of transfer spaces and the wider category of support workspaces in detecting spatial conflicts and COVID-spreading threats.

6 Conclusions

The motivation of this research originated from the need to minimize congested construction sites which can contribute to COVID-19 transmission among construction workers. Hence, a better spatial awareness and consideration is required during the planning phase. Spatial interferences among different crews, even for a limited time, can create a potential scenario for coronavirus transmission; therefore, they must be avoided. To the authors’ knowledge, any tool that supports project engineers in validating work plans, looking to the COVID-secure requirement, does not exist nowadays. For this reason, the authors have proposed a

Table 1. Overview of the pairs of detected conflicting workspaces respectively in the first and the second scenarios.

Pairs of detected conflicting workspaces	First scenario (main workspaces only)		Second Scenario (main and support workspaces)	
	Remove shoring bars 3 rd level north wing E alignment pillars (main workspace) – Pillars crew	Install 3 rd level north wing east façade (main workspace) – Façades crew	Remove shoring bars 3 rd level north wing E alignment pillars (main workspace) – Pillars crew	Install 3 rd level north wing east façade (main workspace) – Façades crew
	Remove shoring bars 3 rd level north wing E alignment pillars (main workspace) – Pillars crew	Install 3 rd level north wing north façade (main workspace) – Façades crew	Remove shoring bars 3 rd level north wing E alignment pillars (main workspace) – Pillars crew	Install 3 rd level north wing north façade (main workspace) – Façades crew
			Remove shoring bars 3 rd level north wing E alignment pillars (main workspace) – Pillars crew	Worker (support workspace) – Façades crew

workspace management framework and the prototype of a spatial conflict simulator for the validation of work plans. Serious game engines technology was used to develop the simulation tool, given its built-in computational capacity and the possibility of simulating and displaying dynamic scenarios (e.g., related to construction operations). A proof-of-concept of the spatial conflict simulator has been tested on a real construction scenario. This aims to demonstrate its contribution in minimizing COVID-spreading threats related to overlapping workspaces. In addition, the authors want to prove the relevance of transfer spaces (i.e., included within the wider category of support workspaces) for extending the number of detected spatial conflicts that could be a source of potential coronavirus transmission.

The prototype presented in this paper has limitations. For example, it cannot compute the severity of the detected conflicts and the delay caused by the work plan refinement. In addition, future work includes an improved version of the proposed tool that can be applied to create the conditions for on-site applicability of proximity tracing devices [35], able to send, in real-time, an alert if social distancing measures are not met during the execution of different construction activities. The validation of work plans is required to detect and resolve eventual spatial interferences inherent to the work schedule. In this way, proximity tracing devices will detect only misbehaving workers in close proximity, avoiding alert overloads not related to unfeasible work plans. In addition, in future works, several activities (e.g., more than 3) and progressively increasing can be considered to quantify the contribution of support workspaces under different complexity conditions of the construction scenarios.

Abstract -

Different factors combined invariably cause construction fatalities at any time, most of which could be avoided if workers followed the on-site regulatory rules. However, compliance of regulatory rules is not strictly enforced among workers due to all kinds of reasons, even after prior education and training. To address the difficulties of on-site safety management, this paper proposes a graph-based time series analysis framework to dynamically integrate visual and linguistic information for on-site occupational hazard identification. A vision-based scene information understanding approach is introduced to process on-site images via a combination of deep learning-based object detection and individual detection, together with a novel dynamic graph structure to represent time-series information for integrated reasoning of hazards identification. As a case study, the hazards of grinder operation were successfully identified in the experiments with high accuracy.

1 Introduction

The construction industry is one of the fields with the highest number of occupational accidents. According to the United States' Bureau of Labor Statistics (BLS), the number of construction fatalities in the U.S. has increased from 924 to 1,066 between 2015 and 2019 [1]. Similarly, in Japan, there were 1,522 construction fatalities between the period 2015-2019 [2].

As the construction is extremely vulnerable to the interference of various subjective and objective factors, once any sudden problem occurs it will pose a potential threat to the life and property safety of the on-site construction workers. Grinding is a commonly used operation on construction sites to produce smooth surfaces, and can also be used to fabricate workpieces such as smoothing welds and performing finishing operations on workpiece surfaces. When using a grinder, the grinding disc generates high rotational speeds, which can be hazardous if the operator lacks expertise and the operation does not follow on-site

regulatory rules. Eye injuries would be a possible serious consequence. According to the National Institute for Occupational Safety and Health (NIOSH), an average of 2,000 United States workers require medical treatment for job-related eye injuries every day [3]. The reasons cited for the majority of eye injuries include the non-wearing of available eye protection or wearing of inappropriate eye protection for the current task [4]. OSHA indicates the workers shall be ensured to wear eye or face protection when exposed to eye or face hazards from flying particles, molten metal, liquid chemicals, acids or caustic liquids, chemical gases or vapors, or potentially injurious light radiation [5]. Additionally, fine dust and particles, gases and vapors can be produced when using a grinder. Silica dust from bricks can cause lung and airway diseases such as emphysema, bronchitis, silicosis, and may increase the risk of cancer. Personal protective equipment (PPE), such as respirators or dust masks, are used to controls these hazards [6]. On the other hand, improper handling grinder can be a dangerous power tool, hands and forearms injure results when the workers using the grinder loses control of it. OSHA indicates the workers shall use two hands to operate the grinder. One hand should grip the handle and dead-man switch (if provided), while the other hand supports the weight of the tool [7].

However, the construction workers do not precisely follow the on-site safety regulations due to various reasons, even after prior education and training. Therefore, the development of an automated on-site occupational hazards identification system is needed to address the increasing importance of safety management, which is capable of automatically carrying out dynamic identification of occupational hazards and effectively preventing various accidents.

To this end, this paper proposes a graph-based time series analysis framework to dynamically integrate visual and linguistic information for on-site occupational hazards identification. (1) A vision-based scene information understanding approach is introduced to process on-site images via a combination of deep learning-based object detection and individual detection. (2) An automated reasoning is developed to encode regulatory information into graph structure and perform occupational hazards identifi-

cation based on graph structure analysis between extracted scene information and regulatory information. The proposed model was able to identify the hazards of grinder operation with high accuracy in the experiments.

2 Related works

Deep learning-based object detection algorithms have shown remarkable performance on most visual tasks in the architecture, engineering, and construction (AEC) industry, and there has been a significant amount of research on vision-based automatic occupational hazards identification approaches using object detection [8, 9, 10]. Fang et al. [8] proposed an object detection-based method using Faster R-CNN to automatically detect construction workers' NHU. A total of 81,000 image frames were collected from various construction sites as a training dataset and the bounding boxes that surround workers in the images were annotated as the ground truth to train the model. Wu et al. [9] deployed Single Shot Multibox Detector (SSD) with presented reverse progressive attention (RPA) for NHU identification. A benchmark dataset GDUT-HWD was created by downloading Internet images retrieved by search engines to train the SSD-RPA model. In contrast to [8], only the head regions of workers were annotated as the ground truth. Nath et al. [10] introduced and tested models built on YOLOv3 architecture to verify PPE (hard hat and vest) compliance of workers. Three approaches were verified concerning different classifiers (e.g., decision tree, VGG-16, ResNet-50, Xception, or Bayesian).

Recently, deep learning-based pose estimation algorithms have achieved impressive results in unconstrained environments, showing the potential for worker detection in complex on-site environments. Compared to object detection-based approaches, human skeletons provide more fine-grained information about a person (e.g., location and visibility), especially in the case of occlusion. Considering such benefits, several efforts are also exploring the integration of object recognition and pose estimation for occupational hazards identification [11, 12]. Chen et al. [11] introduced a vision-based approach to detect the proper use of multi-class radiation PPE in nuclear power plants via a combination of deep learning-based object detection and pose estimation using Euclidean distance between bounding boxes of detected PPE and the neck geometric relationships analysis. Xiong et al. [12] presented an extensible pose-guided anchoring framework aimed at multi-class PPE compliance detection. A pose estimator was deployed to detect individuals and provide joint-level anchors for guiding the localization of different PPE items.

Vision-based approaches have been widely used to automatically identify occupational hazards as introduced above. However, as regulation rules may change at any time in practical engineering, current vision-based ap-

proaches will be significantly reduced in practicality due to their inability to adapt to adjustments in practice. A unified model integrating visual and linguistic information would enable the automatic and effective identification of hazards in compliance with regulatory rules even when changes are made to them. Several explorations to this end have already been carried out [13, 14, 15]. Xiong et al. [13] developed an Automated Hazards Identification System (AHIS) to evaluate the operation descriptions generated from site videos against the safety guidelines extracted from the textual documents with the assistance of the ontology of construction safety. Two types of crucial hazards, i.e., failing to wear a hard hat and walking beneath the cane, were successfully identified. Fang et al. [14] integrated computer vision algorithms with ontology models to develop a knowledge graph that consists of an ontological model for hazards, knowledge extraction, and knowledge inference for hazard identification, which can automatically identify falls from heights hazards in varying contexts from images. As a previous exploration of this work, we provided a novel solution to identify improper use of PPE by the combination of deep learning-based object detection and individual detection using geometric relationships analysis and presented a hierarchical scene graph structure that enables the conditional reasoning for automated hazards identification to address different requirements in each zone of construction sites [15].

3 Methodology

In this section, the proposed dynamic graph-based framework for automated occupational hazards identification is described in detail.

3.1 Scene information extraction

We propose a novel scene understanding approach employing scene graph as the basic notion of information representation structure to extract visual information from images, the base framework of which has been presented in our previous work [15]. An entity extractor for processing images obtained from on-site surveillance cameras is developed. For each image, individual(s) are detected, together with their body joint positions, using OpenPose [16]. Meanwhile, objects (e.g., PPE, tools) are recognized and localized by training an object detection model based on YOLOv4 [17].

We first associate the detected objects with the detected individuals, with the aim of providing a prior knowledge for individual-object relationship analysis and reducing computational complexity. A weighted bipartite graph is constructed to represent the detected entities and we perform individual-object association as a minimum weighted matching in bipartite graphs. Subsequently, we

analyze the individual-object relationship on the associated individual-object pairs M , which address two types of objects in this paper:

- Head protection PPE (hard hats, safety glasses, and dust masks).
- Grinder

3.1.1 Head protection PPE

For each associated individual and head protection PPE $\{i^*, j^*\} \in M$ their relationship is identified by measuring a distance. We take advantage of the Euclidean distance among detected neck keypoint (body parts 1 in Figure 1) and hip keypoints (body parts 8 and 11 in Figure 1) of i^* as a dynamic reference threshold, which will keep changing synchronously when the distance between the individual and the camera changes:

$$\beta_{i^* \leftrightarrow j^*} = \max(\sqrt{(x_{i^*}^{(1)} - x_{i^*}^{(8)})^2 + (y_{i^*}^{(1)} - y_{i^*}^{(8)})^2}, \sqrt{(x_{i^*}^{(1)} - x_{i^*}^{(11)})^2 + (y_{i^*}^{(1)} - y_{i^*}^{(11)})^2}) \cdot \gamma \quad (1)$$

where γ is the scaling coefficient to strike the relationship analysis for different head protection PPE. For hard hats, safety glasses, dust masks, and full-face masks, γ is set to 0.8, 0.7, 0.6, 0.6, respectively.

Figure 1. Output format of OpenPose.

If the Euclidean distance between the position (x_{j^*}, y_{j^*}) of the bounding box of j^* and detected neck keypoint (body parts 1 in Figure 1) of i^* is smaller than the reference threshold $\beta_{i^* \leftrightarrow j^*}$, then the relationship between the i^* and j^* is created; otherwise, even though j^* is associated with i^* , no relationship is created between them:

$$c_{i^* \leftrightarrow j^*} = \begin{cases} \text{"wear"} & , \text{if } d_h(i^*, j^*) < \beta_{i^* \leftrightarrow j^*} \\ N/A & , \text{otherwise} \end{cases} \quad (2)$$

where

$$d_h(i^*, j^*) = \sqrt{(x_{i^*}^{(1)} - x_{j^*})^2 + (y_{i^*}^{(1)} - y_{j^*})^2} \quad (3)$$

and $c_{i^* \leftrightarrow j^*}$ indicates the connection to create the relationship between i^* and j^* as a semantic phrase ($i^*, c_{i^* \leftrightarrow j^*}, j^*$) (e.g., (*person*, *wear*, *hard hat*) or not.

3.1.2 Grinder

Currently in this work, two regulatory rules related to grinder proper use are addressed to create a individual-grinder relationship:

(1) "Always use two hands when operating a grinder"

Let $B_{g^*} = (x_{g^*}, y_{g^*}, w_{g^*}, h_{g^*})$ be the detected bounding box of a grinder g^* which is associated with the detected individual i^* . Firstly, the Euclidean distance from the left wrist keypoint and right wrist keypoint (body parts 7 and 4 in Figure 1) of i^* to the position (x_{g^*}, y_{g^*}) of g^* is calculated (Figure 2):

$$d_l(i^*, g^*) = \sqrt{(x_{i^*}^{(7)} - x_{g^*})^2 + (y_{i^*}^{(7)} - y_{g^*})^2} \quad (4)$$

$$d_r(i^*, g^*) = \sqrt{(x_{i^*}^{(4)} - x_{g^*})^2 + (y_{i^*}^{(4)} - y_{g^*})^2}$$

If the grinder is close enough to the wrists, then the individual is identified as holding the grinder:

$$h_{i^* \leftrightarrow g^*} = \begin{cases} 1 & , \text{if } d_l(i^*, g^*) < \beta_{i^* \leftrightarrow g^*} \text{ or } d_r(i^*, g^*) < \beta_{i^* \leftrightarrow g^*} \\ 0 & , \text{otherwise} \end{cases} \quad (5)$$

where $\beta_{i^* \leftrightarrow g^*}$ is the reference threshold calculated based on the size of the bounding box of g^* :

$$\beta_{i^* \leftrightarrow g^*} = \max(w_{g^*}, h_{g^*}) \quad (6)$$

Figure 2. Relationship identification strategies to address the rule "Always use two hands when operating a grinder".

If $h_{i^* \leftrightarrow g^*} = 1$, then relationship identification needs to be further performed to identify whether the individual i^* is holding the grinder g^* using single hand or two hands.

It's known that when an object is holding by two hands the distance between the wrists is small. Thus, the relationship between i^* and g^* is identified as follows:

$$\begin{aligned} & \text{if } d_{l \leftrightarrow r}(i^*) < \beta_{i^* \leftrightarrow g^*} : \\ & c_{i^* \leftrightarrow h_{i^*}^*}, h_{i^*}^*, c_{h_{i^*}^* \leftrightarrow g^*} = \text{"use", "two hands", "operate"} \\ & \text{otherwise :} \\ & c_{i^* \leftrightarrow h_{i^*}^*}, h_{i^*}^*, c_{h_{i^*}^* \leftrightarrow g^*} = \text{"use", "single hand", "operate"} \end{aligned} \quad (7)$$

where $h_{i^*}^*$ indicates the hands status (e.g., two hands, single hand) when operating a grinder while $c_{i^* \leftrightarrow h_{i^*}^*}$ and $c_{h_{i^*}^* \leftrightarrow g^*}$ create the relationship between i^* and $h_{i^*}^*$, $h_{i^*}^*$ and g^* , as semantic phrases ($i^*, c_{i^* \leftrightarrow h_{i^*}^*}, h_{i^*}^*$), ($h_{i^*}^*, c_{h_{i^*}^* \leftrightarrow g^*}, g^*$), respectively (e.g., the relationship (*person, use, two hands*), (*two hands, operate, grinder*) is created in Figure 2)

(2) "Never operate a grinder near face"

For the detected individual i^* and the associated grinder g^* , the Euclidean distance from the neck keypoint (body part 1 in Figure 1) of i^* to the position (x_{g^*}, y_{g^*}) of the bounding box of g^* is calculated:

$$d_n(i^*, g^*) = \sqrt{(x_{i^*}^{(1)} - x_{g^*})^2 + (y_{i^*}^{(1)} - y_{g^*})^2} \quad (8)$$

Figure 3. Relationship identification strategies to address the rule "Never operate a grinder near face".

If the grinder is close enough to the neck, then the relationship between the grinder and the face of individual is created:

$$c_{i^* \leftrightarrow g^*}^{face} = \begin{cases} \text{"near"} & , \text{if } d_n(i^*, g^*) < \beta_{i^* \leftrightarrow g^*} \\ N/A & , \text{otherwise} \end{cases} \quad (9)$$

where $\beta_{i^* \leftrightarrow g^*}$ is the reference threshold calculated based on the Euclidean distance among detected neck keypoint (body parts 1 in Figure 1) and hip keypoints (body parts 8

and 11 in Figure 1) of i^* with $\gamma = 0.3$:

$$\beta_{i^* \leftrightarrow g^*}^{face} = \max(\sqrt{(x_{i^*}^{(1)} - x_{i^*}^{(8)})^2 + (y_{i^*}^{(1)} - y_{i^*}^{(8)})^2}, \sqrt{(x_{i^*}^{(1)} - x_{i^*}^{(11)})^2 + (y_{i^*}^{(1)} - y_{i^*}^{(11)})^2}) \cdot \gamma \quad (10)$$

and $c_{i^* \leftrightarrow g^*}^{face}$ indicates the connection to create the relationship between the face of i^* and g^* as a semantic phrase ($face, c_{i^* \leftrightarrow g^*}^{face}, g^*$) (e.g., the relationship (*face, near, grinder*) is created in Figure 3)

3.1.3 Scene information representation

Based on the semantic phrases established by individual-object relationship analysis, we generate a scene graph for image information representation for each captured frame from on-site surveillance cameras. An example is illustrated in Figure 4: on-site image (Figure 4(a)) is identified and transformed to semantic phrases triplets (Figure 4(b)), and coded in a scene graph $G(V, E)$ (Figure 4(c)), where V is the set of vertices to represent the objects in the semantic phrase triplets and $E = \{\{\mu, \nu\} : (\mu, \nu) \in V^2, \mu \neq \nu\}$ is the set of edges to represent the relationships in the semantic phrase triplets.

3.2 Automated reasoning for hazards identification

3.2.1 Regulatory Information Representation

To represent regulatory Information from natural language sentences, we have proposed a textual information representation and transformation method to encode the regulatory rules into the graph structure [15]. We first decompose and transform the regulatory rules to semantic phrases which are defined as a triplet (e.g., (object1, relation, object2)). "object1" or "object2" is subjected to a particular ontology in regulations, which can be a "personnel" (e.g., worker) or a "thing" (e.g., PPE). "Relation" semantically connects objects with limitations, such as geometric (e.g., beneath, in, on), and possession (e.g., has). Let $\hat{G}(\hat{V}, \hat{E})$ be the graph of the regulatory rules, where \hat{V} is the set of vertices to represent the elements in the semantic phrase triplets and $\hat{E} = \{\{\mu, \nu, s, r, t\} : (\mu, \nu) \in \hat{V}^2, \mu \neq \nu\}$ is the set of edges to represent the relationships in the semantic phrase triplets (s and r are the connections to represent an entity relationship and an entity status, respectively. t is the edge property to indicate the type of the requirements: obligation rule or prohibition rule).

3.2.2 Frame-level reasoning for hazards identification

Frame-level reasoning for hazards identification is performed by checking compliance of prohibition and obligation regulatory rules based on graph structure analysis

(a) On-site image.

- (person, wear, hard hat)
- (person, use, grinder)
- (person, use, single hand)
- (single hand, operate, grinder)
- (person, wear, dust mask)
- (person, wear, safety glasses)

(b) Semantic phrases triplets.

(c) Scene graph $G(V, E)$.

Figure 4. An example of on-site image and its scene graph

between $G(V, E)$ and $\hat{G}(\hat{V}, \hat{E})$. $\hat{G}(\hat{V}, \hat{E})$ consists of both prohibition and obligation regulatory rules. Thus pruning is first performed to extract the prohibition regulatory rules subgraph $\hat{G}_P(\hat{V}_P, \hat{E}_P)$ and the obligation regulatory rules subgraph $\hat{G}_O(\hat{V}_O, \hat{E}_O)$ (see Figure 5).

Prohibition regulatory rules reasoning is performed based on compliance checking between the scene graph $G(V, E)$ of on-site image and the prohibition regulatory rules subgraph $\hat{G}_P(\hat{V}_P, \hat{E}_P)$. If an edge e_P of \hat{E}_P exists in E , which means a prohibition entities relationship exists in the on-site image scene, then e_P is extracted as a violated regulatory prohibition rule and the on-site image scene is hence identified as hazardous.

Obligation regulatory rules reasoning for hazards identification of the on-site image is performed based on the isomorphism between $G(V, E)$ and $\hat{G}_O(\hat{V}_O, \hat{E}_O)$. In graph theory, an isomorphism is a mapping between two graph structures of the same type that can be reversed by an inverse mapping. $G(V, E)$ is isomorphic to $\hat{G}_O(\hat{V}_O, \hat{E}_O)$, if there exists a bijective function $f: V \rightarrow \hat{V}_O$ such that $\forall u, v \in V, (u, v) \in E \leftrightarrow (f(u), f(v)) \in \hat{E}_O$, which is denoted as $G \cong \hat{G}_O$ [18]. Otherwise, $G(V, E)$ is non-isomorphic to $\hat{G}_O(\hat{V}_O, \hat{E}_O)$ and the violated obligation regulatory rules $H_O = \{(\mu, \nu, \tau) \in \hat{E}_O, (\mu, \nu, s, r) \notin E\}$ from the on-site image are identified.

3.2.3 Sequence-level reasoning for hazards identification

Frame-level hazards identification results are subject to misidentification due to environmental or occlusion reasons, thus we dynamize the graph structure which represents the scene information to perform verification of current frame's identification results with the identification results of historical frames as sequence-level reasoning. For each node of the scene graph the set of identification results of the previous k frames is saved as "window states", which is updated dynamically in the form of "first-in-first-out". The identification results of the current frame is determined by the "window states": for each "window

states" we identify the state with the majority as the final identification results of the current frame according to the "winner-takes-all" (WTA) principle (Figure 6). As an example, Figure 6(c) visualizes the sequence-level reasoning result of image sequence Figure 6(a).

4 Experiments and results

4.1 Regulatory rules

To demonstrate the validity of the proposed approach, we selected five regulatory rules to perform the experiments:

1. "Wear a hard hat."
2. "Wear a dust mask when operating a grinder."
3. "Wear a safety glasses when operating a grinder."
4. "Always use two hands when operating a grinder."
5. "Never operate a grinder near face."

As demonstrated in Figure 7, a graph $\hat{G}(\hat{V}, \hat{E})$ is generated to represent all linguistic information of these five regulatory rules.

4.1.1 Datasets

To create a training dataset for object detection, we collected images of hard hats, dust masks, safety glasses, and grinders from two sources: real-world images and web-mined images. Real-world images were obtained using a SONY $\alpha 5000$ digital camera at six different places (including construction sites, school campus, and experimental rooms) under different environmental conditions (e.g., level of illumination, visual range) and the obtained images are all 1440×1080 in resolution. Web-mined images were retrieved by search engines using a web crawler. The resolution of these collected web images ranges from 150×150 to 4896×3672 . A total of 6029 images containing 12265 objects were collected and annotated as listed in Table 1.

Furthermore, to address compliance with these five regulatory rules, a demo video on the operation of the grinder

Figure 5. (b) $\hat{G}_O(\hat{V}_O, \hat{E}_O)$ and (c) $\hat{G}_P(\hat{V}_P, \hat{E}_P)$ are the obligation and prohibition regulatory rules subgraph extracted from (a) regulatory rules graph $\hat{G}(\hat{V}, \hat{E}, \hat{C})$.

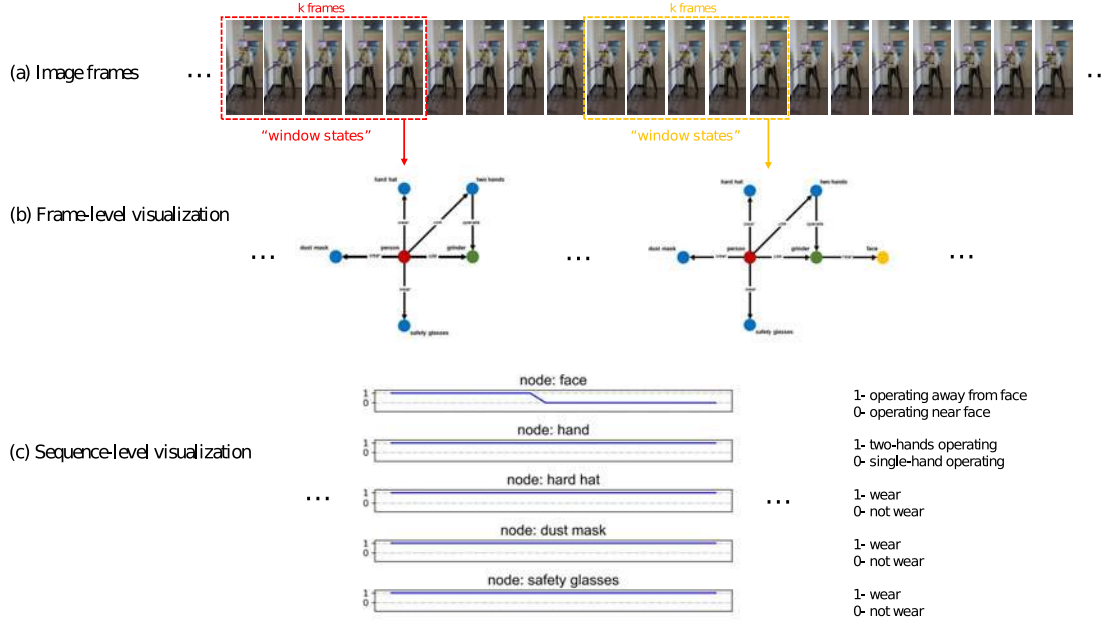

Figure 6. Sequence-level reasoning for hazards identification

was captured as the testing dataset. The demo video consists of 2745 frames and includes both normal and hazardous operations (one-handed and near-face operations).

4.2 Implementation Details

We build the YOLOv4-CSP model using PyTorch and initialize the model based on the pre-trained weights on the MSCOCO 2017 object detection dataset [19]. We train the model for 100 epochs by stochastic gradient descent (SGD), and throughout training we use a batch size of 8, a momentum of 0.9 and a decay of 0.0005. The learning rate is initialized to $1e-2$ and is decreasing following the cosine function. All experiments are performed on a machine with Intel Core i7-7820X (8 cores, 3.6GHz), 32GB DDR4

SDRAM RAM, NVIDIA GeForce GTX 1080 Ti GPU (11GB of GDDR5X memory and 3584 CUDA cores).

4.3 Experimental results

The sequence-level hazards identification results are reported in Figure 8, where the values of windows size k are considered to be 1 (without windows states analysis), 10, 20. When using window states for time-series analysis, sporadically misidentified frames can be well corrected. As shown in Figure 8(b) and Figure 8(c), the proposed approach achieves significant improvements for hazardous operation of grinder near face (95.47% \rightarrow 96.28% \rightarrow 96.36%), improper operation of grinder with single hand (97.74% \rightarrow 98.79% \rightarrow 98.26%), and proper use of dust

Table 1. Information of collected training dataset

	Number of real-world image samples	Number of web-mined image samples	Total
Hard hat	3003	1322	4325
Dust mask	3099	186	3285
Safety glasses	2180	115	2305
Grinder	2005	355	2360
Overall	10287	1978	12265

Figure 7. The graph generated for regulatory information representation.

masks (96.04% \rightarrow 97.94% \rightarrow 97.98%) and safety glasses (84.24% \rightarrow 85.74% \rightarrow 85.78%)¹, which demonstrates the effectiveness of the proposed approach for on-site occupational hazards identification.

5 Conclusion

This paper proposes a graph-based time series analysis framework to dynamically integrate visual and linguistic information for on-site occupational hazard identification. Firstly, a vision-based scene information understanding approach is introduced to process on-site images via a combination of deep learning-based object detection and individual detection. Subsequently, a novel dynamic graph structure to represent time-series information for integrated reasoning of hazards identification using window states analysis. The experimental results demonstrate that the proposed approach can effectively identify the hazards of grinder operation and facilitate improved safety inspection and supervision. Further extensions of this work will be investigated to improve the performance of visual information representation by introducing monocular 3D entity extraction.

¹When operating the grinder near face, both dust masks and safety glasses are not visible in the frame image due to occlusion, therefore these frames are not included in the accuracy calculation for the proper use of dust masks and safety glasses

Abstract

The purpose of this study is to compare the safety climate by project size and construction activity with different risk levels. Accidents tend to occur more frequently at smaller sites. As safety climate has been regarded as one important leading indicator preventing accidents, this study hypothesized that larger project tend to have higher level of safety climate. In addition, this study also hypothesized that labours working for the activities with high level of risk tend to have higher level of safety climate than those for the activities with low level of risk. The hypothesis is related to the theory of homeostasis that humans tend to behave riskier in a situation with low risk and behave less risky in a situation with high risk. This paper presents a research model testing these hypotheses. Literature review about the constructs included in the model and data collection plan are also presented. The test of these hypotheses will contribute to helping practitioners when they establish the plans to increasing the level of safety climate for various projects and activities, which will eventually contribute to better safety performance.

Safety climate, Construction safety; Project size; activities with different levels of risk

1 Introduction

The construction industry is one of the most hazardous industries. In the United States, 1,061 fatalities occurred in the industry in 2019 and the number of deaths has continued to rise since 2010 [1, 3]. For the comparison of accidents by industry sector, 19.9% of fatalities occurred in the construction industry in 2019, which is the highest percentage among all industries [1].

In order to reduce accidents in the construction industry, many researchers have conducted various studies about construction safety. Among these studies, researchers recently have focused on the factors related

to humans. Examples include studies investigating safety climate and safety behavior. Martínez-Córcoles et al. [34] investigated the effect of leadership on safety behavior. Wu et al. [50] found the main factors that appeared most frequently and had large impacts on safety climate through literature review. These factors include safety priority, safety supervisor, training and communication, safety involvement, and safety rule and procedure. The statistical analysis by using data collected by a questionnaire has been the typical research methodology for these topics.

This study investigates the safety climate differences by project size and activity with different risk levels. For the studies investigating safety climate, while there have been a number of studies investigating the indicators measuring safety climate and factors affecting safety climate, the current body of knowledge lacks whether safety climate differs by project size and by activity with different risk levels. Some argued that small projects in terms of total project cost tend to have more accidents than large projects [35]. This study conjectured that safety climate is the main factor contributing to this tendency. In addition, when comparing the human's behavior and circumstances, some studies argued that human behavior is the main direct cause of accidents [22]. If safety climate is the main factor contributing to the prevention of accidents, labours working for the activities with high level of risk should behave more carefully, which will lead to different level of safety climate. Thus, there should exist different level of safety climate by activities with different levels of risk.

This study presents a research model with two hypotheses: 1) Larger projects tend to have higher level of safety climate and 2) Activities with high level of risk tend to have higher level of safety climate. The research model and constructs in the model are presented in this paper. In addition, this paper presents the survey development and data collection plan. The result of this study is expected to help practitioners in establishing more sophisticated plans to enhance safety climate for their construction projects, which will eventually

contribute to preventing accidents.

2 Literature review

This section presents the definition of safety climate and provides some studies investigating safety climate. Two hypotheses of this study are presented as well in this section.

2.1 Safety climate

Zohar [58] firstly proposed a safety climate as a workers' shared perception regarding the safety aspects of their working environments. Based on Zohar's studies, Neal and Griffin [39] described safety climate as "individual perceptions of policies, procedures and practices related to workplace safety". González-Romá [19] summarized that safety climate is a measure that reflects the employees' perceptions and attitudes toward safety within the organizational climate at a specific point in time. Guldenmund [21] defined safety climate as a summary concept representing the beliefs of employees about all safety issues. Glendon and Stanton [18] stated that safe climate includes the current position of the firm. Fang et al. [14] noted that safety climate is a 'snapshot' of safety culture. For some studies, safety culture and safety climate are not distinguished and are used interchangeably [6]. Since then, it has been described that safety climate reflects the state of safety at a specific point of time in an organization [5, 14, 19]. After all, safety climate is a common perception regarding safety shared by employees within an organization at a specific point in time.

It also has been used as an indicator for organizational safety through various studies. Many researchers have found that safety climate contributes to reducing accidents. McCabe et al. [36] found that safe climate accounted for 20% of the variation in the injury rate. Many previous studies have confirmed the positive role of safety climate in improving the safety performance at construction sites [5, 30, 33, 42, 46].

As humans' unsafe behavior is one main cause of accidents, there have been many studies investigating the human factors for safety [26]. Studies about safety climate and safety culture are examples studying the human factors. Griffin and Neal [20] found that the safety climate influences employees' safety motivation, thereby influencing the safety behavior. Many researchers have identified that key dimensions related to safety climate influence safety behavior [15, 31, 34, 38]. Jin et al. [26] found that the most research studies on safety climate and safety culture have been performed in the recent 10 years.

The construction industry is large, complex, and involved in non-routine works compared to other industries [53]. In addition, stakeholders in the field are more diverse than other industries. Based on the literature

review, Al-Bayati et al. [1] presented 12 indicators examining safety culture and safety climate and those indicators were classified into four stakeholders: upper management, safety personnel, frontline supervisors, and workers). The paper summarized the organizational responsibilities of each of the four stakeholders for safety performance and accident reduction. Chen and Jin [4] investigated the multi-level safety culture and safety climate to evaluate newly introduced safety programs. For the investigation, the hierarchy of the construction organization was classified into three (Top management, Middle management, and worker) and the framework for understanding the relationship among safety program, safety culture, and safety climate in each hierarchy was organized based on the literature review. Li et al. [29] studied safety climate dimensions and safety climate indicators by three perspectives (safety management and supervision, construction team workers, the safety environment).

Table 1 summarizes the dimensions which presumably affect the safety climate. As shown in the table, there are various stakeholders being involved in the development of safety climate. Another thing to note is that researchers investigated those factors from the perspective of construction workers because they are the main victims of construction accidents [23].

Table 1 Factors affecting safety climate

Factor	Reference
Management commitment	[6, 8, 10, 14, 31, 38, 51, 56]
Supervisors' role	[6, 8, 10, 14, 27, 38, 55, 56]
Workers' involvement in safety	[12, 14, 31, 38, 51, 56]
Workers' perception of safety	[6, 29, 31, 38, 51]
Co-workers' interaction	[6, 8, 15, 29, 38]
safety environment	[14, 15, 29, 31, 38]

2.2 Research Hypothesis

This study proposes two research hypotheses. The theoretical background for the hypotheses is summarized below.

2.2.1 Project scale and safety climate

The project size is usually determined by project cost. In general, the amount of resources used for safety is influenced by project size. For example, in South Korea, the Occupational Safety and Health Act designated the number of safety managers by the size of construction project [41].

In addition, cost for health, safety, and environment (HSE) is determined by multiplying the direct

construction cost and a standard rate determined by the Occupational Safety and Health Act of Korea. Japan also uses a standard rate offered by the government to determine the HSE cost from the direct cost [9, 41]. Thus, for a project with higher the direct construction cost is, more resources can be used for the safety and health management [9, 41].

Differences in the amount of safety resources can affect the safety performance. Indeed, smaller organizations tend to perform worse in safety than larger organizations. Targoutzidis [47] argued that small organizations account for 67% of employment in all sectors but occupational accidents account for 82% of accidents in Europe.

Based on the fact that the accidents at small organizations, which have relatively lower level of resources available for safety management than large organizations, account for 82% of all accidents, and the number of management personnel and management costs invested in safety management vary slightly depending on the size of the construction, it can be hypothesized that larger projects tend to have higher level of safety climate as the existing literature confirmed that safety climate and safety performance are positively associated [4, 30, 33, 42, 46].

Hypothesis 1. Larger projects tend to have higher level of safety climate.

2.2.2 Risk level of work activity and safety climate

As the degree of risk is different by type of work [28], frequency of potential loss-of-control events varies by work activity [44]. Lee et al. [28] showed that there is a quantitative difference in the risk according to the type of work. They argued that activities involved in roof, elevator, curtain wall, reinforced concrete, and steel are relatively high-risk activities, and finishing, wood, metal, tile, and brick are relatively low-risk activities.

Ronzenfeld et al. [44] conducted the construction job safety analysis (CJSA) and found that frequency of potential loss-of-control events differs by work activity. Particularly, workers executing foundation and structural activities have more loss-of-control events than finishing work activities. Depending on the type of work activity, frequency that workers face the risk of accidents varies. Thus, safety managers should manage such activities more carefully by conducting special safety training, and preparing rules to prevent accidents. Such actions should raise the level of awareness of workers' safety.

Among the theories related to risk perception, Gerald Wilde published the theory of risk homeostasis in 1982 [49]. According to his theory, humans tend to behave riskier in a situation with low risk and behave less risky in a situation with high risk. Thus, this study assumed that the level of risk by type of work would affect the safety

climate of workers.

Based on the studies showing that the level of risk is different by type of work activities and the level of management efforts safety managers spend increased for the work activities with high level of risk, and the theory about the relationship between the level of risk and the behavior of workers, the following hypothesis can be established.

Hypothesis 2. Activities with high level of risk tend to have higher level of safety climate.

3 Research model

To test the hypotheses of this study, it is necessary to quantify the safety climate by project size and activity type. To quantify the safety climate, the authors conducted a thorough literature review and identified seven factors presumably affecting the safety climate of workers. **Error! Reference source not found.** shows the research model. As shown in the figure, the model has seven factors. There are some features to discuss in the model. First, some factors such as management commitment, supervisor's role, and two factors related to workers measure various issues such as safety procedure, communication, and attitude by different hierarchical perspective from top management (management commitment) to workers. As mentioned previously, a construction project is involved in diverse stakeholders. Thus, similar to other studies investigating safety climate [1, 4], this study considers the workers' perceptions on hieratically different types of stakeholders influencing safety climate. Second, while the aforementioned factors are about certain perceptions within a stakeholder, two factors related to co-workers are about interaction among the frontline workers. The last factor, safety environment, is about the circumstances of a site in terms of safety.

3.1 Management Commitment

Management commitment is related to how top managers manage the organization with the safety issue as a priority. Zohar (1980) referred to management's commitment as a central element of the safety climate. Mohamed [38] found that management commitment is a prerequisite for a positive safety climate. Alruqi et al. [60] argued that top manager's assurance that safety is a priority in their organizations is critical for safety climate. In other words, management commitment is a dimension that explains how the top manager prioritizes safety-related issues. Loosemore et al. [31] investigated six dimensions influencing safety climate. They include management commitment, communication, rules and procedure, supportive environment, personal accountability, and training. They found that management commitment shows the highest impact.

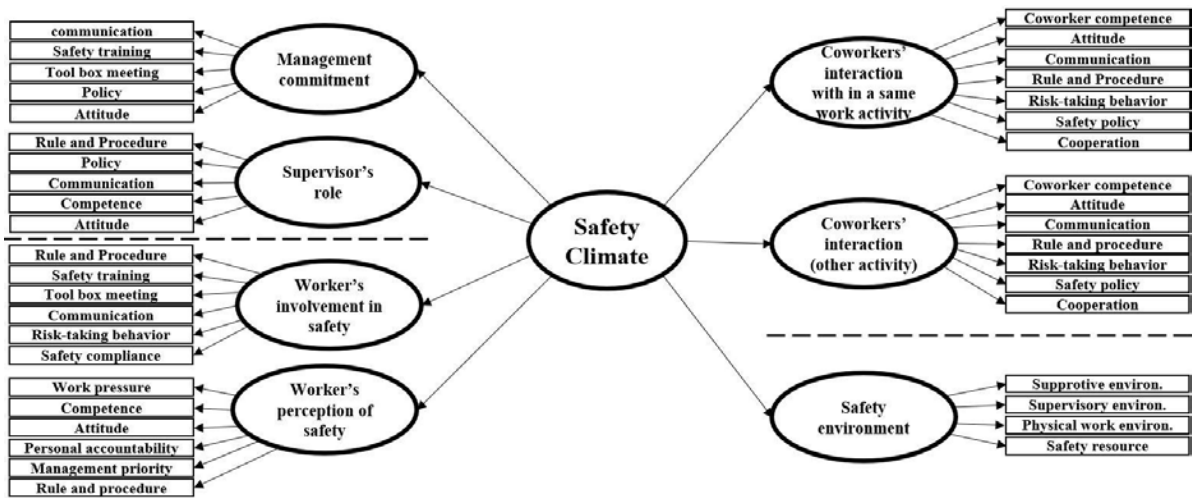

Figure 1. Research model

Items used from previous studies for this factor include safety priority, communication, safety training, tool box meeting, policy, and attitude [31, 38, 60].

3.2 Supervisor's role

Zhang et al. [55] investigated the effect of supervisor's behavior on safety climate and safety behavior of workers. They confirmed that supervisor's behavior improved the safety climate and workers' safety-related behavioral performance. Fang et al. [14] compiled the structure of 10 safety climate dimensions including the supervisor's role. The climate survey tool (CST) developed by the UK Health and Safety Executive has 71 measurement items to measure 10 safety climate factors and supervisor's role is included in the factors. Zohar [59] explained that supervisors play a major role in implementing organizational safety policies and procedures. Alruqi et al. [60] described the supervisory safety response is about how accountable the front-line leaders are for carrying out an organization's safety procedures. In other words, safety supervision can be explained as an index explaining the performance of safety-related tasks in the organization by the supervisor, who plays the most important role in safety practice. The questionnaire items measuring the supervisor's role on safety include rule and procedure, policy, communication, ability, and attitude [14, 55, 60].

3.3 Coworkers' interaction within a same work activity

Li et al. [29] explained that in order to improve the safety climate of workers, it is necessary to create a reliable safe work environment. Such an environment can be created if team members pay attention to each other about unsafe behaviour and safety violations. Many studies highlighted the importance of co-workers'

interaction for safety climate [14, 29]. Mohamed [38] mentioned co-workers as a component of a supportive environment. Fang et al. [14] explained that co-workers can interact with each other through their risk perceptions and mutual attitudes in an environment where they work together in the construction industry. To measure the interaction with co-workers, indicators include co-workers' competence, safety attitude, communication, rules and procedures, risk-taking behaviour, safety policy, and cooperation [14, 29, 38].

3.4 Workers' perception of safety

Workers' perception of safety relates to workers' psychological state, safety attitudes on potentially hazardous situations, as it relates to workers' identification of safety concerns. Li et al. (2017) explained workers' self-perception of safety based on self-perception theory (SPT), observing their own or co-workers' behavior and determining their own psychological state or attitude toward safety. Flin et al. (2000) explained that safety climate can be viewed as a superficial feature of safety culture identified by workers' perceptions and attitudes. Cox and Cheyne [11] explained that workers' awareness of organizational safety rules and procedures is a major factor influencing the level of safety. Items on workers' safety perception included work pressures, competence, attitudes, personal accountability, rules and procedures, management commitment [11, 29].

3.5 Workers' involvement in safety

Workers' involvement is concerned with the efforts of workers to actively participate in safety to ensure their own safety. Workers' involvement has also been described by several researchers as an important component of creating positive safety climate [38, 14, 29,

38, 60]. Reporting injuries and hazardous situations are examples of workers' participations in safety [38]. Li et al. [29] described workers' involvement as workers' efforts to regulate their own safety, including self-protection, participation in safety meetings and training, and adherence to safety procedures. Alruqi et al. [60] described workers' involvement as the extent to which workers are encouraged by senior management to participate in the safety procedures and are asked to participate in the policy. Wu et al. [50] reported that workers' safety involvement is one of the core dimensions appearing in safety climate studies. Workers' involvement responds to the level of participation of workers in their own safety, and the item included rule and procedure, training, tool box meeting, communication, risk-taking behavior, and safety compliance [14, 29, 38, 60].

3.6 Safety environment

The safety environment can be described as a factor related to the physical environment of a construction site, safety resources, and surrounding efforts to support the safety of workers, rather than a factor as one of the organizational hierarchies. Li et al. [29] defined the safety environment as environments involved in all construction activities and working conditions, including four indicators of personal protective equipment, workplace safety status, accidents record, and machine safety status, so that workers can complete their works safely. Niskanen [40] explained that the absence of adequate protective equipment and tools is one main cause an accident. Mohamed [38] explains that the supervisor's ability and safety performance are related to the supervisory environment. The items asking about the safety environment affecting worker safety included supportive environment, supervisory environment, physical working environment, and safety resources [38, 29].

3.7 Coworkers' interaction with different work activities

Through literature review, it was found that co-workers influence the safety of workers [14, 29]. There are various work activities at construction sites. Unlike other industries, construction sites have multiple activities working together on one project, so not only the same work activity group, but also other work activities (groups) can affect workers' safety. Depending on the type of job, type of safety equipment used are different, and the frequencies of loss-of-control events are different. So, the factor investigating the influence of safety climate on workers of other types of work are added. For the items to measure this, same elements to co-workers' interaction within a same work activity are used but the

subjects of questionnaire items are changed to "workers doing other activities".

4 Survey development and data collection

To test two hypotheses, this study developed a survey. The survey consists of two sections. The first section collects information about the size of the project and the type of work activity. The second section consists of a total of 38 items related to seven constructs shown in Figure 1. For the items linked to each construct, how construction workers perceive the items will be asked because workers are most directly exposed to accidents.

The questionnaire plans to be distributed to construction workers and responses will be collected directly at construction sites. Factor analysis will be used to sort out some items and finalize the research model. As this study investigates the safety climate difference by project size and activity with different risk levels, data will be classified into two groups in terms of project size and activity type. In terms of the project size, US\$12 million will be used to divide large and small projects as the size of safety resource is legally different based on the value in South Korea [9, 41]. In terms of the activity type, structural, foundation, roof, temporary, excavation, and wall are classified as high-risk activities and finishing works such as tile, wallpaper, wood, metal, stone, windows and doors are classified as low-risk activities [28]. Structural equation modeling will be used to compare how safety climate differs by project size and activity with different levels of risk.

5 Discussion and Conclusion

There have been many studies in the construction industry investigating safety climate and influential factors for safety climate. Although many studies asserted that there exists a positive association between safety climate and safety performance, the current body of knowledge doesn't have enough evidence on the different safety climate by project size and activity with different risk levels. Two hypotheses about these relationships in this study have some important implications. First, small projects tend to be more involved in accidents. This study tackles that one possible reason for this tendency is that larger projects can spend more resources for safety management thus have high level of safety climate which is known to have direct impacts on safety performance. Thus, if there can be more safety resources available for small projects, the frequency of accidents occurred in small projects can decrease. One issue here is that a higher percentage of cost or resources must be invested in safety, which can be quite challenging for small projects. By verifying the first research hypothesis, this study can contribute to

justifying a decision to spend more resources to cultivate safety culture for small projects. Indeed, some researchers argued that if comparing the cost expended to respond accidents and that used for prevention, responding cost is much greater than prevention cost [2, 48]. Thus, it is possible that the amount of cost necessary to enhance safety climate can be smaller than the cost spent to respond after accidents occurred. Future studies are recommended on this comparison.

Some might argue that safety climate is formed in the level of company or project [13, 14, 35, 43]. But, this study hypothesized that there can exist the safety climate difference by activity with different risk levels. For a construction project, there are various kinds of subcontractors being involved. The levels of risk on the activities they performed vary as well, which means that the level of safety climate for them can be different even though they work in same physical space. This safety climate difference by activity can have negative impacts on co-workers' interaction to reduce accidents. After all, it is possible that activity can be more appropriate level for managing safety climate for a construction project, inferring that more sophisticated plan to develop safety climate is necessary. Overall, the results of this study can contribute to establishing a more strategic and effective plans when establishing new policies, education, and rules related to safety in the future, which will eventually contribute to reducing the accident rate in the construction industry.

Abstract

This study proposes an experiment to find the most effective alarm sound for controlling alert fatigue. Alert fatigue is the phenomenon that an individual is constantly exposed to frequent alarms and becomes desensitized or loses his attention or focus on the alarm. One of the major causes of struck-by accidents caused by construction equipment is the blind spot. Even though many research studies have developed the alarm system to manage the issue, frequent alarm from construction equipment is inevitable because construction equipment and workers on foot usually work in close range. Hence, the alarm sound that manages alert fatigue effectively can reduce the accident caused by the blind spot. This study proposes an experiment design using three different alarm sounds (complex tone, auditory icons, and self-own name) and three different physiological signals (electroencephalography, electrodermal activity, and event-related potential) to measure alert fatigue quantitatively to compare alert fatigue of each alarm sound. This paper suggests two research hypotheses: 1) different alarm sounds induce different levels of alert fatigue and 2) suggested physiological signals are suitable for measuring alert fatigue. A future study testing these hypotheses can contribute to reducing the accidents related to blind spots, which will eventually contribute to better safety performance in the construction industry.

Keywords – Alert fatigue, Physiological signal, EEG, EDA, Alarm sound, Construction equipment safety

1 Introduction

The construction industry has been known as one of the most hazardous industries. In the U.S., accidents related to equipment are the leading cause of work-related injuries and fatalities in the construction industry [1, 2]. Similarly, statistics and many reports have suggested that the struck-by accident between construction equipment and workers on foot is one major

cause of the work-related accident in the construction industry [3, 4]. Teizer et al. (2010) suggested that loss of focus and blind spot are two common hazardous factors in construction equipment. Hence, they recommended to study an alarm system helping equipment operators to recognize possible threats from blind spots promptly [5]. But due to the dynamic circumstances of the construction site, mobile construction equipment and workers on foot frequently work closely at construction sites, which leads to repetitive, frequent, and loud alarm sounds [1, 5].

The authors of this study assumed that managing alert fatigue can contribute to reducing the accidents caused by blind spots. Alert fatigue is the phenomenon of reduced alertness towards the alarm sounds, due to exposure to frequent alarms [6, 7]. As aforementioned, equipment operators' constant exposure to the frequent alarm is inevitable [1, 5]. Such frequent alarms can lead to alert fatigue. Some studies investigated the alarm system of construction equipment [1, 5, 8]. Teizer et al. (2010) suggested the pro-active real-time proximity alarm system using radio frequency remote sensing technology. The system can provide information related to the safety to the equipment operator and workers on foot but cannot manage alert fatigue [5]. Wang and Razavi (2016) used two 4-dimensional models to reduce the rate of false alarms of the recent alarm system. After developing such models, they conducted the simulation and field test to verify the validity of the model [8]. However, even though the reduced false alarm can relate to lowering the rate of alarm, frequent alarm is inevitable. Therefore, the development of the method of managing alert fatigue can help the current alarm system to be more effective for reducing the accidents caused by construction equipment.

This paper presents two hypotheses: 1) alert fatigue is different by an alarm sound and 2) physiological signals (i.e., electroencephalography (EEG), electrodermal activity (EDA), and event-related potential (ERP)) can be useful for measuring alert fatigue.

The main research objective of this study is to develop an experiment design to measure alert fatigue for three different alarm sounds. Alert fatigue will be

measured by the physiological signals and behavioral data. Three alarm sounds include a complex tone (which represents the conventional auditory warning), auditory icon, and self-own name (SON). EEG, EDA, and ERP are the physiological signal included in this experiment design. In addition, behavioral data will be collected by measuring the reaction time of the subject to the alarm sound.

By measuring alert fatigue of each alarm sound, it is expected that the result of the experiment can suggest the most effective alarm sound to control alert fatigue. Such a result can contribute to reducing the equipment accidents caused by blind spots, which will lead to better safety performance in the construction industry.

This paper consists of four sections. After the Introduction section, the second section presents the literature review. Definition of alert fatigue and related research studies are presented in this section. Also, the description of the alarm sounds included in the experiment is presented. The third section is about the methodology of the experiment. In addition to how the alarm sound was designed in the experiment, the description of the physiological signals used in the experiment and the suggested experiment design are presented. The final section presents the expected finding and the discussion of the experiment suggested in this study.

2 Literature Review

The literature review section consists of three sub-sections. In the first sub-section, the definition and studies related to alert fatigue are presented. The following sub-section provides three different alarm sounds used in this study. In the final sub-section, the research hypotheses and objective are presented.

2.1 Alert Fatigue

Blackmon and Gramopadhye (1995) discussed decrement of vigilance in the construction industry. Vigilance means the ability to stay focused on a specific stimulus over a long time. Vigilance decrement is human nature that an individual cannot sustain the attention to the specific stimulus for a long period of time due to the intense stimuli or monotonous stimuli. To avoid such an effect, Blackmon and Gramopadyhe (1995) suggested installing the positive feedback device, so that workers around the backing mobile equipment can sustain their attention by keeping refreshing their attention on the equipment [6].

Alert fatigue is closely related to vigilance decrement but there are some differences. The exact definition of alert fatigue is not agreed upon by researchers yet. Edworthy (2012) defined alert fatigue as the phenomenon that occurs due to false alarms, and the

tendency of people to adjust their attention and response rate to the alarm by the accuracy of the alarm [9]. The everyday safety tailgate talks of the Cornell university defined safety alarm fatigue as the phenomenon that occurs when an individual or group is constantly exposed to alarms long period of time and becomes desensitized to the alarm [7]. Cash (2009) claimed that alert fatigue is the user-desensitization occurred due to the increasing number of the alert [10]. In this study, alert fatigue is defined as the phenomenon of an individual or group constantly exposed to the frequent alarm and becomes desensitized or loses the attention or focus towards the alarm. When comparing vigilance decrement and alert fatigue, while vigilance decrement deals with various kinds of stimulus, alert fatigue is only related to alarm sound.

There have been several studies investigating vigilance decrement and quantitatively measuring the phenomenon. For measuring vigilance quantitatively, researchers used behavioral data such as reaction time or error rate. The others used physiological signals such as EEG, EDA, and PPG. For example, Jung et al. (1997) measured alertness to the auditory targets during the visual task. They used EEG, reaction time, and error rate to measure alertness, which indicates vigilance [11]. Trutschel et al. (2011) used the PERCLOS (Percentage of Eye Closure) to measure alertness of drivers [12].

Compared to vigilance decrement, there have been a relatively small number of studies about alert fatigue. Furthermore, there has been no research study about measuring alert fatigue quantitatively. Even though Edworthy (2012) suggested the alarm sound design principle for avoiding alert fatigue, there is no study comparing the alarm sound to prove that alert fatigue differs for each different alarm sound [9].

2.2 Alarm Sounds

As mentioned above, this study uses three different alarm sounds to measure and compare the effect of alert fatigue. The alarm sounds being tested in this study are complex tone, auditory icon, and SON.

The complex tone is a sound that consists of multiple sinusoidal components of different frequencies [13]. In this study, the complex tone is used for replacing the conventional auditory warning sounds. Belz et al. (1999) used the complex tone as the representative of the conventional auditory warning sounds [14].

The auditory icons, which was suggested by Gaver (1988), are the types of sound that occur in a threat or hazard situation [15]. Auditory icons are well-known for its learnability and recognition performance [16, 17]. The learnability of an alarm sound means how easily the listener understands the urgency or the detail of the threat. Several studies suggested that auditory icons perform better than the conventional warning system in terms of

learnability and recognition performance. Edworthy (2011) suggested that the learnability of auditory icons is better than abstract sound and tonal alarm, and inferior to the speech alarm, as the speech does not require learning process to understand [18]. Cabral and Remjin (2019) suggested the principle of designing auditory icons. They classified the auditory icons into three groups, which are symbolic, iconic, and metaphorical. A symbolic auditory icon is a sound that is generally accepted as the symbol of the event or the threat that does not emulate the sound of the real world. For example, if anyone listens to the siren on the road, the listener will immediately recognize that an ambulance is near. In this case, the siren is the symbolic auditory icon of the ambulance. An iconic auditory icon is a sound related to the physical characteristic of an event. For example, the sound of tire skidding can be used as the alarm sound to alert the driver for the impending crash. A metaphorical auditory icon is a sound in between the iconic and symbolic auditory icon. The sound does not completely emulate the physical aspect of an event but also, it is not a completely random sound. Research suggests that the iconic auditory icon alarms better than the symbolic or the metaphorical auditory icon as the iconic auditory icon did not require the learning process to understand the meaning of the alarm [17]. As previous research studies suggested that auditory icons perform better than the conventional tonal alarm, this study uses auditory icons as one of the new alarm sounds to control alert fatigue.

SON is the sound of a subject's own voice calling his or her own name. SON is one of the self-related stimuli. Self-related stimuli are external stimuli that have a relation with the subject [19]. (e.g., subject's own face, name) Conde et al. (2015) suggested that self-related stimuli induce greater attention than non-self-related stimuli even if the stimuli are task-irrelevant. They tried to explain how such self-related stimuli work. As the self-related stimuli contain more emotional and personal information, therefore the subject will attract more to the self-related stimuli than the non-self-related stimuli. Therefore, greater attention was induced [20]. Also, Tateuchi et al. (2012) reported that as the process of responding to self-own name is based on long-term memory (their name) and neural response, time to realize the threat is shorter than the process of understanding conventional alarm which is based on short-term memory and consisted of multiple steps [21]. As SON can induce more attention than other non-self-related stimuli and the cognitive process is shorter than the other alarm sound, SON is tested to control the alert fatigue in this study.

2.3 Research Objective and Hypotheses

The objective of this study is to design an experiment to test different types of alarm sounds to control alert fatigue. For this, it is important to determine the method

of measuring alert fatigue.

As mentioned previously, many research studies measured vigilance decrement and alertness using the physiological signals [11, 12, 22-24]. But there has been no research measuring alert fatigue using the physiological signals. This research suggests a hypothesis that the physiological signals used to measure vigilance decrement can measure alert fatigue, as two concepts are closely related.

Also, as Edworthy (2011) noted, urgency of an alarm can be affected by the acoustic characteristics of the alarm sound [18]. Therefore, this study suggests a hypothesis that alert fatigue differs by alarm sound type.

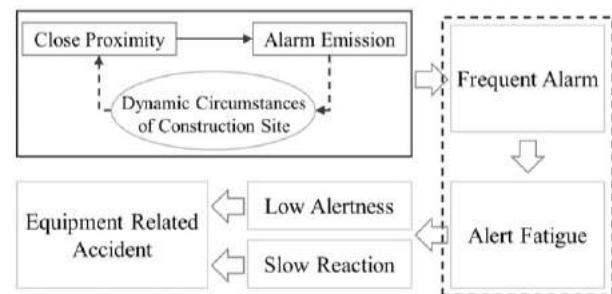

Figure 1. Research model

Figure 1 presents the research flow of this study. The dashed box in Figure 1 indicates the scope of the experiment suggested in this study, which is investigating the relationship between alarm sound and alert fatigue. As aforementioned, due to the circumstances of the construction site, workers on foot and construction equipment frequently work in close range [1, 5]. Also, one of the major obstacles that construction equipment operators facing is the blind spot of the equipment [5]. Therefore, alarm systems warning the operator to prevent accidents have been widely developed. Due to the close working range and the highly developed alarm, the frequent alarm is inevitable. If the operator exposes to alarms frequently, then alert fatigue can occur. Alert fatigue will result in lower alertness towards the alarm, which leads to a longer reaction time. As the alarm system of the construction equipment helps operators to prevent accidents by providing the auditory stimuli that contain the information of the impending accident, lower alertness and longer reaction time can increase the likelihood of the construction equipment-related accidents.

3 Methodology

This section presents how alertness will be measured via a simulated-laboratory experiment. To measure the effect of the alarm sounds on alertness of the construction equipment operators, this study suggests an experiment

design that simulates the equipment operator's action. For three alarm sounds, three physiological signals will be used in the experiment to measure alertness. Also, to give the subject a specific circumstance (i.e., driving the equipment or the vehicle), the subject of this experiment will play the driving simulation during the experiment. By conduct the experiment, three physiological data sets, and one behavioral data set are obtained. Through the data process and analysis, the result can indicate which alarm sound is more effective against alert fatigue.

This section comprises four sub-sections. In the first sub-section, details of the alarm sounds were discussed. The second sub-section is about the physiological signals used to measure alert fatigue. In the third sub-section, the preliminary experiment design is presented. Finally, in the last sub-section, a data analysis plan that can be used in the future study is demonstrated.

3.1 Alarm Sounds Design

3.1.1 Complex Tone

To comparing the effect of alert fatigue for different types of alarm sounds, a reference sound is needed. This study uses the complex tone as the reference for the comparison. Belz et al. (1999) used the complex tone as the substitute for the conventional auditory warning sound. In the paper, the authors used the complex tone that consisted of 500, 1000, 2000, and 3000Hz. [14]. This study uses the same complex tone, and the length of the sound varied to match the length of the SON and the auditory icon.

3.1.2 Auditory Icon

Auditory icons should contain information about the imminent threats or danger. This means that the sound of auditory icons should have a relation to the danger it indicates [18]. Gaver (1988) defined an auditory icon as the natural sound that represents threats or object of the alarm. In case that those do not make any sounds, the author suggested using sound effects [15, 16].

In the experiment, the sound of tire skidding will be used as the auditory icon. This sound will alert the subjects and induce them to react. As the subject of the experiment plays the driving simulation, the subject reacts to the tire skidding sound with the action of pressing the brake. The reaction will be ordered and trained before the test, therefore, auditory icons (tire skidding sound) can successfully lead the subject to react. Such a reaction is the simplified simulation of the action of the operator.

3.1.3 Self-Own Name

SON sound is recorded beforehand. Each subject will be asked to visit the lab before the experiment and record the sound of calling their names. During the record

session, 20 SON sounds will be recorded. The researchers will investigate each recording session and select the most appropriate sound which satisfies adequate length and clear sound with no noise or clipping sound. After selecting the appropriate SON sound, each sound is processed to match its volume and length to other alarm sounds.

3.2 Physiological Signals

As aforementioned, the physiological signals will be used to measure alert fatigue of three types of alarm sounds tested in this study. As the effect of alert fatigue is decrement of alertness or decrement of attention towards the alarm, this study will measure the alertness level of the subject to measure alert fatigue. If alertness of the subject decreases, it will be considered as alert fatigue. The description of the physiological signals used in this study is presented below.

3.2.1 EEG

EEG is the electrical signal collected from the scalp of the subject. Such a signal is generated by activation of the neurons in the brain [25]. EEG is a widely used signal to investigate activation of the brain [25-27]. EEG signal comprises delta (0.5~4Hz), theta (4~8Hz), alpha (8~13Hz), beta (13~30Hz), and gamma (>30Hz) in frequency domain perspective. Each frequency domain represents different types of brain activity or state of a human body. For example, the delta domain represents the deep sleep state [28].

The experiment will use the alpha and beta frequency domains to measure alertness. The alpha frequency domain has been used to measure alertness of the subject [29-31] as it is related to a relaxed state [32]. Therefore, the decreased alpha value means increasing alertness.

Alertness can also be defined as the state of general wakefulness [29]. Previous research has been proved that the beta frequency domain represents wakefulness [25]. Also, there are research studies that used the beta frequency domain to measure alertness [30, 31]. Therefore, in addition to the alpha frequency, this study will use the beta frequency domain to measure alertness.

To eliminate the possible inter-individual difference of the absolute power of EEG due to the difference of the conduction of the skull and scalp, this study suggests using relative alpha and relative beta data for measuring alertness [33]. Relative EEG data is obtained by dividing the alpha and beta power with the power of the overall frequency band.

The raw EEG signal will be processed with the bandpass filter and ICA (Independent Component Analysis) method to eliminate the intrinsic and extrinsic artifacts [28, 34].

The extrinsic artifacts are occurred due to the noise from the outside of the body. For example, an electric

device near the EEG device or the electric node popping noise is classified as extrinsic artifacts. The extrinsic artifacts are eliminated via a bandpass filter as the frequency range of such artifacts is different from the EEG signal [25].

The intrinsic artifacts are the noise from the inside of the body [26]. For example, the EEG device can detect the electrical signal that occurs by the heartbeat. Also, as the EEG device is located at the head of the subject, movement of the eyeball can induce the noise. The bandpass filter cannot eliminate the intrinsic artifacts as the frequency range of the intrinsic artifacts is similar to the range of EEG signals. Therefore, the ICA method is used to eliminate the intrinsic artifacts [26, 28]. The ICA method is a data processing method assuming that raw EEG data can be decomposed to the independent components. Each component is analyzed and classified as artifacts or EEG signals. The artifact component is eliminated, and the EEG signal component remains [28].

The EEGLab software will be used to process raw EEG data. The EEGLab is the open-source program developed by the Swartz center for computational neuroscience at the University of San Diego [35].

After the data processing, the PSD (Power Spectral Density) value of each frequency range can be obtained. By dividing the alpha and beta PSD values with the PSD value of the overall frequency range, the relative alpha and beta value can be calculated.

When comparing the absolute values of the relative alpha and beta values before and after the alarm, if the value decreases, it means alert fatigue is detected [29].

The wireless EEG measuring device, EPOC+ (EMOTIV, USA), will be used to collect EEG data. This device has been widely used for collecting EEG data in previous studies [25-28].

3.2.2 EDA

EDA is the skin conductance signal obtained from the skin surface by placing two electric nodes and passing the small electrical current [36]. The sweating is controlled by the ANS (Autonomic Nervous System), especially, SNS (Sympathetic Nervous System). Under the controlled conditions, sweating is only activated by activation of SNS. Activation of SNS means the body is stimulated [28]. As mentioned previously, alertness means wakefulness of the body. Therefore, an increase of the EDA value can be considered as the alert of a subject [37, 38].

Similar to EEG, raw EDA data should be processed due to the artifacts [36]. The high pass filter and the moving average filter will be used to eliminate the artifacts in raw EDA data. The high pass filter will smooth the EDA signal and the moving average filter will remove the artifacts within the signal [39, 40].

EDA can be decomposed into two components, tonic

components (Electrodermal level, EDL) and phasic components (Electrodermal response, EDR). The EDL represents the change of EDA in the long duration. The EDR represents the change of EDA in the short duration and response toward the stimuli [36]. Therefore, as this study will use EDA data to measure alertness that occurs due to the alarm, which is the auditory stimuli, the EDR will be used to measure alertness of the subject.

To decompose processed EDA data, the convex optimization based EDA model (cvxEDA method), sparsEDA, and the continuous decomposition analysis (CDA) will be used [39-43].

After the decomposition stage, EDR data will be obtained. The alertness can be measured by comparing the EDR values before the alarm. If the difference in the EDR values decreases with time, it means alert fatigue is detected with the EDR.

The Empatica E4 wristband, which has been widely used to measure EDA data, will be used for collecting EDA data [28, 40].

3.2.3 ERP

ERP is the time-locked electric potential for an event. ERP means the synchronous activity of a large population of neurons that occurs due to an external or internal event [44]. P300-ERP, which means positive potential evoked after the 300ms from the event, is related to the external stimulus. Research reveals that P300-ERP is related to the auditory stimulus [45]. Therefore, this study will use P300-ERP data to measure alertness of the subject.

As ERP data can be derived from EEG data, processed EEG data will be used to obtain ERP data. The occipital region of the 10-20 system (i.e., O1 and O2) is known to use to measure P300-ERP [46].

If the magnitude of P300-ERP decreases with time, it means alert fatigue is detected.

3.3 Preliminary Experiment Design

3.3.1 Experiment design

The main purpose of the experiment is to simulate the equipment operator's action in the laboratory. Through the experiment in the laboratory, alert fatigue difference by three different types of alarm sounds will be tested by using physiological signals such as EEG, EDA, and ERP.

Figure 2 demonstrates the experiment design. The red objects indicate the physiological signal measuring devices. The red arc on the subject's head is the EEG device (i.e., Emotiv EPOC+). The red line on the wrist of a subject is the EDA device (i.e., Empatica E4). Orange objects indicate the auditory stimulus-related devices. The orange box behind the subject is the speaker that plays the alarm (i.e., the auditory stimulus). The orange rectangle under the table is the pedal used for measuring

the reaction time to the auditory stimulus. Blue objects indicate the visual stimulus-related devices. The blue rectangle on the table is the keyboard, which is the input device for the non-target reaction. The vertical rectangle in the figure is the monitor providing the visual stimulus.

Figure 2. Experiment Diagram

During the experiment, the subject will be exposed to two different stimuli. The first stimulus is the visual stimulus, which is the simple driving simulation. The subject will control the game with the directional key on the keyboard. As the objective of this experiment is to measure alertness of the alarm sound, the visual stimulus is the non-target stimulus. Playing the game with the keyboard is the non-target reaction. This non-target stimulus and non-target reaction are designed to give the subject a specific circumstance, which is driving the equipment or the vehicle. Also, a method of reacting to the target stimulus while focusing on the non-target stimulus is the oddball paradigm, and such a paradigm is widely used to measure alertness to the target stimulus [21, 47]. The second stimulus is the auditory stimulus, which is the alarm sound provided with the speaker while the subject playing the game. Subjects will be instructed in advance to press the button located under the desk with their foot right after detecting the alarm sound. The auditory stimulus is the target stimulus and pressing the button with the foot is the target reaction. Visual and auditory stimuli, and target and non-target reactions are the simplified simulations of the action of the operator of the construction equipment. Hence, through this experiment, alert fatigue of the operator of the construction equipment can be measured indirectly. The subjects' reaction time to push the pedal after they are stimulated by an alarm sound will be measured to collect behavioral data.

3.4 Data Analysis Plan

After collecting processed physiological data, whether or not each physiological data can successfully measure alert fatigue will be tested by comparing those data to behavioral data, the reaction time.

Figure 3. show the expected data analysis process. For every alarm that goes off during the experiment, physiological signals measured before and after the auditory stimulus will be calculated. By comparing those values, alert fatigue can be measured. In addition, by comparing each of the physiological data results to the behavioral data results, feasibility of measuring alert fatigue by different types of physiological signals will be tested. From these comparisons, different effects of alert fatigue by three different alarm sounds will be evaluated.

Figure 3. Expected Data Analysis Diagram

4 Expected Findings and Discussion

4.1 Expected Findings

By conducting the experiment, alert fatigue of each different alarm sound can be measured. The effects of SON and auditory icons in terms of learnability or recognition performance have been tested by previous research studies [19,20,23]. Even though learnability and recognition performance are different dimensions from alert fatigue, based on the previous research studies, it can be conjectured that alert fatigue occurs from auditory icon and SON is lower than alert fatigue occurs due to the conventional auditory alarm or the complex tone.

In addition, the physiological signals suggested in this study are supported by previous studies that such signals can measure vigilance and alertness successfully [30,33-35,46]. Hence by comparing each physiological data to behavioral data, the authors expect to validate that various physiological data can successfully measure alert fatigue.

4.2 Discussion

4.2.1 Expected Contribution

The expected result of the experiment designed in this study will suggest the most effective alarm sound to control alert fatigue. Knowing such an alarm sound can contribute to improving the performance of alarm systems by providing the method to reduce alert fatigue. This improvement will eventually contribute to reducing

accidents caused by the blind spot.

Another contribution of the experiment is to test feasibility of measuring alert fatigue by physiological signals. This result can contribute to the current body of knowledge as no research measures alert fatigue with the physiological signals.

4.2.2 Limitation and Future Study

As the main objective of this paper is to design an experiment that can find the most effective alarm sound against alert fatigue of the operator of the construction equipment, the experiment suggested in this paper tries to simulate the action of the operator. However, the experiment cannot reproduce the circumstance of the operator perfectly. If future study using the experiment successfully investigates alert fatigue, the experiment can be tested on real construction equipment operators with different alarm sounds installed in their equipment. By doing so, the most effective alarm sound for controlling alert fatigue can be verified in a real situation. Such a result can lead to a more sophisticated alarm system design.

ACKNOWLEDGMENT

Abstract -

Zoom camera is essential for detect top-view. The deep learning detection handle scale invariance, especially for put size is changed in an extremely wide zoom feature can enhance the quality of worker detection. In this paper, we propose a automatic zoom control approach and demonstrate real-world top-view object detection. Through gathering and extensive re-training, the method of the load-view crane camera with deep learning algorithm, specifically in the problem. The finite state machine is used as strategies to adapt the zoom level to ensure consistent detection but also abrupt during lifting operation. As the result, the system can detect a small size object by smooth control without additional training.

Construction safety, Worker detection, Visibility assistance, Adaptive zoom control, Automatic zoom adjustment, Zoom tracking

1 Introduction

On the construction site, there are a great number of accidents caused by visibility. The vision-based autonomous technology can help workers and remove the human factor to reduce injury and fatality. In autonomous construction tasks, object detection is one of the main components in the perception pipeline. It provides the baseline to allow the robot or machine to further extract semantic information at a higher level such as worker safety monitoring [12] and crane lifting assistance system [4].

The primary problem with top view detection is scale variation. Despite less occlusion compared to the frontal view, the viewpoint of the object is changed and the target size becomes very small which make it more difficult for detectors to recognize, also for the human because of the small size and less information—only a head and a shoulder of a person can be seen from the top view. Furthermore, the size can be changed in different altitudes. Although there are many deep learning object detection studies, the research in detecting objects from top view or aerial images remains limited, particularly in the construction domain. The applications using top view images include surveillance, traffic, inspection, and construction. The image sensor can be installed on Unmanned Aerial

Figure 1. Crane load-view camera where red arrow points to, mounting on pendulum bracket.

Vehicle (UAV), buildings, or large machines such as a mobile crane. To address the problem, there is great effort to augment training small object size dataset for training to yield better accuracy of the data-driven methods [5].

Another possibility to tackle the scale variant issue in object detection is using *adaptive zoom*. Zoom camera is widely used in many applications such as construction site or surveillance. The zoom feature is used to retain the image quality in a wide field of view or provide a close-up view for better recognition. For example, the zoom camera can enhance the load view for the crane operator to observe the safety proximity surrounding the load during the lift operation. The surveillance zoom camera can track the movement of suspects and zoom in to their faces for accurate facial recognition [3]. Nevertheless, it is crucial to control the zoom level automatically because it requires stable zoom control to hold each zoom constraint. In general, it is challenging to adjust the zoom level smoothly, given the noisy sensor data. Moreover, zoom control has rarely been studied directly. The research is mainly focused on adaptive zoom conditions rather than how to implement an effective zoom control. In other words, the

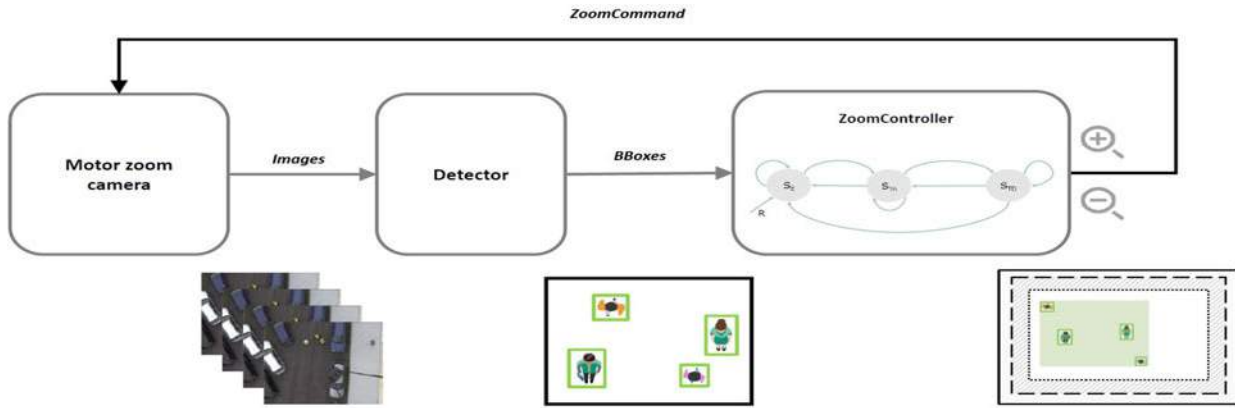

Figure 2. Dataflow of the adaptive zoom control architecture.

previous studies[6, 15] do not provide evidence on how to conduct the zoom control to reach the desired zoom level, but only zoom constraints. For instance, the authors in [6] merely mentioned that the camera is zoomed to hold a defined pixel range. However, there are many factors that should be considered such as inconsistent detection, zoom speed, which can cause zoom oscillation.

In the construction domain, Azar [1] improves construction equipment detection for an automated monitoring system for productivity. The construction equipment is detected via AprilTag [11]—a visual marker. The author proposed an automated zoom control algorithm in order to have reliable detection. The active zoom control maintains the minimum tag pixel resolution [2]. The zoom function of the crane load-view camera is essential for the crane operator. Vierling et al. [15] propose an automatic zoom load-view camera based on the working zone and load occlusion. The authors trained four CNNs with the load-view images as input. Each CNN corresponds to one zoom level. At the end, the arbiter picks the optimal zoom level which provides less occlusion and is suitable for the operator. Li et al. [6] increase the precision in tracking tower crane hook during hoisting to avoid blind-lifting. To capture the hook movement, the author used the pan-tilt-zoom (PTZ) surveillance camera to detect the hoist cable instead. The adaptive zoom is used to maintain the hook size on the monitor display.

Zoom camera is one of the essential stages in the object detection pipeline. Nonetheless, no study to date has examined the zoom mechanism on a mobile crane for object detection. To fill this literature gap, this paper identifies the adaptive zoom control method to maintain the quality of the worker detection from a load-view crane camera. The goal is to avoid data gathering and re-training deep learning algorithms. Second, the adaptive zoom gives a significant advantage for the crane operators as they have

to simultaneously work on many tasks during the lifting. The proof of the adaptive zoom control is verified by using AprilTag detector. To our knowledge, no prior studies have examined zoom function on the mobile crane to improve worker detection for safety monitoring.

2 Proposed Approach

In this work, we propose an adaptive zoom control method to eliminate the re-training and data augmentation process in object detection using deep learning algorithm, and meanwhile increase the situational awareness of a crane operator.

The data-driven method mandates a large amount of training data to reach high accuracy. Detecting objects from a load-view crane camera is challenging especially in the construction area. The object appears in wide-ranging size and appearance. During lifting, the distance between the load-view camera and the ground is dynamically changing because the boom arm can be lowered or extended. Hence, the detected objects appear differently—small, medium or large¹ [9]. Additionally, the background is full of features that can be easily misclassified as a worker. On the other hand, recording data from the crane for training data-driven detector is expensive and effort demanding such as crane rental, (un)mounting sensor on the huge machine, and data annotation.

The image sensor in this work is a Motec MC5200 crane motor zoom camera mounted at the boom tip of the mobile crane with a pendulum bracket, see Fig. 1. The video output is analog which contains an interlaced display. It results a partially interlaced image after digitalization. The camera can do basic controller function by sending the output control command, *Zoom in* (O_{zi}) and *Zoom out*

¹small (BBBox < 32 × 32 px), medium (32 × 32 px < BBBox < 96 × 96 px) and large (BBBox > 96 × 96 px). BBBox stands for bounding box.

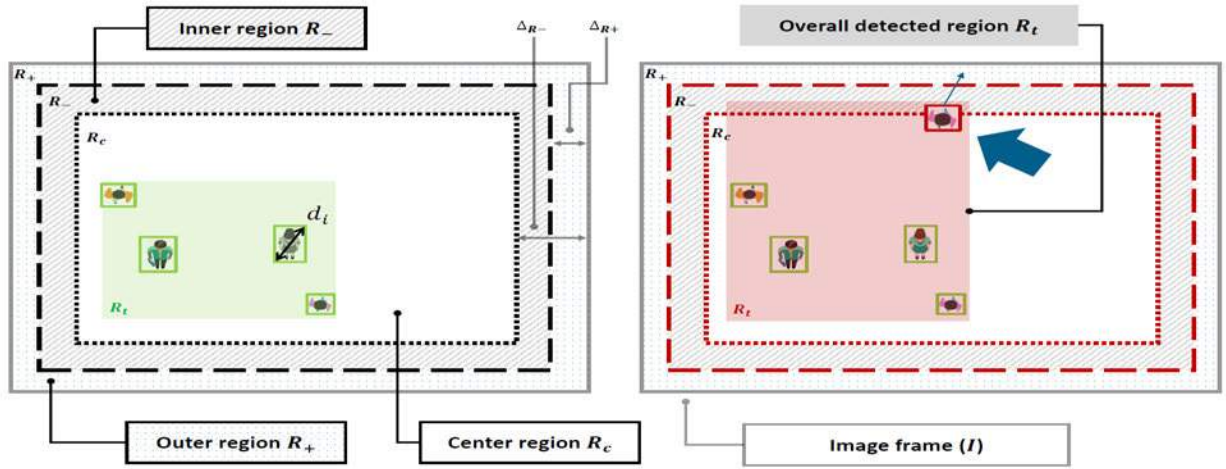

Figure 3. The sketches illustrate two scenarios of the proposed FSM, target size preservation (left) and target area preservation (right). R_+ is the outer region filled with a dot pattern. R_- is the inner region filled with an upward diagonal. R_c is the center region. R_t is the overall detected region which is shown in translucent. On the left figure, the green translucent region R_t identifies the satisfied constraints of size including the borders which show in black. On the other hand, the right figure depicts the violated case of both size and region which are identified by the red translucent rectangle and red border. d_i is a bounding box diagonal of target x_i in pixel.

(O_{zo}) which make the objects inside the image becomes larger and smaller, respectively.

2.1 System Architecture

In our system modules, there are two main components, namely perception, and control. First, the perception part is an object detector. In a real-world application, a worker detection using deep learning approach, whereas AprilTag detector, which is adopted from [11] used to evaluate our proposed zoom control method. Second, the control regulates the zoom level to satisfy the defined constraints. We applied a finite state machine (FSM) for control strategies to generate O_{zi} and O_{zo} pulse command as the output from our *ZoomController* by incrementally increase or decrease, respectively. The detail of the control logic will be further discussed in Sec. 3. The system data flow is shown in Fig. 2. The load-view crane camera feeds image frames to the detector. The detector processes the image and subsequently passes the recognized bounding boxes (BBoxes) to *ZoomController*. Finally, the controller generates the zoom command based on the observation back to the camera to adjust the zoom level.

2.2 Detectors

AprilTag Detector: The incoming sensor data, like the worker detector, can be inconsistent. It can cause difficulty to assess the zoom control logic. To decouple the control

part from the perception, we then verify our control using AprilTag. The AprilTag detector is used as a reference of sensor data. This fiducial marker detector provides relatively more reliable and consistent sensor data. In other words, using the visual fiducial marker creates more measurable and controllable experiments[11]. Additionally, the output from both detectors, which is BBoxes, is comparable.

Worker Detector: In the real application, we adopted the load-view worker detector based on RetinaNet from [12]. The network of the detector is fine-tuned with the crane camera images. The data is collected from both simulation platform [13, 14] and the real construction environment. RetinaNet [8], a single-stage detector, introduced the focal loss to solve the class imbalance problem on top of Feature Pyramid Network (FPN) [7]. The featurized image pyramid addresses the problem of object detection at multiscale, while the focal loss is defined to penalize easy negative examples.

3 Zoom Controller

The proposed solution exploits the zoom function of the standard crane camera to keep the quality of the detector instead of parameter tuning and re-training the deep learning network. The principle idea of the method is to maintain the BBox size of all target instances while keeping them in the image frame as long as possible. In

particular, the zoom method preserves the targets in the image frame not to let them out of the camera field of view (FOV). The regions, R_{\pm}, R_c are additionally defined to restrict targets by two image frame offsets ΔR_{\pm} , shown in Fig. 3. Each offset is equally positioned in both x- and y-axis. The outer region R_+ is a prohibited zone, where any target should not be inside. R_- is an inner region while R_c is a center region.

The zoom control logic in *ZoomController* is mathematically modeled in the Mealy FSM, see Fig. 4. The nomenclature of the zoom control is described in Table. 1. The FSM is defined using a 6-tuple $(S, S_0, \Sigma, \Lambda, T, G)$ as the following.

- A finite set of all states $S = \{S_E, S_{TA}, S_{TD}\}$
- An initial or reset state $S_0 = S_E$
- A set of inputs $\Sigma = \{\bar{N}, \bar{D}, \bar{A}\}$
- A set of outputs $\Lambda = \{O_{zi}, O_{zo}\}$
- Transition function $T : S \times \Sigma \rightarrow S$
- Output function $G : S \times \Sigma \rightarrow \Lambda$
- A set of parameters $\Pi = \{D_D \pm \Delta_D, \alpha, R_{\pm}, R_c\}$.

The inputs of FSM are obtained by preprocessing the raw data X_t . The component of a detected target BBox consists of top left box point x_{tl}, y_{tl}, w , and h in an image coordinate. In addition to the set of inputs Σ , we have a set of parameters Π . The values of Π are chosen by trial and error experiments. The moving average (MA) is applied to the input data as a noise filter.

The set of states $S = \{S_E, S_{TA}, S_{TD}\}$ is designed to associate to three following scenarios, namely target loss, target area preservation and target size preservation, respectively. Fig. 3 depicts the last two scenarios. The pseudocode of the method is described in Alg. 1. We manipulate the zoom control by zoom level and perception. Zoom level Z ideally represents how much the camera lens has move based on the zoom pulse command as there is no original zoom control access. The following presents the definition of state machine in Fig. 4 including the transition T and output G function.

- State *Explore* S_E - This state corresponds to target loss case ($T, G: \text{SearchTarget}$). When there is no target or the detector is unable to recognize the target, the camera should explore or search for the target(s) by zooming in or out. The scenarios is depicted in Fig. 3 on the left. The state machine is initiated or reset to this state. The zoom level Z of the camera must be set first at the zoom out max ($Z_0 = 0$). Then the camera starts to *search* for targets until the target appears in the image frame or the detector is able to

Figure 4. Mealy finite state machine diagram of the *ZoomController* logic. \mathcal{R} is a reset signal.

recognize it, which implies $\bar{N} > 0$. The searching procedure is carried out by zooming in ($O_{zi}: Z_{t+1} = Z_t + 1$) until the camera reaches maximum zoom in ($Z_t = Z_{ci, max}$) then it starts to zoom out ($O_{zo}: Z_{t+1} = Z_t - 1$). The procedure repeats until a reliable target is found. In this case, the next state goes to S_{TA} to further observe the overall target area.

- State *TrackArea* S_{TA} - This state corresponds to target area preservation case which the overall target area is assured in the center area ($T, G: \text{AdjustRegion}$). Any target steps into the region R_+ , the camera should adjust the zoom level to keep the target inside at least in the inner region R_- or the center region R_c as long as it is not beyond the camera FOV limit, see Fig. 3 on the right. In other words, if \bar{A} intersects R_+ , the camera zooms out until \bar{A} intersects R_- or \bar{A} does not anymore overlap with R_+ . When the area criterion is satisfied, the next state goes to S_{TD} .
- State *TrackDiagonal* S_{TD} - This state corresponds to target size preservation case ($T, G: \text{AdjustDiag}$). The camera should adapt the zoom level to keep the average diagonal value of overall detected objects \bar{D} to the ideal diagonal D_D which is suitable to the selected deep learning detector. In particular, this condition $(D_D - \Delta_D) \leq \bar{D} \leq (D_D + \Delta_D)$ should be satisfied. When the \bar{D} is lower than the desired diagonal range, the camera zooms in to observe the targets closer, and vice versa. Unless the overall detected area \bar{A} complies, the next state goes back to S_{TA} because the area criterion has higher priority than the diagonal one.

3.1 Zoom Controller Verification

This section presents the verification of the zoom controller using AprilTag as a reference target to evaluate the controller function. The AprilTag family is 36h11 with the size of 16×16 cm. The test was set up in a hallway. Both camera and the tag were placed on the same ground plane. The maximum distance from the camera to the corridor end was 20.3 meters. During the experiment, only the tag

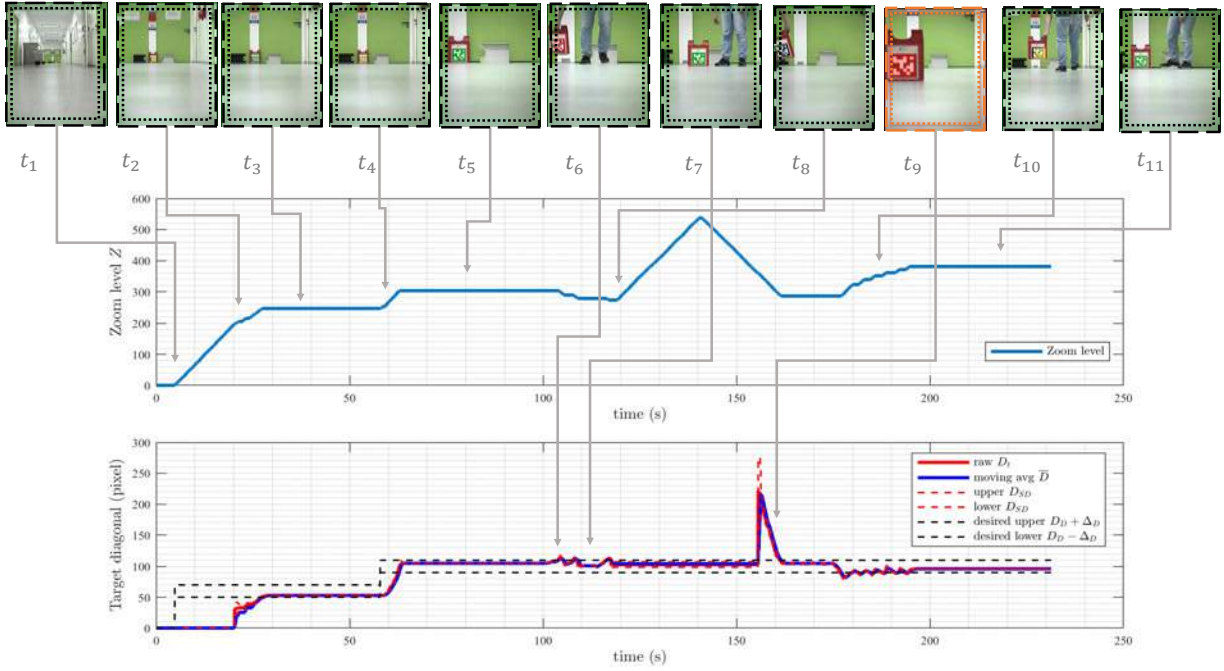

Figure 5. *ZoomController* verification using AprilTag. The dashed line locates in between the region R_+ and the region R_- , while the dotted line divides between the region R_- and the region R_c . The translucency on the tag identifies the size violation. The green tag at $t_{3,5,7,11}$ means \bar{D} are in target range, $(D_D - \Delta_D) < \bar{D} < (D_D + \Delta_D)$. The yellow tag at $t_{2,4,10}$ means it is below the range, $\bar{D} < (D_D - \Delta_D)$. The red tag at $t_{6,9}$ means it is over the range, $\bar{D} > (D_D + \Delta_D)$. The red border at t_9 identifies the area violation i.e., \bar{A} overlaps with R_+ .

was moved farther away or nearer to the camera. The D_D is primarily set to 60 with its offset Δ_D of 10 pixels. The graph in Fig. 5 shows how the zoom level Z adapted to the target. In each image frame, the dashed line locates in between the region R_+ and the region R_- , while the dotted line divides between the region R_- and the region R_c .

At t_1 , both \bar{D} and Z_t are zero because no tag was found. Therefore, the FSM started to search for the target by O_{zi} . Despite the tag was found at t_2 , the FSM continued to zoom in because \bar{D} remained lower than the floor of D_D . At t_3 , Z_t started to be steady as it met the diagonal criterion. At t_4 , D_D was later manually increased, thus the zoom control started to zoom in and \bar{D} was then back again in range at t_5 .

From t_6 to t_7 , Z_t slightly depreciated because *ZoomController* tried to maintain the size by O_{zo} as the tag was moved toward the camera which caused \bar{D} became larger and accordingly exceeded $D_D + \Delta_D$.

Between t_8 and t_9 , the tag was removed out of the camera FOV. For this reason, *ZoomController* went to the explored state S_E . At t_9 , \bar{D} suddenly soared up during the searching because the tag immediately appeared with violated \bar{D} and \bar{A} where the tag was colored in translucent red and the borders visualized in red, respectively.

At t_{10} , The zoom level Z_t gradually rose because the tag is moved away from the camera. \bar{D} became lower than the desired range where the tag was colored in translucent yellow. *ZoomController* simultaneously tried to handle until the tag is back in the D_D range at t_{11} .

4 Experiment

For the worker detector, we simulated the camera position on the crane by mounting the camera from the rooftop of a building. The camera looked down to the parking lot which has an even surface. The approximate distance from the camera to the ground was 22 meters which is equivalent to the height of a 6-story building. The $D_D \pm \Delta_D$ was initially set to 60 ± 10 pixels. During the experiment, four workers walked into the camera field of view. In spite of worker safety requirements, the workers did not wear any protective gear or PPE. Most of the traditional detector methods exploited the PPE appearance to ease the detector which allowed the detector to see the target better [12]. However, there are many incidents of non-compliant workers violating the rules [10]. Thus, it is better to set the construction environment as close as possible.

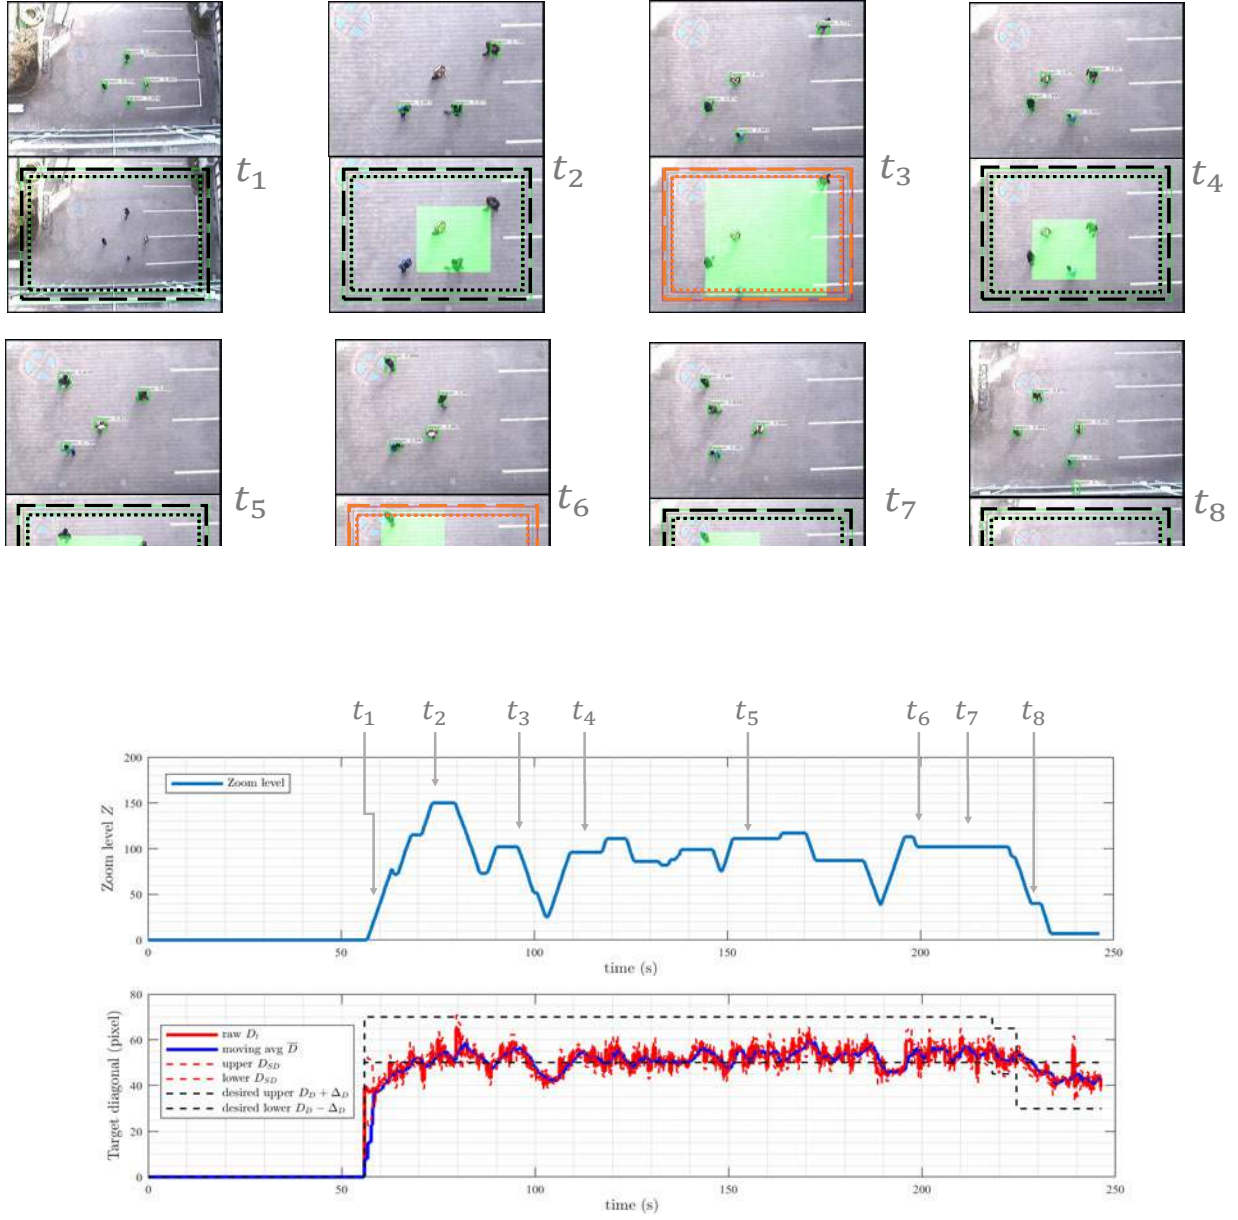

Figure 6. *ZoomController* experiment with the worker detection from load-view crane camera. The upper image row of each timepoint shows the raw data from the detector while the lower image shows the visualized result from the *ZoomController*. The red border identified the area violation which means there is an intersection area between \bar{A} and R_+ .

4.1 Result

The graph in Fig. 6 shows how the zoom level Z adapted to the detected workers. The figure consists of two main parts, which are snapshot image frames and the zoom control result. In the image section, the 1st and 3rd row of images show the detection result while the 2nd and 4th

row display the same image frame with the result for zoom control logic.

At t_1 , Z_t swiftly increased because the average overall diagonal size \bar{D} was below the floor of D_D . At t_2 , Z_t is stable because the size preservation was complied.

At t_3 , the border violation occurred. Two of the workers walked near toward the prohibited region R_+ . One

end

worker was toward the top right corner and the other was toward the bottom of the image frame. Consequently, Z_t decreased in between t_3 and t_4 until the workers stayed inside the inner region R_- . After the area adjustment, the zoom level went up because of the size violation before t_4 where *ZoomController* reached the stable state S_E . At t_5 including the nearby period, the zoom level was gently changed and kept \bar{D} in the desired diagonal range because of the size change. Likewise, the border violation again happened as the border showed in red at t_6 . One worker walked toward the top of the frame. As the result, the camera zoomed out and later Z_t became consistent at t_7 . At t_8 , the camera again plunged because the parameter D_D was configured to a smaller value.

In summary, our results demonstrated that adaptive zoom control can improve the quality of data-driven worker detection. To evaluate the zoom control logic, we replaced the worker detector with AprilTag detector which provides a reference target. The verification performs well, giving the correct result as is defined in the

Table 1. Nomenclature for zoom controller.

Symbol	Definition	Value
Input		
\bar{A}	Moving average R_t	-
d_i	Bounding box diagonal of target x_i (pixel), see Fig. 3	-
D_{SD}	Standard deviation of D_t (pixel)	-
D_t	Instant average diagonal of all targets (pixel)	-
\bar{D}	Moving average of D_t (pixel)	-
I	Image frame	-
N	Instant target number	-
\bar{N}	Moving average of N	-
P_X, P_Y	A set of instant target BBox coordinates in x- and y-axis	-
R_t	Instant overall detected region, see Fig. 3	-
X_t	A set of detected targets at time t	-
Output		
O_{zi}, O_{zo}	Input zoom control command in and out	-
Z_t	Instant zoom level	$[0, Z_{ci,max}]$
Parameters		
D_D	Desired BBox diagonal (pixel)	60
R_{\pm}	Outer and inner region, see Fig. 3	-
R_c	Center region, see Fig. 3	-
α	Moving average window size	5
Δ_D	Range of the desired BBox diagonal D_D (pixel)	10
$\Delta_{R+,T}, \Delta_{R-,T}$	Image frame offset of R_+ and R_- for tag detector	(5,35)
$\Delta_{R+,W}, \Delta_{R-,W}$	Image frame offset of R_+ and R_- for worker detector	(45,75)

FSM. The zoom level was adjusted without jitters. The camera first could not detect the target because of the too-small size object. With adaptive zoom control, the target was able to be recognized from distance. When comparing AprilTag results to the worker detector, it must be pointed out that there is a lot of noise from the sensor data. In other words, the RetinaNet could not constantly detect all four workers despite the MA filter. However, the *ZoomController* functions in the same manner without any zoom oscillation. The controller is able to handle the side effect of the detector such as miss detection, anomaly, and outlier detection. Furthermore, running deep learning detector on less powerful hardware including the video transmission introduced a delay of approximately two seconds in our experiment. Our proposed method can be adjusted to this lagging via the parameters Π .

A major source of limitation is the lack of camera control information access such as zoom level. In the proposed method, we use an approximate estimation of zoom level Z by incrementing the Z counter up and down when zooming in/out is executed. Additionally, the crane control information panel of the operator e.g., hook length measurement and boom angle are definitely would be beneficial to refine the detector. For instance, the zoom controller can be performed based on hook cable length in addition to the proposed criteria.

5 Conclusion and Outlook

In this paper, we investigated the adaptive zoom control of the load-view crane camera for worker detection. This is an important finding in the understanding of how to handle the zoom control to reach the zoom criteria. We exploited the zoom mechanism which exists in typical mobile crane cameras. The proposed method adopts the

Mealy FSM to observe and determine the zoom command which suitable for the given situations, namely target loss, target area preservation, and target size preservation. The state definition is characterized by the three scenarios. The evaluation is first verified by using the reliable and controllable detector, AprilTag. Our proposed zoom control method is able to smoothly adapt to the problem of deep learning object detection, which is inconsistent detection and detecting small size objects.

Further studies should investigate sensor fusion with more access to crane information for zoom control improvement. An additional monocular camera can be installed nearby the zoom camera. The monocular camera provides overview information to the zoom camera. Although the zoom camera status is in maximum zoom in, the overview camera can notify *ZoomController* of the zoom camera if there is a new incoming target then the zoom camera can zoom out. Moreover, the position of workers including the velocity in world coordinate can be estimated by camera projection and object tracking. Hence, the risk of each worker can be assessed for the operator safety assistance system. For instance, if the worker walks away from the crane, the risk of the worker getting hit by the crane is low.

Abstract

The construction industry is known to have one of the most hazardous work environments leading to a high number of accidents and both serious and fatal injuries. One way to mitigate these accidents is by implementing proper safety training for construction workers. Traditionally, safety training is implemented using passive methods such as toolbox meetings, informative presentations, or videos. Recently, game engines have started gaining attention for safety training purposes. However, despite the extensive research on game engine-based safety training, still no research has developed a location-based tool to assess and train construction workers on safety measures. Moreover, this research focused on studying the adoption of such digital training methods for workers in the Middle East. The proposed tool was tested on 25 construction workers from the Middle East. Workers' feedback showed that 91% of participants preferred serious games over traditional training methods indicating the readiness of the construction industry to adopt such digital methods.

Keywords – Safety Training; Game Engines, Technology; Simulation; Construction Training.

1 Introduction

The construction industry is considered to be one of the most dangerous and fatal industries. In the UK, the construction industry accounts for the highest percentage of fatalities among all other industries [1]. According to the Occupational Safety and Health Administration (OSHA), the construction industry reported 971 fatalities in 2017, which accounted for 20.7% of fatalities among all other industries. Therefore, on a global scale, more effort has been channeled towards mitigating construction accidents [1]. Despite these efforts, the Middle East region is still falling short where by 48% of fatalities were solely reported from the construction industry in Saudi Arabia, and 33.2% in Kuwait [2].

A proactive way of mitigating construction accidents

is through the proper training of workers. However, the commonly used safety training methods (e.g. toolbox meetings, presentations, handouts, brochures, and videos) are seen to be outdated and ineffective as workers do not have any engaging role and rather play a passive role throughout the training sessions by listening and absorbing the safety information. Moreover, these methods fall short when workers do not fully understand the language used to present the material [3]. As such, researchers have resorted to advanced technologies such as game engines to create interactive, realistic, and engaging training material for workers, which in some cases are referred to as serious games [4]. The use of game engines for construction safety training applications was found to have a positive impact on workers' motivation for training. It facilitated the learning experience, and had a more effective transfer of knowledge in comparison to the traditional training methods [5–8].

This research study takes the initial steps and aims to study the potential adoption of digital training methods in the Middle East. The study starts by giving a brief overview on the application of game engines in construction safety, and the personality factors which affect the safety behavior of workers on site. After that, the proposed tool's development is explained while highlighting the feedback obtained from construction workers who tested the tool.

2 Literature Review

2.1 Use of Game Engines in Safety Applications

Game engines have been gaining a lot of popularity especially in construction safety applications. Zhao et al. developed a training application to train heavy machinery operators on how to safely maneuver when near electric dangers such as electric poles and wires. Dickinson et al. developed a serious game to train workers on how to safely excavate trenches. Li et al. developed a multiple-choice question (MCQ)-based safety training tool where

workers had to answer questions based on virtual scenarios played within a game environment [9]. To enhance user experience and training realism, Yuan Ling et al. proposed the integration of BIM 4D with safety training. The researchers developed a tool which trained workers on excavation, structural, and exterior finishing phases [6]. While the aforementioned research studies focused solely on safety training applications, other studies used game engines to train workers on both skill and safety. Hafsia et al. trained workers on how to properly and safely erect steel formwork [10]. Using a similar method, Vahdatikhaki et al. developed an agent-based training simulator for pavement grading and compacting. The tool targeted training machine operators on how to compact asphalt pavements while both meeting safety and quality requirements [11]. More recent trends in safety training consist of the use of Augmented and Virtual Reality (AR/VR) technologies. In fact, researchers have found that the use of AR and VR for safety training offer workers a more immersive and realistic training environment [12,13].

All previous studies proved the effectiveness of using serious game engines over traditional training tools. As a matter of fact, the research conducted by Lin et al. showed that 100% of participants answered “Yes” to whether the game motivated them to refresh their knowledge on safety topics. Moreover, 80% of participants gave a score of 5 and 20% gave a score of 4 to assess how much the game increased their learning interests [5]. A similar assessment of another developed safety video game showed that 81% of participants answered “Yes” to whether the game facilitated their learning experience, and 86.5% answered “Yes” to whether the training method was more enjoyable than traditional training tools [6]. Another study showed that 80% of participants thought that the training program developed using the Unity game engine in particular was more useful than traditional training tools [9]. Furthermore, a framework, developed for safety integration within construction using serious game engines, scored 4 out of 5 on the ability to effectively transfer knowledge to users [7].

2.2 Factors Affecting Safety Behavior

In the attempt to mitigate safety hazards, several researchers have focused on developing mathematical models to link and predict safety climate, safety behaviors, and injuries based on different factors. Safety Climate has been defined as the perception or understanding of the organizational safety policies and procedures which the employees have towards their work environment [14,15]. Safety behavior has been defined as the worker’s behavior in following safety and health requirements which, in turn, can mitigate accidents and injuries [16]. Additionally, Abbas et al. suggested that the

years of experience of a worker may have a significant effect on his risk perception and thus on his safety performance [17]. Fang et al. studied the relation between different personal traits of workers and their safety climate. The research used factors such as marital status, number of family members to support, educational level, and safety knowledge. The findings of the research showed that individuals who are older, married, or have more family members are more likely to have a positive appreciation of the safety climate [18]. In a similar study, Zhou et al. used Bayesian networks to establish relationships between safety climate factors and personal traits with safety behavior. Personal traits included in the study were work experience, education, and drinking habits. The study showed that although higher work and education experience have a positive effect on safety behavior, other factors such as management commitment and workmate’s influence had a higher effect. However, the optimal way to enhance safety behavior is by a joint strategy of enhancing all aforementioned traits [19]. Patel and Jha used 10 safety climate factors to predict the safe behavior of workers. The study showed that competence and individual perception of risk were found to be crucial for the prediction of safety behavior [20]. Another research studied the effect of economic features, self-esteem, and experience on safety behavior. The study showed that workers with a higher work experience showed more awareness vis-à-vis safety requirements and those with low self-esteem put themselves in many different unsafe situations. [21]. Beus et al. studied the effect of psychological traits on the safety of the workplace. Results revealed that individuals who are extraverts are more likely to engage in unsafe behaviors in an attempt to compete with others and achieve their goals and those who are conscientious are responsible and prefer to follow safety rules and avoid risks [22].

Despite the advancements in the literature, further development could be made in the application of game engines in construction safety. First, no research has investigated how a location-based training tool could be developed. Second, personality factors were not taken into consideration during the development phase of the training scenarios within the tools. Finally, no study has investigated the applicability of these training methods in the Middle East region. Thus, the overarching objective of this research is to develop a location-based safety assessment and training tool using game engines. As part of this objective, this research will propose how some personality traits can be used in the assessment and training programs to increase safety moral and understanding among construction workers. Finally, the research will test the developed tool on construction workers in the Middle East region, and thus highlighting the possible adoption of such technologies in this region.

3 Methodology

This study uses Design Science Research (DSR) as the research methodology. DSR focuses on developing sound and practical tools to solve real world problems which are faced in the construction industry [23]. This research uses the game engine Unity to develop the proposed safety assessment and training tool. The tool has two main functions; (1) to assess and score each worker's safety knowledge and risk perception skills, (2) to safety train workers on the safety measures of their activity based on its upcoming execution location. After identifying the personality factors which have a direct effect on the worker's safety behavior, the assessment and training scenarios will be developed in Unity according to selected factors. Once the tool has been developed, it will be tested on construction workers and feedback regarding the effectiveness of the tool will be taken.

4 The Proposed Tool

4.1 Location-Based Navigation

The Activity Safety Trainer contains two programs, the Assessment Program and the Training Program. The UI was developed such that the user chooses the desired program at first as seen in Figure 1- a. Ideally, each worker will go through both programs. Figure 1 - b shows that if the user chooses the Assessment Program, the user then has to choose the required activity he wishes to perform the assessment on. On the other hand, Figure 2 - a and 2 - b show that if the user chooses the Training Program, the user will first choose the required activity and then the required execution location to train in. As this tool was developed to in a location-based perspective, the user will be trained based on the upcoming execution location of the activity. This is important as the training material does not only differ from one activity to the other, but also from one location to the other within the same location.

Figure 1 – (a) Home Screen

Figure 1 – (b) Assessment UI

Figure 2 – (a) Training Activity Selection

Figure 2 – (b) Training Location Selection

4.2 Integrating Personality Factors

Table 1 summarizes the personality factors that are sought to have a direct effect on the safety behavior of workers, as extracted from the literature. For simplicity, this study integrates only two of these factors in the development of assessment scenes, namely Safety Knowledge and Experience, and Risk Perception. The scenarios were developed such that 60% are focused on Safety Knowledge and Experience, while the remaining 40% is focused on Risk Perception. In the Assessment Program, the score is also divided the same way. Scenarios which focus on Safety Knowledge and Experience are those related to workers identifying missing Personal Protective Equipment (PPE) and other safety equipment. On the other hand, the scenarios which focus on Risk Perception develop dangerous incidents to check if the worker would notice or perceive them as

being hazardous. Figure 3 shows an example of how scenarios are developed for each case.

Figure 3 – Factors' Integration in Game Development

Table 1 – Effect of a Worker's Personality on Safety

Factor	Effect on Safety Behavior	References
Safety Knowledge & Experience	Positive	[18] [19] [20] [21] [24] [25]
Conscientiousness	Positive	[22]
Family Members to Support	Positive	[18]
Risk Perception	Positive	[20] [24]
Extraversion	Negative	[22]
Anxiety and Stress	Negative	[22]
Adventurous and Curious	Negative	[22]
Self Esteem	Negative	[21]

4.3 Gameplay Controls

The developed serious game covers different scenarios which enhance worker's safety knowledge and risk perception. Some scenarios were developed in different ways than others, and hence required a different type of gameplay controls. Game controls were

developed in a way to be simple and easy to use by all workers regardless of their age and gaming skills. In the assessment program, certain scenarios are question-based scenarios where the user uses the mouse to press the button to indicate the right move or answer. Other assessment scenarios are played from a third person view where workers have to use the up and down arrow keys to move forward and backward respectively, and they have to use the right and left arrow keys to turn around or rotate. In these scenarios, workers are also required to use the mouse to point and click on safety hazards and missing measures. In the training program, the user has to only use the arrow keys to navigate through the site to learn about the safety hazards and measures.

4.4 Assessment Module

The assessment module aims to test the worker's safety traits and to allow planners to know whether this worker is qualified to safely work on the given activity. To achieve this objective, the worker went through a series of scenarios and obtained at the end a Safety Score (SS) ranging from 0 to 70 depending on the performance throughout the game. Figure 4 shows the virtual assessment environment within Unity.

Figure 4 – Assessment Program Environment

4.5 Training Module

The Training Program was developed in a way that would be understandable by all workers despite their age and educational level. Some workers might not know how to read or they read and speak a different language than the one adopted in the game. For this reason, the training game environment relies on visual aids to teach workers on correct and safe procedures as seen in Figure 5.

Figure 5 – Training Program Environment

5 Tool Testing and Results

Twenty-five construction workers from the Middle East tested the tool and gave their feedback by means of a survey. Their age ranged from 20 to 60 years old and their construction work experience ranged from 1 year to almost 40 years.

The workers were first asked to insert the Safety Score (SS) they got while testing the safety training program. 56% of the workers acquired an SS between 30 and 50 which is a medium SS range, while the other 44% acquired a score between 50 and 70 which is a high SS range. Despite having workers with very few years of experience, or old workers which might possess low computer proficiency skills, no worker got a score in the low score range between 0 and 30. These results might indicate the effectiveness of the use of serious games in safety training where workers were motivated to increase their training score. This can be supported by the fact that when asked if the game increased their motivation for learning, 96% acknowledged that digital games truly increased their interest in learning. Furthermore, all participants found that the game refreshed their safety knowledge where all workers strongly agreed that the game enhanced their perception of risks. Additionally, 96% of the participants found that the SS truly reflect their safety awareness, knowledge, and risk perception.

The participants were also asked whether they preferred being trained using traditional methods such as presentations, videos, and handouts, or using serious games. In this case, 92% of the participants opted for serious games while only 8% chose the traditional methods. Moreover, 92% of the workers were in favor of serious games being implemented in the Middle East. These results thereby indicate that the construction sector in the Middle East is ready to undergo a digital transition in its safety training methods.

6 Conclusion and Future Work

The overarching objective of this research was to test the deployment of digital training methods in the Middle

East. This research study developed a tool for construction safety assessment and training using the Unity game engine. The tool was developed using a location-based approach so that workers are trained based on their assigned activity and its upcoming execution location. Moreover, various workers' personality traits sought to have a direct effect on their safety behavior were extracted from the literature and used in the development of the training game. The study also aimed at studying the potential adoption and implementation of digital games for safety training in the Middle East region. As such, the game was tested by 25 construction workers from the Middle East who answered a questionnaire related to the tool. Results revealed that workers were satisfied with the developed tool and approved of its effectiveness in mimicking the real construction environment and providing a realistic experience. In addition, the workers found it efficient in assessing and scoring their safety knowledge and risk perception skills and thereby showed excitement in having such a developed tool being implemented in the Middle East in lieu of traditional training methods. In a nutshell, the tool proved to increase workers' motivation for learning and interest in safety training in general.

This research is part of more detailed study regarding the use of serious games for safety training in construction. This study only focused on presenting the preliminary results regarding the development of the training modules and the feedback of the construction workers. The research was limited to a few number of participants due to the Covid-19 outbreak. Future work will focus on increasing the number of participants to gain more insight and feedback regarding the perception of workers toward these methods in the Middle East in particular. Moreover, more research needs to be done on how other personality factors or traits can be better integrated in the training and assessment programs.

Abstract

Predicting the outcomes of safety incidents on construction projects is of a great value to various project stakeholders. Accurate estimates allow construction managers to take appropriate preventive measures based on the severity of the outcomes. Such estimates can be predicted using machine learning algorithms, although the quality of these estimates is dictated by factors including the types of algorithms employed and the dataset used to train them. Moreover, the metrics used to evaluate the algorithms can be misleading, indicating satisfactory performance when this may not be the case. In light of these considerations, this study trains a set of machine learning algorithms to predict the severity of safety incidents, highlighting the importance of confirming the credibility of performance evaluation results, and compares the performance of the algorithms. The results show that the support vector machine and k-nearest neighbors prediction models exhibit the best overall performance, with support vector machine achieving a mean absolute percentage error value of 18.78% and k-nearest neighbors an accuracy of 64.84%. On the other hand, the results also reveal that the models performed poorly in predicting some classes as a result of a high degree of imbalance identified in the dataset used for training and testing the models. The study's main contribution is to highlight the possibility of making biased performance evaluations of machine learning algorithms, depending on the performance measures used for the evaluation.

Construction, Safety, Machine Learning Algorithms, Prediction, Performance, Data Imbalance

1 Introduction

Given their hazardous nature, construction projects involve numerous high-risk activities during which safety incidents of high frequency and impact may occur. In Canada, more than 450 deaths and 63,000 injuries were recorded over a period spanning the period 2006 to 2017 [1]. High-risk activities can result in injuries, fatalities, schedule delays, and financial losses. In fact, healthcare expenditures in response to construction safety incidents in Canada amount to about 19.8 billion dollars each year [1]. The growing costs of incidents and the increased related pressure imposed by owners have increased contractors' awareness of the significance of safety risks [2]. Accordingly, there have been major efforts made and strict regulations introduced to control and minimize the risks associated with safety incidents.

Knowing the possible outcomes of safety incidents could help in mitigating the risk of their occurrence by assisting decision makers in taking the necessary preventive measures. With the large volumes of data being collected thanks to modern technology, artificial intelligence algorithms can be used for predicting the outcomes of incidents. In fact, multiple studies have developed models to predict and classify different aspects of construction incidents [3-12]. However, different algorithms can vary in performance depending on the dataset used for the training, and, hence, the algorithm to be used must be carefully selected. Moreover, evaluating the performance of the algorithms is a critical step that must be handled with special care. The metrics used to evaluate the algorithms could lead to an errant indication of satisfactory performance. The risk of this occurring is especially high when dealing with poor quality, insufficient, or complex data. This issue is manifest in a recent study by Ayhan & Tokdemir [3] aimed at predicting the severity of safety incidents on construction projects. The dataset used in their study was characterized by a high level of

heterogeneity and could thus be considered highly complex. The authors attempted to address the issue of heterogeneity by clustering the data prior to training the algorithms. Nevertheless, their results still showed high values of error, with the mean absolute percentage error reaching 225%. Despite this high error value, their study relied on an overall mean absolute percentage error of 18%—which was biased due to the high degree of imbalance found in the dataset—to judge the performance of their algorithms.

In this context, the present study aims to train a set of machine learning algorithms using the same dataset used by Ayhan & Tokdemir [3] in order to predict the severity of safety incidents on construction projects while targeting the following objectives: (1) highlight the importance of properly evaluating the performance of algorithms; (2) compare the performance of various algorithms when trained using the same dataset; and (3) find the best performing algorithm for predicting the severity of safety incidents.

2 Relevant Applications

Many studies have endeavoured to train machine learning algorithms for applications related to safety incidents on construction projects. These algorithms have been deployed for a wide variety of applications related to enforcing safety measures, predicting safety risks, identifying causal factors, and detecting hazards, to name a few. A summary of some of these applications is presented in Table 1.

Table 1. Literature summary

Study	Goal	Algorithms
[3]	Predict the severity level of safety incidents	Artificial Neural Network Case-Based Reasoning
[4]	Predict safety climate (i.e., employees' perceptions of existing safety practices) on construction projects	Artificial Neural Network
[5]	Assess construction workers' risk perceptions in terms of the probability and severity of the consequences of safety hazards	Gaussian Support Vector Machine K-Nearest Neighbor Decision Tree Bagging Tree

[6,7]	Detect safety helmet wearing on construction sites	Deep learning Convolutional Neural Network
[8]	Analyse site fall accidents in order to identify related causal factors, classify the factors, and identify the correlation between the type of accident and the causal factor(s)	Text mining
[9]	Predict safety risk factors on construction projects	Back Propagation Neural Network
[10]	Detect safety hazard issues based on the project's schedule and the sounds generated by work activities and equipment operating on construction sites	K-Nearest Neighbor
[11]	Detect fires on construction sites in real-time	Convolutional Neural Network
[12]	Identify construction safety hazards	Case-Based Reasoning

3 A Brief Overview of the Previous Study

The study conducted by Ayhan & Tokdemir [3] aimed at predicting the severity of safety incidents that occur on construction projects. The prediction outcomes subsume six levels of severity including, from low to high: (1) Level 1: At risk behavior/near miss; (2) Level 2: Accident with material damage; (3) Level 3: Accident with first aid; (4) Level 4: Partial failure/accident with medical intervention; (5) Level 5: Lost workday cases; and (6) Level 6: Fatalities. The dataset used by Ayhan & Tokdemir [3] covers 5,224 cases of actual incidents that occurred on megaprojects in the Euro-Asia region. The data provides information on the severity level of each incident and a corresponding list of 60 attributes classified into nine categories, subsuming the time of the day, age, experience, occupation, activities, hazardous cases, risky behaviours, human factors, and workplace factors. The time of the day is binned into eight 3-hour intervals starting from 6:00 a.m., age is binned into four categories (18–25 years, 25–35 years, 35–45 years, and 45–65 years), experience is binned into six categories (1 month, 1–3 months, 3–6 months, 6–12 months, 12–24 months, and 24 months), and occupation could be any of seven specified positions including administrative affairs, construction equipment operator, repairman, rough work crew, finishing work crew, mechanical assembly crew, engineer or, otherwise,

labelled as others. Meanwhile, the attributes belonging to the remaining categories are modelled as binary variables that take the value of “1” if the factor is found in the incident case and “0” if not.

To address the issue of the high level of heterogeneity found in the collected dataset, the authors clustered the data using Latent Class Clustering Analysis (LCCA). The authors used Artificial Neural Networks (ANN) and Case-Based Reasoning (CBR) to predict the severity of the outcome of an incident.

4 Methodology

RapidMiner software was employed in this study to train and test the machine learning models. Figure 1 depicts a sample of the machine learning process built using RapidMiner software, and the steps followed to design the process are described in the following subsections.

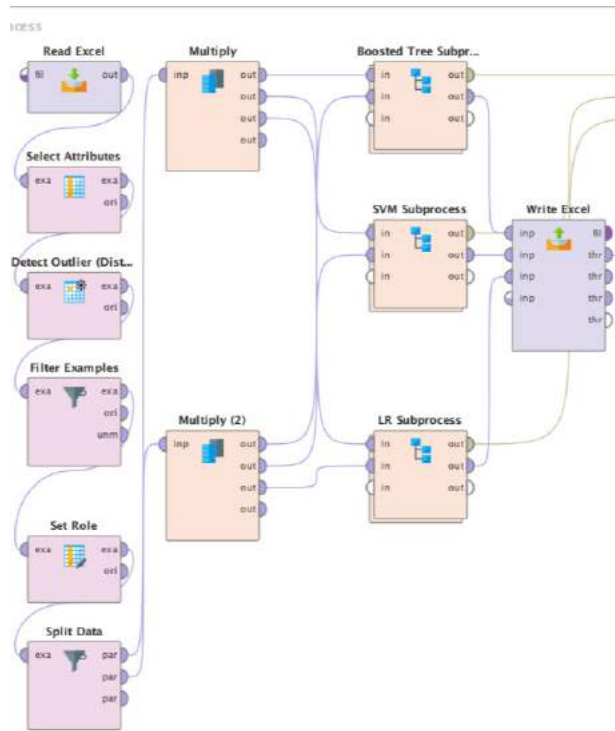

Figure 1. Machine learning process

4.1 Data Pre-processing & Exploration

4.1.1 Type of Prediction Problem

The type of class to be predicted (i.e., incident severity) is nominal, as it only assumes the value of one of the six severity levels in the provided dataset. However, the numbers corresponding to these levels

(i.e., 1 to 6) are ordinal, since the severity of an incident is higher for higher levels. In reality, data on safety incidents could be considered continuous since the data could fall between the specified categories. For instance, an incident that results in a minor injury (e.g., a scratch) that does not necessitate first aid is less severe than Level 2 incidents but more severe than incidents that only involve material damage. As such, a decimal number falling between any two levels is helpful in terms of accurately representing reality. Hence, one set of machine learning algorithms were trained to estimate a numerical value of the severity level, and another set was trained to classify the outcome of the incidents. However, it should be noted that, in the interest of simplicity, the difference between the severity levels is assumed to be linear. In the study by Ayhan & Tokdemir [3], the class was treated as a numerical value where the severity level was estimated as a decimal number.

4.1.2 Data Cleansing

The dataset considered in this study was tidy and did not require significant cleansing. The data was evaluated to identify any missing attribute values. Only the experience attribute had missing values, and in only four of the 5,224 cases. Given the small proportion of missing values, these instances were simply excluded from the dataset. No additional errors or duplicates were identified.

4.1.3 Data Preparation

Typically, data is aggregated based on specific attributes in order to absorb variability and increase accuracy. As the age, experience, and time of day attributes have been already divided into bins, no further processing was deemed necessary at this stage.

It is integral to detect outliers in the data and remove them in order to minimize noise and, consequently, improve the accuracy of the prediction models. The process of removing outliers was undertaken in an iterative manner to avoid any detrimental effect on the performance of the prediction models as a result of removing core points. Density-based outlier detection was undertaken using Euclidean distances and ten neighbours. In this method, it should be noted, the neighbourhood of each datapoint is checked for the existence of ten neighbour datapoints. Accordingly, a point is considered an outlier if its neighbourhood does not contain enough datapoints. The number of outliers to be identified was initially set to ten points only. Then, this number was iteratively modified to maximize the accuracy of the prediction models. Two hundred outliers were ultimately identified and removed from the dataset.

It is critical to note that the data was highly imbalanced, meaning that some classes had a

significantly higher frequency than others. As shown in Figure 2, Level 3 severity had 3,070 observations, as compared to only four observations in the case of Level 6 severity. Such an imbalance in the dataset could result in building inaccurate models that exhibit satisfactory performance even when tested on a portion of the data that was not part of the training data. This is due to the fact that, if the model predicts that all the instances in the testing dataset belong to Level 3 class, its accuracy would still be high since the majority of the instances are of Level 3. The problem of imbalance is typically addressed by under-sampling or over-sampling the dataset [13]. Oversampling refers to the practice of duplicating instances from the minority classes to increase their cardinality, while under-sampling consists of taking subsets of the majority classes in order to reduce their frequency relative to that of the minority classes [13]. These techniques translate into replicating instances in Level 1, Level 2, Level 5, and Level 6 classes or taking subsets of Level 3 and Level 4 classes. Both of these strategies were tested when building the models.

Figure 2. Class frequency

4.2 Machine Learning Models

4.2.1 Model Selection and Description

A trial-and-error approach was adopted to select the machine learning models exhibiting the best performance in predicting the severity level of incidents. The models selected for the numerical estimation of the severity level were Support Vector Machine (SVM), Linear Regression (LR), and Gradient Boosted Trees (GBT). For predicting the severity level as a nominal class, K-Nearest Neighbour (KNN), GBT, Random Forest (RF), and Generalized Linear Model (GLM) were selected.

A brief description of the selected models is summarized in Table 2 below.

Table 2. Description of models [14]

Model	Description
SVM	SVM is a non-probabilistic binary linear classifier that takes input data and forecasts which of two possible classes contains the input.
LR	LR models the relationship between a scalar variable and one or more explanatory variables by fitting a linear equation to the labelled training data.
GBT	GBT is an ensemble of classification tree models or regression models. It predicts classes through estimations that are gradually improved.
KNN	KNN compares a new example with k examples from the training dataset that are the nearest neighbours to the new example.
RF	RF is an ensemble of random trees. When given new examples, each random tree predicts the label of the input by following the corresponding branches. Class predictions are based on the majority of the trees' predictions, while estimations are the average of the trees' predictions.
GLM	GLM is a generalization of the traditional regression model that allows for the use of variables that are not normally distributed.

4.2.2 Models' Development and Validation

It is important to set aside a portion of the data to be used for testing purposes once the models have been trained. This helps mitigate the risk of overfitting, which is more likely to occur if the machine learning model is trained and tested using the same dataset. In specific, overfitting occurs when the model captures the noise in the training dataset and, consequently, fails to accurately predict new data [15]. Hence, the models were trained using 80% of the dataset, and their performance was evaluated using the performance measures explained in Section 4.2.3. The parameters of each model were continuously tuned to optimize their performance. Finally, the models were tested and validated using the remaining 20% of the dataset.

4.2.3 Models' Performance Evaluation

Ten-fold cross validation was used to train and evaluate the selected models. For the numerical estimation models, the mean absolute percentage error (MAPE) (1) and the root mean squared error (RMSE) (2) were used to evaluate performance.

$$MAPE = \frac{1}{n} \sum_{t=1}^n \left| \frac{A_t - F_t}{A_t} \right| \times 100 \quad (1)$$

$$RMSE = \sqrt{\frac{\sum_{t=1}^n (F_t - A_t)^2}{n}} \quad (2)$$

where A_t is the actual instance, F_t is the predicted instance, and n is the total number of instances. As for the class prediction models, classification error (3) and accuracy (4) were used to evaluate their performance.

$$E = \frac{f}{n} \times 100 \quad (3)$$

$$\% \text{ Accuracy} = \frac{TP + TN}{TP + TN + FP + FN} \times 100 \quad (4)$$

where f is the number of incorrectly classified classes, TP is the number of true positives, TN is the number of true negatives, FP is the number of false positives, and FN is the number of false negatives.

Recall (5) and precision (6) metrics were also computed in order to provide more context for understanding the accuracy evaluation metric. Computing recall values, it should be noted, addresses the following question: among the safety incidents that will actually occur, how many are we able to predict using our models? The recall measure is significant for the purpose of this study, as failing to anticipate incidents could result in financial and/or human losses. As for the precision metric, it answers the following question: among the incidents that are predicted to occur, how many will actually occur? When incidents are expected to occur, mitigation measures are undertaken accordingly to minimize the risk of occurrence. This translates into additional project costs associated with the safety measures. Therefore, the recall metric is deemed more critical than the precision metric in the context of this study, as it could be related to human losses.

$$\% \text{ Recall} = \frac{TP}{TP + FN} \times 100 \quad (5)$$

$$\% \text{ Precision} = \frac{TP}{TP + FP} \times 100 \quad (6)$$

5 Results and Discussion

5.1 Imbalanced Data Problem

The results of both techniques employed for addressing the problem of data imbalance (i.e., under-sampling and over-sampling) were found to be unsatisfactory. This was mainly due to the significant gap between the frequencies of different classes. Under-sampling resulted in poor performance of the models, largely attributable to the fact that the size of the dataset had to be significantly reduced in order to achieve balance, and thus it was not of a sufficient size to both train and test the models. On the contrary, over-

sampling served to increase considerably the accuracy of the models. However, this accuracy is misleading, as it was largely the result of the testing data having contained instances of data points that were used in both testing and training of the models as a result of making duplicates. Over-sampling in the case of this dataset introduced the problem of overfitting. In light of this, the dataset was left as is, and the models were evaluated against each other to assess their overall performance and select the most optimal ones.

5.2 Performance Evaluation Results

The values of evaluation metrics computed for the different models are summarized in Table 3.

Table 3. Evaluation results

Numerical Estimation		
Model	MAPE	RMSE
SVM	18.29% +/- 2.68%	0.850 +/- 0.051
LR	20.83% +/- 2.31%	0.738 +/- 0.044
GBT	20.01% +/- 1.04%	0.732 +/- 0.029
Class Prediction		
Model	Classification Error	Accuracy
GBT	37.16% +/- 2.26%	62.84% +/- 2.26%
KNN	37.48 % +/- 1.65%	62.52% +/- 1.65%
RF	39.35% +/- 0.43%	60.65% +/- 0.43%
GLM	37.61% +/- 1.58%	62.39% +/- 1.58%

For the numerical estimation models, SVM was found to have the lowest MAPE and GBT the lowest RMSE, while LR exhibited poorer performance. As for the class prediction models, the classification error and the accuracy values for GBT, KNN, and GLM were found to be relatively close, while RF had higher error and lower accuracy. Moreover, the value of recall and precision metrics were found to be acceptable for all the models, the one exception being the RF model, in which the value of class' recall was 99.75% for Level 3 and 0.28% for Level 4, as the model predicted that most of the instances belong to class Level 3. This means that the RF model failed to predict Level 4 incidents, which include those necessitating medical intervention. Such values of the recall metric confirm the criticality of verifying the credibility of some performance evaluation measures (i.e., the accuracy metric in this case) to avoid misleading results. If the accuracy value was solely used to judge the performance of the algorithms, the RF model's performance would not have been considered significantly inferior to that of others'.

Therefore, the LR and RF models were excluded at

this stage, and the final selection among the remaining models was based on the validation results as explained in the following section.

5.3 Validation Results

In conducting the validation, the trained models did not yield promising results, as the error reached 37.15%. However, similar results were recorded for all the models, mainly attributable to the low quality of the training dataset.

The validation results were used to select the best-performing models. As shown in Table 4, for the class prediction models, KNN was found to perform better than GBT and GLM, with a classification error of 35.16% and an accuracy of 64.84%. As for the numerical estimation models, the notion of an optimal model is contingent on the choice of the performance evaluation measure. In other words, SVM is the better option if MAPE is used for identifying the best model, while GBT is considered a better choice if RMSE is used. For the purpose of comparison with the previous study, MAPE was chosen as the decision-making criterion, and SVM was correspondingly selected.

Table 4. Validation results

Model	RMSE
SVM	0.844 \pm 0.000
GBT	0.710 \pm 0.000
Model	Accuracy
GBT	62.85%
KNN	64.84%
GLM	63.65%

5.4 Additional Assessment of the Models

A satisfactory value of MAPE computed for the whole dataset does not guarantee good performance of the models. This is especially critical given the high degree of imbalance found in the dataset. Hence, MAPE was also computed for each class separately to ensure that the large number of Level 3 instances is not skewing the results. This was done for both SVM and KNN; the results are plotted in Figure 3.

Figure 3. Validation results

The results show comparable performance for the two models. The error, however, was found to be significant for Level 1 predictions (170.59% for SVM and 185.42% for KNN), while that of the Level 3 predictions was found to be very low (0.04% for SVM and 2.48% for KNN). Meanwhile, the error was found to be reasonably acceptable for the other classes. It should be noted that the testing dataset did not include any Level 6 incidents resulting in null values for the Level 6 class prediction performance measures.

As anticipated, the reasonably acceptable performance of the models is a result of the misleadingly low error value obtained in predicting the Level 3 class instances. Given the high degree of imbalance in the dataset, it stands to reason that predicting that any new instance belongs to Level 3 class would give relatively acceptable results as compared to those obtained using the selected algorithms. In fact, the performance of the selected models was only slightly better than that of the Zero Rule classifier, as shown in Figure 4. Hence, the results obtained were deemed to be unsatisfactory. In other words, although the overall error of these models was found to be acceptable, this was due to imbalance skewing the Level 3 class predictions towards zero. As such, the developed models are not generally recommended for use, as they are not capable of reliably generalizing new datasets, given the low quality of the dataset used for training.

Figure 4. Zero Rule classifier performance results

6 Comparison

The error pattern found in the data predicted using SVM and KNN models matched that corresponding to the ANN and CBR models developed by Ayhan & Tokdemir [3], as shown in Table 5. The same issue identified in the SVM and KNN predictions was observed in the results generated by their models: the MAPE values were very high in the case of the Level 1 prediction, very low for Level 3 prediction, and relatively acceptable for the other classes. However, the variation between the MAPE values for different classes was found to be smaller in the case of CBR and ANN. This is presumably a result of the clustering analysis performed by Ayhan & Tokdemir [3]. Nevertheless, the lowest overall MAPE achieved amounted to 17.41% for CBR—close to the overall MAPE of 18.8% achieved using SVM in this study.

Table 5. Summary of MAPE values

	Previous Study	
	ANN	CBR
Lowest MAPE (found for Level 3 predictions)	7.95%	≈ 5%
Highest MAPE (found for Level 1 predictions)	225.35%	≈ 215%
	Current Study	
	SVM	KNN
Lowest MAPE (found for Level 3 predictions)	0.04%	2.48%
Highest MAPE (found for Level 1 predictions)	170.59%	185.42%

It can be concluded that the clustering analysis performed by Ayhan & Tokdemir [3] did not play a significant role in improving the quality of the dataset

and reducing its heterogeneity. Despite the significant effort on the part of Ayhan & Tokdemir [3] to improve the dataset, the results were close to those obtained in the present study in which minor data preparation was performed prior to the models' development. Accordingly, the available dataset is considered insufficient to train machine learning algorithms for predicting the severity level of safety incidents on construction projects.

7 Conclusion

The SVM and KNN prediction models exhibited the highest performance among the various machine learning algorithms for predicting the severity level of safety incidents on construction projects. Nevertheless, although both algorithms yielded acceptable overall values of performance evaluation metrics (an overall MAPE of 18.78% for SVM and an accuracy of 64.84% for KNN), these values were not representative of the actual performance of the models. This was confirmed by computing the MAPE separately for each class, resulting in a value of 185.42% for KNN prediction of Level 1 class as compared to 2.48% for KNN prediction of Level 3 class. The high variation in MAPE values between the different classes is attributable to the high degree of imbalance found in the dataset (i.e., approximately 59% of its instances belong to the Level 3 class).

The results of this study reinforce the following points:

- The perception of the performance of machine learning algorithms could be highly biased depending on the metrics used for performance evaluation. For instance, if the final selection in this study had been solely based on the overall errors computed for validation purposes, the performance of the algorithms would have been considered relatively acceptable, whereas the actual results were unfavourable. A combination of different performance measures and validation techniques should be utilized to ensure that an unbiased decision is made.
- The quality of the training dataset could diminish the value of deploying advanced machine learning algorithms and make the use of simpler classifiers, such as the Zero Rule classifier, more desirable.
- When the quality of the dataset is questionable, it is critical to perform multiple levels of performance evaluation to confirm the credibility of the evaluation results.

E-mail: songbo.hu@monash.edu; yihai.fang@monash.edu; robert.moehler@monash.edu

Abstract -

Tower cranes play an essential role in the execution of most construction projects. Unfortunately, they are also a major source of fatalities and injuries in the industry, owing to their great mass and large footprint on the site. Aiming to proactively identify and mitigate safety hazards in the design and planning stage, Prevention through Design (PtD) has been proven effective in various construction scenarios. The advent of Building Information Modeling (BIM) further strengthens the power of PtD by providing early access to comprehensive and accurate project data. This study proposes a conceptual framework aiming to automatically identify and quantitatively estimate the exposure of hazards associated with the operation of tower cranes. A literature review on crane lift safety is first carried out to identify major hazards related to tower cranes. Based on the results from path planning algorithms, a quantitative approach is presented to estimate hazard exposure during the operation of tower cranes in any given period during the construction. Thirdly, BIM entities and attributes necessary to describe tower-crane-related hazards are defined. Lastly, an application scenario is discussed to demonstrate the potentials of the proposed method. Findings in this study are expected to expand the application of PtD in more dynamic and complex construction scenarios and facilitate its integration with emerging automation and information technologies.

Tower crane; lift safety; hazard exposure; path planning

1 Introduction

Tower cranes are one of the most valuable and indispensable material handling equipment on construction sites [1]. Yet, it is also among the major contributors to construction accidents, very likely leading to disastrous consequences [2]. As estimated by Neitzel et al., up to one-third of the fatalities in the construction

industry are associated with cranes (including both mobile cranes and tower cranes) [3]. Particularly, accidents related to tower cranes are inherently more difficult to recognize and mitigate due to busy and congested construction activities taking place within the extensive workspace of tower cranes [4].

An accident could be postulated as an abnormal exchange of energy exceeding the human body's resistance [5]. Based on the "epidemiological triangle", stopping any of the connections between energy, victim and the environment would prevent accidents [6]. In the context of crane safety, abundant research works have attempted to separate the energy output to the victims in time or space. For example, various safety management systems have been developed using cutting-edge localization and sensing technologies to monitor the movements of cranes and prevent consequential spatial conflicts with other onsite workers and objects in real-time. However, not all hazards can be detected in time and it's often very costly and sometimes impossible to mitigate such hazards on the spot. In fact, a large amount of safety hazards could be addressed through appropriate design, planning and organization of construction sites and activities in the pre-construction phase (Albert et al. 2014). This safety management philosophy is also known as the Prevention through Design (PtD) [7].

This study proposes a method to quantitatively estimate the hazard exposure in tower crane operations in the construction planning phase using path planning algorithms and BIM. Towards this goal, a conceptual framework is formulated by (1) classifying and characterizing hazards related to tower cranes via literature review; (2) integrating a novel path planning algorithm; (3) proposing a quantitative approach to estimate the hazard exposure based on algorithm-planned paths; and (4) describing necessary BIM entities and attributes to facilitate the automatic generation, storage and visualization of the hazard exposure.

2 Related work

Analyzing energy sources is a crucial method to recognize hazards on the construction site. Recent studies systematically summarized ten energy sources to identify

hazards before construction works begin, including gravity, motion, mechanical, pressure, temperature, chemical, radiation, and sound [8]. Thus, this section further delineates the tower crane hazards in previous literature and categorizes them according to their energy sources. This categorization then provides a unified framework to discuss the efforts that parameterize, assess and control different categories of hazards so that the method for estimating hazard exposure can be developed.

2.1 Hazards related to tower cranes

Recognizing hazards related to cranes is a valuable yet challenging research task that has been intensively investigated for decades. Many researchers adopted an empirical method that studies accident reports statistically and establishes taxonomy to provide insights into the extent, nature, and patterns of these crane accidents. As one of the earliest empirical studies, Shepherd et al. explored the forms of damaging energy and organized 525 crane fatalities between 1985-1995 into three categories: electrical energy, gravitational energy, and machine energy (i.e., motion and mechanical energy) [9]. This energy-based taxonomy proved to be effective and invaluable to describe large quantities of fatality data; however, this study was conducted before the widespread use of modern safety-assistant technologies and fatality data only were analyzed.

More recently, Beaver et al. analyzed 125 fatalities between 1997-2003 and proposed seven proximate causes (i.e., struck by load, electrocution, crushed during assembly/disassembly, failure of boom/cable, crane tip over, struck by cab/counterweight, and falls) and specified the physical contributing factors for each proximate cause (e.g., rigging failure and unbalanced load) [10]. Meanwhile, researchers have investigated not only the fatalities but damages and near-misses, so that a wider spectrum of accident types is recognized. For example, Milazzo et al. investigated 937 mobile crane and tower crane incidents between 2011 to 2015 and categorized them into twelve types [11]. It is worth mentioning that Milazzo et al.'s work has two unique incident types, namely "man struck by boom/load and fall" and "fire explosion". The former indicates that, in the context of cranes, the "fall-from-height" hazard is related to crane motion energy, while the latter suggested the existence of chemical energy as a hazard for both mobile cranes and tower cranes. Focusing on tower cranes, Tam and Fung summarized four major types of accidents based on accident statistics between 1998 to 2005 in Hong Kong, including fall-from-height, struck with/by moving objects, struck by falling objects, and trapped by collapsed objects [12]. Raviv et al. [2] thoroughly discussed the differences between mobile cranes and tower cranes and constructed a more detailed taxonomy of tower crane accidents, which further added

load drops, part of load fell, electrocution, collision between cranes, collapse of cranes, fall of crane parts, crane tip over, loss of load control, load caught in static point, falls of element affected by load on top of Tam and Fung's taxonomy.

Since every empirical study applies to a group of accident reports only, it is necessary to combine different perspectives to understand the pattern of tower crane accidents. As a result, the authors organized the tower-crane-related hazards into an energy-based classification framework (see Table 1). It is worth noting that the proposed classification is subjected to the proximate causes or physical causes at the construction site level. Thus, managerial and behavioral factors are not included, neither are numerous research efforts that establish their causation models upon ergonomics, organizational, and regulatory analysis.

2.2 Efforts to quantify hazards

Targeting at tower-crane-related hazards, researchers have made unremitting efforts to reduce their likelihood of occurrence during lifting operations. Two strategies have been widely adopted: (1) eliminating collisions of the crane and loads with static obstacles (corresponding to H1.2, H1.3, H2.3) and (2) estimating hazard exposure for dynamic victims to the dropping crane parts and loads (corresponding to H3.1, H3.2, H3.3, H3.4). The first strategy is enabled by path planning algorithms that automatically generate a collision-free path from the supply point to the demand point [13], while the other strategy quantifies hazard exposure via spatial-temporal analysis of the crane location or lifting movements. For example, multiple quantitative hazard assessment models have been proposed for site layout planning, which focused on the estimation of gravitational hazard exposure of tower cranes. El-Rayes and Khalafallah proposed a piecewise-defined function to derive the risk of falling objects hazard (i.e., H3.1 and H3.2) and crane collapse hazard (i.e., H3.3 and H3.4) based on tower crane location, operating angles, and crane dimensions [14]. This function also takes the sensitivity of other facilities into account to minimize the safety impact aroused by tower crane operations. Similarly, Abunemeh et al. analyzed the safety impact among site facilities and assumed that the likelihood of falling object hazards linearly decays with the distance to the tower crane [15]. The same linear model was adopted by Ning et al. [16] but the model neglected the hazard types and crane specifications compared with El-Rayes & Khalafallah's model. These studies evaluate the hazards for the entire construction phase, which has a low granularity in terms of temporal analysis.

A more thorough model combines spatial analysis with schedule information to predict the likelihood of hazards [17]. The time granularity is single lifting

activities, based on which the method assesses load dropping hazards at the supply area, demand area and

Table 1. An energy-based taxonomy for hazards related to tower crane

Energy sources	Hazards	References
(1) Electricity	H1.1: Direct human contact with powerlines*	[9]
	H1.2: Human contacts with powerlines through load handling	[9] [11]
	H1.3: Human contacts with powerlines through crane parts	[9][10] [11]

* hazards not occurring during crane operations are not addressed by the proposed method in this study.

intermediate area, respectively, to reflect the characteristic of the lifting activities. By integrating hazard exposure assessment with monitoring technologies, Luo et al. created a real-time approach for hazard exposure quantification [18]. This approach considers the geometry of the hazard source (i.e., point hazard, line hazard and area hazard) and assumes that the likelihood of occurrence is proportional to the reciprocal square of the distance. More importantly, it breaks down a lifting activity as multiple coordinates along the lift path to increase the time granularity of the path information. However, both methods have limitations: Sacks et al. presented an unrealistic assumption that the loads are lifted along a straight line [17], while Luo et al. did not support proactive assessment of hazard exposure in the planning stage. Furthermore, although these methods provide insights into hazard assessment of tower crane operations, none of them comprehensively assesses all tower-crane-related hazards. More specifically, these models merely identified and quantified gravitational hazards without discussing the motion and electrical hazards. Thirdly, although hazards exist in a 3D space [19], the level of hazard exposure was mainly reflected on a 2D map in previous studies.

3 Research Method

To estimate hazard exposure in tower crane operations, the proposed method first utilizes a novel path planning algorithm (PSRRT*) that is able to find a short and collision-free path from the supply point to the demand point [20]. Paths planned by this algorithm are guaranteed to avoid collision between the crane-load system and static obstacles (i.e., H1.2, H2.3). Based on the algorithm-planned paths, a generic hazard-exposure estimation algorithm is introduced to identify and quantify five major types of operational hazards, including electrical hazards (i.e., H1.3), motion hazards (i.e., H2.1, H2.2), gravitational hazards associated with loads (i.e., H3.1), failure of boom and other crane parts (i.e., H3.2, H3.3), and crane tip-over (i.e., H3.4). Other hazards that are not directly related to crane operations (i.e., H1.1, H1.4, H3.5, H3.6 and H4.1) or involve coordination of multiple cranes (i.e., H2.4) are out of the scope in this study, since the primary objective of which is analyzing the safety impact of tower crane operations to the workers and plants on construction sites. Later, the hazard exposure estimated by the generic estimation algorithm is stored and visualized on a BIM platform.

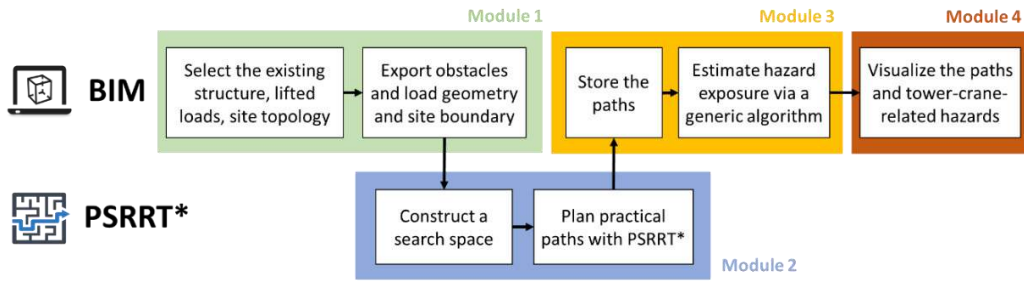

Figure 1. Research framework of the proposed method

Table 2. Equation to calculate the HE for different types of hazards

For a specific location (x_0, y_0, z_0), the hazard exposure (HE) is $HE(x_0, y_0, z_0) = \sum_{i=1}^5 (W_i \times P_i \times E_i)$					
No.	Hazard type	W_i	P_i	E_i	
1	Electrical hazards	P_m	$P_{e-high} = 1 \quad (d < D_{e1})$	$E_e = E_{e0}$ where, E_{e0} is a constant energy defined by the user	
			$P_{e-medium} = \frac{D_{e2}-d}{D_{e2}-D_{e1}} \quad (D_{e1} < d < D_{e2})$		
2	Motion hazards	1	$P_{m-high} = 1 \quad (d < D_{m1})$	$E_m = \frac{1}{2} m_l v ^2$ where, m_l is the mass of the load, $ v $ is the lifting speed	
			$P_{m-medium} = \frac{D_{m2}-d}{D_{m2}-D_{m1}} \quad (D_{m1} < d < D_{m2})$		
3	Gravitational hazards (falling load)	W_3	$P_{g-high} = 1 \quad (d < D_{g1})$	$E_g = m_l \times g \times (h_l - z_0)$ where, g is gravitational field; h_l is the height of the geometry center of load to the ground;	
			$P_{g-medium} = \frac{D_{g2}-d}{D_{g2}-D_{g1}} \quad (D_{g1} < d < D_{g2})$		
4	Failure of boom	$0.1 W_3$	$P_{g-boom\ failure} = 1 \quad (d < L_c)$ Where H_c is the height of the crane;	$E_{fb} = m_b \times g \times H_c$ where, m_b is the mass of the boom or other falling parts; H_c is the height of the crane;	
5	Crane tip-over	$0.1 W_3$	$P_{g-tipover} = 1 \quad (d < H_c)$	$E_{ct} = \frac{1}{2} (m_t \times g \times H_c)$ where, m_t is the mass of the tower crane;	

BIM is known as a shared resource of information about a site facility, which enables the automatic identification of hazards such as fall-from-height [19] and crane collisions [21]. In the proposed method, BIM serves as a 4D spatial-temporal analysis platform that provides up-to-date information to the path planning algorithm and stores and visualizes essential hazard information (e.g., type, location, and exposure strength). The conceptual framework of the proposed method is illustrated in Figure 1. As the first two modules have been introduced by the authors in [20], the rest of this section introduces the hazard-exposure estimation algorithm (module 3) and discusses how to store and visualize the hazard information on BIM (module 4).

3.1 Estimate hazard exposure based on algorithm-planned path (module 3)

The extent of hazard exposure (HE) describes the extent of risk at a certain location on construction sites, which is the accumulation of all hazards present at that location. The risk for each hazard equals the product of the likelihood of occurrence and the severity. The likelihood of occurrence is described by two variables: W_i describes the occurrence likelihood of different

hazard types using a 0 to 1 scale, and P_i describes the function of the distance to the energy source (d) for each hazard type. W_i could be empirically derived from past accident reports and statistics. P_i has been modeled in various ways and this study adopts the linear model in [16] to describe the decay of hazards. Moreover, this paper measures the electrical, kinematic and potential energy (E_i) to describe the severity to be consistent with the energy-based hazard classification. The equations to calculate W_i , P_i , and E_i are summarized in Table 2, which are established upon several assumptions: 1) the effect of strong wind are ignored so that the potential and kinematic energy could be directly derived from the elevation, mass and the lifting speed; 2) the load is lifted at a constant speed $|v|$; 3) for load dropping, crane parts falling, and crane tip-over processes, the energy consumed by fractures or structure deformation is conservatively neglected; and 4) the center of mass for lifted loads coincides with the geometry center and the center of mass for the tower crane locates at the middle of the crane mast.

In the equations, W_i has been assigned as different values to represent the likelihood of occurrence within the hazardous zone. For example, 1 means the hazard

Figure 2. Hazardous zones for electrical hazards (left) and motion hazards (right)

Figure 3. Hazardous zones for gravitational hazards associated to the lifted load (falling load)

certainly happens when the worker enters a hazardous zone (e.g., motion hazards), and other values indicate that corresponding hazards will not always happen (e.g., failure of the boom). Electrical hazards, in particular, happen when: (1) the load or cable contacts the powerlines and (2) workers enter close proximity to the crane mast. Thus, W_1 denotes the likelihood of powerline contact, which equals P_m . Furthermore, W_3 is a constant representing the likelihood of falling load, which is 10 times the likelihood of boom failure and crane tip-over

[14]. P_i describes a hazardous zone as a high-risk zone, where the hazard is certainly happening, and the medium risk zone, where the hazard is likely to happen and the likelihood linearly decays due to uncontrolled load sway. The upper limits for high/medium risk hazardous zones are denoted as D_{e1} , D_{e2} , D_{m1} , D_{m2} , D_{g1} , D_{g2} and illustrated in Figures 2 and 3, respectively. The hazardous zones for crane boom failure and crane tip-over are modeled by two columns with the radius of crane length and crane height, respectively, within which the hazard

exists in a uniform pattern. The height of two columns is 3 meters, considering the height clearance of worker and plant workspaces. Although these equations are designed for a T-structure tower crane, they can be easily extended to other types (e.g., luffing cranes) by re-configuring some parameters. For example, the length of the crane boom (L) can be replaced by the lifting radius to incorporate luffing cranes.

3.2 Store and visualize hazard exposure on BIM platform (module 4)

BIM-enabled visualization has a great potential of facilitating the communication of crane-related risks [22]. Thus, the next step in the proposed method is to transform the results of the hazard exposure algorithm to a data format that can be stored and visualized in BIM. Through this transformation, the spatial relationship among of building, site layout, and hazards are specified and the distribution of hazards for one or multiple crane lifts can be graphically presented (e.g., heatmaps). Several rules are set for integrating building/site information and hazard information. Firstly, the hazard exposure for a certain location is stored in a voxel entity on the BIM platform. Such entity has 5 attributes to describe the location, size, hazard types, quantified hazard exposure (HS), and ID of the lift operation(s) that causes these hazards. Secondly, voxelization employs a midpoint algorithm to determine whether a voxel entity is within a certain hazardous zone. Thirdly, the lift path is segmented into 1-meter intervals for estimating the hazards exposure. Fourthly, the tower-crane-related hazards only influence workers on the ground, on the top surfaces of the building, and within 2-meter proximity of sidewalls of the building in progress, while electrical hazards and gravitational hazards are visualized up to 3 meters above working surfaces (i.e., the top surface of buildings or the ground). Implementation of this module presents in future works with a real-world case study.

4 Discussion

The proposed method embraces the PtD concept by leveraging the crane path planning algorithm and BIM for 4D spatial-temporal estimation of hazard exposure. The most obvious application scenario is to generate a hazard heatmap for a particular lift path to highlight areas subject to substantial lift safety risks so that they can be mitigated ahead of time. By superimposing hazard exposures for multiple lifting operations, a hazard heatmap for an extended period (e.g., one day or one week) can be generated to indicate potential needs of improving resource allocation (e.g., installing safety barriers), changing lift sequence, rescheduling works with excessive hazard exposure, or relocating site

facilities. Apart from the visualization that supports communications and decision-making, the proposed method is expected to collaborate with planning and optimization algorithms (e.g., location planning algorithm and scheduling optimization algorithms) to allow a fully automated lift planning workflow.

5 Conclusion

Complex construction scenarios present enormous challenges to traditional methods for assessing tower-crane-related hazard exposure. They are typically based on 2D layout plans and make over-simplified assumptions on the lift paths. To precisely and comprehensively identify and quantify the tower-crane-related hazards, this study proposes a novel method to estimate the exposure of electrical, motion and gravitational hazards in 3D construction spaces, through the integration of path planning algorithm and BIM. This study contributes to the knowledge body by (1) comprehensively analyzing the tower-crane-related hazards through an energy-based taxonomy, (2) proposing an exposure estimation algorithm for major hazards by analyzing the algorithm-planned lift paths, and (3) specifying the BIM data format to store and visualize the hazard to enable effective and efficient hazard management. Future work will be directed to: (1) specifying the BIM data schema required to facilitate automatic path planning and hazard estimation processes, (2) implementing the hazard exposure estimation method on BIM models of complex building projects, and (3) proposing an automated workflow to manage hazards by optimizing lift sequence, scheduling, and site layout based on the quantified hazard exposure.

Abstract

Construction workers are required to wear a safety harness while working at height, and safety managers need to ensure that a safety hook is attached to proper anchorage points to prevent falls from height. However, it is difficult for the managers to monitor all the worker's hook attachments continuously and remotely in dynamic workplace environments. This study developed an approach to detect an individual worker's hook attachments by assessing the relative movements between the hook and the worker's body. An Inertial Measurement Unit sensor was attached to the hook and the body strap to monitor the relative movements. The collected IMU data was transformed into image data by Markov Transition Field. The detection algorithm was developed based on the convolution neural networks that classify the worker's postures, activities, and hook attachments simultaneously, and the developed detection system provided classification accuracies of 86.40%, 86.97%, and 96.58, respectively. The results validated that the relative movement between the hook and the worker's body is a key feature for hook attachment detection.

1 Introduction

Falls from height (FFH) have been identified as a significant source of fatal accidents at construction sites [1]. In order to protect workers from FFH, some prevention measures have been proposed [2]. For example, the use of a safety harness is required while working at height. However, workers could often be reluctant to use a safety harness because of non-compliance and restrictions to movement [3]. Although construction worker education and training are effective ways to address the reluctance, these are not always effective entirely [4,5]. Real-time monitoring and

warning of the improper use of a safety harness would contribute to change workers' safety behaviors. One of the safety manager's tasks is to frequently monitor workers and site conditions to get real-time data through direct observation and interaction with workers [6]. Although a safety manager should identify workers who do not properly use a safety harness in a hazardous zone (e.g., a roof and top floor), it would be a challenge to monitor all the workers who are working at height from the ground level, continuously and remotely.

In recent years, advances in sensing technology and machine learning algorithms have enabled safety managers to monitor the activity and physical status of workers in real-time [7]. Previous studies have applied these technical improvements to develop detection systems for the use of a safety harness. A previous study [8] developed an approach that uses an image classification algorithm to detect whether a worker wears a safety harness. In this study images of workers taken with a monocular camera were used, but the quality of image data is affected by environmental factors (e.g., weather and light) that would degrade the detection performance. In another previous study [9], based on the distance between the hook and the lifeline, it was detected whether the worker attached the safety hook to the lifeline. This approach used Bluetooth Low Energy beacons to measure the distance based on the worker's location. If the distance is less than the threshold, the safety hook is considered to be attached to the lifeline. However, a close distance between the hook and the lifeline does not always guarantee the connection.

In this context, this study aims to develop a novel detection approach for the proper use of a safety harness. The sensing sources of the developed approach were safety hook and worker's bodily movements, measured by wearable Inertial Measurement Unit (IMU) sensors. In this current study, a distinct body movement pattern according to postures and activities and a distinct hook movement pattern according to attachments were assessed. The developed system simultaneously detects the worker's posture, activity, and hook attachment. Therefore, the main contribution of this study is to detect

the proper use of a safety harness while undertaking various construction tasks at the workplace.

2 Background

2.1 Wearable Sensors in Construction Worker Safety

Various sensor technologies have been used to improve the safety of workers on construction sites. For example, Real-Time Locating Systems (RTLS) have been implemented by Radio-Frequency Identification (RFID) and Bluetooth Low Energy (BLE) technologies [10]. These systems consist of a transmitter and several receivers. The transmitter is attached to a worker while transmitting radio signals with an identification number, and the receivers are attached to a moving object, PPE, or located in hazardous areas. RTLS measures the current location of the worker based on the distance between the transmitter and the receiver. One parameter for calculating the distance is the Received Signal Strength Indicator (RSSI), which measures the attenuated power at the receiver. For construction safety management, RTLS has been used to warn workers when entering hazardous zones (e.g., a roof and top floor) or approaching dangerous moving objects (e.g., heavy machines) [11]. RTLS can warn workers of danger even in blind spots because radio signals can penetrate or reflect from some obstacles to reach the receivers in non-line of sight environments [12]. Additionally, the transmitter can be attached to PPE, such as a safety helmet or harness to monitor whether individual workers wear PPE in the workplace [9]. However, since RFID and BLE beacons have a limited coverage area and signal propagation can be affected by environmental factors, the accuracy can decrease as the distance between beacons increases.

Physical response measurement systems have been also implemented to improve worker safety management. IMU sensors have frequently been used to assess workers' physical changes while undertaking construction tasks. A typical IMU sensor consists of an accelerometer and a gyroscope. The IMU sensor is attached to the worker's body part and measures the movement of the body part in three-axis acceleration and angular velocity. Most construction tasks require physical demands without sufficient rest, which can lead to work-related musculoskeletal disorders (WMSDs) [13]. Therefore, measuring a worker's physical response to repetitive and prolonged construction tasks would help prevent overexertion injuries. Measured bodily movements were used to detect awkward postures [14,15], excessive load carrying that produced distinct patterns of bodily movements [16]. Gait kinematics were also measured by IMU sensors to assess exposure to slip, trip, and fall (STF)

hazards that generated abnormal gait patterns [17]. Because IMU-based monitoring systems directly record the worker's bodily movement, their performances are less affected by environmental factors (e.g., light or weather). However, the bodily movements could be different for each worker and may vary depending on the worker's physical status, which may cause performance variations depending on training data.

2.2 Monitoring Use of Safety Harness in Construction

A previous study [8] developed an approach to detect whether workers are wearing their safety harnesses using an image classification algorithm. The developed approach has two phases: (1) worker presence detection and (2) safety harness identification. Although this approach provided 99% and 80% precision performance on phases 1 and 2, respectively, this approach did not detect hook attachments. Even if a worker wears a harness, the worker may not properly use the safety harness. For example, the safety hook would be attached to the worker's body or placed on the ground. Therefore, it is necessary to monitor not only wearing a safety harness but also properly using the safety harness.

Another previous study [9] developed a system detecting the proper use of a safety harness using BLE technologies. This system detected whether the safety hook is attached to the lifeline hook according to the distance between the lifeline hook and the worker who needs to attach the safety hook. Once the worker attaches the safety hook to the lifeline hook, the worker's location would be identical to the lifeline hook. A BLE receiver was attached to the worker's safety hook and a BLE beacon was attached to the lifeline hook. The distance between these BLE devices was calculated based on RSSI. Another BLE beacon was located in the hazardous zone where the worker must attach the safety hook to the lifeline. The third BLE beacon was placed at an interval of 2m, where the working began at height. Due to the limited coverage area of the BLE beacons, a distance between 1 and 2 m was required between beacons. Although this system was validated in a field experiment, this approach had some practical limitations. Multiple BLE beacons are required to cover the space, and those beacons need to be relocated when the working environment changes. Also, the distance-based detection approach would produce false detection if the worker is working near the lifeline without attaching the safety hook to the lifeline.

In this context, this study developed a new detection system for the proper use of a safety harness. This study measured the hook and the bodily movements using IMU sensors attached to the hook and body strap and found that the hook movement is affected by both the worker's bodily movement and hook attachment points (e.g.,

attaching to a rigid structure and the worker's body or placing on the ground). Therefore, the hook attachment can be detected by assessing the relative movements between the worker's body and the safety hook.

3 Methodology

3.1 Data Collection

Five subjects participated in the experiment to collect IMU data of the safety hook and bodily movements while performing different activities: (1) walking, (2) moving bricks, and (3) using a drill machine. While performing the activities, the safety hook was attached at several points: (1) attached to scaffolding, (2) attached to the body strap (chest), and (3) placed on the ground. Also, moving bricks and using a drill machine were performed by two postures: (1) standing and (2) kneeling. Therefore, 18 cases of relative movements between the hook and the body were collected from each subject (2 postures, 3 activities, and 3 attachment points). Figure 1 shows an example of moving bricks while standing with a scaffolding attachment. The subjects performed each activity repeatedly for 3 minutes. They did not change their locations while moving bricks and using a drill machine, but randomly changed locations when walking. While the hook was always attached to the chest for a body strap attachment, the subjects attached the safety hook to various parts of the scaffolding.

During the experiment, an IMU sensor was attached to the safety hook and the body strap (back), indicated by blue circles in Figure 1. The IMU sensors collected

acceleration and angular velocity data along three axes at a 50 Hz sampling rate. Figure 2 shows the IMU data collected while moving bricks by kneeling—(a), (b), and (c)—and standing—(d), (e), and (f). For each hook attachment point, the hook IMU data show a distinct pattern, whereas the back-worn IMU data show a very similar pattern for the same posture. Moreover, different postures generate different patterns of hook IMU data even for an identical hook attachment point, (see Figure 2(b) and (d)). Therefore, the hook IMU data depended on both the attachment point and the bodily movement related to activity and posture.

This study assessed the unique relative movement between the hook and the subject's body to detect hook attachments in various postures and activities.

Figure 1. Moving bricks with a scaffolding attachment

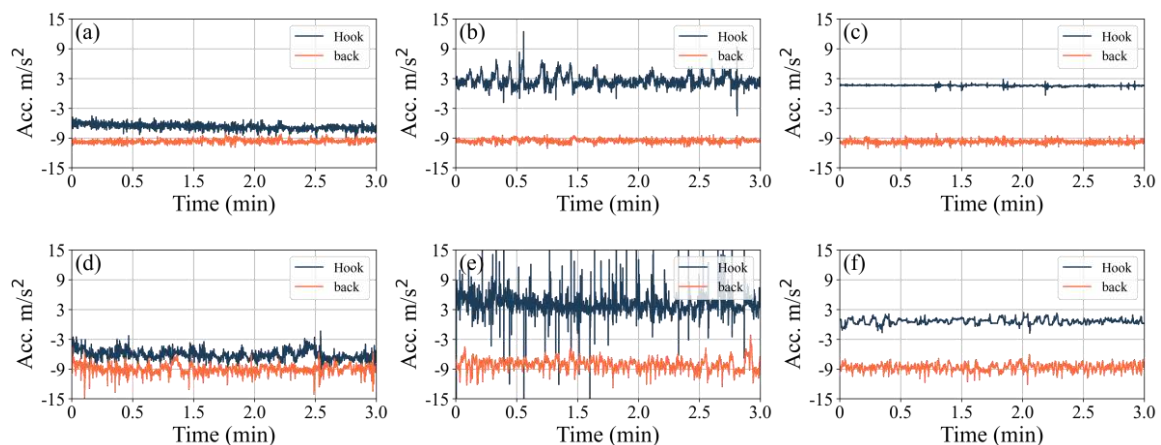

Figure 2. Collected IMU data while moving bricks: (a) kneeling with a scaffolding attachment; (b) kneeling with a body attachment; (c) kneeling with the hook on the ground; (d) standing with a scaffolding attachment; (e) standing with a body attachment; (f) standing with the hook on the ground

3.2 Preprocessing

The collected IMU data were first filtered by a fifth-

order low-pass filter with a 10 Hz cut-off frequency to remove high-frequency noise. The denoised IMU data were sampled by a 3-second moving window with a 2-

second overlap. A previous study has demonstrated that transforming time-series data into image data using Markov Transition Fields and extracting features by Convolutional Neural Networks (CNN) provides more stable and better classification results than raw data [18]. This study also transformed each IMU sample to an MTF that generated a $128 \times 128 \times 6$ tensor for each IMU sample, where 128×128 represents the size of the image data, and 6 represents the number of channels composed of 3-axis acceleration and angular velocity data. Figure 3 shows examples of transformed image data for hook and back-worn IMU data. Both image data were simultaneously used to detect hook attachments.

Figure 3. Transformed image data: (a) hook IMU data and (b) back-worn IMU data

3.3 Model Structure

CNNs were used to build a model to classify postures, activities, and hook attachment points from the transformed image data. Figure 4 shows the model structure consisting of three classifiers, C^1 , C^2 , and C^3 , for the posture, activity, and hook attachment point, respectively. From the input data, four feature extractors, F^1 , F^2 , F^3 , and F^4 extract features for each classifier. F^1 and F^2 extract features from the image data collected from the back and the hook, respectively. The extracted features by F^1 are used to classify the worker's postures by C^1 and the features are also inputted to the next feature extractor, F^3 . The extracted features by F^3 are inputted to C^2 to classify the worker's activity. Each set of features extracted by F^1 and F^2 is concatenated and inputted to F^4 . Also, each set of features extracted by F^2 and F^4 is concatenated and inputted to C^3 . Therefore, the developed model detects the worker's posture, activity, and hook attachment at the same time.

Tables 1 and 2 summarize the model structures of the feature extractors. Since the input data of F^4 is the concatenated features of F^1 and F^2 , the size of the input layer of F^4 is twice that of F^3 . Table 3 shows the model structures of the classifiers. The output shape of the last dense layer means that each classifier classifies three different classes.

During the training, the model is trained to reduce the combined classification loss of C^1 , C^2 , and C^3 , meaning

that better classification accuracies on the posture and activity help to improve the classification of hook attachment points.

4 Results

70% of the total data were randomly selected as the training data (9,345 samples), and the remaining 30% of the total data were used as the testing data (4,005 samples). The developed model was trained for 6,000 epochs in a 10-batch size. The classification results provided 86.40% of posture, 86.97% of activity, and 96.58% of hook attachment accuracies, respectively. While the back-worn IMU data were only used for the posture and activity classifications, the developed approach utilized both hook and back-worn IMU data to classify the hook attachment point. Therefore, the classification accuracy for the hook attachment was higher than that for the posture and activity classifications.

Figure 5 shows the training curves for each classification accuracy. In this study, the approach was designed to reduce overfitting by applying kernel regularization, dropout layers, and batch normalization layers. However, the developed model was slightly overfitted for the posture classification as compared to the activity and hook attachment classifications. One reason for this overfitting issue could be related to the number of features extracted by each feature extractor because too many features may fit the training dataset but fail to be generalized to the test dataset. For the posture classification, the number of features extracted by F^1 was 28,224 while F^3 extracted 6,400 features and F^4 extracted 12,800 features.

The developed approach provided a relatively lower performance on the posture and activity detections than the hook attachment. Figure 6 shows the confusion matrix for each classification result. In the posture classification, the developed model misclassified some cases of kneeling and standing because similar bodily movements could occur between kneeling and standing. For example, while using a drill, subjects often did not bend their backs when both kneeling and standing. Conversely, while moving bricks, the subjects gradually bent their backs as they were being exhausted when both kneeling and standing. In the activity classification, some cases of moving bricks and using a drill machine were misclassified. For each posture, the two different activities were performed by moving arms mainly, which could generate invariant back movements for activity. In this case, similar patterns of the IMU data could be collected from the back, thereby reducing the overall performance of the activity classification.

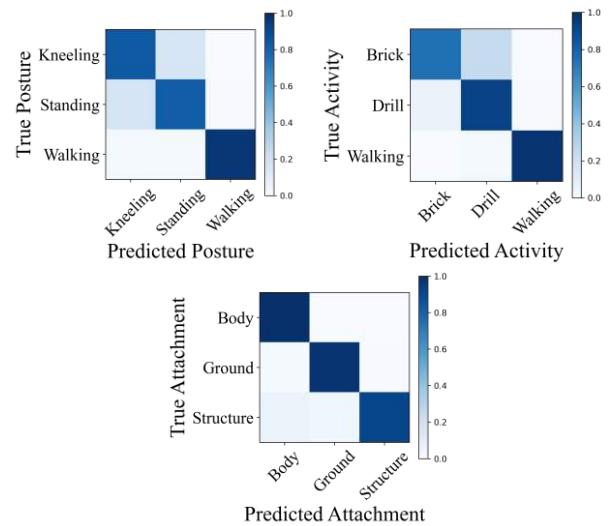

Figure 6. Confusion matrix of classification results

5 Discussion

5.1 Methodological Contribution

The previous study [9] detected the proper use of a safety harness based on the distance between the safety hook and the lifeline. Therefore, the previous approach would identify lifeline attachment whenever the worker is closed to the lifeline regardless of the hook attachment. However, the current study detected the proper use of a safety harness based on the relative movement between the hook and the worker's body. Since this approach directly detects the hook attachment, the developed approach could monitor the proper use of a safety harness wherever they are working.

Additionally, the previous approach would require further development to monitor multiple workers because the distance between the lifeline and the safety hook is

the calculated distance of a pair of BLE beacons. Therefore, if multiple workers are working at height, more BLE beacons are required for each worker. The previous approach would need to detect each worker's pair of beacons and filter the signals receiving from other beacons. However, in this current study, hook attachments were detected based on the IMU data collected from an individual worker's safety harness. Therefore, the developed system is able to monitor the safety hook attachment individually, allowing to monitor multiple workers simultaneously without further methodological improvement.

5.2 Practical Application

The developed system detected hook attachments by utilizing attachable IMU sensors to the existing safety harness. This implementation would make it easy to deploy this detection system to construction sites without additional devices. In addition, a LED bulb can be attached to a safety harness and indicate the status of the hook attachment. This application would empower safety managers to monitor the proper use of the safety harness from a distance without any communication networks.

The developed system could monitor construction workers for a long period without causing intrusive associated with wearing additional sensors by attaching IMU sensors to the safety harness. The application of the developed system could allow safety managers to identify workers at risk of FFH as repeated improper use of the safety harness can be a precursor to FFH. This high-risk worker identification would serve as objective data for worker education and training that could effectively change the safety behavior of high-risk workers.

6 Conclusion

The developed approach provided an accuracy of 96.58% for hook attachment detection, and the approach provided a consistent performance on different activities and postures. The detection approach also provided classification accuracies of 86.40% and 86.97% for the postures and the activity, respectively. The hook movement is affected not only by the attachment point but also by the worker's posture and activity. These results validated that the relative movement between the hook and the worker's body is a key feature for hook attachment detection.

The developed system, in this study, was implemented by two IMU sensors that can be attachable to existing safety harnesses, allowing this system to be extended as the construction environment evolves in practice. By applying the developed detection system to construction sites, it would be possible to reduce FFH and to increase construction safety by reliably identifying

high-risk workers to FFH.

However, the performance of this learning-based approach would be affected by the quality of the training data and have practical limitations as the training data needs to be collected from each worker. Therefore, a subject-independent approach needs to be developed for further study.

Abstract –

The construction industry accounts for a considerable portion of work-related accidents annually. Taking appropriate pre-construction measures can significantly lessen the probability of these accidents occurring. An essential step toward achieving this goal is identifying the unsafe attributes before construction begins. This research introduces a semi-automatic method for identifying and reporting construction hazards in the early phases of the project. The presented method benefits from Building Information Modeling (BIM) object-oriented and visualization capabilities combined with the project schedule (4D BIM). An excavation and stabilization operation of an actual residential building project case is used to demonstrate the method's applicability. A hazard database is created and linked to the 4D BIM model of the project to identify the hazardous attributes causing struck-by accidents. According to feedback collected from the project team and safety experts, reducing hazard identification time and increased accuracy were considered the two most significant benefits of this method.

Keywords –

Safety; Hazard Identification; Building Information Modeling (BIM); 4D BIM; Automation

1 Introduction

The number of casualties and fatalities in the construction industry is disproportionately high. While the construction industry employed 7.2% of the US workforce in 2020 [1], 19.9% of all fatal occupational injuries occurred in this section [2]. The need to reduce the number and severity of accidents in the construction industry has caught the attention of researchers in recent years. One of the appropriate strategies is to identify the

hazards in pre-construction phases and try to eliminate, reduce or manage them and their impacts. In many construction projects, the contractor is the sole responsible for the safety of the project. However, designers can also play a significant role in implementing projects with fewer safety accidents by considering the best practices and standards to achieve a safe design [3]. Identifying safety hazards in the planning phase can also considerably reduce construction accidents [4].

Advances in new technologies have provided great tools for identifying hazardous situations and eliminating or managing them in the construction industry. One of these technologies is Building Information Modeling (BIM). The increased usage of BIM in the implementation of many construction projects has provided new opportunities for greater utilization of this tool to improve the safety of projects. 4-dimensional (4D) BIM is created by integrating the 3-dimensional (3D) model of the building to the schedule of activities and can be used as a rich database with appropriate visual features to identify hazardous attributes in the project implementation process [5]. Despite its widespread applications in the safety management of construction projects, BIM's applicability, especially when integrated with the project schedule (4D BIM), has received less attention in identifying safety hazards before starting the construction phase.

Accordingly, this study introduces a semi-automatic method to identify the potential struck-by hazards in the pre-construction phases of an actual excavation and stabilization project case. This method employs 4D BIM to ease hazard identification and provide spatial insights for the safety planners. The results show that project managers can use this method to identify the potential construction hazards in pre-construction phases with high accuracy and speed, thus facilitating project planning and increasing project safety. First, the relevant literature is reviewed in Section 2. Section 3 introduces the method of identifying hazardous attributes in the early phases of

the project using 4D BIM. In Section 4, the method is implemented to identify attributes that cause the struck-by accidents, one of the four most frequent accidents in the construction industry, on an actual project's excavation and stabilization operation. Finally, the research is concluded in Section 5.

2 Research Background

2.1 Hazard Identification in Pre-construction Phases

If the safety risks are not adequately identified, the analysis phase will never begin, and subsequent control measures will never be considered and implemented. Therefore, the activities will be performed without the necessary protection, and there will always be a risk of an accident for the ongoing activities. Considering safety tips and risks in the project design and planning phases can significantly impact reducing accidents [4].

Malekitabar et al. [6] examined 363 accident reports and found that a significant number of the risk factors causing these accidents could be identified at the design phase. Design for Construction Safety was introduced as a concept to address this importance. Another concept that points to the importance of safety at the design stage is Prevention through Design (PtD). This concept encourages project stakeholders to consider project safety from the design stage to eliminate or control hazards [7]. Due to the complexity and uncertainty of the construction industry, the designers and safety planners have used new technologies and tools to identify as many risks and predictable situations as possible in the construction process. The use of project simulation tools is an example of these. Baniassadi et al. [8] suggested a framework for concurrent safety and productivity assessment of different work scenarios before the construction activity begins to choose the best scenario in terms of safety and productivity. They used project simulation tools and expert judgment to identify the risks. Using new technologies with proper visualization capabilities can also improve hazard identification capability in the project's planning phase [9]. Esmaeili et al. [10] presented a method of identifying and analyzing safety risks based on safety attributes (called Attribute-Based Safety Risk Assessment) and the lessons learned from past events and injury reports. With this method, safety risks can be identified and modeled independently from specific activities or building components. This theory believes that any injury or accident results from an interaction between a worker or a group of workers and a limited number of hazardous work environment attributes. By analyzing injury reports, a database of past accidents can be created, including the hazardous attributes, which are the cause of the accident, and the

outcome of each event [11]. The database generated can predict accidents caused by these hazardous attributes in future projects [12], [13].

Current methods for identifying hazards during pre-construction phases rely heavily on expert judgment or consider the project schedule without visualizing how the operational tasks are implemented. These issues seriously complicate construction safety analysis. Using new technologies such as 4D BIM, which combines scheduling with a 3D model, could provide greater accuracy in identifying hazards, but little attention has been paid to them so far.

2.2 BIM and Project Safety

Malekitabar et al. [6] proposed using BIM capabilities to identify safety hazards and risks at the design stage. Bansal [14] combined BIM and GIS technology to help workers visually observe the sequence of activities and the environment around each of them in the pre-construction stage. This allowed them to better understand the interactions between activities and the safety points and issues associated with these activities. Ciribini et al. [15] used BIM to monitor the progress of ongoing activities. Their research showed that by comparing the BIM model and the executed map obtained from laser scanners, the project manager could effectively identify and modify safety components forgotten in the structure, such as guardrails or safety nets. Ganah & John [16] researched the use of BIM to improve workers' training. Their research examined the effectiveness of this technology in increasing the understanding of workers and stakeholders of the project to safety challenges during construction.

By connecting the 3D BIM model to the activity schedule, the 4D BIM model is created. Many people involved in the construction industry believe construction accidents can be eliminated or lessened using 4D BIM. Collins et al. [17] investigated the impact of 4D BIM in assisting safety managers in implementing preventive strategies for scaffolding activities in construction projects. This study used the experts' opinions and safety risk factors in conjunction with the 4D BIM model. Zhang et al. [4] used 4D BIM to identify and eliminate the risk of falling from a height in the early stages of the project planning phase. Their goal was to automatically detect unsafe conditions during project construction and locate them in a 3D model. Then, solutions to reduce the identified hazards were provided interactively with the opinion of safety experts or automatically. Jin et al. [7] proposed a tool for assessing construction risks during design phases of projects at an activity level and in a 4D environment. In this study, safety risk quantification for design elements is based on survey results from construction field personnel and expert judgment to assess construction risks. Abed et al.

[18] used 4D BIM simulation to help the safety managers understand the details and sequence of work. They demonstrated the effectiveness of this technique in hazard identification by relying on the opinions of safety experts.

Based on the literature reviewed, 4D BIM is an appropriate tool for identifying hazards in the pre-construction phases. Regulation rule checking and using expert opinion are the most common approaches to identifying hazards. These can be upgraded using safety experiences from past safety incidents. Considering the hazardous attributes identified from past incidents, identifying these attributes with the help of 4D BIM can complement past research.

3 Semi-automatic Hazard Identification Method

This method primarily aims to identify safety hazards in the early stages of construction projects with less time and more accuracy. This goal is achieved by using the capabilities of the 4D BIM model and the automatic processing power of computers. Figure 1 shows the different parts of the method

The 3D BIM model of the project and the schedule of activities provide input for the method. A 4D BIM model for the project is made by connecting the 3D BIM model with the schedule of activities. A 4D BIM model typically contains spatial and geometric data, as well as the schedule of activities. For the safety analysis, further assumptions and details are also needed to be provided. In most cases, these details are not added to the model by default because the project owners may not see a need for them, or protocols are not defined for providing them. For example, to identify the struck-by hazards in an excavation project, as discussed in Section 4, the user should include some additional information such as the safe distance from the material storage place on the project site, the safe distance from the material transport route, the safe distance from the roadway, and the rotation radius of boomed vehicles. The user enters this additional information into a separate database, which is created based on the data extracted from the 4D BIM model. A specific identification algorithm is then designed and developed for identifying each of the hazardous attributes. Next, appropriate queries are written on the prepared database to examine its content according to the developed algorithms and identify hazardous activities and attributes. Once the hazardous attributes are identified, they are transferred to the 4D BIM model to create the 4D+ BIM model. The 4D+ BIM model is the 4D model of the project enhanced with safety information resulting from this method.

4 Method Implementation

To demonstrate the method's capabilities presented in Section 3, the researchers implemented it on an excavation and stabilization operation of a real project. In this sample implementation, struck-by accidents, one of the four most frequent accidents in the construction industry, were selected as a sample category of construction accidents. The implementation process of the method is described as follows.

4.1 Identification Algorithms

By reviewing 1,812 struck-by accident reports, Esmaeili et al. [10] introduced a group of hazardous attributes leading to the occurrence of this type of accident. Eleven of these attributes were selected as samples to create the construction hazard database of this study. The following are 11 selected hazardous attributes:

1. Working in the swing area of a boomed vehicle
2. Working with heavy equipment
3. Working in a material storage zone
4. Working in a material-transportation zone (horizontally)
5. Working near an active roadway
6. Workers on foot with moving equipment
7. Driving heavy equipment, falling out
8. Driving vehicle
9. Working with a nail gun
10. Working with power tools/large tools
11. Working in falling objects zone

The researchers determined the identification algorithms for each of these eleven attributes. The algorithm for identifying the hazardous attribute no. 1 (working in the swing area of a boomed vehicle) is described in detail as a sample.

4.1.1 Hazardous attribute no. 1 (working in the swing area of a boomed vehicle)

The following algorithm was taken to identify activities in which there is hazardous attribute no. 1.

1. First, consider the activities in which the boomed vehicle has been allocated as a resource. Then consider the time planned for the implementation of these activities as a period of risk.
2. The hazard zone with a risk of occurring the struck-by accident is determined based on the minimum and maximum coordinates of X and Y of the boomed vehicle's location in the model and considering the maximum rotation radius of the machine (R). The range of the hazard zone is determined by summing up R with the maximum coordinates and subtracting R from the minimum coordinates of the boomed vehicle's location. As

shown in Figure 2, the hazard zone is estimated as a cube.

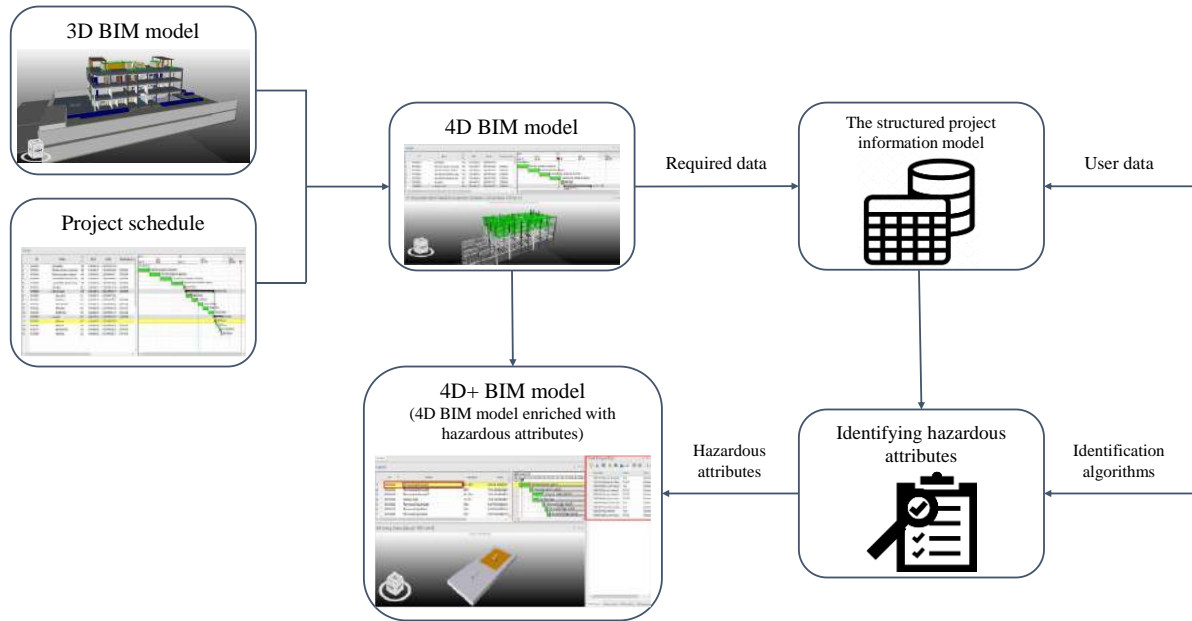

Figure 1. Semi-automatic hazard identification method

3. Activities that, at the time of operation of the boomed vehicle (specified in step 1), their resources are located in the hazard zone (determined in step 2) are identified.

4.2 Project Description

The project is an 8-story residential building located in Tehran, Iran. This case study is limited to some of the activities related to excavation and stabilization of the pit walls.

4.2.1 Steps of the Excavation Operation

The excavation operation was executed in six general

steps as follows.

1. Excavating the middle of the pit and moving the nails to the side of the pit
2. Excavating the side of the pit
3. Smoothing the walls around the pit, straightening it, and making it parallel to plumb line
4. Drilling of piles and injection of concrete into the nails
5. Installation of steel network bases by workers and then installation of steel networks
6. Shotcrete walls

Figure 3 displays each of these execution steps.

Figure 2. Determining the hazard zone in an activity where a boomed vehicle is used

Figure 3. The execution steps of the excavation

4.3 4D BIM Model

First, the 3D BIM model of the project was created. The schedule for excavation and stabilization of the pit was then connected to the model elements. Therefore, a

4D BIM model of the project was developed. Figure 4 shows a view of the generated 4D BIM model.

4.4 Structured Hazard Information System

In this study, an independent database was created to store the safety hazards knowledge. Although this database is linked to the information model of the project under study, its independent nature allows it to be used to identify risks of future projects as well. The researchers designed the database's structure, tables, the properties of each table, and the connection between them. Figure 5 shows the tables, the relationship between them, and the characteristics of each. The desired data was then extracted from the generated 4D BIM model and stored in the created database. Additionally, some data, as explained in Section 3, is also taken from the user.

4.5 Hazardous Attributes Identification

The algorithms determined to identify each hazardous attribute were implemented with the help of information systems capabilities to write queries. The hazardous attributes for each planned activity are identified and stored in the activity risk table by implementing these algorithms. The output of the developed information system is the risk table of activities, which shows the identified or non-identified hazardous attributes for each activity. Figure 6 illustrates a sample form designed to display the information stored in the table after analyzing the case study project.

Figure 6. Designed form to view the identified hazardous attributes of each activity in the project's 4D+ BIM

The results from the previous step were integrated with the 4D BIM model of the project to create the 4D+ BIM model. Figure 7 shows a view of the resulted 4D+ BIM model of the project. As shown in Figures 6 and 7, 6 hazardous attributes have been identified for the activity titled "Removal center part A." As shown in

Figure 7, an excavator has been used as a resource for this activity. This resource has increased the presence of hazardous attributes in this activity, so it is necessary to consider appropriate strategies in project planning for its safer implementation

4.6 Expected Benefits and Future Works

Based on the case implementation and feedback from the project team and safety experts, the method's benefits are as follows.

1. The 4D BIM made it possible to use computer tools and, consequently, to automate the hazard identification process. The automation of hazard identification allows the process to be performed more straightforwardly, more quickly, and less costly.
2. Due to the consideration of the relationships between elements and activities, the hazardous attributes are identified with higher accuracy compared to conventional methods.

Even though the proposed method has received positive feedback from safety experts, it is still necessary to quantify and compare its results with conventional methods. In addition, future research needs to address further automatization of the method, including minimizing the user's role and standardizing the database so that it can apply to a variety of construction projects.

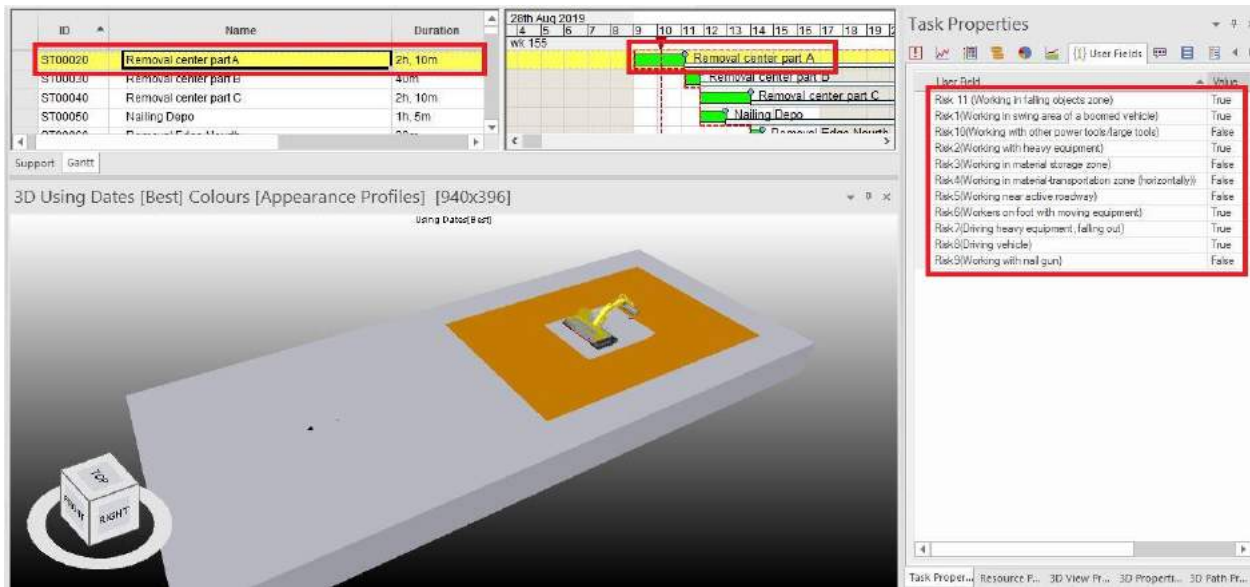

Figure 7. A view of the project's 4D+ BIM model representing the presence or absence of the hazardous attributes in the activity's property menu

5 Discussions and Conclusions

The most important way to control hazards in construction projects is to identify them before occurring. The object-oriented nature and interoperability with other databases of BIM have provided the ability to review conditions and check rules in a short time, low cost, and high accuracy. Therefore, BIM allows the automation of the risk identification process. As a result, 4D BIM was used in this study to identify hazardous attributes in the pre-construction phase of a project. Accordingly, the conceptual method was presented. The method was then implemented on a real project to identify the hazardous attributes causing struck-by accidents in the planning phase. Finally, the expected benefits of the implemented model were presented. Faster and more accurate hazard identification than traditional methods were mentioned as the main benefits of the implemented method.

The method can be used as an efficient tool for Job Hazard Analysis (JHA) procedure. Job Hazard Analysis (JHA) is usually implemented before performing each activity to identify the risks and hazards that threaten its implementation in the project. Using this method in the JHA procedure, risk factors can be quickly identified at the project's planning phase.

Nowadays, toolbox meetings are among the new and effective methods used to express the safety challenges during construction in the project site. The implemented method can help improve the quality of these meetings. It is possible to simulate all activities performed daily, weekly or monthly, along with the risks and hazardous attributes affecting each of these activities in this period.

Another advantage of the implemented method is that it helps maintain and transfer project knowledge. Information about the resources used in the project can be stored in the designed database. This database could then be used in subsequent projects and collectively store project experiences. Modular construction and using robotics in construction are the two most expanding concepts in construction management. This research can help to expand these concepts by taking a step towards automating the hazard identification process. Investigating the effects of using the method implemented in this research on reducing accidents and increasing productivity in projects using robots in the construction and modular construction projects can be considered a subject for future research.

Abstract–

One of the problems with unmanned construction is the lack of visual information, which reduces work efficiency to less than half of that in onboard operation. Therefore, methods to provide visual information using drones and image processing were studied in the past. However, the addition of information causes the operator to fall into cognitive tunneling in which the attention is focused only on a specific image. In this study, we attempted to develop a method that can prevent cognitive tunneling and shift the operator attention to an appropriate view according to the working state of heavy machinery. Cognitive tunneling is caused by low visual momentum (which represents ease in information integration between views) and high visual saliency (which represents ease in attention). Therefore, because visual momentum can be improved by presenting the same landmark in different camera images, useful landmarks for each work state were included in each image. In addition, because humans tend to pay attention to objects that vibrate in the useful field of view, we presented the image of an external camera in the useful field of view and allowed the image to vibrate when the work state was switched. To investigate the effectiveness of the proposed method, an experiment was conducted on an actual hydraulic excavator. Although the proposed method did not improve the work efficiency of some operators, we believed that the proposed interface could direct the eyes of the operator to an appropriate image according to the work state.

Keywords–

Unmanned construction; Remote operation; Cognitive tunneling; Visual momentum; Visual saliency; Visual support

1 Introduction

Demand for unmanned-construction technology to remotely operate heavy machinery at disaster sites appears to be increasing because of the risk of secondary disasters when people directly enter the site to work[1]. However, in unmanned construction, the operator must recognize the complex situation at the site based on limited information from the image captured by onboard camera mounted on the construction machine (cab view) and those images captured by external cameras installed at the work site (external views) [2]. Therefore, the task is very cognitively demanding, and the work efficiency is only approximately 50% compared with that in the boarding operation [3]. To solve this problem, conventional research has been conducted to increase the amount of information by adding other viewpoint cameras and types of sensors mounted on heavy machinery and by providing the operator with multiple displays [4]. However, the increased amount of information requires the operator to select and integrate this information, which can increase the operator cognitive load and reduce work efficiency. In addition, cognitive tunneling may occur under a high cognitive load [5], which makes selection of appropriate information difficult using the conventional multi-display presentation methods. In the present study, we developed a novel visual interface that reduces cognitive tunneling of the operator and supports efficient information selection.

2 Visual Interface Design

2.1 Design Policy

The causes of cognitive tunneling can be mainly divided into two categories.

First, “Visual Momentum,” which represents the ease in eye transition among the information presented

on multiple screens, is low, which makes information integration difficult. This condition makes the operator suffer from the difficulty of paying attention to other images when the operator attempts to work only with the information obtained from one image type. Second, the operator attention is fixed on the information with high “Visual Saliency” and does not look at other images [6]. In particular, remote operators tend to fix their attention on cab view. Therefore, a visual presentation method that frees the attention of operators from cab view and directs their attention to an appropriate image is needed.

According to the aforementioned conditions, we set two design policies for visual interface: one was to extract and present information that increases visual momentum and the other was to present the information that directs the operator attention. In line with the aforementioned design policies, we proposed the following methods: (1) selecting and presenting external views according to the work state, (2) deriving the optimal viewpoint position for external views, and (3) presenting information that considers the visual field characteristics of humans. We then constructed a visual interface.

2.2 Selection and Presentation of External Views According to the Working State

To increase visual momentum, the image presented to the operator must be related to the current work content. In this study, we developed a method of selecting images that increased the degree of agreement between the landmarks that the operator must recognize as work cues and those contained in the images to define the relationship between the work contents and provided images. The landmarks that must be recognized by the operator were considered to be different depending on the work state. The landmarks that must be recognized in each work state were analyzed based on a teleoperation experiment in a virtual-reality [7] environment and a field survey at Mt. Unzen-Fugen. In particular, the work states were divided into four types: moving, grasping, transporting, and releasing. When moving, it is required to avoid accidental contact with obstacles. So an external camera image that can help the operator understand the distance between the body of heavy machinery and the obstacle is needed. On the other hand, in manipulation work, which includes grasping, transporting, and releasing, an external camera image that shows the positional relationship between the grasped object and the grapple of heavy machinery is necessary. Besides, another external camera image that shows the positional relationship between the grasped object and the placing position is needed.

2.3 Derivation of the Optimal Viewpoint Position for External Views

We experimentally derived the viewpoint position of external views where the operator could most efficiently capture the positional relationship between the work-site environment and heavy machinery and where the work efficiency could be improved [8]. In particular, we compared the working time for grasping and releasing, which required a particularly high-precision work by changing the camera position, and derived the position of the external camera that offered the highest work efficiency. The experimental result demonstrated that the optimum pan angle was $\phi = 90^\circ$ and the optimum tilt angle was $\theta = 60^\circ$ in a polar coordinate system using the object to be grasped as a pole. We also believed that the optimal ranges of ϕ from 60° to 120° and θ from 60° to 90° did not significantly affect the work efficiency.

2.4 Method for Presenting Information Considering the Human Visual Characteristics

To enable the operator to efficiently refer to the information determined by our proposed method, we used a single display that could present external views in the useful field of view and all the images in a stable gazing field of view by considering the human information-reception behavior. In addition, to shift the operator attention, which tended to be fixed on cab view, the screen of external view was made to vibrate at approximately 5 Hz when the external view was selected and presented to encourage the operator to shift his gaze [9]. Figure 1 shows an overview of our developed visual interface.

Figure 1 Overview of the visual interface developed

3 Experiment

In order to verify the effectiveness of the proposed visual presentation method, an experiment was conducted using an actual hydraulic excavator (Hitachi ZAXIS 35U, Figure 2) at the outdoor test site of the Public Works Research Institute.

Figure 2 HITACHI ZAXIS 35U

3.1 Experimental Conditions

The experimental task was set by referring to the model task proposed by the Public Works Research Institute [10]. In this test, the vehicle made one round trip along an L-shaped course, as shown in Figure 4, while grasping and releasing the grasped object (Figure 3) four times. From the starting point shown in Figure 4, the vehicle grasped the object at its front and rotated by approximately 90° to put it down. Then, the vehicle moved along the course, grasped the second grasped object at its front, and rotated by approximately 90° to put it down. Finally, the vehicle moved back to the starting point and repeated the previous steps in the reverse order to complete the task. In addition to cab view, external views from the side are necessary for the operator to obtain depth information in the manipulation work. The positions of the external cameras used in this experiment (External cameras ① to ③) are fixed, and the angle of camera image is changed according to the work state. The angle of camera image is set to be within the range of the optimal pan angle and tilt angle described in section 2.3. Table 1 summarizes which cameras were used according to the work state in this experiment.

In this experiment, a familiarization task was conducted before the main test. In the proficiency task, the vehicle started at the corner of the L-shaped course shown in Figure 4, moved along the straight course at the long side, grasped the object at the right (left) side of the excavator from the direction of travel, turned 180°, released the object in place, and finally moved to the starting point.

The subjects were four operators who were skilled in boarding operations. In the experimental flow, the operator first performed the mastery task until he or she

became fully proficient in the operation. The criterion for proficiency was that the error should be within $\pm 5\%$ when the working time was measured and compared with the three nearest working times. The proficiency task was terminated when the abovementioned criterion was met. However, even if the conditions were not satisfied, the task was terminated after a maximum repetition of 10 times. We performed the abovementioned task three times using the conventional method of presenting multiple images on multiple displays (Figure 5) and three times using our novel visual interface. In the new visual interface, the camera switcher decided the work state of the actual device and switched the images. To eliminate the effects of habituation caused by repeating the same task under the same conditions, the order in which the experiments were conducted was divided into two patterns of two people each, as shown in Figure 6.

Figure 3 Grasped object

Figure 4 Test field

Figure 5 Multi-Display presentation method

Table 1. The camera image presented in each work state

Work states	Camera

Releasing ^①	Camera ^①	-	-
Moving ^②	-	Camera ^②	Camera ^③
Grasping ^②	Camera ^②	-	-
Releasing ^②	Camera ^③	-	-

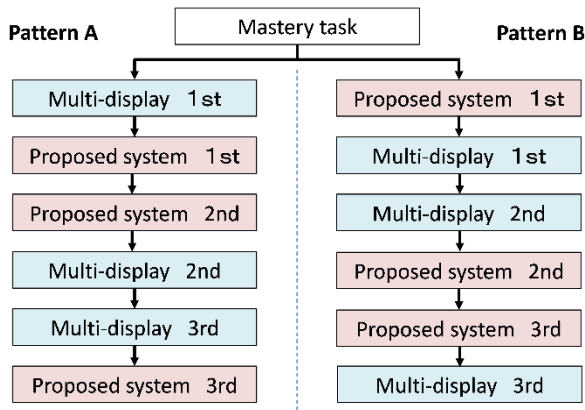

Figure 6 Test flow

We measured the working time, placement error, and number of false contacts as indexes to evaluate the work efficiency. The gaze was evaluated to confirm the effectiveness of the gaze guidance.

In this experiment, placement error was defined as the deviation between the center position of the marker and grasped object. Only the distance between the center of the marker and grasped object was measured, and the rotation angle was not considered. The number of erroneous contacts was defined as the number of

contacts between the heavy machinery and the traffic cones that served as the moving course.

3.2 Results and Discussion

3.2.1 Working Time

The results of the Wilcoxon signed-rank sum test showed that no significant difference existed between the conventional and proposed methods in terms of the total working, moving, transporting and releasing times (Figure 7). The results also suggested that the conventional method could better reduce the grasping time than the proposed method.

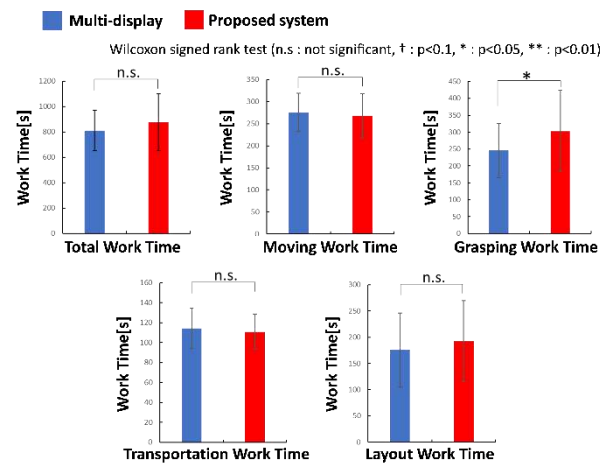

Figure 7 Result on work time

Our study revealed that the working time could not be reduced. In this experiment, the conventional method presented four images to the subject without switching the images, and the angle of view was always the same. Therefore, while working under the condition where all images were constantly visible, we believed that understanding of the images that were not being looked up subconsciously deepened. Thus, no time was required to understand the images when shifting the gaze between images. On the other hand, in the proposed visual interface, because the images were switched according to the work state, time was needed to understand the images every time they were switched. We believed that this “time to understand the image” was a factor that did not lead to reduction in the working time.

3.2.2 Gaze

Figure 8 shows the results of the gazing process. The visual momentum was evaluated according to the ratio of time spent gazing at one image for more than 1.5 s during one task. The cognitive tunneling was evaluated according to the number of times a gazed image was

switched from cab view to external views in 1 s to determine if the attention shifted from an image with high visual saliency. The number of times the gazed image was switched from cab view to external views was used to evaluate whether cognitive tunneling was reduced.

The result of the Wilcoxon signed-rank sum test of the four subjects revealed no significant difference between the conventional and proposed methods in terms of the ratio of watching the same image for more than 1.5 s and the number of times of switching from cab view to external views and the number of switching the gazed images.

Figure 8 Result on gaze

In the experiments that used the scaled model, we believed that the proposed method significantly reduced the percentage of gaze pauses for 1.5 s or longer and significantly increased the number of gaze changes in each of the previously mentioned evaluation indexes. This point is discussed in this paper. In the experiment that used the scaled model, nine images were presented to the subject using a multi-display presentation method to verify the effect on the work efficiency by reducing the time to select an appropriate image according to the work state. In the experiment using an actual machine, however, the number of presented images was reduced to four to reflect an environment that was closer to that of an actual unmanned-construction site. This process made selection of appropriate images and integration of information among images easier. In addition, whereas the subjects in the experiment that used the scaled model were inexperienced in the operation of an actual machine, the subjects in this experiment were skilled in the operation of boarding machines. Therefore, they were considered skilled in the ability to select the image

to be viewed according to the work state. Hence, a possibility existed that no significant difference could be confirmed in each evaluation index.

Next, when we organized the individual differences in terms of the different cognitive characteristics, behavior, and learning mechanisms of the subjects, we were able to identify the operators who were comfortable with the proposed visual interface, as shown in Figure 8. For Subjects B and D, we confirmed that the number of times the gazing image was switched from cab view and that when the gazed image was switched significantly increased using the proposed method. This result suggested that the proposed method can direct the attention of some operators from cab view with high visual saliency to external views with low visual saliency and can reduce cognitive tunneling.

On the other hand, no significant difference was observed in terms of percentage for Subjects B and D in watching the same image for more than 1.5 s in the time on one task (Figure 9). As described earlier, the conventional presentation method always presented four images with the same angle of view. Therefore, the time required to understand the images was likely reduced compared with that in the proposed method. In other words, when the number of images presented was only four, the proposed method could reduce the time required to select an image. However, it required time to understand the image each time it was switched, and the latter had a greater effect on work efficiency. Although the latter process succeeded in directing the gaze to some extent, it did not improve the visual momentum, which could be the reason why the working time was not reduced.

Figure 9 Result on gaze (Subjects B and D only)

3.2.3 Placement Error and Number of False Contacts

Figure 10 shows the results of the placement error and number of erroneous contacts using the Wilcoxon signed-rank sum test.

Figure 10 Result on placement error and number of false contacts

Figure 11 Picture angle for each video presentation method

The fact that the placement error and number of false contacts could not be reduced using the proposed method is discussed. Figure 11 shows that the view angles of the images provided by the conventional method and those presented by the proposed method were the same in this experiment. Therefore, when the

performance of the placement error and number of false contacts were improved, the proposed method could appropriately assist the selection of the image to be viewed. However, in this experiment, in contrast to the scaled-model experiment, the subjects were likely to already possess a high level of ability to select the images to be viewed. Further, because the number of types of images presented was significantly reduced, selection of the images was easy. In this case, we believe that the effects on the placement error and number of false contacts are less likely to occur.

4 Conclusion

In this study, we developed a visual presentation method that can reduce cognitive tunneling to improve the efficiency of unmanned construction. The cause for cognitive tunneling is that the operator attention is fixed only on the images with low visual momentum and high visual saliency. Therefore, we aimed to improve the visual momentum by including the same landmark in each image. In addition, by presenting external views with low visual saliency in the useful field of view using vibration, the operator attention was directed from cab view with high visual saliency. The results from experiment that used an actual system showed that some operators were able to successfully direct their gaze; however, it did not lead to improvement in the work efficiency. The reason for the lack of improvement in the work efficiency was believed to be the need for time to understand the new external view by switching the image, which is a feature of the proposed interface.

This result indicates that even if the gaze can be directed to the image corresponding to the work state, it cannot solve the essential problem unless it can assist in understanding of the image.

Therefore, in the future, we aim to improve the work efficiency by introducing a system that can assist understanding of spatially discrete images when switching or displaying new images.

5 Acknowledgments

We would like to thank staff members of the Public Works Research Institute for their help with the experiments. We also thank Japan Institute of Geography and Engineering for the research grant. This research was supported in part by the Research Institute for Science and Engineering, Waseda University.

Abstract

Construction sites are complex and dynamic, and this tends to increase the cognitive loads for construction workers. Developing and maintaining an adequate level of situation awareness (SA) at different levels (e.g., workers, supervisors, and project managers) is essential to improve the individuals' capability of managing site safety. Despite the fact that there have been studies that applied SA to construction safety, SA is still an under-researched concept in construction safety. It remains unclear how SA impacts safety behaviours, site safety management processes, and accident prevention strategies. To fill the research gaps, a critical literature review is conducted to: (1) identify and analyse current studies that integrate the concept of SA for managing construction safety, (2) investigate the conceptual linkages between SA, DT, and construction safety, and (3) recommend future research directions towards building a digitalised situation-aware construction safety management system. A five-step systematic review method was adopted, including literature search, selection, coding, data analysis, and discussion. Previous research on (1) elements of SA related to construction safety, (2) SA measurement, (3) digital technologies for SA, (4) SA and safety behaviour and hazard identification was reviewed and summarised. This paper recommends four specific future research directions to advance the research on SA for managing construction safety. Apposite utilization of the findings can assist digitalization revolution on construction safety management for both research and practice.

Keywords –

Construction safety; Digital technology (DT); Situation awareness (SA)

1 Introduction

The construction sites are highly hazardous, due to the dynamic and complex nature of the construction activities. The construction industry has been suffering from a high injury rate at the global level. For example, from 2011 to 2017, the New Zealand construction industry has seen yearly increasing work-related injuries, ranging from 26,394 to 37,659 [1].

Over the past decade, the construction industry has started using digital technology (DT) in managing various aspects of project management. There has been increased research interest in applying DT for managing construction safety in this ongoing shift towards digitalisation. For example, Guo et al. [2] reviewed DT for construction safety and discussed the conceptual linkages between safety planning, real-time hazard management, and safety knowledge engineering.

Given the fact that construction sites are complex and dynamic, and this tends to increase the cognitive loads for construction workers [3, 4] and create information gaps between individuals (e.g., frontline workers, supervisors, and managers) and site conditions [5, 6]. As a result, workers are often unaware of new hazards that emerge from interactions among activities and thus unable to predict possible hazardous scenarios, which are often beyond their cognitive capacity and boundary. Traditional construction safety practices focus mainly on pre-activity safety planning and are ineffective in bridging the information and awareness gaps caused by the site dynamics. Developing and maintaining an adequate level of situation awareness (SA) at different levels (e.g., workers, supervisors, and project managers) is essential to improve the individuals' capability of managing site safety.

SA was defined as “the perception of the elements in the environment within a volume of time and space, the comprehension of their meaning, and the projection of

their status in the near future” [7]. It is a multi-dimensional concept that first originated from the military aviation domain during the First World War. Endsley proposed a model of SA, which defines SA at three ascending levels: perception, comprehension, and projection [7]. Since then, the concept has received attention from researchers in different domains, such as engineering [8], computer science [9], psychology [10], and military [11].

Many researchers have applied the concept of SA to enhance the understanding of safety awareness and behaviours [12-14]. Despite these efforts, SA is still an under-researched concept in construction safety. It seems that SA is an important concept that has shown the potential to conceptually link DT and safety management and science. However, it remains unclear that how SA impacts safety behaviours, site safety management processes, and accident prevention strategies. Therefore, more research is needed to investigate the fundamental linkages to site safety.

To fill the research gaps, a critical literature review is conducted to: (1) identify and analyse current studies that integrate the concept of SA for managing construction safety, (2) investigate the conceptual linkages between SA, DT, and construction safety, and (3) recommend future research directions towards building a digitalised situation-aware construction safety management system.

2 Methodology

The study adopted the systematic review method. The method consists of five main steps: literature search, selection, coding, data analysis, and discussion. Scopus was selected for literature search due to its comprehensive coverage of relevant peer-refereed academic papers. The search keywords and terms are presented in Table 1.

The 1st, 2nd, and 3rd rounds of search identified 71, 64, and 14 papers, respectively. Only articles, book chapters, and conference papers were kept for data analysis during the screening and selection stage. In addition, papers that are irrelevant to the construction industry were excluded. Duplicate articles that were identified in the three rounds of the search were also excluded. As a result, a total of 74 papers were kept for further analysis.

The authors, title, year, country or region (country of the first author's unit), cited by, industry, SA aspect, technology used, equipment, SA measurement methods, statistical analyses method used, and statistical analyses indicator were coded, the coding results are presented in Table 2, Table 3, Table 4, and Table 5. The emphasis was placed on the elements, measurement of SA for construction safety, the relationships between SA,

construction safety, and DT.

Table 1. Search keywords and terms

Round of search	Keywords
1st	“situation awareness” AND “construction” AND “safety” OR “hazard” OR “accident” OR “risk” OR “health”

3 Key review results

3.1 Temporal distribution of publications

According to Figure 1, the earliest relevant paper was published at the International Conference on Computational Intelligence and Security in 2006. The number of relevant studies remains low until 2017. Starting from 2017, the topic of self-awareness was under the spotlight, and the number of relevant papers began to increase and reached its peak in 2020.

Figure 1. Distribution of publications by year

3.2 Elements of SA related to construction safety

The element of SA is about what constitutes SA at three different levels (i.e., perception, comprehension, and projection). It is a question of what are the essential data/information elements that enable an individual to develop an appropriate knowledge state for perceiving, comprehending, or predicting site safety-related scenarios. In general, no study has been conducted to explicitly identify a comprehensive set of elements of SA for construction safety. Nevertheless, there are fragmented studies that link SA to a specific aspect/object of construction projects.

SA elements of interest mainly cover three main dimensions: people, machinery, and environment from a safety management perspective. SA elements of people can be further categorised into physical and psychosocial aspects. SA elements of people identified from the literature review are presented in Table 2.

Data and information regarding machinery are also essential for site safety management, as they tend to create various hazards. Attention has been paid to location [15, 16], motion/behaviour [15, 17-19], and conditions [20, 21] of machineries.

At the environment level, physical and psychosocial conditions are of interest for safety purposes. SA elements of environment identified from the literature review are presented in Table 3.

Table 2. SA elements of people

Category	SA Elements	Study
Physical	Location	[16, 22]
	Movement	[22-24]
	Behaviour	[17, 23]
	Roles	[25]
Psychosocial	Stress; fatigue	[24]
	Time pressure	[18]
	Mental/cognitive load	[18, 26, 27]
	Areas of interest (AOI)	[27, 28]
	Emotional stability	[28]

Table 3. SA elements of the environment

Category	SA Elements	Study
Physical conditions	Temperature	[22]
	Weather	[15]

	The geometry and location of existing structures	[16, 20]
	The geometry of site topology	[20]
	Hazards	[16, 18, 22]
Psychosocial conditions	Safety climate	[24]

3.3 SA measurement methods for construction safety

Several SA measurement methods were developed for construction safety, based on existing ones developed in other domains. A summary is presented in Table 4.

For instance, Fang et al. developed a query-based SA measurement method inspired by Situation Present Assessment Method (SPAM) to quantify SA [21]. Javier and Masoud applied the Goal-Directed Cognitive Task Analysis (GDCA) technique to investigate the key goals and SA requirements and develop SA-centered construction management methods and an IT tool to improve stakeholder decision-making processes [29].

3.4 Digital technologies for situation awareness

Various DTs have been applied to measure, develop, and maintain SA at different levels (i.e., perception, comprehension, and projection). A summary of DT technologies for SA is presented in Table 5.

VR was adopted to investigate the impact of tasks intricacy on forklift driver's SA [30]. The research indicates that the task complexity will significantly influence the forklift operator's SA [30]. The result manifests that the characteristic of mission on-site can be one diminution of SA.

Seokyon employed Ultra-wideband (UWB) technology and Angle-of-Arrival, Time-of-Arrival and Time-Difference-of-Arrival methods, axial-rotation and random-move collision preventing strategies was proposed to improve equipment operator's SA to avoid unexpected collisions [31]. This research demonstrates that UWB is an advanced real-time site object spatial data collection method.

Table 4. SA measurement methods

SA measurement methods	Study
Use eye-movement metrics, human errors, attention to measure cognitive processes	[32]
Direct measures of SA (eye-tracking) and Subjective SA measurement using Participant subjective situation awareness questionnaire (PSAQ) and Situation awareness rating technique (SART)	[33]
GDTA	[34]
Direct measures of SA (eye-tracking), AOI, and big five personality questionnaire	[28]
Direct measures of SA (Bluetooth energy power, position, temperature, battery volume and acceleration from BLE sensor)	[22]

3.5 SA and safety behaviour

Previous research on safety behaviour was mainly focused on identifying and testing antecedents (e.g., safety motivation, safety knowledge, management commitment to safety) based on existing behaviour and motivation theories (e.g., theory of planned behaviour).

The literature review results suggest that research on the impact of SA on safety behaviour in the construction domain has been limited. There is no research conducted to statistically test the relationship between SA and safety behaviour in the construction industry.

Sneddon et al. [12] tested the relationships between actors (i.e., sleep disruption, fatigue, stress), worker's SA, and unsafe behaviours, accidents, and near-miss accidents, based on the data collected in the oil and gas industry. The results indicated that SA is significantly related to unsafe behaviour. Mohammadfam [13]

performed a path analysis to investigate the relationship between SA and human errors based on the survey data collected from multiple industries. The results suggested that the relationships between factors (i.e., sleepiness, fatigue, safety knowledge, and safety locus of control) and SA are statistically significant. SA was also significantly correlated to human error and safety behaviour.

SA has been applied as a concept that links digitalisation and automation in crane operation to safety performance. For example, Fang [18] developed a cognitive-based real-time crane operation assistance system to perform autonomous hazard identification. This research proposes a measurable cognitive-based effectiveness validation approach that demonstrates the potential of an evaluating method to examine the relationship between the system design vision and system actual performance. Utilizing real-time motion sensing and 3D modeling technology, Fang et al. [19] proposed a mobile crane operator-assistance system to improve the SA of operators. In addition, a collision-prevention strategy and UWB-based algorithms were created by Seokyon. The system can perform equipment collision detection [31]. By leveraging eye-tracking and task observation technology, a field experiment was conducted by Markus to investigate the operator visual information acquisition process [40]. Employ VR environment, Choi et al. applied SAGAT to examine the impact of subtasks on forklift operator's SA [30].

3.6 SA and hazard identification

Research efforts were made to investigate the impacts of SA on workers' ability of hazard identification. Hasanzadeh et al. [32, 33] suggested that eye movements can be a reliable indicator of workers' attention and comprehension of construction hazards. The research used eye-tracking technology to measure SA. The results indicated that SA varies significantly depending on workload, state of the area of interest, and experience.

Several studies [26, 27, 36] have been conducted to identify that mental load will significantly affect worker's SA. In addition, Eskandar et al. [24] identified that the high production and coordination pressure might influence the stakeholder's response. One of the first efforts adopting mobile eye-tracking technology to investigate the relationship between SA and worker's attention was conducted by Hasanzadeh [41]. Li et al. [42] revealed that knowledge sharing and construction safety awareness are critical to hazard identification.

4 Discussion

The critical review aims to investigate the current conceptual position of SA in site safety and analyse the impact of DT on improving or maintaining SA.

4.1 A digitalised situation-aware site for safety

Although DT has been well researched and implemented for managing construction safety, there are conceptual gaps in the role of DT in accident causation models and safety science. Few studies have been conducted to conceptualise the role of DT. Due to the limitation of human cognition capacity, workers cannot process all relevant information for site safety. Accidents and near misses can be attributed to this limitation. DTs have demonstrated significant potentials to address the limitation by capturing data, generating new information and knowledge, and facilitating information flow.

An assumption behind using the concept of SA is that if workers and managers can access an adequate amount of right information at the right time regarding site safety, accidents can be prevented. This assumption has been implicitly applied to justify most of the previous studies on DT for construction safety. The results of the literature review suggest that there is a solid conceptual basis underpinning the assumption. The conceptual basis is formed based on the theoretical linkages among SA, DT, and construction safety management. First, SA and attention are fundamental concepts of human behaviours. SA is a concept that has been applied to link human behaviour and hazards, which are two main contributing factors in accident causation models (e.g., Domino model by [43]). Second, there is solid evidence that DT can provide relevant information and knowledge to develop and maintain SA at the individual and group level. As such, SA is a helpful concept that links DT and construction safety management and safety science.

DT can be developed, selected, and integrated into a coherent platform to provide a comprehensive situation picture (SP) following the same rationale line. Kärkkäinen et al. [44] defined SP as “A state where the scope, quality and accessibility of produced operational information is adequate for controlling the workflow and improving production processes.”. Another working definition of SP from a safety management perspective can be:

“A state where the scope, quality and accessibility of all relevant information produced by DT is adequate for making informed decisions and improving safety performance.” To realise this ideal state, it is essential to understand what the relevant information is, how to capture and communicate the information to the right

people at the right time, and how the construction site can be (re)designed to facilitate the information capturing and communication. This design thinking can create various interfaces between humans and the environment. The interfaces help an individual or a group to get the right information at the right time. Knowing something will never guarantee safe behaviour [45], however, the information and knowledge generated from the interfaces can significantly enhance the capability and capacity of individuals and groups to manage the dynamics and complexity of construction activities. The theoretical stance is that DTs do not improve safety level directly; instead, they improve the safety level by empowering people.

4.2 Future research directions

The application of the concept of SA for managing construction safety is still in its infancy. More research is needed to further develop its conceptual linkages to construction safety. The efforts should be focused on conceptualising the role of DT in construction safety management and science. Three specific future research directions are recommended as follows.

First, research efforts are needed to identify elements of SA by levels (e.g., perception, comprehension, and projection), stakeholders (i.e., individual workers, team, supervisors, and project manager), and tasks. The results of the recommended research can potentially help design and integrate a network of DT and techniques to develop and enhance SA in various scenarios.

Second, based on the results from this research, an ontology (or taxonomy) of SA is needed to represent the knowledge of safety information in the construction domain. The ontology can help people understand what information/knowledge is relevant to site safety and capture the relations of concepts for reasoning from a low level of SA (i.e., perception) to higher levels (i.e., comprehension and projection).

Third, as aforementioned, there is a need for research on investigating the statistical relationships between SA and safety behaviour. SA can be measured at the worker level using either subjective or experimental measurements. Statistical testing methods such as factor analysis can be performed to explore the structure of SA. A structural equation model can be conducted to test the relationship between SA and other safety factors (e.g., safety behaviour, stress, management commitment to safety, social support). The statistical results can provide significant empirical evidence regarding the usefulness of the concept of SA in construction safety management.

Finally, future research efforts should be made to conceptualise the role of DT in accident prevention strategies (e.g., safety management system, safety

culture/climate, resilience engineering). SA seems useful in connecting DT with classical accident causation models (e.g., Swiss cheese model). These efforts can lay a scientific foundation to integrate various DT into a platform to achieve a zero-harm vision.

5 Conclusions

By using a systematic review methodology, this paper reviewed studies that investigate the concept of SA for construction safety. The results suggested that SA elements can be divided into three categories: human, machine, and environment. A more comprehensive SA taxonomy remains an undeveloped domain. Several SA measurement methods were identified. The selection of method is highly dependent on the researcher's experience and the system architecture on measuring SA. A comprehensive understanding of SA is essential for improving SA measurement efficiency and effectiveness. The relationship between SA and DT, SA and safety behaviour, SA and hazard identification attract considerable attention. Furthermore, further efforts on developing an innovative digitalised situation-aware site that can deliver the right information to the right people at the right time were proposed by this research.

Asymmetrical Multiplayer Serious Game and Vibrotactile Haptic Feedback for Safety in Virtual Reality to Demonstrate Construction Worker Exposure to Overhead Crane Loads

Ingvild Moelmen, Haavard L. Grim, Emil L. Jacobsen, and Jochen Teizer

Department of Civil and Architectural Engineering, Aarhus University, Denmark

E-mail: elj@cae.au.dk, teizer@cae.au.dk

Abstract –

Construction still has high numbers of nonfatal and fatal occupational injuries. Works in highly dynamic and continuously changing environments involving heavy equipment pose numerous types of hazards. Potential struck-by incidents for pedestrian workers from overhead crane loads are a concern to many practitioners. Safety best practices suggest to avoid unsafe acts by early implementation of appropriate safety training. Serious games in Virtual Reality (VR) have proven efficient for such purpose because they engage and motivate the participants in the learning effort more than traditional methods can. However, most VR experiences are limited to one participant, and strict roleplay allows little interaction with the hazards. This paper demonstrates that an asymmetrical multiplayer serious game in VR can represent a more realistic work environment. The developed scenario contains several of the inherently embedded hazards and unpredictable human interactions involved in the specific use case of crane lift operations. Three players, of which two represent construction site personnel using head-mounted displays (HMD) and one operating a (gantry) crane using a remote desktop computer user interface, complete their work tasks in virtuality. Test results from 18 volunteering users, half of whom receive vibrotactile haptic feedback when confronted with hazards, show that such feedback positively impacts their hazard recognition rate. User awareness was also up to 35% higher while decreasing their time spent underneath a crane load.

Keywords –

Asymmetrical virtual reality, construction safety training, crane load hazards, multiplayer serious game, unsafe acts, vibrotactile haptic feedback

1 Introduction

The construction industry is one of the industries with the highest number of nonfatal and fatal occupational

injuries. Construction operations can often be very complex and usually involve heavy equipment, various hand-powered machines and tools. As such, work in construction can be dangerous [1].

One of the leading causes of construction workplace accidents, according to the Occupational Safety and Health Administration's [2] 'Fatal Four', are struck-by accidents. The most common accidents involving lifting operations are related to struck-by incidents when workers are frequently within the danger zones of the crane or parts of it. In the latter case, these are, for example, loads that are attached to a crane hook [3].

For such reasons, construction workers receive appropriate safety training. However, traditional safety training methods in construction have been criticized for becoming less effective when participants demonstrate a low level of personal engagement [4]. Among many other reasons, Virtual Reality (VR) has been proposed as an additional method for the safety training curriculum. As earlier research has shown, VR has proven to be a useful method to enhance the visual understanding of complex work tasks in various industries [5].

Since construction workers are susceptible to accidents, VR tools have already been specifically researched to improve safety training [6]. VR can provide trainees with the hands-on experience of dangers as it simulates reality in a safe virtual work environment. This approach eliminates exposing any participant to real dangers and gives a more significant learning outcome than traditional methods, says Sepasgozar [7]. Nevertheless, VR still faces many socio-technical challenges that research needs to address.

For example, displaying struck-by hazards such as those coming from heavy equipment in VR serious games have typically been automated, following predefined paths in experiencing them [8,9]. To resolve this limitation for good, asymmetrical multiplayer VR serious gaming is proposed. It permits user interaction by applying different display devices (immersive head-mounted displays and desktop computer displays) [10].

The objective and scope of this study are to investigate construction worker safety, particularly their

awareness of hazards in a dense and highly dynamic work environment. For this purpose, an asymmetrical multiplayer VR serious game is developed for testing participants in their roles of co-workers on an indoor construction site. Furthermore, the impact of receiving vibrotactile haptic feedback is studied. While individuals of one group of the participants receive the feedback in the form of warning signals as soon as they encounter danger, the ones belonging to the second group do not.

The following sections first review the most relevant construction safety background. The method section introduces a first-of-a-kind asymmetrical multiplayer VR serious game for construction safety training. While this work is still a prototype, early testing with participants is explained. Results that are encouraging lead to the section of implementation, limitations, and future work.

2 Background

2.1 Crane safety numbers and safe operation

Struck-by incidents are among the leading causes of fatalities in the construction industry. In 2019 struck-by hazards accounted for 15% of all construction fatalities in the United States [11]. It is also the largest contributor to nonfatal injuries in the construction industry, with 23.4% in 2019 [11]. Struck-by accidents account for many different hazards, including struck by heavy equipment and other vehicles, such as excavators, dump trucks, cranes (tower, mobile, gantry), or parts of thereof.

The most common accidents related to struck-by incidents involve lifting operations where workers are within the *danger zone* of the crane (def. *area where harmful contact(s) can occur with either the equipment itself or part(s) of it*) [1]. Hoisting operations are essential during construction projects. Cranes often operate with loads both near and above workers, often in crowded work areas that at times overlap with multiple crews on the ground [12].

The US Bureau of Labor Statistics reported 297 crane-related fatalities between 2011-2017 [13], of which over half involved a pedestrian worker being struck by moving parts or falling objects.

Recent years in the construction industry have seen a steady increase in the lifting operations performed on construction sites and off-site. One reason is the industry's trend towards using more prefabricated elements and modular building components [14]. Given the weights and sizes, such elements require lifting at some point in time in the construction supply chain and assembly process.

Therefore, Fard et al. [15] investigated 125 accidents related to modular and prefabricated building components. The results showed that 62% of those accidents occurred on the construction site, and most

were experienced during the installation task.

A similar analysis on accidents related to prefabricated elements was carried out by the Norwegian Labor Inspection Authority [3]. It investigated 21 accidents. In over 50% of the identified accident cases, workers were located in the danger zones [3].

The complexity of conducting safe crane operations requires considerable knowledge and experience. This is why it is essential to get the appropriate training and certification for operating cranes. As noted in regulations, among many other requirements, a crane operator shall correctly use and understand the crane operation controls and loading charts [16]. Furthermore, pedestrian workers must always ensure that they are aware of their surrounding environment, incl. the cranes. In the case of a crane's presence at work, workers need to familiarise themselves with staying out of any danger zones or not finding themselves inside areas where falling loads or crane components can strike them.

2.2 Existing and modern crane safety training

A typical construction safety training includes traditional classroom teaching, on-the-job training (OJT), and on-site safety meetings [17]. Classroom information is usually presented through textbooks, slideshows, and videos and is often referred to as *passive training*. On the other hand, *active training* is referred to as company-based training because it is linked to actual work tasks learned through active participation. The *safety meetings* on-site are often weekly or even daily and are an essential part of safety training. A current challenge is how effective workers learn and how well they use their safety knowledge in practice.

As experienced in many vocational schools in construction worldwide, the individual backgrounds of apprentices intending to become certified crane operators vary widely. Teizer et al. [4] argue that the traditional methods are ineffective for some participants. This may challenge passive training effectiveness, which is often little engaging and provides limited personalized feedback. Therefore, research proposes a shift towards engaging, motivating, and efficient training methods. These ultimately can ensure that long-term hazard recollection improves workers' awareness of risks while at work [18].

Alternative methods have been investigated to improve learning outcomes for students that are more engaging and motivating. One method that has been proven to be beneficial for safety training is the use of VR. VR is a computer-generated environment where the fundamental idea is to enable participant immersion. It provides the opportunity to explore and interact with the virtual environment (VE) and its components [19]. Therefore, creating training scenarios in VE where workers can simulate feeling present on a real

construction site allows them to experience hazardous situations that would otherwise be difficult or impossible to replicate in the real world.

Different display devices define the level of immersion the participant experiences. A desktop computer device with a mouse and keyboard gives the lowest degree of immersion. Head-mounted displays (HMDs), which are the most common form of displaying VEs, provide the user with a high level of immersion. If the hardware components can completely block out the real world, the user can become fully immersed in the environment and possibly achieve high illusions of presence and a high level of realism [5].

Recent game developments for entertainment have increased the use of several different display devices in one collaborative multiplayer VR environment. This is called *asymmetrical VR*. One or more players can be immersed in the same simulation with HMDs, while other players can simultaneously join through different displays such as smartphones or desktops [10]. This setup can be beneficial when there are limited VR-compatible devices as it can become quite costly to purchase multiple systems. In addition, asymmetrical VR also allows the inclusion of players who are susceptible to VR sickness.

Serious games for construction have not implemented asymmetrical VR components in the currently available VR serious games. This finding coincides with the fact that there are limited multiplayer virtual environments within the construction safety training field. However, the construction industry is greatly dependent on different professions working together, and there should be a greater focus on developing shared immersive experiences [20].

One of the first attempts to examine multiplayer environments for construction was developed by [21]. It was a VR multiplayer serious game developed to teach lean construction, with three participants interacting in a shared virtual environment while performing construction tasks in a less wasteful way.

Noteworthy to mention is also the pre-existing experiences of (some of the co-) authors with VR games for construction safety purposes. As seen in previous serious games [4, 8, 9], equipment performing lifting and transporting operations have been 'hardcoded' (automated) in these VE experiences. However, research is needed to prove whether or not such 'robots in VR' represent or get close to near-human behavior.

In addition, Golovina et al. [9] developed a VR serious game where data of the players' paths were tracked. The data included trajectories and timestamped locations of collisions when participants were in a danger zone or collided with equipment. The data log was used for run-time or post-experience analysis. Their novel approach allows for detailed instructor-student feedback, which demonstrated to improve learning outcomes.

However, all previously mentioned serious games were single-player environments and where equipment followed predetermined paths. This could potentially lead to players getting too quickly accustomed to and predicting the machines' pathway. Ultimately, this can eventually lower the level of realism of the user experience and adversely impact learning effectiveness.

In sum, current research gaps exist concerning safety training in virtuality utilizing the potential of multiplayer and asymmetrical VR components for creating more realistic training environments. The next paper section explains the method of developing the asymmetrical VR multiplayer scenario created to demonstrate worker exposure to overhead crane loads. An indoor environment was selected because previous research by Bükür et al. [22] showed success in limiting the visible workspace so participants would not lose oversight.

3 Methodology

The system used for the game development takes advantage of several different hardware and software tools and the cross-platform communication between these. The software and hardware tools presented in Figure 1 were used for developing, testing, and analyzing the serious game. This figure also shows how the data communication works with a central server and all clients communicating to ensure efficient data transferring. The developed virtual environment is created for cross-platform use, meaning devices from different suppliers can be used simultaneously in the multiplayer scenario. The game engine used for the development of the serious game was Unity 3D. The virtual environment was based on an already existing multiplayer serious game developed by the co-authors Jacobsen et al. [21]. It was significantly modified to fit the purpose of this research.

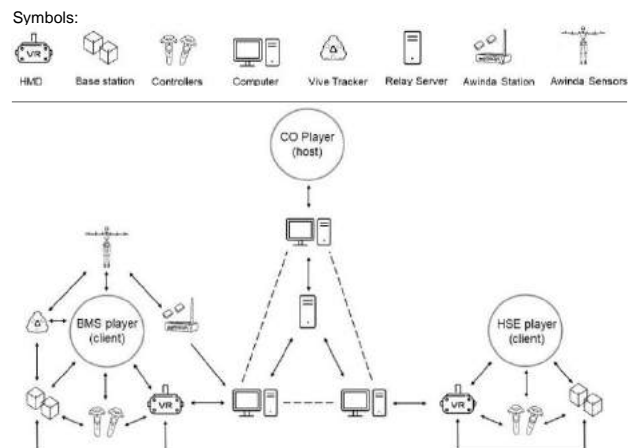

Figure 1. System architecture of the asymmetrical multiplayer virtual reality serious game.

Modifications were done by editing the scene in Unity and implementing motion data streaming from the external software MVN Analyse. Photon Unity Networking (PUN) provided the connectivity between the clients. The reason was that PUN proved successful in supporting a multiplayer environment in previous research [21]. Figure 2 shows how the developed asymmetrical multiplayer VR serious game environment that three human participants in the roles of, respectively, one worker (called BMS player), one crane operator (CO player), and one health, safety, and environment coordinator (HSE player).

Figure 2. Overview of the workspace in the asymmetrical multiplayer virtual environment.

To add complexity to the scenario, a (sometimes) moving robot on a fixed platform and a human-like robotic avatar were placed in the same scene (Figure 3).

Figure 3. Robotic arm and avatar of robotic player.

For most of the work time, the avatar was outside the safe area of the robotic arm. To make the avatar's motion most realistic to human body motions, an asset developed by Xsens was used to stream human body motion data from MVN Analyse into Unity 3D. This asset provided the opportunity of implementing a pre-recorded avatar

from MVN Analyse into the Unity scene. As motion data recording was created and imported into Unity, run-time performance was not tested but is optional for implementation. This can further improve the level of realism in the scene and add more features to disrupt the players in their assigned work environment. For simplicity reasons, the pre-recorded avatar is walking between a workstation and a stationary robotic arm in the center of the warehouse to do maintenance work.

Likewise, the previously mentioned industrial robot is placed in the center of the warehouse and enriches the game scene to be more realistic and creates a task for the pre-recorded avatar to facilitate interactions with the players. An animation was made to make the robot move more realistically. In addition, there is an opening in the safety barricades on each side of the robot station. This was done to create a shortcut that the players could potentially use. This area is classified as a danger zone and should not be entered.

The gantry crane controlled by one of the participants (CO player) is installed in the ceiling and can freely be moved across the warehouse. The area underneath the moving crane hook is divided into three safety zones, a red zone, a yellow zone, and a green zone. These zones are not visible to the players.

The red zone is the most dangerous area below the crane, which is directly underneath the load. A circle defines this area with the crane hook as the center and a radius equivalent to the farthest distance to any point on the suspended load [23]. The yellow zone is defined as a danger zone underneath the crane load, an area outside the red zone with a given radius from the center of the crane hook. This radius is equal to the red zone radius with an additional clearance distance. This additional distance is usually between 1.5 and 3 meters and is decided by a safety professional, taking the surrounding environment's nature, and the crane loads characteristics into account [22]. For the experiment, it was set to 2.52 m with the possibility of changing it via a slider in Unity (Figure 4).

Figure 4. Two colliders associated with crane load.

If any worker enters the red or yellow zone, a warning signal is given immediately to realize the hazardous situation and take action. In this research, this is done to

one of the two groups by vibrotactile haptic feedback. Finally, the green zone is defined as the area where ground workers are unlikely to get struck by falling crane load hazards [23] and therefore, no alarm is given.

4 Implementation

The VR multiplayer game environment set inside the warehouse is developed for the three players performing different tasks. Two players are immersed with HMDs and interact with the VE through controllers, whereas the third player operates the gantry crane using a computer screen and keyboard. To simplify, the players are divided into three categories: A construction worker wearing a Body Motion Suit (BMS) player, a Health Safety and Environment (HSE) player, and a Crane Operator (CO) player. Two of them were in the same room, the third one (HSE) was located in a different VR room at the research facility (Figure 4).

11. Boxes for CO players' task
12. Pre-recorded avatar
13. Robot arm station

Figure 5. Components of the virtual environment indicating the work tasks and their locations.

The Body Motion Suit (BMS) player is wearing the MVN Awinda sensors and HMD with controllers. Due to limitations in game development experience, the motion data could not be used to visualize a virtual avatar. The data, however, was used for post-game analysis. The BMS player has three different tasks shown through a virtual instructions board (see #1 in Figure 5). The tasks are placing six drywall sheets (#4), installing a toilet and sink with associated pipes (#5), and placing two electrical wires and lamps (#7).

An untidy workplace with unorganized equipment, material and waste have a negative effect on safety. This, combined with poor material storage, affects where and how workers move around a construction site, thereby also which hazards they might be subjected to.

The Health, Safety and Environment (HSE) player is the other player that works inside the warehouse using the HMD and controllers. The HSE player's task is to clean up the workstation and make it safe. This includes multiple objects and equipment scattered around on the warehouse floor. Furthermore, the HSE player has to place two safety barricades (placed just under #2) around the robot arm station to secure this restricted area (#13). Pictorial instructions are given (#2) at the start of the experience. While this forces the HSE to move, (unintended) interactions with the crane load may occur.

Before starting any work, the BMS and HSE player should put on a safety helmet placed on a shelf by the instruction boards (#3). This is required, as the personal protective equipment (PPE) visualizes the workers, making it easier for the crane operator to see them.

The Crane Operator (CO) player is the only player not immersed with the HMD and instead interacts through a desktop display. The task of the CO player is to move four boxes from two loading docks (#11) to a zone in front of one of the warehouse doors (#9). The boxes must be arranged in an order given on the instructions board. Because of the specific arrangement, a temporary loading zone (#10) is implemented in the robot arm station (#13), separated (and eventually secured) by barricades to allow for the rearrangement of boxes. All other components of the virtual environment not explained are listed and visible in plan view in Figure 5.

The arrangement encourages and forces interactions among the players and their roles. For example, the BMS benefits if the HSE does a good job cleaning the workspace or shielding off the robotic arm area. Unsafe acts like players entering this area when the robotic arm is in motion are then less likely to occur.

When all the clients have joined the multiplayer scene, the players can begin their tasks. Two different test scenarios were created and tested on two groups of several rounds to determine how the players on the ground performed relative to the gantry crane and its load.

The first scene, which was tested on the first group,

did not give warning signals to the players when they were within the danger zone of the crane. The second scene tested on the second group gave warning signals through vibrotactile haptic feedback. For simplicity reasons, players experience automatic vibrotactile haptic feedback as constant vibrations in the controllers.

The haptic feedback is given when a player enters the long-range distance. This warning from danger implies taking action. If the players do not take immediate action after the initial haptic feedback warning, they can find themselves inside the short-range distance. When a player enters the long-range distance or the short-range distance, their X and Y coordinates are written to a log file for further (immediate or later) analysis.

An experiment was conducted with participants that studied or worked within the construction engineering field. 18 participants were divided into two different test groups to measure a potential difference in performance when vibrotactile haptic feedback was enabled and disabled. A total of six rounds were conducted, three rounds per group, with three participants per round. Before starting, the second group participants were informed that vibrations in the controllers could occur and that the vibrations were warning signals of being in danger. However, they were not told what the cause of the danger might be. This was to avoid affecting their awareness of the overhead crane.

After the experiment, participants were asked to fill out questionnaires to evaluate the usability and user experience. The *System Usability Scale* (SUS [24]) and *User Experience Questionnaire* (UEQ) [25] were used for this purpose. Due to the limited space, this is not further analyzed in this paper.

Two rooms and three computers were needed for the experiment. As explained earlier, the CO and BMS players were in the same room, and the HSE player was in another, separate room. Due to how the multiplayer scenario is developed, all players needed to be connected through different computers.

5 Data collection and analysis

The data collection was done within Unity using C# scripts, which collected X- and Y-coordinates of objects in the scene in run-time. The coordinates were collected as tracking coordinates for both the workers and crane and as collision coordinates between the workers and the crane. The tracking coordinates were collected continuously during the entire game, while the collision coordinates were collected when a player entered a predefined zone (crane danger zone or the robotic arm area of the site). The data was written to a .txt file for simplicity in further analysis. This setup was done for both players in VR. The data was imported to MATLAB and visualized to show the movements of players and

crane in the scene. Furthermore, the collision coordinates visualize where the player had been in danger.

6 Results

Note that the 9 participants in the first group were given minimal information about how to implement safe behavior in the VE. Table 1 presents the comparison of the total crane collision occurrences and durations between the two groups.

Table 1. Crane load collider incidents in groups 1 and 2 (with and without haptic feedback (HF), respectively),

Group	Long-range distance (2.52 m)		Short-range distance (1 m)	
	Count [No.]	Time [s]	Count [No.]	Time [s]
1 (w/o HF)	57	314	11	35
2 (w/ HF)	47	203	11	24
Delta [%]	-17.5	-35.4	0	-31.4

A significant decrease can be seen in both duration and occurrence for the participants who received warning signals when experiencing the dangerous zone underneath the crane load. The total duration underneath the long-range distance decreased by 111 seconds (35.4%). There was a total of 10 occurrences less for group 2 (17.5% decrease). Furthermore, the total duration underneath the short-range distance decreased by 11 seconds (31.4%), while the total occurrences were the same as group 1. Figure 6 shows example illustrations from two of the participants, one belonging to each group. The plots generated automatically in Matlab[®] precisely document where and how frequent these incidents occurred.

It indicates that the players in group 2, who received haptic feedback, were more aware of the crane and their safety, as they had an average decrease in all parameters measured, except occurrence. Participants did not always know which direction the crane was moving. It was observed that when participants were walking, and the crane came behind them, they backed away as they assumed it was in front of them, thereby walking further into the danger zone of the crane. Yet, the change in short-range duration demonstrates how much faster the participants from the second group retreated from the hazardous area due to the shorter duration. The results suggest haptic feedback affected their safety awareness.

There were no changes seen concerning the short-range distance. The skillset of the players might be a reason. Furthermore, the results were highly dependent on the CO. Some CO players were more careful and kept to one side of the warehouse, as seen when comparing the play rounds in Figure 7. Since three computer systems

needed to send information back and forth instantly, minor synchronization errors were experienced, as shown in Figure 7. Such delay leads to minor errors in the results. To avoid this from happening, all information was taken from the computer of the participant that was in focus. This means that crane trajectory data was also taken from the BMS system when analyzing the BMS player. This ensured that what the player saw was also what was used for data analysis.

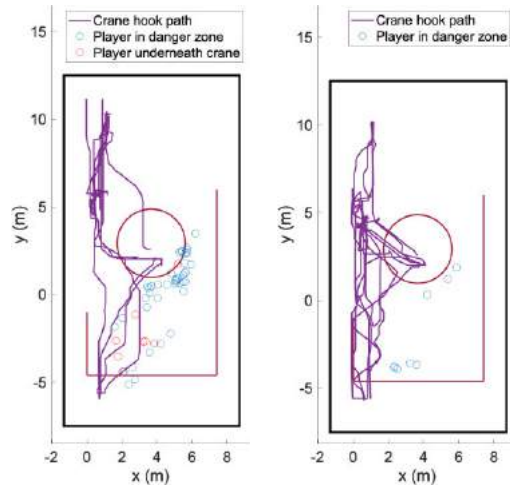

Figure 6. One sample participant of groups 1 and 2, respectively: #1.2.1 (left) and #2.3.1 (right).

Figure 7. Slight deviations in the crane hook paths in the multiplayer asymmetrical serious game as experienced by the 3 players (BMS, HSE, and CO) in the virtual environment.

Based on the track path analysis, it was observed that all crane paths were unique and different even though the tasks were the same for all six rounds. In addition, results from the UEQ showed that the participants immersed with the HMDs experienced the scene more unpredictable than the COs. This verifies that including a human-controlled crane in a VR serious game creates

more realistic paths that the other players (workers on the ground) cannot predict easily.

7 Conclusion

An asymmetrical multiplayer VR serious game was developed for the first time for construction safety training purposes. The game's novelty is that it allows players to immerse themselves in a highly dynamic virtual work environment with others via both head-mounted display and desktop display to experience safe exposure to hazards. This allows for the training to be more realistic as other participants are in the environment just as in reality. While the external player operating a gantry crane can act unsafely, such as exposing fellow players to an overhanging load, incident data is collected. Furthermore, the study quantified the effect of vibrotactile haptic feedback on safety awareness, and therefore also how this could change the behavior and safety performance of participants.

In-game data analysis and evaluations of participant user experiences indicate that both asymmetrical virtual environments and vibrotactile haptic feedback are useful in safety training. The first created unpredictable and thus more realistic interactions in the VE than existing serious games demonstrate. The second reduced the frequency and length of hazard exposure. Proven was that players with feedback also left hazards areas quicker.

Based on further findings from participants' feedback, players fully immersed in the scene experienced the scenario much more unpredictable than the players operating the crane through a desktop display. The virtual environment benefited from a human controlling the load.

Some technical limitations and that the particular serious game tested only human-machine interactions encourage further research and development, e.g., an analysis of the usability and user experience.

Abstract –

The construction industry is suffering from a high rate of accidents that significantly affect the overall performance of projects. Compared to the conventional safety training methods, Virtual Reality (VR) games offer a more immersive and interactive learning experience for the participants. However, training scenarios in most of the existing VR games lack complex tasks and the realistic environment required for actual construction. This work proposes a conceptual framework for dynamically updating VR training games through information streaming from the digital twins. The training scenarios in VR games are automatically created from the project intent information, project status knowledge, safety regulations, and historical knowledge provided by the digital twins. Therefore, construction workers can be trained in realistic training environments with relevant tasks they soon afterwards pursue. Dynamic VR training is expected mutually beneficial for enhanced digital twins and periodic construction safety management. Inadequate technology readiness level of the construction industry and difficulty in collecting good quality data are some of the major challenges for implementing this framework.

Keywords –

Digital Twins; Virtual Reality; Construction Safety; Safety Training; Human-Computer Interaction.

1 Introduction

The construction industry remains one of the most dangerous workplaces for the past several years, and the latest report shows the highest increase in fatalities since 2007 [1]. Several training sessions are conducted for construction workers to create safety awareness. However, the injury rates in the industry remain high [2], and there is a compelling need to improve safety training methods. Even though the effectiveness of traditional training methods is supported by statistical evidence, the computer-aided training methods are superior to them in many aspects [3]. Better engagement of trainees,

provision of text-free interfaces and representation of actual workplaces are notable advantages of computer-aided training methods such as VR games. Besides, recent studies in VR training demonstrate the possibility of automated performance assessment [4] through runtime data collection and collaborative training using multiplayer games [5].

The Digital Twin (DT) is an up-to-date digital counterpart of the physical entities in a system [6]. The physical entities in construction include objects and processes in a construction project. The vast potential of digital twins for various applications such as construction safety, progress monitoring, resource allocation and decision making is yet to be explored. Seamless data collection and transfer through DT is possible with state-of-the-art sensing technologies. The information from digital twins can significantly improve VR training in many aspects. This study proposes a conceptual framework for dynamically updating the VR environments and task scenarios for construction safety training through digital twin technology. The possibilities and limitations of the existing technologies for this purpose are evaluated.

2 Background

2.1 Virtual Reality for safety training

VR has been an integral part of training in several industries such as construction, education, healthcare, design, manufacturing and defence. It offers a vivid, immersive and interactive experience to the users in a safe environment. Even though the earliest adoption of VR in construction dates back to the 1990s, the past decades have seen a tremendous increase in its applications [7]. The primary application areas in construction include visualisation, planning, collaboration and training related to engineering design, project management, safety, construction equipment, and workers [8, 9].

The platforms for VR vary in scale and level of immersion the users' experience. It can be stationary displays in the form of desktop computers or surrounding

screens like CAVE. Other than that, VR platforms include head-mounted displays (HMD) such as helmets and hand-held displays such as tablets or smartphones [10]. Among these, HMD offers the highest level of immersion for the users. In addition to headsets, treadmills, haptic devices such as data gloves and body motion suits enable human-computer interaction through VR environments.

The serious games in virtual reality were designed to expose users to numerous situations that prepare them for future scenarios [11]. The awareness inculcated in the users through highly engaging and challenging gaming experiences would be translated into timely responses in the workplace. The workers can be trained with high-impact trade-related incidents without exposing them to dangerous conditions. Besides, construction activities often demand collaboration between various workers and trade groups. Multiplayer VR environments provide users with a collaborative experience similar to that of an actual construction site [5].

The VR technology has been extensively used for safety training in construction. However, the potential of data mining to improve the performance of the participants were not fully explored. Golovina et al. [4] proposed a method to automatically collect data related to safety violations during VR training. The object colliders of the players, hazardous objects and construction equipment in serious games collect data of close call events and harmful collisions. This critical information, which is seldom available in conventional training methods, helps to provide personalised feedback to the players. The immersion level of the players can be further enhanced by Augmented Virtuality (AV) training environments. Wolf et al. [12] deployed a modified angle grinder as an AV controller to provide the players with an enhanced learning experience and transferrable safety awareness. They furthermore implemented in-game questions through pop-up boards, which tested the players' actions and their understanding.

The VR environments were earlier criticised that their level of sophistication is less than what is required for reality [13]. The creation of VR scenarios from conception to execution is as complex as any other entertainment industry project regarding the level of details and programming efforts [14]. Some of the existing studies have proposed the use of information from BIM to enhance the VR training environments [4], [15, 16]. The current study envisions to create realistic and dynamically evolving training scenarios through digital twins of construction projects.

2.2 Digital twins for construction safety

An efficient Job Hazard Analysis (JHA) is essential for alleviating accidents in construction sites. Even in this era of advanced technologies such as Building

Information Modelling (BIM), JHA is performed manually, resulting in erroneous and ineffective reporting and mediocre safety management [17]. Safety engineers are assigned to analyse the hazardous elements in each task and determine the order of priority for mitigation. They categorise the risk of the incidents by analysing their level of severity and probability of occurrence [18]. Those two measures rank the potential risk on a scale from the most negligible to the most severe outcome. The process of job site safety analysis is divided into three tasks: (a) loss-of-control identification associated job or activity, (b) assessment of the level of risk for the identified incidents, and (c) action controlling the risk to reduce or eliminate it [19].

As Sacks et al. [20] point out, federated building models representing as-designed and as-planned states of a project are not digital twins. Building information models as the digital representation of buildings or infrastructure lacks frequent as-built and as-performed states essential to understand and continuously improve the construction workflow. To make matters worse, construction safety is far behind other disciplines in BIM for which somewhat structured processes and tools exist, for example, estimating construction costs and schedules [21]. Likewise, numerous data acquisition technologies exist that hardly touch the world of construction safety [2].

There is a significant opportunity for digital twins explicitly tailored for construction safety to provide new kinds of decision support to key stakeholders. Primary stakeholders are the health, safety, and environmental (HSE) coordinators but include all others who have the same responsibility in their job profile (e.g., engineers, planners, construction managers, workers). The digital twin technology has great potential to stimulate various scenarios for construction safety research. However, many research efforts often only target the use of a singular technology without integrating the technology and subsequent analysis into a broader, more comprehensive framework for identifying and preventing hazards [15]. The current study proposes to integrate VR safety training with digital twin information streams.

2.3 Integration of Virtual Reality and digital twins

Serious games in VR have been increasingly adopted for construction safety training. Training scenarios in most of the existing VR games lack complex tasks and the realistic environment required for actual construction. This study proposes to enhance the VR training scenarios through project-specific details from the digital twin. This concept may appear ambitious considering the technology readiness level of the construction industry. Besides, data acquisition and transfer in the construction industry are much more challenging than more organised

industries like manufacturing and design. Consequently, there are early attempts to integrate digital twin and VR in other industries. Even though most of these studies are on a conceptual level, there is a great possibility for their implementation in the near future.

Tao et al. [6] proposed a generic framework for integrating VR and AR (Augmented Reality) with a digital twin. The possible seamless integration of physical entities and virtual entities through interaction functions and VR/AR devices is outlined in the framework. The physical entities include machines, materials and the environment; virtual entities are their virtual counterparts. The virtual entities interact with physical entities and are synchronised through interaction functions, VR/AR devices, and sensors. The interaction functions include data import, image processing, rendering, tracking and simulation. VR/AR devices can be HMD, data gloves or handle. The digital twin data would be in the form of point clouds, images or videos. The users can experience and monitor various industrial processes in the physical entities through the virtual environment. They can intuitively perceive the internal operations in machines through immersive VR/AR devices. Examples for application of VR - digital twin integration include remote surgery [22], customised product development [23], manufacturing planning [24] and machining process monitoring [25].

3 Digital twins and Virtual Reality for construction safety

Using VR environments for teaching has throughout the literature shown more remarkable results than traditional lectures [3]. By basing the VR environment on project status knowledge (as-built and as-performed), it is possible to do learning scenarios based on real-life events for the given project. Simulating the safety status will allow for lessons learned to be transferred back to the digital twin and optimise current safety plans. Figure 1 shows the conceptual diagram of Digital Twin for Construction Safety (DTCS) and how dynamic VR training can be integrated with the DT.

3.1 Prevention through design and planning

Alternative construction plans are handed to the prevention through the design and planning module (shown in green) of the DTCS and enhanced with safety, based on the safety regulation of the construction site. The system analyses the hazard spaces identified in the design and hazard spaces identified in the process (e.g., crews working simultaneously on different stories, creating hazard zones in terms of being struck by an object from above). The safe alternative plans are returned to the Digital Twin for Production Planning

(DTPP) for decision-makers' (stakeholders of the project) selection, consequently updating the baseline plan from which the construction site is built.

3.2 Conformance checking

The conformance checking module (shown in yellow) should find and classify discrepancies, including severity level, between the plan and reality. This information should be stored, and when the HSE expert has visited the problem, they can provide new information on the correctness of the output (in terms of both incident classification and its severity). This information provided by the HSE should be used to improve the classification of future occurrences and to update the best practice. An example of an updated best practice could be to use a safety net in some situations to avoid the repeated removal of a guardrail.

3.3 Right-time analysis and mitigation

The right-time analysis and mitigation module (shown in red) perform complex event processing and classification based on the reality of the construction site, the raw safety monitoring data, historical knowledge, and safety regulation. Then the workers are alerted to prevent both accidents (i.e., fatalities, serious injury, and minor injury) and incidents (i.e., close calls and unsafe acts) before they occur. The module subsequently performs an accident investigation, where the root cause of the incident or accident can be determined and prevented in the future. Besides, the feedback to and from the decision-makers are stored and used in processing/classification- and-investigation-mechanisms in this module. These are updated and used in the prevention through design and planning module (i.e., the first component of the DTCS), conceptually closing the loop of the digital twin for construction safety.

3.4 Dynamic Virtual Reality training

The dynamic VR training module (represented in blue) includes updating VR games and periodic training of workers using the latest information from the DTCS. By feeding the model with the accident type and the area, the smart VR environment can produce relevant scenarios for each incident fed into the system. This will be done based on the location and type of hazard. Both colliders and data collection capabilities will be automatically created from this scenario before a game is conducted. The workforce and the digital twin mutually benefit from this. The worker receives training, and the digital twin receives knowledge that can be utilised when other prevention approaches are used. Besides, this knowledge can be utilised when the Safety Key Performance Indicators (SKPI) are assessed for a plan.

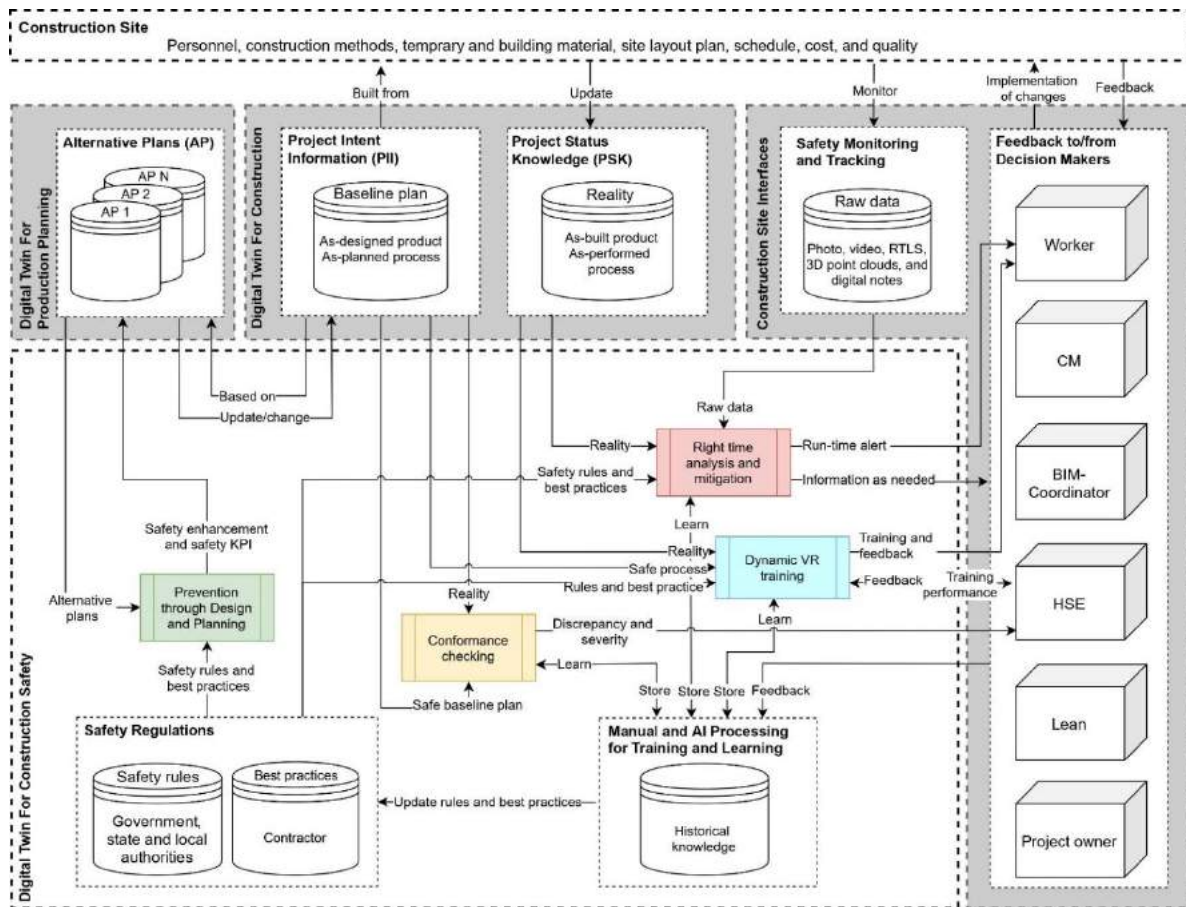

Figure 1. The concept diagram of the digital twin for construction safety and interaction between various components. The dynamically updated VR training module is presented in blue.

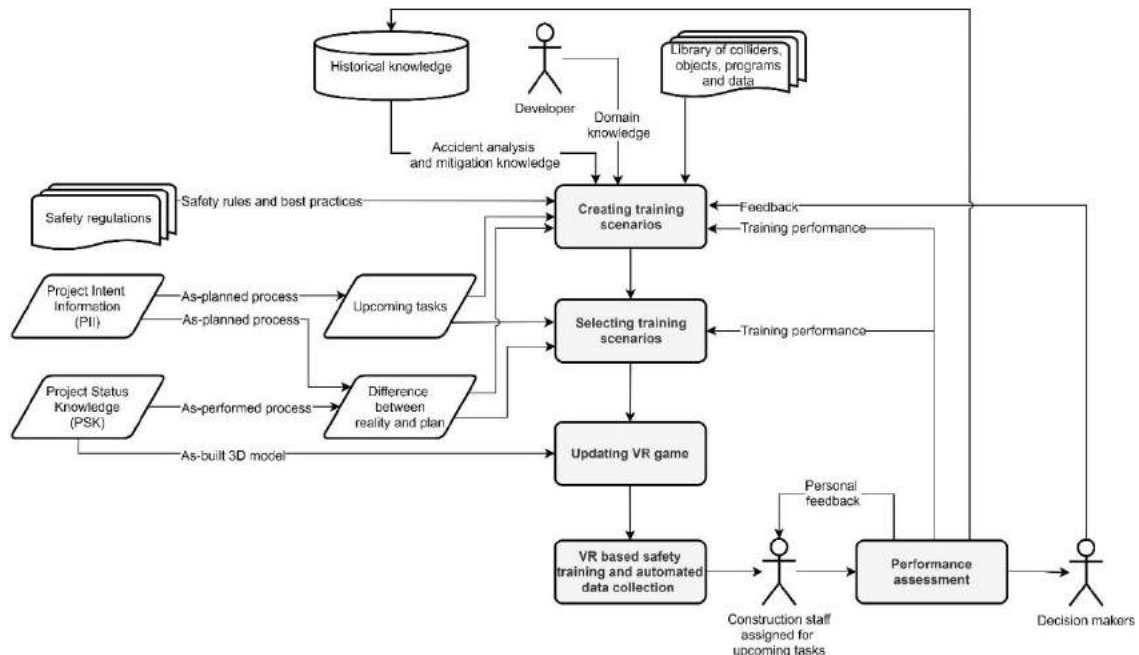

Figure 2. The framework for dynamic VR training for construction safety.

4 The conceptual framework for dynamic Virtual Reality training

A construction site is inherently complex, and the participating agents are presented with frequent unprecedented challenges. This is one of the main reasons for high accident rates, which involves even experienced workers. The accidents can be reduced to a great extent if the labours are trained in a work environment similar to what they face in real life. The dynamic VR games present the labours with training environments that are created from the digital twin of their construction site. The training scenarios are periodically updated with the progress of the work. Therefore, the labours can perform the tasks, make mistakes and learn without fearing the possibility of injury.

The conceptual framework for development and implementation of the dynamically updated VR training games are illustrated in Figure 2. The first set of training scenarios is created with information from various digital twin databases such as historical knowledge, safety regulations and a predefined object library. Then the training environments are periodically updated based on the information streams from the digital twin.

4.1 Creating and selecting initial training scenarios

Creating safety training scenarios requires geometrical information, hazardous zones and objects for interaction. The initial geometry of the training environment is created based on as-designed 3D models and training tasks based on as planned process from the Project Intent Information (PII). The geometrical information is later updated based on as-built products and training tasks based on as-performed processes from Project Status Knowledge (PSK). If there is any difference between reality and plan, the geometry and training tasks in the VR game are modified accordingly. Once the initial set of training scenarios are generated, all scenarios relevant to the upcoming tasks and work environment are selected from them for training. An example for creating and selecting training scenarios is shown in Figure 3 [26]. Here, the geometry of the building is created based on PII and PSK. The upcoming task is plastering as inferred from the project completion status. Therefore, the workers will be trained to perform plastering in the VR environment. All training scenarios relevant for plastering work are selected for updating the VR training game.

The potential hazardous zones are generated using the

historical safety database and a library of predefined standard safety solutions. This library contains objects, colliders, programs and data related to probable accident mitigation methods. The objects are created to interact with the training scenarios and rectify the hazards [26]. (for example, a guard rail is used at a leading edge or a cover over a hole). This interaction is enabled by creating object colliders that can be used to ‘snatch’ objects to a location. This information needs to be created automatically for updating the VR games.

Consider Figure 3 for determining hazardous zones. This is a leading-edge scenario where a guardrail is missing. The scenario task is to locate the hazard and choose the right rectification strategy. According to safety regulations and historical knowledge, the leading-edges should be adequately secured to avoid falling from height. The current scenario task is rectifying the hazard by placing a guardrail. A specialised developer manually creates these scenarios. As new hazards can be introduced to the system using the information from the digital twin, the development is a continuous process that will be iterated throughout the project.

4.2 VR based safety training and automated data collection

Once the VR game is updated with all scenarios relevant to the upcoming tasks, the labours can be trained before their work. Each training task is designed as per safety regulations to inculcate awareness and teach best practices to the labours. The serious games are updated with potential hazard zones, construction equipment and relevant objects for interaction. Colliders are created at locations where possible interaction would result in close calls or accidents. These colliders are programmed to collect safety violation data automatically. Therefore, the VR training can provide personalised feedback to the participants. Besides, the possible accident zones can be identified before starting the work.

In the example illustrated in Figure 3, the leading-edge and the virtual avatars of the workers are assigned with safety envelopes. The safety envelopes are colliders of certain size specified by safety regulations and historical knowledge. Whenever the workers move close to the leading edge, the safety envelopes interact. Then data related to these interactions such as time, duration, proximity and number of violations are automatically recorded. This data is used for performance assessment. The training scenarios in the game are updated based on the PSK. Therefore, the accident zones such as unguarded leading-edges and cluttered workplaces can be identified during VR training and rectified before the commencement of actual work.

Figure 3. An example of a training scenario for construction safety involves missing or inadequate guard rails at an elevated work station [26].

4.3 Performance assessment

The data relating to the performance of the players in terms of task execution, completion and safety violations are recorded during training. Automated assessment of the performance of individuals or groups is readily available after completing the training. The decision-makers and instructors can provide feedback to improve the performance. These trained labourers tend to have more situational awareness than those trained in an unrelated work environment without personalised feedback [5, 26]. Examples for data collected from the training scenario in Figure 3: the number of close-call events such as workers moving closer to the leading-edge, and time taken by the workers to detect the hazard, rectify the hazard and complete the task. Each worker can improve their performance in detecting the hazard or rectifying it based on personalised feedback.

4.4 Creating and selecting new training scenarios and updating VR games

After the initial set of training, VR games are updated based on the performance of the labours and feedback from the decision-makers. If most of the players face difficulty performing certain tasks, the training scenarios need to be evaluated. Suppose there is an undetected hazard in the training scenario, and all participants are interacting with it. In that case, it needs to be included, even if it is not part of the upcoming task (for example, a cluttered workplace that may cause slips or trips). If the labours are unfamiliar with the available safety solutions or are underperforming, they should be further trained to achieve the required performance. New safety solutions should be introduced from the library whenever

necessary (If guard rails in the leading-edge are being removed frequently, introduce safety nets). The new safety solutions can be generated based on the historical knowledge database. Besides, the newly created safety knowledge from the VR training is added to the knowledge database.

Alternate training scenarios should be introduced, or new training scenarios must be created if the existing scenarios are inadequate (The workers in Figure 3 should wear safety lanyards if the barricading do not provide enough protection). The decision-makers should be informed of any significant safety issues identified in the as-designed model during VR training (for example, issues in the site layout or logistics that may pose frequent and unintended interaction between workers and moving equipment). The VR environments should be updated after rectifying the issues on the construction site.

As the construction work progresses, the VR environment must be updated with the as-built 3D model from the digital twin. The training scenarios are either created or selected from the existing scenarios based on the difference between reality and plan. Therefore, the labours are always trained with the latest VR game before their work. Consider the example of updating in the VR environment with an as-built 3D model that contains unguarded leading edges. Here the program would look through the list of training scenarios and find the scenario linked to the potential incident. The found scenario is then placed on top of the as-built model as intractable objects, such as guardrails. The scenarios will also be created from the information obtained from as-planned process, to ensure workers are trained in upcoming environments. The VR training games are dynamically updated until the completion of the project.

5 Discussion and conclusions

High accident rates in the construction industry are one of the primary reasons for its low productivity. Conventional safety training methods seem to be inadequate for inducing safety awareness in workers. Safety training through VR technologies provides more immersive and interactive training experiences. These training experiences create significant interest in participants and result in enhanced safety performance. The data generated during VR training has great potential for improving the training process yet is seldom explored. Earlier studies have shown that these data can be used for automated performance assessment and provide personalised feedback to the participants.

The current study proposes a new concept for integrating VR training with information streams from the digital twins. The training scenarios are automatically created from the project intent information, project status knowledge, safety regulations and historical knowledge provided by the digital twins. Therefore, the workers can be trained in realistic training environments with tasks relevant to their assigned work. The accidents can be reduced to a great extent due to prior experience in similar work environments. The knowledge generated through dynamic VR training is updated to the digital twin database. Conflicts in site layout, planned processes, or resource allocation can be identified before execution through VR training. Periodic data streams from digital twins enhance training scenarios. Therefore, dynamic VR training is mutually beneficial for digital twins and construction safety management.

6 Challenges and future work

The concepts discussed in the paper aims to explore the possibilities of digital twin and VR for holistic construction safety training. Even though these technologies have been adopted in other industries such as manufacturing, aviation, and health care; the construction industry still lags behind. The current technology readiness level of the construction industry is inadequate for successfully implementing dynamic VR training for safety. Although BIM has been gaining momentum in the industry for the past couple of years, the digital twin technology is relatively new.

The digital twins are expected to deliver the states of the project to update the VR games for training. Most of the time, the quality of data and level of information collected from construction sites are not sufficient to create a realistic training environment. Collecting and frequent streaming of high-quality data through digital twin may be computationally expensive and economically demanding. The high investment in digital twins and dynamic VR training can be justified by

reducing accidents and loss of working hours, in addition to improvement in productivity and overall performance of the project. Future work includes validation of the proposed conceptual framework through the information streams from the digital twin.

The nuances of implementing digital twins for a construction project are yet to be explored. For example, it is hard to obtain repeatable and ready-to-use solutions from past construction projects due to the uniqueness and inherent complexity of every project. Therefore, every construction project needs to invest a lot of time and effort in creating project-specific training scenarios and VR environments. Currently, the developer manually creates training scenarios by identifying the semantic relationships of objects and the surrounding environment. Consider a labourer working at height near a leading edge: A human developer would easily understand that barricading the leading edge is not enough to avoid potential accidents. The labourer should be provided with PPE and safety lanyards to avoid potential fall from the height. Therefore, the safety training scenarios should be created with due diligence. This process is often tedious and time consuming for a continuously evolving construction project. The future works explore the possibility of automating the creation of semantically meaningful training scenarios.

Abstract -

Construction sites are dynamic, and the environment is changing fast, which means the collective safety equipment, such as fall protection barriers, should also be changed to keep it compliant with the construction codes. However, any safety equipment can become non-compliant for several reasons, e.g., temporal removal in combination with incorrect or omitted re-installation or changes in the building process. Thus, there is a demand for frequent inspection of the equipment, which is time- and labor-intensive as this is currently done through manual examination by safety experts. In this work, we utilize an unmanned aerial vehicle (UAV) to detect the presence, absence, and defects of safety equipment in construction work-site environments. Furthermore, the UAV continuously inspects and provides safety object location information that human collaborators can use to improve safety within the environment. We utilize an 3D occupancy grid representation to map the environment and compact point pair feature representations for efficient and robust object recognition and pose estimation. To assess the applicability and accuracy of our methods for model-based pose estimation of Building Information Model (BIM) structures, we created a realistic, simulated construction environment. Our experiment demonstrates the applicability and precision of drone-aided localization and inspection of safety equipment in the construction industries.

1 Introduction

Construction is considered one of the most dangerous industries due to the continuous change in the environment [1]. Construction safety design and planning is, therefore, a vital part of the construction business. Thus, comprehensive regulations and guidelines have been developed to keep construction workers safe while construction work is undertaken. Despite the labor-intensiveness of the creation of a safe construction plan, it is paramount. As this is the case, time and effort are allocated to facilitate and ensure health and well-being for the workers and prevent fatalities, severe injuries, minor injuries, and close call accidents (also referred to as prevention through design (PtD)). A statistical analysis of industries and their hazard types has been compiled into [2] in the US. The report

Figure 1. Simulation mission of an autonomous construction site inspection task using a multi-stereo camera UAV.

from 2019 shows that fatalities in the private construction industry correspond to 21.6% of fatalities (4907). Furthermore, the report shows that fatalities exclusively as a result of falls correspond to 33.5%. This is the reason that our work is focusing on fall hazards and more concretely protective barriers. We base the safe design on a software system called SafeCon [3], which automatically identifies the hazard fall-spaces in the BIM according to the regulation described in BG Bau 100 [4]. The system enhances the model with the safety equipment necessary to adhere to the [4] regulation. Another indispensable aspect of safety in construction operations is inspecting and localizing missing or deficient safety equipment (e.g., guardrails). Inspecting collective safety equipment is also a labor-intensive task as construction sites are very dynamic; thus, the inspection must happen with high frequency. Often, the installation of the measure differs from the intended quality designed in digital models. Using data from an UAV provides a real-time object location to centralized or distributed systems. As-planned vs. as-performed comparisons can extract deviations that have to be followed up and addressed.

The proposed method identifies critical incidents and

points these out to the responsible personnel in a construction site's centralized safety operations center or individual workers through augmented reality (AR) glasses. A solution for autonomous barrier detection and pose estimation in construction environments is made by mapping the environment using stereo camera systems and utilizes 3D point cloud information to detect the type and location of barriers in the environment. We base our work on the method presented in [5] representing objects using a hash table of shape features, which efficiently allows matching features that vote for object pose hypotheses. An experiment in a realistic gazebo environment demonstrate the applicability of our method for localization and pose estimation of barrier structures in construction site environments.

2 Related Work

In order to create a safe construction design and plan, one must include both the rules that apply to the country and region where the construction is undertaken. The rules describe clearly what, for example, a guard rail has to comply with to be correctly installed. A safeBIM can be modeled manually, where the as-designed baseline plan is enhanced with safety equipment by safety experts according to the safety rules, which is the typical approach nowadays [6]. Another approach of turning the empty BIM into a safeBIM is utilizing an automated framework, like SafeCon [3]. In this work, the safety regulation is modeled into a logic-based domain model, consisting of spatial artifacts that can be used to analyze and enhance the incoming BIM. The process flags the presence of fall hazard paces, which need mitigation by collective protective equipment (e.g., guardrails). The output is a safeBIM (as-designed) plan that can be used to compare the actual state (as-built) of a construction site captured in, e.g., point cloud data.

In terms of automated safety inspection in construction, two main branches of research exist: (1) is based on sensors placed on UAV. Therefore, the acquisition of the as-built-state is included in the research, and (2) where the focus is more on the training and comparing different computer vision methods/approaches and less on the data acquisition. In the first branch, different research methods have been carried out. [7] presents a well-defined process (using IDEF0-modeling) to apply drones on a construction site and integrate UAV and BIM. [8] also presents a workflow that is more dedicated to detecting and locating guardrails and openings on surfaces. The analysis is based on point cloud data that is generated from RGB images and video feeds. A pilot study was carried out in a mock-up setting, where the UAV records a guardrail and an opening in the testbed. The study in [9] is another example where a UAV is applied for guardrail inspection. The objective is to analyze the guardrails' level of compliance with safety

regulations. The inspection is performed based on visual, physical markers placed on the guardrail boards and a distance calculation. The distance between makers facilitates the compliance checking of the guardrail. [10, 11] develop a UAV platform that can be used in the construction industry and analyze the accuracy and barriers in UAV application in this industry. Finally, [12, 13] utilizes the UAV as help to reach inaccessible, hard-to-reach, and unsafe areas for safety assessment. The analysis is mainly based on manual inspection of the video/image feed.

The other branch of fall hazard prevention equipment inspection concentrates more on computer vision than image acquisition. [14] applies an R-CNN to detect workers in the scene and, afterward, a CNN to detect if a worker uses a safety harness [15]. Investigates safety rule compliance of guardrails on scaffolds using 3d point cloud data. They first find the working platforms by slicing the point cloud and locating the guardrails in the close vicinity. Subsequently, the guardrails are conformance checked. [16] applies transfer learning in their process of detecting guardrails.

Object recognition and pose estimation play a role of significant importance in robotics applications. In the following, we review the related work on this topic in regards to 3D point cloud data. There are two main approaches to this problem that depend on the availability of 3D object models: 3D model-based and learning-based. If one has a description of the 3D shape of the object, either given by a parametric surface representation or by a CAD mesh representation, the 3D model-based methods are often used for simultaneous object recognition, and 3D pose estimation [17]. On the other hand, if such representations are not available, the dominant approaches rely on machine learning techniques that learn an internal model representation given a set of image samples of the object, acquired by the robot sensors [18].

One of the most successful approaches for model-based 3D object recognition using point clouds are based on [19],[20] where a global descriptor for a given object shape model is created, using point pair features. The CAD model of the object is used to create an extensive database of features. At run-time, the matching process is done locally using an efficient and robust voting scheme similar to the Generalized Hough Transform [21]. Each point pair detected in the environment casts a vote for a particular object from a database of known objects, and a 3D pose [22],[5].

In this work, we study the suitability of the latter methods for object detection in construction environments, since we assume that geometric models (i.e., 3D CAD) representing known objects in the environment are provided.

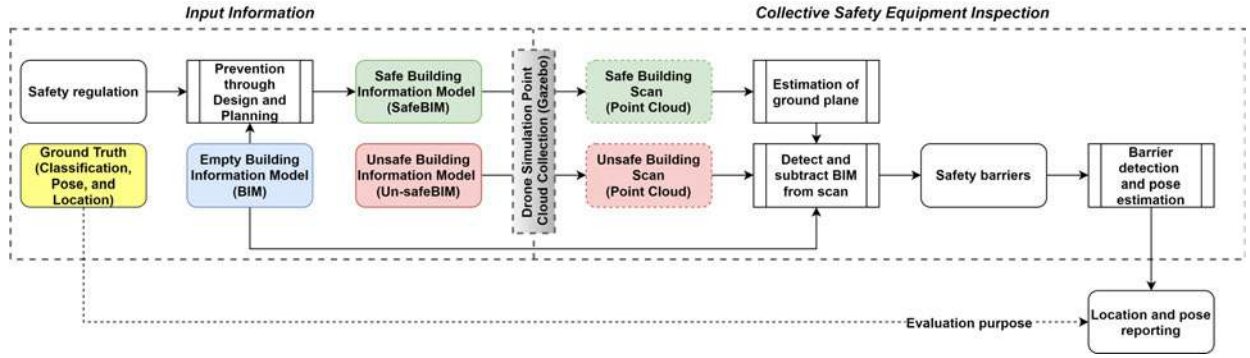

Figure 2. Overview of steps included in automated collective construction safety equipment inspection.

3 Methodology

In this work, we follow the overall approach illustrated in Figure 2, which include three inputs: (1) the empty BIM, that is assumed to be available for most construction projects, (2) A safeBIM containing the demanded safety barriers accordingly to safety regulation [4], and is relying on the SafeCon-application developed in [3], and (3) database of safe and unsafe objects created based on same safety regulation [4].

To perceive and capture the environment, we utilize point cloud data acquired from RGB-D cameras. These point clouds are used for recognition and estimation of the pose of safety barrier objects in construction sites (safe and unsafe) simultaneously. As shown in Figure 2 we use the point cloud data collected by the UAV to (I) Extract the ground plane, (II) Detect and subtract empty BIM from the point cloud data, and (III) perform barrier detection, location, and pose estimation. The first step of the framework is performed by detecting the predominant plane in the scene using a RANSAC plane fitting approach. Then, the second step is utilizing a combination of Point Pair Feature (PPF) and Generalized Hough Transform (GHT) detect the empty building using a pre-existing CAD model. Finally, the same method is employed iteratively to detect barrier structures.

We rely on the method of [23] that extracts point-pair features (PPF) from 3D point clouds with associated normals [20] as local descriptors and employs a GHT to simultaneously estimate the pose and object type, using a clever voting scheme.

In an offline phase, we build a database of known objects from existing CAD models. Then, we extract a point cloud with associated normals for each model and build a hash table containing all model PPFs.

Let $\mathbf{s}_r = (\mathbf{p}_r, \mathbf{n}_r)$ and $\mathbf{s}_i = (\mathbf{p}_i, \mathbf{n}_i)$ represent two surflets (i.e. point and associated normal). For each surflet pair (see Figure 3) belonging to the model point cloud, we store

them in a hashtable using the following hash function:

$$\text{PPF}(\mathbf{s}_r, \mathbf{s}_i) = (||\mathbf{d}||, \angle(\mathbf{n}_r, \mathbf{d}), \angle(\mathbf{n}_i, \mathbf{d}), (\mathbf{n}_r, \mathbf{n}_i)) \quad (1)$$

We extract PPFs from the captured point clouds during the online recognition phase and match them against the hash table, and compute the pose that align PPF matches. Then, the candidate poses with the highest number of votes in the Hough accumulator are retrieved. This step is performed for each model in the database of known objects. The model and pose with the highest score are selected. Finally, since the Hough voting space is discrete, we employ an iterative closest point (ICP) algorithm [24] to fine-tune the estimated pose of the object. The ICP algorithm iteratively searches for the transformation that minimizes the distance between points belonging to the scene, and the ones belonging to the most voted CAD model one. In each iteration, the points from the scene will be matched to the closest points in the model from the database. Subsequently, the transformation that minimizes the sum of the error between corresponding points is estimated, using a gradient descent optimization method. Finally, the transformation is performed to the point cloud, and the process starts over until it converges, i.e., no reassignment of the points is performed. We initialize the ICP method with the discretized pose determined with the GHT method, to speed-up convergence speed.

Figure 3. Point pair feature.

Figure 4. Environment 3D reconstruction from point cloud data collected by a UAV and estimated locations of known objects (i.e., CAD models).

4 Experiment

In our experiment, we let the UAV fly around the construction site and build a 3D map of the environment. In an offline phase, we train our detector with different types of barriers, building a hash-table of point pair feature descriptors for each barrier type. In the online phase, we apply the detector to point cloud mapping data, to find instances of barriers.

4.1 Experimental Setup

We perform the experiment in a simulated construction site (see Figure 4), and introduced an infrared noise with Gaussian distribution of fixed mean value of $0mm$, and a standard deviation of $1mm$ in the collected point cloud data. The colors in the 3D occupancy grid (see Figure 4) representing the environment reconstructed with point cloud data represent relative height. Figure 4(c) shows the super-imposed building CAD model after estimation and detected ground plane and building location, that is performed after completion of point cloud data acquisi-

tion. In order to evaluate location and pose estimation error performance, we developed two different experimental scenarios, in a realistic gazebo simulation environment [25].

Figure 5. Safety code BG Bau 100 [4] illustration using horizontal boards with a thickness of $4mm$ and height of $200mm$.

The experimental study is based on the BG Bau 100 safety code [4], which is illustrated in Figure 5. This building code describes installing compliant and safety barriers in a construction site, such as high-rise buildings. The safety code describes how to comply using different board dimensions, but the one used and illustrated in this work utilizing $40 \times 200mm$ boards. Besides the safe version of the BIM, we have created an unsafe version, where non-compliant and hazardous scenarios are introduced on purpose (see Figure 8, third row).

We modeled the faulty and hazardous scenarios to create unsafe BIM, introducing different safety code violations. An overview of the violations is shown in Figure 6, where we introduce issues regarding six different violations:

1. Absence of horizontal boards
2. Absence of vertical poles
3. Combination of absence of horizontal and vertical boards
4. Part of guardrail is absent or guardrail completely absent
5. Horizontal board is diagonal
6. Horizontal board placed too close to bottom or top, and the vertical pole placed too far to the left

The placement of the faulty object are represented graphically in Figure 7, which is an overview of the south and north facing facade, where hazardous situations are introduced in the unsafe BIM. Therefore, the east and west face are not altered in the unsafe model (also visible in Figure 8). Furthermore, we provide an overview of the introduced scenarios in Table 1, where the number of occurrences of each variation has been counted for later ground truth comparison, which also contains translation and rotation from the BIM origin to each of the guardrails.

Figure 6. Object overview: safe variations are compliant with regulation, and unsafe objects violating with regulation [4].

Figure 7. Overview of the placement of the different faulty scenarios shown in Figure 6. Non-labeled squares are not altered and are therefore safe and compliant with the safety code.

4.2 Evaluation Metrics

In order to assess the performance of our 6D pose estimation approach, we consider the error of the estimated pose $\hat{\mathbf{P}} = (\hat{\mathbf{R}}, \hat{\mathbf{t}})$, with respect to the ground truth pose $\mathbf{P} = (\mathbf{R}, \mathbf{t})$, according to

$$e_{\text{trans}} = \|\mathbf{t} - \hat{\mathbf{t}}\| \quad (2)$$

$$e_{\text{rot}} = \|\mathbf{R} - \hat{\mathbf{R}}\| \quad (3)$$

Table 1. Number of different correct and anomalous (incl. variation) in Figure 6, placed in the safe and unsafe BIM (Figure 7)

Guardrail scenario	Safe Model [No.]	Unsafe [No. (Var1,2,3)]
Correct	194	139
Anomalous	0	36
Horizontal	0	6(2,2,2)
Vertical	0	6(2,2,2)
Combination	0	6(2,2,2)
Part	0	6(2,2,2)
Diagonal	0	6(2,2,2)
Spacing	0	6(2,2,2)

where \mathbf{R} and \mathbf{t} represent rotation and translation, and e_{trans} , and e_{rot} the translation and rotational errors, respectively.

From Table 2 we observe that the performance of the proposed method is relatively good as the average translation and rotation errors are low in comparison to the sizes of the models. The environment we operate has the dimensions of approximately $43 \times 41 \times 33 \text{ m}$ ($W \times D \times H$), where a deviation of 0.54 m corresponds to 1.64% . We calculate this by averaging the dimension corresponding to 39 m . This is reasonable as the error in Table 2 is also based on the average along all three axes (translational error). Furthermore, the rotational error of 0.88° corresponds to a deviation of 0.99% , which is also impressively low.

Table 2. Resulting average translation and rotation error of 6D pose estimation performing PPF in combination with ICP

Method	Average e_{trans} [m]	Average e_{rot} [°]
PPF+ICP	0.540652	0.880321

5 Discussion

Our framework for automatic safety barrier detection and inspection in construction sites using vision-based UAVs and a database of CAD models, which can be extended to contain other types of safety railing. The obtained results in a realistic simulation environment demonstrate our method's potential applicability in real construction sites. Furthermore, our results show that we could estimate the location of BIM structures accurately with sub-meter and sub-degree precision, corresponding to 1.63% and 0.99% in terms of translation and rotation, respectively. Based on these results and experience with correspondence between reality and the realistic simulation environment, we intend to employ this method in an actual construction setting and confirm its applicability. A system like the one we are proposing would assist the safety expert in pointing out issues that are not discovered

Figure 8. Overview of all four faces (south, west, north, and west, column 1 to 4 respectively) of the three utilized models (empty, safe, and unsafe, row 1 to 3 respectively).

manually and improve the safety at the construction site. As the system improves, it could very well also fully automate the inspection of some objects. However, this should still be a collaboration where the safety expert can solve issues instead of wasting time looking at correctly installed barriers. Furthermore, we will study ways to classify the detected barriers to separate the hazards and even propose mitigations in future work. Furthermore, automating the launch of the UAV and improving the autonomous exploration of the construction would be beneficial for the applicability and a promising future research direction.

6 Conclusion

This paper proposes a system utilizing UAVs to handle the labor-intensive tasks of collective safety equipment inspection. Much effort is put into inspection of the construction site, and some of these tasks should be automated to get a higher temporal resolution. The proposed system is initially analyzed in a simulation tool with the objective of determining feasibility and applicability. Our experiments demonstrate that automation of the inspection is possible with high precision, which can eventually lead to the actual replacement of current practices.

Abstract –

Inspecting the exteriors of buildings is a slow and risky task for workers, especially in high-rise buildings. Moreover, some areas are difficult to reach for large buildings, and in some cases, the inspections cannot be adequately done. In recent years, there has been an increase in open-source artificial intelligence (AI) technologies and commercially available Unmanned Aerial Vehicles (UAVs) with AI-assisted deep learning capabilities. They can provide a low-cost, open-source, and customizable methodology for building exterior inspections that are readily accessible for construction and facility managers.

This study presents a methodology to use UAVs and deep learning technology to conduct an automated inspection for cracks on high-rise buildings - improving the efficiency of the process and the workers' safety while reducing data-collection errors. The proposed methodology is divided into four components: 1) Developing a UAV system to capture the exterior wall images of the building in an autonomous way, 2) Collecting data, 3) Processing and analyzing the images captured for cracks using deep learning, and 4) Rendering the identified locations of the cracks on a 3D model of the building, constructed using photogrammetry, for clear visualization.

This study focuses on the virtual simulation of the methodology. The UAV used contains a built-in camera to capture the images of the building from different sides. Data Collection, Image-Analysis, and Photogrammetry are done using publicly available open-source deep learning and simulation technologies. The generated code for the UAV simulation and the crack detection algorithm with the pre-trained data model are released on GitHub.

Artificial Intelligence; Crack Detection; Building Defects

1 Introduction

Building inspection using only manual labor (i.e., human workers) is a time-consuming and, in some cases, dangerous process. Traditionally, the visual inspection part of the exterior of a building requires an inspector to abseil down over different sides of a building [1]. Not only is this a risky process, but also subjective and prone to errors. Moreover, the inspection of buildings for quality and identification of defects is a repeating process with intervals usually between 5 to 10 years, depending on the maintenance plan [2]. In general, manual inspections do not leave consistent computerized (i.e., digital) data that can be later used to compare the results of successive inspections over time.

One of the most common indicators determined in visual inspection to assess the damage or deterioration of a building is the cracks on the walls. In recent years, there has been an increase in research that utilizes image processing techniques and Artificial Intelligence (AI) technologies to detect and classify cracks with varying levels of success [3].

The emergence and widespread use of commercial Unmanned Aerial Vehicles (UAVs) in this decade have allowed an easier method to collect image and video data. Therefore, the ability to capture building image data using UAVs and analyze them for defects using AI and image-processing techniques has become a reality. The use of UAVs for the data collection process is already being used in some aspects of the industry, but the automation of the processing of said data is still something that has not been fully implemented. To address that, this approach helps with the automation of the whole inspection process and can improve the precision compared to traditional (i.e., manual) building inspection methods.

This study proposes one readily accessible and cost-effective methodology for the inspection of building exteriors. The rest of this article is organized as follows. First, a literature review discusses the recent state-of-the-art research, including a discussion of UAVs, flight path planning, crack detection using deep learning, and the photogrammetry visualization process of UAV captured images. Then, the research methodology section discusses the process of developing an Automated Building Exterior Crack Inspection System (ABECIS), along with assumptions made and limitations of the study. After that, an example illustrates the methodology with a proof-of-concept demonstration in a virtual simulation environment. Finally, the rest summarizes the results, discussion, and outlook.

2 Literature Review

For this study, the literature review focused on publications in the proceedings of the International Symposium on Automation and Robotics in Construction (ISARC), as well as *ICACT* [4], *Automation in Construction* [5], and *Drones* [6].

Through keyword-based search, this study identified the state-of-the-art research trends in construction automation, using the following keywords: “Deep Learning”, “photogrammetry”, “UAVs”, “crack detection”, “building inspection”, and “computer simulation”. The sources are selected based on the clarity and novelty in the methods they present.

From the literature review, it was found that many ISARC papers deal with topics relating to building crack analysis and UAV path planning. Similar studies on crack detection using UAVs include the work by Phung et al. [7], who carried out crack detection experiments on wooden walls. They used a UAV to take images of the suspected surfaces, which then were stitched and processed based on histogram analysis. They developed a peak detection algorithm for image clustering and a locally adjustable thresholding technique for crack detection. Results from their experiments showed that out of two crack candidates, only one was detected. The authors planned to extend their work to improve their algorithms to account for other crack properties such as length, width, and orientation.

In literature outside ISARC, attempts to make use of UAVs for building inspection have been investigated. For example, Choi and Kim [4] used an open-source hardware-based Hexa-copter (UAV with six propellers) to acquire building images and videos. Afterward, the images and videos were converted to grayscale, and the Canny edge detection algorithm was used to detect the edges and cracks. The authors proposed follow-up studies by installing various sensors and thermal infrared cameras on the UAV.

The study by Rakha and Gorodetsky [5] provides a comprehensive literature review on the use of UAVs to visualize the heat transfer in buildings with infrared imaging and create digital models using 3D photogrammetry. They presented a procedure to generate a 3D model of a Syracuse University building using a DJI Inspire 1 drone. Their procedure can be summarized as follows. First, images of the building were captured by the drone with autonomous path planning. Then, the Pix4D program was used to generate a 3D point cloud of the building from the 2D images captured. However, the software used in their study was not open-source.

A summary of literature utilizing UAV and image-processing techniques for crack detection is given in Table 1.

Table 1. Comparison of UAV and image processing-based methodologies for crack detection

Author	Level of automation*	Open-source software used?	Consumer drones used?
Choi and Kim[4]	N/A	No	No
Rakha and Gorodetsky [5]	FA	No	Yes
Phung et al. [7]	FA	No	Yes
Kim et al. [8]	N/A	No	Yes

*Fully autonomous (FA), Not mentioned (N/A)

Within the scope of this specific literature review, there have not been studies that emphasize the possibility of utilizing publicly available open-source software and off-the-shelf consumer drones to carry out building crack detection processes. Therefore, to make it more accessible, the proposed method only considers open-source software to provide a cost-effective and easy-to-replicate approach compared to existing ones since expensive or specialized hardware and software are not necessary.

2.1 UAV for Building Exterior Inspection

2.1.1 Commercially Available UAVs

UAVs, also known as drones, had origins in military research. However, small and inexpensive commercially available UAVs, built from easily available components, are becoming increasingly common as an emerging technology. Some of the leading consumer UAVs include DJI, 3DRobotics, and Parrot [9].

For this research, a DJI Mavic 2 drone (Figure 1) is used in a simulated environment. The drone used is a lightweight UAV with a high-resolution camera and uses GPS and GLONASS technologies for navigation. Once fully charged, it has an autonomy of 31 minutes under normal conditions and usage [8].

Figure 1. DJI Mavic 2 [10]

2.1.2 Advantages and Limitations of UAVs

The benefits of using UAVs for building inspection are numerous. Autonomous navigation enables a high level of automation, and the flight ability allows the UAV to reach points on structures or roofs, which are otherwise difficult or dangerous to access. Nevertheless, the current autonomous features of the UAVs are quite limited. For instance, there are inevitable mismatches between the planned flight paths and real paths followed by the drone due to localization errors caused by built-in GPS [7], and under most regulations, drones are not allowed to fly without an operator and need to stay within the operator's visual line of sight [11].

2.1.3 Flight Path Planning Methods

Multiple flight patterns exist for UAVs to explore areas (Figure 2) [6]. Nevertheless, for building exterior inspections, varying external conditions such as different viewpoints, view angles, and daylight must be considered for a successful exploration [12]. The process is simpler when the building is divided into rectangular walls for the UAV to explore in multiple phases. For the drone to inspect the greatest area while remaining autonomous, the back-and-forth path in Figures 2 (a) and (b) prove sufficient and effective.

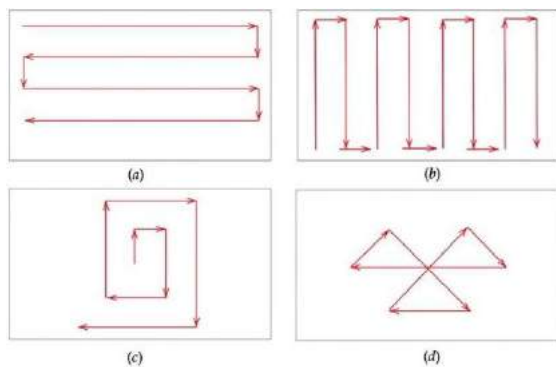

Figure 2. Simple UAV flight patterns in rectangular areas (a) Parallel; (b) Creeping Line; (c) Square; (d) Sector Search (adapted from [6])

2.2 Building Cracks

2.2.1 Crack Classification

In visual building inspection for cracks, three factors, namely the distribution, width, and the depth of the cracks, are identified, with the distribution and the width being more important factors than depth [2].

Moreover, the building cracks can be classified based on their pattern [13] into one of the following categories: (a) alligator cracking; (b) block cracking; (c) longitudinal cracking; (d) hair cracking; (e) diagonal cracking; (f) multi cracking; and (g) transverse cracking. For this research, the cracks considered are those discussed above, except for the alligator cracking and hair cracking due to data limitations to training the algorithm.

2.3 Deep Learning and Crack Detection

2.3.1 Open-Source Deep Learning Frameworks

Deep Learning is a branch of artificial neural networks, an AI technique widely used to classify images [14]. Deep Learning image classification methods began gaining popularity in 2012 [15] and outperform existing classification methods (such as Local Binary Patterns (LBP) and shape-based algorithms [14]). In recent years, there has been an increase in publicly available open-source software libraries which allow users to build artificial neural networks for Deep Learning very easily, with Keras [16] being the most popular open-source library. This research utilizes Keras to build a network to classify the segments of the collected images of the building as “containing crack” or “no crack.”

2.3.2 Crack Detection Algorithm

In order to classify images using Deep Learning, the algorithm must be trained first. The training requires thousands of pre-classified images. The dataset can be obtained by oneself or using publicly available data sets.

Regarding the crack detection on walls, researchers, such as Özgenel, have shared their dataset containing pre-classified images of wall cracks publicly online [3]. This study uses Özgenel's dataset to train the Deep Learning algorithm.

2.4 Photogrammetry Visualization

In order to visualize the data collected from UAVs, two methods, namely LiDAR and photogrammetry, can be used. However, LiDAR requires specialized, expensive, and heavy equipment (around 14 kg [17]), which is not ideal to be mounted on a commercial off-the-shelf UAV, which typically has a limited payload (0.83 kg in the case of the DJI Mavic 2 [18]).

Therefore, in this research, photogrammetry is used for a 3D reconstruction from the data collected from a UAV. Photogrammetry is the technique of building a 3D model from numerous images captured from multiple viewpoints around an object (in this case, a building). Normally, specialized professional drone mapping software such as Pix4D [19] is used in the industry. However, such software can be quite costly. An alternative is to look at open-source photogrammetry

software developed by the community. For example, Meshroom [20] by AliceVision is an open-source software that provides results comparable to most industry-grade software. In addition, Meshroom can perform photogrammetry autonomously and has a very easy learning curve, making it ideal for this application.

3 Research Methodology

3.1.1 Real-world constraints and Assumptions

In the real world, numerous constraints can interfere with the use of UAVs for building inspections. Some of these practical challenges include the following:

- According to US Federal Aviation Administration regulations, UAVs need to be operated by a registered operator, and they must fly within the visual line of sight of the operator [11].
- The image data collection will only yield optimal results if favorable lighting and weather conditions are fulfilled.
- In urban areas, the existence of adjacent buildings can interfere with the autonomous path planning of the UAV. Moreover, flying over pedestrians, traffic, etc., is also a big constraint.
- Photogrammetry technology has limitations. Depending on the camera angle, shadows in images, and blind spots, the constructed 3D visualization and image-processing results could diverge from real-world data [21].
- Moreover, the UAV, especially the off-the-shelf commercial ones, have limited battery life, and the survey might need to be done in multiple stages.

For this study, these constraints are relaxed. An ideal situation with only one building of interest, isolated in the middle of an open and flat area under favorable weather conditions and lighting, was studied via computer simulation.

3.1.2 System Architecture

The overall system architecture for crack detection using UAVs and deep learning is proposed in Figure 3. It includes the UAV system, 3D model photogrammetry, and deep learning image analysis. The code for the UAV simulation and the crack detection algorithm with the pre-trained data model [22] have been released on GitHub for other researchers to use.

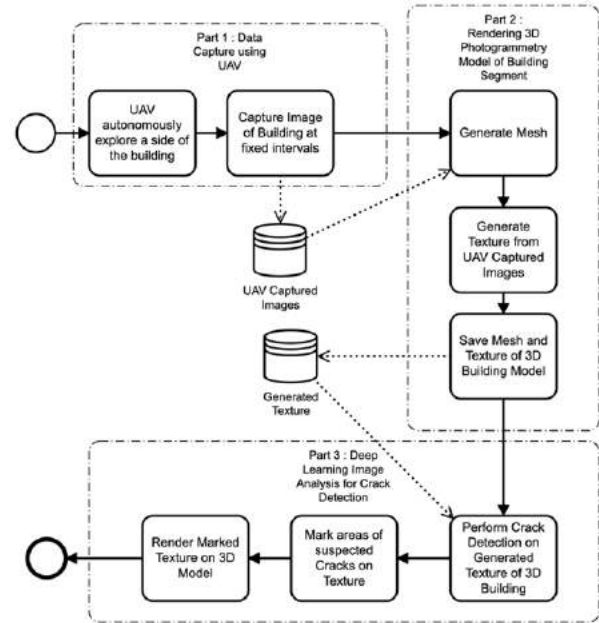

Figure 3. System architecture of the Automated Building Exterior Crack Inspection System (ABECIS)

3.1.3 Part 1: Data Capture using UAV

An algorithm was developed in C by implementing a Proportional-Integral-Derivative (PID) controller [23] to control the position of the drone hovering in mid-air. The algorithm uses the Creeping Line flight pattern, shown in Figure 2 (b), to autonomously explore one side of the rectangular wall of the building. Images from the drone camera are captured when the drone is near the wall at fixed intervals. The entire process is autonomous, and a human operator is only required to activate the drone and place it at the bottom of the wall to be analyzed. The operator could also assist (i.e., take control of the UAV) in case of emergency.

The algorithm and the autonomous drone image capture process are simulated using Webots, a free open-source mobile robot simulation software [24]. The captured images are then stored for further analysis.

3.1.4 Part 2: 3D Photogrammetry Model

Using the images captured by the drone, a 3D model of the building segment is generated using Meshroom photogrammetry software for clear visualization. Meshroom creates a 3D mesh and a texture automatically from the images. The generated texture is to be analyzed for cracks using deep learning and rendered later on the 3D model of the building.

3.1.5 Part 3: Deep Learning Image Analysis

A deep learning image classification algorithm was developed and trained based on Google's Xception convolutional neural network [25]. Özgenel's dataset

[3], composed of 20,001 non-crack images and 20,001 crack images with 227×227 pixels resolution, was used to train the image classification algorithm. Figure 4 shows an example of the sample training data from the dataset used.

Figure 4. (a) Sample non-crack images from original dataset (b) Sample crack images from the original dataset (reproduced from [3])

The image classification algorithm was developed using Keras, an open-source Python deep learning library. The algorithm operates in the following steps: 1) load pre-trained model 2) take the input image (the texture generated by 3D photogrammetry), 3) split each image into an array of rectangular segments, 4) perform analysis on each segment and classify it as “crack” or “no-crack”, 5) mark the segments which are classified as “crack” for visualization later. The process is visualized in Figure 5.

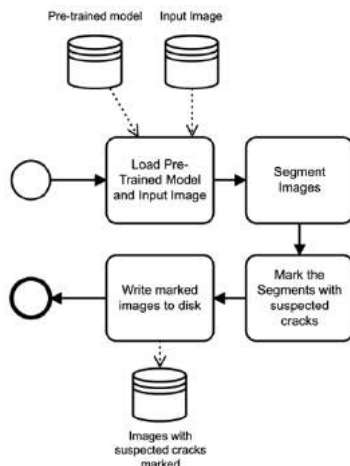

Figure 5. Deep Learning Image Analysis Algorithm

4 Implementation

A small example implementation in an ideal simulated environment is then carried out to illustrate the

research methodology discussed. The following objects are investigated for cracks in this study.

1. A tall building with cracks on the top floor and
2. A rectangular wall with cracks

The rectangular wall is painted plain white, contains a single long crack, and is used to study whether the algorithm can identify the location of the cracks. The tall building contains cracks present on the colored tiles and is used to study whether the algorithm can identify the cracks superimposed on other textures.

In the following examples, many assumptions are being made. Firstly, the drone inspection is carried out on a single building or a wall without any neighboring buildings. Secondly, the environment is free from obstacles that might interfere with the drone in the real world, such as trees, overhead cables, pedestrians, and vehicles.

For *Part 1: Data Capture* using UAV, a simulated environment was constructed (Figures 6 and 7). The UAV autonomously captures a wall of the building following a Creeping Line flight pattern. The autonomous flight algorithm takes the starting coordinate, length of the wall, distance from the wall, and minimum/maximum heights as input parameters. The building images are taken every second by the drone and are transferred to the computer for analysis.

Figure 6. Autonomously Capturing Images of a tall building with UAV (Webots Simulation)

Figure 7. Autonomously Capturing Images of a wall with UAV (Webots Simulation)

Once the drone captured images are ready, *Part 2: 3D Photogrammetry* model generation is carried out using Meshroom photogrammetry software for both the building and the wall. Meshroom analyzes the different angles that the images are taken from and constructs the

3D mesh of the back wall of the building (Figure 8). A texture is also generated with the model (Figure 9 a and b).

Figure 8. Rendering 3D Photogrammetry Model of Building Segment from captured images in Meshroom

Figure 9. Textures of (a) the building and (b) the wall, generated from captured images by Meshroom

Once the texture and 3D mesh are generated by Meshroom, *Part 3: Deep Learning Image Analysis* is carried out using the generated building texture as the input image for the deep learning algorithm. The deep learning algorithm used has the following adjustable parameters:

1. **Tile Resolution (TR):** The dimensions of the smallest square images that the algorithm will split the building textures. Then, the algorithm performs analysis for cracks on each tile, and
2. **Confidence Interval (CI):** The cut-off confidence threshold in % to decide whether each tile contains a crack or not.

The deep learning algorithm segments the texture into multiple smaller square images (tiles) and analyses each image to see if cracks are present. Images with a “crack” confidence interval greater than 85% are marked with red crosses. The 85% CI was chosen based on previous experiments since this value gives the lowest number of false positives. From experiments, 75% CI gives two false positives, 85% gives no false positives, and 100% does not detect cracks. Finally, all smaller

images are stitched together to form the original building texture, but with the cracks marked. This analyzed texture is then rendered onto the 3D model of the building generated in Part 2 to generate a 3D report as in Figure 10 and Figure 11.

Figure 10. Example of a 3D report for building, with the suspected areas of cracks on the 3D model of the wall marked with an ‘X’

Figure 11. Example of a 3D report for wall, with the suspected areas of cracks on the 3D model of the wall marked with an ‘X’

5 Results and Discussion

On the 3D report for the building (Figure 10), the proposed method correctly identified the location of most cracks. In the case of the wall (Figure 11), it missed a very thin hairline crack on the right-hand side.

It is suspected that two parameters (TR and CI) contribute to the failure of detection of cracks in our implementation example. Firstly, the cracks may be too small to be seen by a camera mounted on the drone, perhaps due to bad lighting conditions. Secondly, the resolution of textures used for cracks may be altered by the Webots simulation environment, making the crack textures not as realistic as they can be.

This study examines a general overview of the crack detection process (i.e., is a part of one crack detected?) rather than how much detail of one crack is detected. To provide a quantitative measure for the success of our approach, we used a measure called Success Percentage. To calculate Success Percentage, the total number of

cracks on generated building texture, NT, and the number of cracks correctly detected (partly or fully), NC are counted. Success Percentage is then defined as

$$\text{Success Percentage} = \frac{N_c}{N_T} \times 100$$

Figure 12. Texture of the wall with cracks identified

The calculated Success Percentages are given in Table 2 below.

Table 2. Success Percentage Results

Object	Total Number of cracks	Number of cracks detected (partly or fully)	Success Percentage
Building	2	2	100%
Wall	10	8	80%

In this particular example, the Success Percentage for the wall crack detections is quite high. Except for hairline cracks on the wall, most cracks are detected.

		Tile Resolution (TR)	
		High	Low
Confidence Interval (CI)	High	Some cracks are not detected	Cracks larger than the TR not detected
	Low	Some False Positives Detected	Many False Positives Detected

Table 3. Possible negative outcomes of different input parameters

However, the Success Percentage can be increased or decreased by varying the tile resolution and confidence interval input parameters of the algorithm. Possible undesirable outcomes for using too high or too low input parameters for the algorithm are summarized in Table 3. From experiments, CI of 98% and above does not detect

cracks. The input parameter should be tuned to suit the inspection requirements.

Nevertheless, the proposed method can accurately pinpoint the estimated locations of most cracks on the wall's surface at a high level (i.e., whether a crack exists or not). Once the estimated locations are identified, one can repeat the process on the suspected areas and move the drone closer to the wall for a clear view of the cracks for further investigation.

6 Conclusion and Outlook

This study proposes a low-cost and accessible methodology for identifying cracks on walls using off-the-shelf consumer drones, free and open-source photogrammetry software, and Deep Learning libraries. Although the process failed to detect very thin cracks in the simulated environment, it was able to identify the estimated locations of most cracks correctly. Interested readers can easily replicate our method by using the software mentioned above and our algorithm that has been released on GitHub [22].

Ongoing work by the authors includes extending this study to use an actual drone to conduct the data capturing process in a real environment. We also expect to improve the quality of crack images taken by flying the drones close enough to the building. Moreover, future work includes performing a detailed analysis of each of the cracks and providing more information, such as crack lengths, type of cracks, and the estimated scope and cost of repair to building owners and facility managers.

Unmanned Aerial System Integration for Monitoring and Management of Landslide: A Case of Dominican Republic

H. Reynoso Vanderhorst^a

^aFaculty Faculty of Science and Engineering, University of Wolverhampton, United Kingdom
E-mail: h.d.reynosovanderhorst@wlv.ac.uk

Abstract

The Unmanned Aerial System (UAS), Aerial Robot or Drone has been a multi-purpose tool for professionals, especially for its unknown versatile applications and regardless of its challenges in adoption. In the built environment and the current global situation, the topic of disaster management has grabbed attention from the scientific community, raising questions of cyberspace linking the COVID-19. As a result, the case study shows how UAS is used to evaluate the landslide provoked as cascading effect of a bridge site construction and the digital data required to feed in 2D and 3D a database of urban planning development. The findings reveal that the application of UAS reduced physical inspections, allowed professionals to obtain inaccessible data, and helped to overview the site conditions identifying the cause of the phenomenon. A safety design factor of the critical building of the school in the community to mitigate the landslide hazards at Santa Maria, Dominican Republic was recommended. Future works in 360° evaluation for similar cases in construction are recommended.

1 Introduction

Disasters are defined by the degree of damage caused to alive and living entities.

In a philosophical sense, disaster may mean molecular and structural arrangements of matter welcoming experiences, opportunities, and invitations to understand and teach knowledge and wisdom to humans regarding their capabilities of transcendence with and without a technology base.

Engineers, in their various ramifications, have used science to fabricate biological and non-biological technological solutions to address the threats of humankind. Consequently, each timeline and space country contain unique settlements of threats and

solutions for risk reduction and recovery of disasters.

According to their technological integration, the solution could be called “intelligent”, “digital” or “smart”.

The dimension in which the solution is applied indicates the field and variables to consider, for example: “construction”, “infrastructure” or the combination of both adding human interactions in “cities”.

The approach of evaluating the effectiveness of the cities interactions with technologies relies on the allocation and provisions of the design of the cities rather than the adaptation of the cities to the technological evolution [1]. In other words, the meaning of a “smart city” can refer to a city that integrates technologies to improve the lives of its citizens as well as other social techniques and practices.

In rural and undeveloped emerging communities in developing countries, this concept could be referred to as a design for its use or a later integration. In any case, disasters concerned about construction, as landslides, may happen by different causes and mitigation plans of the cascading effects and recovery phase are imperative and necessary to develop.

The team of geologists and engineers attempt to assess the phenomenon and describe possible solutions in case that the landslide would imminently collapse the school structure. Because of the lack of knowledge by contractors and limitations of the site, the UAS allowed the data gathering process to assure quality and data preservation of the study.

Therefore, the aim of this paper is to illustrate a framework that integrates the UAS outcomes for risk evaluation in the Dominican Republic undertaking a UAS approach of data collection of a landslide near a primary school in a small town in the Dominican Republic in 2018. The following section revised the literature regarding operations of UAS in landslides and developed a conceptual framework for future cases on this matter.

2 Literature Review

Landslides are originated from high rainfall saturation, subterranean aquifer expansion, water

infiltration via porous rocks, and soil surface erosion. They can also be generated as a cascading effect of earthquakes, hurricanes, floods, deforestation, and earthworks (drillings, blasting, excavation, soil consolidation, etc.).

Landslides are phenomena interconnected to the restructuring of minuscule solid particles and the displacement of the particles into a low altitude state, provoking alterations and changes to the underground and surface of the earth.

The demand for methods and assessments before construction works in urban areas are enormous after several disasters occurred in recent years. Nevertheless, old and unsupervised urban and rural constructions made before these upgrades require agile mitigation and technological disaster recovery plans.

Modern professionals in the field of planning and construction of urban areas from public, private or non-profit sectors have been implementing sophisticated tools such as robots, sensors, and software to address quality assurance, data storage, long-term cost reduction, and other tasks to their projects [2]. However, the adaptation and acceptance of sophisticated tools present the barriers of the learning curve, knowledge transfer, viability from some professionals and organisations [3]. Hence, the application of robots, sensors, and software oriented to urban planning and construction should be diversified and standardised with the actual best practices and regulations in force.

The one that applies to this study is the Unmanned Aerial Systems (UAS) for human-made construction pits or natural landslides.

In the literature, the methods to address evaluations of landslides with UAS are commonly implemented by applying photogrammetry techniques and reconstructing the surface and terrain models in the cyberspace. A complete description of a case was made in [4]. This case describes the types of UAS (fixed wings and quadcopters) utilised for the assessment; modes of operations (autonomous or manual); adequate parameters of accuracy in regard to the height, type of sensors, ground control points, software, and essential data to reconstruct the digital terrain model of the area of study. However, the challenge of accuracy remains in the study when a generalisation case is willing to be addressed. [5] explain and demonstrate that the biggest challenge of UAS photogrammetry with vegetation can be defeated by including LiDAR sensors for accurate terrain models. Despite the combination of these sensors and techniques, post-processing software has advanced enough to reduce, automate, and facilitate the dependency of LiDAR and discrepancies of the photogrammetry according to the level of detail required for the operation.

Going forward through time, a study by [6] contributes with a framework for UAS landslide

monitoring expressing the relevancy of regularly assessing the landslide sites. The UAS used was more advanced, similar to the models used nowadays; and explained the principle of ground sample distance or the equivalency pixel/cm. This approach shows the manual system carried out to produce desired outcomes. Nevertheless, the reconstruction process represents a time-consuming and specialised skill set to learn that the data collection process may not look as it is according to [7]. However, recent studies present a global view of data collection with UAS appearing as a standard as [8].

Furthermore, [9] shared a framework for adoption in the Dominican Republic but did not cover details of the cases to acquire data with UAS and the technical parameters to apply them.

The adoption process of UAS within the construction of urban areas relies on the technological tools to find solutions and approaches to erect projects. The most used technologies for these purposes are the 2D multi-layers of Geographic Information System (GIS) for land project distribution and the CAD software for building designs (Revit, ArchiCAD, Vector Works, Civil 3D, and others).

This software accepts a variety of file formats to enable representations of the blueprints or current site conditions. In the same manner, the UAS and their workflows permit feeding the digital part or cyberspace of the project with realistic site conditions for better interpretation and representation of the dynamics involved. An example of the explanation can be seen in Diagram 1, showing how the current workflows are updated with the UAS implementation and a possible definition of smart city. The diagram illustrates the process of risk evaluation in the workflow of disaster management according to the literature.

In the aspect of extending the UAS implementation, the UAS future could be understood by the adoption and merging of multiple technologies of the 4th industrial revolution such as the benefits of cloud computing [10], virtual reality training, 6G internet of things [11], visual-spatial information in real-time with Building Information Modelling (BIM) & GIS [12] for autonomous monitoring tasks with artificial intelligence (AI) in the definition of a data-driven smart city.

Future trends would also allow another range of tools and applications to be involved, such as apps and wearables technologies. Examples of the applications can be forecasting of COVID-19 propagations with AI, anxiety levels after a disaster, emotional experiences of buildings and infrastructure usages through heart bits vibration, body temperature, and other mediums.

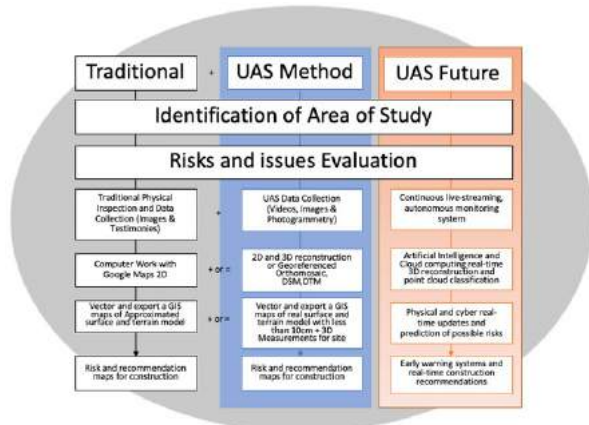

Diagram 1. The framework of UAS Data Collection and trends

Diagram 1 describes the traditional methodology of data collection for multidimensional risk evaluation. In blue is defined the when and where the UAS outcome could be used during the traditional method approach. Finally, in orange are the trends of UAS with other technologies and possible implications in the workflow in a scenario that indicates the applicability of the smart city concept.

For disaster in construction and urban areas, the dimensions and methodologies that the UAS provides, currently, are visual information useful for assessment in the dimension of social, infrastructure and environmental aspects for urban planning development in mitigation and post disaster plans [13].

To identify the most compromised dimensions, it is required to evaluate the total risk (R_t) of the elements in investigation with Equation 1:

$$R_t = E \times H \times V \quad (1)$$

Equation 1 describes how the total risk is estimated calculating the expression of E as element (School or Small homes), H as hazard (Landslide, or earthquake) and V as vulnerability (weakness). These values are categorised between 1 to 10 according to the level of relevancy and the risk of a specific aspect of the city.

The values of the Equation 1 can be assigned through visual data collection in urban areas as in orthomosaics and GIS identification. The threats against communities, houses or environment evaluation of the structural weakness or vulnerability that may face the element can be assessed for strength, transfer, or disesteem easily [14].

However, beyond the future of these new methodologies assisted with aerial robots and other technologies, there are challenges in their adoption that make the future trends reachable in a distant time from now.

The challenges are classified by the inconsistencies in sensors in size, software for data processing, energy source, and interoperability of the software. The adoption and insertion of the UAS files to their full potential — applicability of the outcomes for the investigation — can be stressful if employees and contractors for not communicate appropriately the implications of UAS for the organisation in this matter.

For this reason, the following illustration is presented to provide ideas of how construction organisation may address their due diligence in risky areas, councils may get awareness of another method of communication between departments, researchers can assess their duties faster, and trust in the development and application of robots [15].

3 Case of Study

The Caribbean country of the Dominican Republic shares the island territory with the Republic of Haiti. The geographical location of the country determines its risks before earthquakes such as 2003 Dominican Republic Earthquake [16], 2010 Haiti Earthquake [17]; hurricanes, and floods recurrently every year [9]. The school buildings, infrastructures, policies regarding the safety factor of construction, urban development, and education systems before disasters require several improvements [18]. An example of these issues is the community of Santa Maria at San Cristóbal providence in the Dominican Republic. This hamlet, with a cathedral, is in a zone composed of alluvium and lower terrace of the Nigua River, with a general composition between sand, silt, and gravel. The composition of the soil is sensitive to the cascading effects of erosions, ground saturation, telluric movements natural or by drillings, blasting, and raw material production from the river as a landslide. Since 2017 the community has experienced land cracks with more than 15cm of expansion and spontaneous landslides that attempt the safety of houses, schools, and the route of land communication of the highway 6 of November as Figure 1 and Figure 2 respectively presents [19].

Figure 1. Community site near landslide effects

Figure 2. Highway affected by landslide

The primary school serves as a safe centre for the citizens in the event of a hurricane; therefore, the integrity of the building is compromised to an imminent risk of collapsing and diverse methods were utilised to verify the security design factor of the building foundations in which the UAS photogrammetry was applied to identify the site conditions and risks involved in the area.

4 Methodology

The case study was developed by collecting documents, reports, historical data, and interviews in a public institution in the Dominican Republic. The National Geological Service (SGN acronym in Spanish) is the institution responsible for carrying out investigations related to environmental detriment, adequate practices of urban planning and sustainability of natural resources and more. Then, the Nvivo 2020 software was used to identify the fields inside construction that the UAS were applicable as the following case is.

The landslide site was recorded with videos and images. Later, a 3D reconstructed utilising a UAS Phantom 3 professional with 4000x3000 resolution, FOV 94° 20 mm - f/2.8 focus at ∞, 1280g weight in deployment moment and an average of 65m (215 ft) height from the starting point according to the Exif files with the Pix4D software were carried out. For the site reconstruction, 203 images were taken with the sensor in

zenith position (90°) between 12:40-13:20 hours to avoid hard shadows in the model. Then, images in specific points were taken to collect the GPS position and compute them into the GIS system for risk analysis. The regulations in the country in 2018 were not restrictive for UAS less than 2 kg and operations should take the basic safety measurements for the deployment. In addition to the UAS assessment a caution walking assessment was made to assure the quality of the works.

The operations took place outside of the city centre, where the most significant landslide effects were felt and seen. Some areas were dangerous to access and difficult to obtain measurements physically of the cracks. The landslide impacted negative 2 families drastically breaking the foundations of the house as shown in Figure 3. The UAS video was utilised to examine the surroundings of the community and determine the potential threats involved, such as a falling of high-tension electrical lines.

Figure 3. House foundation cracks

The high-tension electrical lines that were not visible on the GIS maps of the organisation were located using images with GPS coordinates encoded in them. Therefore, a multidimensional risk assessment of the site was made evaluating the critical infrastructures with Equation 1. After the assessment the reconstruction of this first site, utilising the photogrammetry technique and Pix4D, was made to measure the inaccessible landslide cracks deformation and make estimations of the landslide slopes as shown in Figures 4 & 5. Furthermore, some of the results are based on the experience shared and the

interpretation of the data acquired by the authors.

Figure 4. Identification 3D and 2D of the Landslides

Figure 5. 3D measurement of the Landslides 1 and 2

5 Results and Discussion

The outcome of the data gathered was divided into three aspects: (i) Recover trust from previews UAS application that resulted in low quality works in other projects; (ii) Overview of the site conditions and landslide effect to the community and the school; (iii) an upgrade of the actual GIS maps of the organisation and provide guidance for further research in terms of foundation factors of the school.

A major concern from the organisation was the question of opening a new position for UAS operations would be cost-effective or hire them according to the requirements of projects alternatively? According to [7] the UAS is a cost-effective solution for data collection. However, due to the lack of personnel qualified and the access to the UAS, the institution has adopted the position to integrate UAS outcomes in their projects by utilising contractors externally by agreements, commercially or from another government organisation. Furthermore, this approach did not assure the adequacy of the outcomes for the purposes of the investigations.

After the data was presented in 2D, the most challenging outcome to share, understand, and navigate was the 3D model with measurements due to the capability of the computers to open a cloud platform. The limitation was surpassed by utilising a computer with higher video ram memory (16GB) allowing to measure the height and the visible extension of the landslide as in Figure 5. The information permit to estimate the type and root of the landslide along with the contour lines. The

surface was irregular and an estimated shape was taken for the purpose of identifying the type of landslide. The benefit of this approach involved the risk reduction of the personnel and suitable estimations with up to 30 cm of accuracy for the calculations against visit the site and make the analyses.

However, the trees represent an issue for the 3D model but the software was able to produce a 2D and 3D Digital Terrain Model (DTM) from the 2D and 3D Digital Surface Model (DSM) or orthomosaic georeferenced. This information provided the contour lines to assess the slope of the different landslides and identify their type. Moreover, the 3D models were printed and attached with the other 2D data for better interpretation and shareability.

Despite the effectiveness of visual assessments for the community, the 3D reconstruction made for estimating the length of the fissure was difficult to compare physically and some fissures were unavailable to measure utilising the method by the vegetation. For this reason, LiDAR would be preferable to mix with the photogrammetry for more accurate observation as mentioned before by [6].

Furthermore, the limitations that this method could bring around the urban area is related to safety and privacy. The UAS operation should comply with specific standards of piloting, UAS danger operation perception, aircraft airworthiness (noise reduction tools and obstacle avoidance), and specific height requirements to restrict cases of privacy disruption. Furthermore, the community may be notified the day of flying to avoid issues.

The advantage of a monitoring system or maintenance system after construction phases such as this, permit to prevent disasters in the future such as bridge failures during floods or electrical infrastructure explosion.

The conclusions of the study were that the extraction of raw materials and erosion at the edge of the River Nigua were the key factors of the landslide by the type of landslide in sequence in the same area. In the video, it was appreciated the overview of site conditions in a 360° view and recordings were made in specific points. The UAS operation to overfly the sector in a circular trajectory allowed the investigators to understand the influence of external factors on the community, for example, a bridge construction and other elements that were assumed as a main factor of the landslide as shown in Figure 6 and 7. Further applications of BIM and UAS could prevent this kind of circumstance.

Figure 6. Construction site of the Bridge

Figure 7. Opposite side of the Landslide and Community

The effects of the landslide have a focalised damages categorised as minor by the assessment of the highway and 2 families in contrast to the rest of the community taking the Equation 1. Furthermore, the community were confident that after the termination of the construction works side effects of the landslide would stop. Furthermore, the maps were updated with the visual data and further research was carried out regarding the school design factor by a local university.

It is recommended that if an active monitoring of vulnerable zones is desired, an integration of the city council is required to reduce time in sharing technical information and avoiding delays on physical inspections. As mentioned in the literature, the Diagram 1 showed the process, considerations, and future trends that would bring adopting UAS in their workflow.

The risk analysis utilising Equation 1 allowed the professionals to identify the critical structural elements in the community at risk and safeguard them against threats such as the school and the cascading effects as in Table 1 is shown according to the information provided by the citizens of the town. The engineering explanations of the landslide was concerned with seismic waves provoked by the material extraction and the erosion.

Table 1. Cascading Effects. The order of events describes the types of actions that provoked the disaster and school risk evaluation.

Order	Event	Type
1	Flood	Natural
2	Bridge Destruction	Natural
3	Community without access	Human Made

4	Earth Works	Human Made
5	Landslide	Natural
6	Collapsing Houses	Natural
7	School Threats	Natural

Another future technical solution that could emerge from UAS data integrating the concept of smart city or digital city is the use of apps. For example: apps for alert risks in the community or an alert that describe the risks involved in certain areas of the community or the country visiting in case of investors and citizens. However, the penetration of smart devices and technological platforms should be enhanced in the country to make it fully operable. The 5G and 6G internet platforms, BIM and AI could be a step forward for the future of smart communities in developing countries such as the Dominican Republic and others.

6 Conclusion

In conclusion, the adoption into the investigation allowed the engineering team to understand and communicate clearly the problem and identify the source of the landslides, provide recommendations for the citizens, and evaluate the construction factors of the school in their foundations. The Diagram 1 was useful to identify the role of UAS for these activities. Despite the digital challenges and low capabilities that the adoption of 3D modelling from the UAS, images, videos and orthomosaic encountered, the workflow supports the update of the 2D GIS maps, provides an overview of the risks, and facilitates the situational awareness of the zone. Trust in the technology was gained and as a result of the study only 2 families were impacted negatively by the cascading effects of the constructions. Furthermore, the smart city concept could be integrated after the penetration of technologies of the 4th industrial revolution and applications are the common platform for living in comfort. As nowadays computers and smartphones are an imposing need, the adoption allowed different platforms to build under these foundations such as Twitter, Whatsapp and Wechat. Furthermore, the delivery and use of 3D representation for this type of assessment should incorporate LiDAR.

Further works were carried out regarding the school safety but the implications of 360° images, videos, virtual reality, and 3D reconstruction with UAS for similar cases related to construction are suggested with frameworks and studies to preserve the security of these buildings. Exploration of the quality factors and BIM integration are also recommended.

Abstract -

Building air leakage and moisture issues can result in significant energy loss, shorten the building envelope life cycle, and require additional maintenance costs. While these issues present risks to a building and its occupants, they could be difficult to detect during building maintenance and early stages of retrofit projects. Currently, mapping air leakage and moisture issues over a building's envelope relies on manual inspections. These methods are intrusive, expensive, and hazardous to inspectors' safety. To address these challenges, we propose a non-invasive and safe conceptual solution, a Robotic Envelope Assessment System for Energy Efficiency (EASEEbot), to locate and document moisture intrusion, thermal bridges, and air leaks. EASEEbot is a high-power wall climbing drone and comes with a multi-function toolbox. It can capture 3D thermal images and auto-generate 3D models using image-based Structure from Motion (SfM) and Visual Simultaneous Localization and Mapping (VS-LAM). Our deep learning algorithms will rapidly identify common building envelope defects from multi-modal sensing data. EASEEbot is also designed with a tethered wall-climbing mode and will use long-wave ground penetrating radar (GPR) to detect hidden trapped interstitial moisture and other major envelope defects.

Keywords -

Building Envelope Inspection; Remote Inspection System; Building Moisture; Thermal Leak Detection

1 Introduction

In the United States, buildings account for 28% of total primary energy usage and 40% greenhouse gas (GHG) emissions [1, 2]. To combat climate change, major US cities require energy benchmarking and regular energy audits for large multifamily and commercial buildings [3, 4, 5]. Recently, governments are also offering incentives and programs for low-rise residential building energy audits [6, 7]. Based on previous studies, thermal exchange through the building envelope is one of the primary sources

Figure 1. Three main application scenarios. 1. 3D thermal reconstruction of building envelope. 2. Detailed inspection by using GPR sensor and tethered wall-climbing drone. 3. Interior envelope inspection in attic spaces.

of energy loss. Some studies estimate energy costs could be reduced by up to 20% by sealing the building envelope [8, 9]. Therefore, rapidly detecting and locating areas of significant heat loss and air leakage on the building envelope remains a key challenge for improving the energy efficiency of buildings.

Conventional building envelope inspections involve in-person site visits and manual mapping of located issues on paper documents. Depending on the size of the building, inspectors can spend a significant amount of time surveying an entire envelope. Inspectors may also need to access hazardous areas like roofs, elevated exterior wall sections, and attic spaces without structural flooring [10]. Considering their own safety and productivity, inspectors will typically limit the scope of their envelope assessments, only examining a select number of representative areas. With the popularity and improved reliability of drones, recent research has proposed to use drones to assist envelope inspectors in accessing hazardous building areas

*Equal contributions.

and detecting envelope issues over a larger area with less physical effort and time [11].

Current conventional testing often involves an invasive blower door test [8] which pressurizes the building and forces occupants out. Less invasive infrared thermography (IRT) can find specific air leakage pathways, thermal bridges, and trapped moisture [12, 13]. However, IRT images can be easily distorted by sunlight or reflectance and require a highly trained and specialized thermal imaging experts. IRT images are also not reliable for detecting moisture deep within envelope assemblies. Recently, research has attempted to utilize Ground Penetrating Radar (GPR) to detect hidden envelope moisture by analyzing radar images [14].

In this paper, we propose an automated energy loss detection solution for building envelopes. As shown in Figure 1, various modular sensors can be attached to the drone for scanning the building envelope in different scenarios. In Section 3, we demonstrated our solutions in three different simulation environments. Future work on the proposed prototype will develop a proof of concept for assistance on real-world building retrofit projects. The following are our main contributions in this paper:

- We propose a quadcopter, EASEEbot, equipped with an RGBD camera, thermal sensor, and GPR sensor to automatically survey a building envelope in less time, especially over hazardous and inaccessible areas.
- We design a multi-function robot toolbox to support EASEEbot. It can be used as a storage case during travel or as a power source for EASEEbot in its tethered wall-climbing mode.
- We integrate thermal data with image-based SfM and

VSLAM algorithms to generate 3D thermal reconstruction data.

- We present our entire workflow in three simulation scenarios.

2 Related Work

Our robotic system is based on various past research in robot-assisted building inspections and sensing technologies. While past research has attempted to standardize a framework for in person building envelope inspections, our paper is focused on developing specific robot and sensing capabilities for inspectors where they most need assistance [15]. In this section, we will discuss past developments of drones and portable sensors for building inspections.

Inspection Sensors. Most state-of-art inspection methods prefer non-invasive instruments. Compared with invasive inspection, non-invasive devices may involve less setup time and avoid requiring occupants to leave the building. The most significant source of energy loss in building envelope assemblies is heat transfer through direct air leakage pathways, which can be indicated by moisture condensation. Checking envelope airtightness and moisture level of building envelope sections are primary items on inspection checklists.

Cooper et al. [16] developed a low-pressure pulse pressurization technique to avoid large fluid flow and monitor the building envelope in real-time. Recently, Casillas et al. [17] introduced Micro-electromechanical systems (MEMS)-based sensors into building monitoring systems to establish two absolute pressure sensors for determining pressure differences between different locations in buildings.

As an alternative to traditional wall moisture meters and

Figure 3. Simulation in three scenarios: low-rise residential building, commercial high-rise building and roof attic interior.

GPR scanning, detection methods using different material properties have been proposed for the moisture sensors. Healy and his team [18] utilized the change of optical fiber's refractive index in different moisture levels. Mergu et al. [19] accounted for chemical properties to detect moisture levels in the wall section by colorimetrics.

Inspection Robotic Solutions. The current state-of-art solutions for building envelope inspection are mainly focused on portable and automated approaches. Portable refers to the use of smartphone computing power to process and visualize the inspection results by communicating with additional sensors. Wang et al. [20] implemented a deep-learning-based building façade damage detection method and used a smartphone camera for real-time inspection. By using mobile robots or drones as vehicle platforms, researchers could attach various sensors and apply algorithms to detect issues across the entire building envelope automatically. Rakha et al. [21] presented a solution using drones and thermal cameras to survey the building envelope and map the heat loss areas rapidly.

3 System Design

Our system contains a multi-function toolbox and a dual mode quadcopter drone, EASEEbot. In section 4, we present the details of our hardware design. To achieve automation, we integrated a learning-based visual algorithm with drone flight control to automatically combine 3D point clouds with thermal imaging data. All of the software algorithms are introduced in section 5.

System Workflow. As Figure 2 shows, we propose a workflow from building envelope surveys to issue-labeled 3D maps. First, our drone will fly around the building along a user-specified trajectory. During flight, the onboard RGBD and thermal camera will simultaneously record 3D point cloud data and thermal data. This step will locate areas of high heat loss and help the inspector quickly assess the building envelope's overall condition. For each area of high heat loss, GPR can be used to understand the damage level inside of envelope assemblies. Unlike the working principle of other sensors, GPR needs to be in direct contact with the inspection surface. To this

end, we need to switch our EASEEBOT to its climbing mode. Throughout the building envelope survey, the inspector's tablet will update, integrate, and visualize the collected data from different sensors onto the building's 3D model.

Workflow Simulation. To better visualize the entire workflow, we use the Microsoft AIRSIM simulator [22] to present our EASEEbot working in different scenarios. Figure 3 shows the three main scenarios in our simulation: low-rise residential building, commercial building, and interior attic. The entire simulation is done through the third-person perspective. There are three additional windows at the bottom showing the images captured by the onboard sensors. The center yellow box displays the RGB camera on the drone. The depth data is displayed in the left green box. The blue box on the right shows the segmentation image, which will help the algorithm detect the potential air leakage areas. The full video can be seen at: <https://youtu.be/Gr07d4nLkpc>.

4 Hardware Design

Our hardware is mainly composed of three parts: the EASEEbot, a robot toolbox, and different types of sensor attachments. The EASEEbot drone can be attached with different types of sensors to scan the building envelope and find the energy leakage. We can put sensors and drones into the toolbox for convenient transportation or storage. The following is our specific design.

Multi-function Toolbox. The size of the toolbox is: 44.88in (L) x 33.07in (W) x 16.54in (H). The toolbox is made of multiple layers with different materials as illustrated in the Figure 5. From outside to inside, the toolbox has rubber bumpers, the polycarbonate (PC) outer shell, carbon fiber strips to enhance the toolbox's durability, and ethylene-vinyl acetate (EVA) foam used as an inner lining to safely house equipment. Since PC material has been widely used in the luggage industry, it has proven to be an ideal sturdy, lightweight and low-cost shell material. In addition, the internal protective material, EVA, not only firmly holds up the internal drone but also protects important equipment and sensors during transportation or

Figure 4. Detailed design of multi-function toolbox

Figure 5. Multiple layers section view of the toolbox

accidents.

As shown in Figure 4, the inside of the toolbox is divided into four zones. We use the lid of the toolbox to place the tablet, user manuals, and work documents. The tablet is used as both a drone controller and real-time data monitor. On the left side of the toolbox is our high-power quadcopter drone, EASEEbot. When the drone is removed from the toolbox, we can place the sensors and other equipment underneath. On the bottom left, there are four main sensors that could be attached to the drone: RGBD camera, LIDAR, Thermal camera, and GPR sensor. Since our drone could directly take off from the toolbox, we designed enough space in the middle of the left side of the toolbox for the gimbal and sensors attached under the drone. The upper left grid is used to place some additional equipment, such as the front gimbal and other sensors that the user may add in the future. The power supply zone is designed on the right side of the toolbox. Space here is used to house power cords, batteries, and external power converters. By setting the battery slot, our toolbox can provide power to the drone when it connects the power cord or charges the drone battery when the toolbox is closed. Many construction workers have cordless tools. In order to save unnecessary costs and more effectively use those batteries, we choose to use cordless tool batteries as our mobile power source. This toolbox also has a built-in 800w DC power supply. When there is a wall plug, we can switch the supply power to an external power supply.

EASEEbot Drone. The size of our drone is 30in (L) x 30in (W) x 5in (H). To ensure flight safety and reduce the technical requirements for the users, we adopted a traditional fully-enclosed quadcopter design. The fully-enclosed design helps prevent a propeller from hitting an obstacle. We use carbon fiber as the main material of the drone's body to provide high structural capacity without

increasing its weight. We deployed eight distance sensors around the body to automatically adjust the drone's posture to cross obstacles, such as attic roof trusses. At the bottom of the drone, we set up two Li-Po battery holders and a control board cabin. This drone is designed with two attachment ports. One is in front of the drone, and the other is at the bottom of the drone. Our drone can be installed with two gimbals and inspection sensors through these two ports simultaneously. It can also be attached with one gimbal and use the other port as the external power supply by connecting a power cord.

For the drone to be able to scan the building's facade with its sensors, we designed a four-axes rotation system for each propeller. We installed four motors on rotatable strips. The mini servos are installed and connected to those strips for controlling the rotation angle of the motor. When the drone is under flight mode, we always keep the propellers parallel to the ground. If we switch the drone to the climbing mode, the controller will send commands to the servo motors for rotating an angle and automatically balance the lift force and pressure force through a learning-based control algorithm.

We chose the Nvidia Jetson Nano or Jetson Xavier NX for the drone's control board. Compared with other control boards, these two Single Board Computers (SBCs) have good computing performance with acceptable power consumption. The main functions of the SBC are to calculate the drone's posture, communicate with the flight controller, collect the sensors' data, and transmit them to the tablet on the ground. The flight controller, which is the driver board for four motors, uses the TXRX interface to communicate with SBC. In our design, we used 4 Turnigy G90 Brushless Outrunner Motors with 15x8 Propellers. Based on the thrust calculator, our drone can provide 12.2kg of thrust, which could let us carry a large

Figure 6. ESAEEbot Design. Left: Drone platform design. Middle: Flight mode sensor setting. Right: Climbing mode sensor and power setting.

capacity battery and sensor equipment.

Operation Modes. Our EASEEbot design has two working modes, fly and climb, to meet the requirements of different sensor attachments. In flight mode, we can quickly survey a building envelope using attached RGB and infrared cameras. The data captured in flight mode can produce an efficient, non-invasive, and preliminary scan of the building envelope's heat loss. Such thermal imaging are affected by a number of external factors and may not always reveal hidden and trapped moisture [23, 24]. Therefore, we designed a climbing mode to addresses these limitations.

In climbing mode, we will scan along a building elevation with the use of microwave based GPR, since such a sensor must be in physical contact with the building surface for defect detection. Microwave-based GPR and through wall imaging technology is routinely deployed in the construction and building space to detect underground pipes and utility lines and embedded rebar within concrete members [25, 26, 27, 28, 29]. Microwave-based grid scans over a building will yield a baseline pattern that accounts for the underlying structure. All grid scans will then be compared to the baseline to find anomalies, such as trapped moisture.

We preset these two control algorithms in the flight controller. When we need to switch to climb mode, we need to remove the front RGBD camera, connect the power cable, and replace the bottom thermal camera with a GPR sensor. Meanwhile, we will switch to the climb mode in the control tablet.

Onboard Sensors. To effectively assess a building we will need to capture environmental data using a number of sensors. Our solution will capture RGB data, thermal data, depth data, and long-wave/microwave radar data. RGB data will be captured with depth data simultaneously by Intel Realsense D435 RGBD camera [30]. In those indoor environments, the Intel Realsense L515 Lidar [31] will replace Intel D435 RGBD camera and provide more accurate and dense depth data. Thermal data will be recorded

by an FLIR C3-X camera [32] and attach on the bottom of the drone. FLIR C3-X is a portable thermal camera that could provide thermal information and RGB information at the same time. Proceq GP8800, a ultra-portable GPR sensor [33], will be installed on the bottom port and use for capturing long-wave/microwave radar data.

5 Software Algorithm

To achieve fully automatic defect detection and flight control, we plan to use the state-of-art and well-developed machine learning algorithms. These algorithms include drone adaptive control, data visualization, abnormal detection and 3D reconstruction. The following are the details of the algorithm that we are going to use in the prototype.

Adaptive Control. To avoid unexpected obstacles and fly the designated route, we will use an adaptive control algorithm to control our drone robot. Model Reference Adaptive Control (MRAC) [34] is the most common adaptive controller in recent years. Compared with the fixed-gain approach, it can enable safer and quicker drone landings when its actuator fails. We use MRAC instead of Self-Tuning Control System (STC) [35] because the MRAC drone flight control model is easier to formulate, especially given its well-developed status within the drone research community. Compared to previous work, our drone has added a wall climbing mode. We plan to extend the direct MRAC to the climbing control of drone, especially for the angle control of the motor shaft.

Thermal Anomaly Detection. Thermal cameras have been widely used in energy inspection for building envelopes. Our solution features the large-scale energy inspection via onboard thermal camera. Since the output of FLIR C3-X is already a color code image, we only need to find those abnormal colors in the bounding box, whether is dark cold blue or hot red. Due to the different thermal conductivity of materials, we plan to use contour detection to exclude those false positive results. Once the screening is completed, we will record the coordinates of the abnormal

color patterns for further inspection.

Radar Wave Visualization. If any problems are detected in the camera survey, we will perform finer-scale moisture inspection. In the building space, microwaves have been extensively used for detection and analysis. GPR and through wall imaging radar use microwaves to detect covered and buried objects. Microwave-based radar has been used extensively to find buried pipes and rebar embedded in concrete. Pipe and rebar detection works by establishing a baseline microwave reflectance signal and searching for differences from that baseline. Based on this principle, microwave-based radar has also been used for detecting moisture in building components. Through more complex signal analysis, it has been extended to tracking people behind walls and extracting internal structure of a wall assembly itself.

In our previous work, we developed learning-based radar wave visualization [36]. This algorithm was originally used to detect objects and estimate poses through the wall. If we use this algorithm in building envelope moisture detection, we need some additional preparations. First, we need to collect the water leakage data of building envelope. In the original paper, the author trained a Convolutional Neural Network (CNN) to visualize the radar images. In our prototype, we will replace the RGB data with thermal images and numerical data from moisture meter. This algorithm will provide us a three-dimensional thermal data instead of 2D thermal images.

3D Reconstruction, Mapping, and Visualization. In order to accurately and effectively convey the size, scope, and location of an issue, building envelope issues will be overlaid onto a digital twin of the site being inspected. This digital twin will be created through image-based SfM, VSLAM and depth data [37]. VSLAM will give us a specific 6 degree-of-freedom pose that will allow us to know how all the images, RGB or thermal, relate to each other. Using SfM, we can piece these images together to create 3D color and thermal digital twins of the inspection site. Depth data can provide additional surety of shape and structure of the inspection site. All of this data can be rectified and combined to produce a point cloud of data. This point cloud will allow a human or AI reviewer to easily understand the location, scale, quantity and type of damage. We will also employ additional techniques to aid in 3D reconstruction and visualization. We will use our patented point-plane SLAM algorithm to perform highly accurate 3D mapping of an indoor structure using our RGB and depth data [38]. We will also use our DeepMapping algorithm which enables fully automated indoor 3D mapping without human attendance [39]. These mapping methods will use machine learning to create a detailed and accurate 3D map of the inspected building envelope.

Augmented Reality and Retrofits. After a 3D thermal

map has been created that shows the size, location, scope, and type of building envelope issues, this information can be used to aid envelope retrofit projects. Augmented reality (AR) can help inspectors understand the location and size of building envelope failures much more effectively. We can achieve glassless AR by using our smartphone or tablet included in the robot toolbox. This will allow us to directly show the virtual 3D information with camera images on the screen. This greatly reduces the technical and experience requirements for inspectors, such as understanding complicated radar images.

6 Conclusion and Future Work

This paper proposed a robotic toolkit and software pipeline that could rapidly diagnose, quantify, and locate building envelope issues. Our two mode tethered quadcopter drone has a variety of environmental sensors that can be used to capture RGB, thermal, microwave, depth, and pose data. This data is then sent into the software pipeline where it is processed to find, classify, and quantify building envelope issues. These issues are then overlaid onto a digital point cloud twin. At this stage, if it is visualized to a building inspector, they will be able to easily understand the location, scale, quantity, and failure type. Additionally, they will be able to use this knowledge to develop a location specific scope of work for building repair or retrofits.

End-User Benefits. Ultimately, this envelope inspection pipeline has two major benefits for its users. By automating the inspection process, we reduce the time and domain knowledge required to carry out an inspection. This could enable people to carry out inspections more often, allowing a more consistent monitoring of building envelope conditions. Secondly, we clearly visualize the location, size, and type of envelope problem so that decisions on repairs can be data driven and proactive instead of reactionary and complaint driven. We believe that building scientists and property managers will benefit from this toolkit for performing robust high-level inspections cheaply, quickly, and routinely.

Future Work. Our future work will focus on making prototypes that can achieve all of the above-mentioned functions. We will also develop our own algorithm for the thermal anomaly detection and wall climbing control. The conceptual design we present here lays the groundwork for future testing of hardware prototype and defect detection algorithms on small-scale envelope section mockups and real buildings for inspection speed and detection accuracy. Overall, we believe that our work can provide a safer environment for inspectors and reduce the technology and experience requirements for inspectors.

Abstract

Robots have typically improved workers' health and safety and increased productivity and quality in manufacturing. Current advances in robotic and computer technology, combined with BIM, have led to new applications in construction. However, there is no general framework to guide the implementation of robots under current construction working schemes. Many questions and challenges need to be answered and overcome before robots can be economically and safely introduced to construction sites. Some questions include: 1) How does it affect the planning and workflow of related activities? 2) What are the implications regarding health & safety, and quality? 3) What is the best way to assess the viability of introducing robots onsite? 4) What are the organizational implications of using such systems? Still, there is plenty of work to do when considering common project management elements when using robots. To assist with that, this paper presents a case study in which we gathered real-world data on the overhead drilling work of an on-site semi-autonomous robot. In addition to the traditional analyses for changes in workflow, productivity, health & safety, and quality, as well as the implications to the schedule and cost of the tasks carried on by the robotic system, this study proposes a project management framework to help contractors better prepare for the introduction of robotic systems into their projects when similar scenarios arise. In addition, this study gives an insight into human-robot interaction experiences in real construction projects.

Keywords –

Project Management Framework; Productivity; Semi-autonomous Drilling Operations; Construction Robots

1 Introduction

The use of robots in the construction industry has been considered for quite some time to handle inefficiencies and low productivity. Technology advancement in construction is changing how a project is carried out, as a considerable amount of on-site work can be conducted automatically. However, many factors limit the wide adoption of robotics in the construction industry, such as incompatibility of technologies, the fragmented nature of the construction, and high initial capital investment [1]. In addition, due to the multidisciplinary and complex nature of construction projects, robotic systems and automation technology are often not general [2], there are no consistent methods to sufficiently analyze the feasibility and efficiency of the robotic system to be used [3]. In previous research, the emphasis on implementing construction robotics has been mostly on identifying technological issues and challenges [4]. The interaction between robotic systems with management and human factors may raise new interest in future research. In the meantime, to support the project and business decision on robotic adoption, a generalized framework for robotic-oriented management is also needed.

This research uses a case study related to the engineering, planning, and production data of a concrete drilling robot in a real project to help the industry figure out a solution and a framework to review and advance the usage of robots in a systematic manner. The research methodology used is summarized in Fig. 1. In general, it consists of a literature review and a single case study from which qualitative and quantitative data were collected and analyzed. Qualitative includes basic project information, the usage of the robotic system, the planning and organizational procedures, and the stakeholders' opinions from interviews. Quantitative data came from the robot's task reports, which detailed information such as time in operation and the number of holes drilled.

Based on previous literature, a comprehensive

feasibility analysis was carried out to assess the drilling robot in the case study. We involved a feasibility analysis procedure in helping decision-makers evaluate and decide the implementation of the new robotic system. This study investigates the impacts of utilizing robots based on the conventional performance criteria such as productivity, health & safety, and accuracy. Then we identified challenges that limited the adoption and proposed solutions to overcome the challenges. Based on these procedures, we proposed a systematic framework for robotic-oriented management to optimize the outcome of the robotic construction.

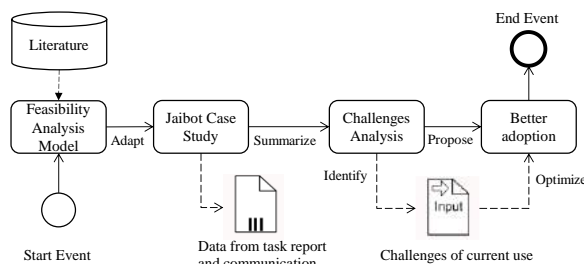

Fig. 1 General structure of the research methodology used in this study.

2 Feasibility analysis model

With the introduction of new technologies, it is critical to analyze the potential and actual impact of that technology (e.g., the deployment of robots in construction sites). In this work, we present a feasibility analysis model for the general adoption of construction robotics. The feasibility analysis model sets up a modeling procedure to evaluate the feasibility of developing robotics and justifying their implementation for certain construction operations [5]. The feasibility analysis model consists of three key elements: project description, performance criteria analysis, and human factors analysis, as shown in Fig. 2.

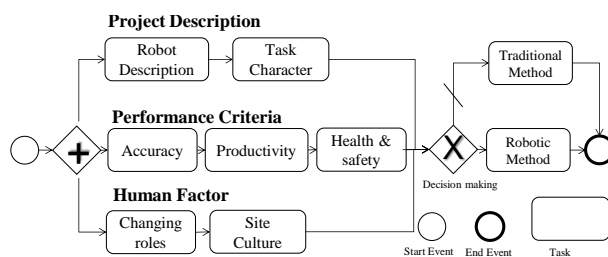

Fig. 2 Feasibility analysis model

2.1 Project Description

The adoption of construction robots is project-oriented [6]. In the project description stage, a comprehensive analysis should be made to identify the

construction automation levels of robotics [2]. A robotic system generally comprises many modules working together to perform a task. The description of the robotic system should list the basic structures as well as functionalities and capacity of the robot to show potential usage in specific tasks. Principles of the tasks and influences from the environment will highly influence the robot's performance [7]. Task characteristics should be defined for coordination with the robots.

2.2 Performance Criteria

2.2.1 Accuracy

Using robots in construction sites can minimize mistakes caused by human errors and help improve accuracy [8]. Still, with advanced technology, robots can fulfill repetitive work with high speed and accuracy; fewer mistakes will result in fewer delays and repair/rework activities [9], also will lead to more enduring construction structures [10].

2.2.2 Productivity

Previous research has utilized productivity as an important metric to analyze the adoption of construction robots. For example, García de Soto et al. [11] presented a productivity analysis based on the robotized construction of a reinforced concrete wall. Usmanov [12] studied the productivity impacts of an automated bricklaying robot versus the traditional construction method. Previous research has shown that higher-level automation allows construction managers (CMs) to plan their projects more effectively, provide an easier way to meet deadlines, and save time and financial resources. However, a construction project is unique. The uncertainty caused by design changes, dynamic environment, and human activities will greatly influence the outcome.

2.2.3 Health & Safety

Robotic systems can reduce injuries and free workers from conducting dangerous tasks [13]. Moreover, workplace safety will be improved by replacing workers with robots in tasks that involve difficult physical work or exposure to unhealthy environments. Although so many benefits, robots work simultaneously with humans when we implement robots on the construction site. This will cause management issues and safety concerns when humans and robots interact in the same environment [14].

2.3 Human factors

2.3.1 Changing roles

The advent of robots within different construction processes will offer opportunities to people who have a strong interest in new technologies, but at the same time,

it will cut a considerable number of on-site jobs. Robotic machinery cannot fully replace human presence, but it can reduce it significantly [1]. Also, it is expected that current construction roles will evolve, and new roles will be created [16]. New roles such as digital model designer and robotic expertise will take more responsibilities during the construction process.

2.3.2 Worker's attitude towards change

Performing human-robotic collaborative tasks require workers to have the ability to understand how to achieve team coordination and communication with the robotic system, effectively monitor the construction process by recognizing problems, and intervene during certain circumstances. Thus, the construction labor markets will turn to specialists and qualified employees, and job security issues could result in workers' aversion to change in the construction culture [1].

3 Case Study: Jaibot for overhead drilling operations

To assess the real-world implementation of on-site construction robots, we conducted a case study in collaboration with ALEC Engineering & Contracting (ALEC), a construction company in the United Arab Emirates, and Hilti, a company that develops and manufactures products for the construction industry.

3.1 Project description

The project used for this study is the One Za'abeel in Dubai, consisting of 2 skyscrapers, Tower A and Tower B. To promote innovation and digital transformation in the construction industry, ALEC, the main contractor of the project, attempted to adopt a semi-automated robotic system, the Jaibot by Hilti, to complete overhead drilling operations for the subsequent installation of MEP systems. The real-site robotic execution on Tower A took place in September 2020.

3.1.1 Robotic description

Table 1 summarizes the key information about the Jaibot with the basic functions and capabilities.

Table 1 Summary of Jaibot features

Component	Function	Capacity
Drill	Drilling	Holes (6 – 16 mm).
Total station	Position	Locate drill bit within an accuracy of ± 5 mm.
Robotic Arm	Stretch	2.65 – 5.0 m above.
Jobsite tablet	Control	Move the robot
Hilti's cloud service	Instruct the robot	Locate drill position; Progress updating

The Jaibot is a semi-automated construction robot designed for mechanical, electrical, plumbing, and interior finishing installation work. Based on the information provided by ALEC, the robot starts with coordinating the tasks, including collecting design information from BIM models and setting reference points. When it comes to the real site execution, design files are loaded wirelessly via Hilti's control panel and downloaded from Hilti's cloud service. After arriving at each workstation controlled by the operator, the robot will reach and drill all the identified holes automatically based on the specifications.

3.1.2 Task characteristic

The work was taking place on an ongoing construction site with multiple operations underway and multiple subcontractors. As a result, some obstructions prevented the completion of the full levels at one time. ALEC defined four levels of Tower A in which overhead holes with different diameters (12mm and 15mm) were drilled for subsequent installation of MEP elements. There were 3,488 holes planned. The size of the holes was designed to standardize the drill diameters and control the quality. The allocation of each hole type and their number per level are summarized in Table 2. By the time of this research, the total number of holes drilled in this project was 3,058. For this study, we only considered the holes drilled between levels 34-37 (1,537 holes).

Table 2 Size and numbers of holes to be drilled.

Hole size	Level			
	L34	L35	L36	L37
12 mm \varnothing	628	638	638	646
15 mm \varnothing	236	234	234	234

3.2 Performance criteria

3.2.1 Accuracy

The system recorded details of each hole drilled. This includes location (x, y), depth (z), and diameter. All this information could be observed in real-time on the dashboard provided by Hilti.

The drill diameter or depth did not cause any deviations in the current practice, as the diameter was based upon the drill bit. Holes remained the same size until the drill bit was changed. When applicable, the drill bit was replaced by the operator. The depth was preprogrammed, and the robot automatically notified the operator if the depth could not be achieved.

Factors that influence the robotic drilling include calibration errors in the total station, errors from the ceiling plane sensor, accuracy in planning (BIM), and human errors on robot control. For instance, planning and communication errors led to deviations between as-

planned BIM coordinates and as-built coordinates, which impacted the robot accuracy because the robot could not tell whether the site conditions differed from the BIM model; it would continue to drill according to plan without notifying the variance.

3.2.2 Productivity

3.2.2.1 Basement test

In the early stages of evaluating the capabilities of the Jaibot, a demonstration was done in the basement to compare traditional and robotic drilling methods for productivity analysis. The list of tasks and workflow for drilling operations using manual or traditional techniques are summarized in Fig. 3.

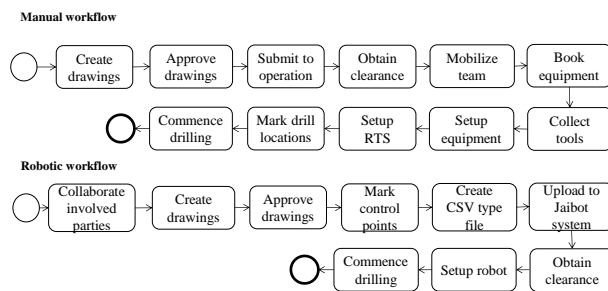

Fig. 3 Workflow of manual and robotic drilling operations

Based on the task report from ALEC, the manual drilling process took about 270 seconds, with a cost of 5.85 AED per hole. Robotic productivity was measured using the same parameters as human workers. For an 8-hour working day, 600 holes were drilled, which shows the productivity of the robot is 48 seconds per hole. The cost per day for the robotic system is 3,507.65 AED with 600 holes or an average of 5.85 AED per hole for robotic drilling. This information is summarized in Table 3.

Table 3 Comparison between Jaibot and traditional method during the test at the basement

Method	Productivity	
	Cost (AED)/hole	Duration (sec)/hole
Traditional	5.85	270
Robotic	5.85	48

From the production data in Table 3, the Jaibot reduces the duration of the drilling process from 270 secs/hole to 48 secs/hole, which shortens the on-site drilling process. This can also be explained by comparing the workflow of two procedures (Fig. 3). The big differences between the two methods rely on the process of marking the drilling positions instead of manual marking based on the drawings; the robot could easily find references from pre-defined control points. That is less time-consuming and more reliable (i.e., reducing

human errors). However, the cost and duration for the preparing stage, such as collaborating with all parties, initializing the BIM models (insert drill depth in terms of the requirements of the robot), setting up cloud service and equipment, are not yet considered in this test. Further analysis needs to be conducted when robots come into the real site.

3.2.2.2 On-site execution

After accessing the Jaibot data with the real construction process, the productivity was not as great as expected. Although detailed information on the preparing stage was not available, some of the reasons include the time used for transporting the robot or cleaning the job site. In the task report, only the effective construction duration with successful holes drilled was considered to calculate the productivity.

One thousand five hundred thirty-seven holes were completed with the Jaibot in 9 days. The task report indicated that the average daily hours operated by the robot (e.g., in Fig 4) were about 3.86 [hours per day].

Fig. 4 Working hours of Jaibot during the testing period

Fig. 5 Production rate of Jaibot during the testing period

With the number of holes drilled each day stated in the task report, we can calculate the production rate and compare it with the experimental ones. From Fig 5, we

have an average productivity of 86.5 secs/hole, which is not as good as the 48 secs/hole base experiment.

The deviation comes from multiple aspects. For example, the current workflow is not as smooth as the planned ones. The design and operations teams must be aligned with all schedules (civil works, subcontractor packages, design packages, client signoff, etc.) to ensure the work area is ready; however, design changes usually occur while the project is underway, which can cause a major delay.

Besides, holes could fall out of accuracy requirements due to errors in sensing or differences from the original design. In addition, site managers might decide to skip the holes due to awkward positions (for example, if a drill operation hit rebar and did not penetrate fully). Among the 1,537 holes drilled, 96 holes failed for certain reasons. On average, the failure rate was 6.71% for the 9 days. Failed holes and skipped ones could result in a great amount of time to be remeasured and reevaluated. These failures will greatly influence productivity.

3.2.2.3 Longer operation better productivity

To find a general reason why the productivity varies in these 9 days, we conducted the further analysis. From Fig. 4 and Fig. 5, we can see that, on 09/13/2020 and 09/22/2020, the working hours are the least among the 9 days, with 1.75 and 3 hours, respectively. On those days, the production rate is the lowest (126 secs/hole and 103 secs/hole), which indicates the drilling process takes longer in these two days. In contrast, on 09/14/2020, there was a significant increase in the working hours to 7 hours and a significant increase in the production rate to 84.84 secs/hole. Therefore, it could be stated that with more time the robot drilled, the required duration for drilling one hole would be less. To verify that conjecture, we calculated the Pearson's Correlation Coefficient (r) to identify any linear correlation between these two sets of data. The result shows that Pearson's Correlation equals -0.608. A strong negative relationship between these two parameters indicates that longer operation will have a greater probability of better productivity for robotic drilling. Many reasons could cause the longer manipulation of the robot, for example, open area that is easy for the robot to transform; skilled operator on duty that facilitates the process; smoother schedule with less intervention of surroundings; or the drilling position is easy to access with less failure or skip. With limited information right now, we could not find the exact reasons; also, the sample size is rather small, which does not allow for a generalization of the results obtained.

3.2.3 Health and Safety

Robotic drilling improved the task ergonomics, reducing the muscle strain work hours (measuring and drilling overhead). It can reduce the Work-Related Musculoskeletal Disorder conditions and vibrations.

Based on Hilti's feedback, the Jaibot could also reduce noise levels from the drill bits and distanced the workers from the source of drilling noise. Besides, the robot's modular integrated vacuum could reduce workers' exposure to respirable crystalline silica and dust, providing a better working environment for on-site construction.

Based on an interview with ALEC's site team, they gave an overall high evaluation of the health and safety performance of the Jaibot. 90% of the interviewees strongly agree that the Jaibot is reliable on safety performance. However, in another set of questions regarding the adoption of construction robots for applications of all kinds, some interviewees were concerned about safety when working with construction robots. One of the reasons for that could be that there is not much experience with real-world robotic applications in construction projects. Thus, when operating in the same environment as robots, workers might feel uncertain or insecure in such environments. Besides, construction sites are dynamic and hard to control environments; unexpected health and safety issues could come out because of human errors or omissions when dealing with onsite robotic systems or vice versa.

3.3 Human factors

3.3.1 Changing Roles

As part of its role as the main building contractor, ALEC facilitated coordination and communication among the different project participants. In addition to conventional tasks, such as defining a site management strategy or the work scope, ALEC had to put extra effort into communicating work packages with different parties, setting up communication among subcontractors and Hilti to ensure proper integration of the Jaibot. Subcontractors also had to adjust their workflows to incorporate the requirements from the robotic system.

For example, ALEMCO was the subcontractor responsible for installing the MEP package on Tower A. The Jaibot team operated as an additional subcontractor, collaborating with other trades on site. ALEMCO used the IFC files from the base design supplied by the client and developed a BIM model for coordination and building procedures, also used for the robotic tasks. ALEMCO was responsible to define a reference system in the form of a building axis for the robot to use. They also created a CSV-type file to be used by the Jaibot. Hilti's Jaibot team also had several roles during this process. They provided skillful operators for on-site support for the robotic system and gave valuable feedback on monitoring and control processes during the robotic adoption. For instance, the site team of Hilti coordinated with the site surveyor to define the measuring process. Meantime, the team should have the

list of prerequisites delivered to the main contractor to get the necessary support on the job site.

3.3.2 Worker's attitude towards change

To better understand the workers' attitudes towards changes due to the use of the Jaibot, we conducted a questionnaire to gather extra information. A copy of the questionnaire can be found in [15]. The questionnaire consisted of 40 questions broken down into eight parts, namely (1) Performance; (2) Compatibility; (3) Challenges; (4) Organizational support; (5) Technical Support; (6) Regulatory & public support; (7) Attitudes towards adoption; and (8) Industry atmosphere.

The questionnaire was distributed to the site team of ALEC and Hilti. Eight responses were provided during the time we worked on the research. Hilti representatives operated the Jaibot. This could be a problem that limited future adoption; drilling workers might not be compatible with new roles to operate the robot. New organization support needs to be established to raise more interest in robotic learning and practice. Attitude mostly comes from operators, modelers, and managers, which shows that robotic adoption will not greatly influence their job opportunities; however, the manual drilling workers' job opportunity is lost. Thus, the management framework needs to acknowledge these changing roles.

4 Jaibot adoption optimization

To solve the problems mentioned in the previous section. Based on the literature review, we summarize the current challenges of Jaibot adoption and put forward strategies to overcome such problems.

4.1 Performance criteria

4.1.1 Accuracy

As previously defined, errors were coming from sensing strategy in state estimation for robotics. To increase accuracy and robustness, a growing number of applications have started to rely on data from multiple complementary sensors. For example, Furgale and Siegwart [17] proposed a unified method of determining fixed time offsets between sensors using maximum-likelihood estimation. By registering different sensors spatially concerning each other, sensor fusion can easily eliminate spatial displacement. For the current usage of the robot, the Jaibot already has a reference sensor as the total station, it can achieve great accuracy, but with higher goals on eliminating errors to guarantee the quality of the product, extra sensors such as laser scanning could be adopted to catch these deviations.

Based on an interview with ALEC's representatives, the design change is a huge difficulty within the construction industry, specifically in Dubai and

surrounding regions. To solve this problem, updating the robot with real-time information of the construction site is necessary; thus, we can rely on digital twin construction (DTC) such as real-time updated BIM models. For example, Ye et al. [18] established a real-time interaction mechanism between digital design and physical construction. The design outcome is a dynamic, data-driven model, which would be updated by material conditions on-site. This could help the robot with real-time data instructions to guarantee the robot understands the design changes, which will reduce the effort and time on redesigning and rework.

4.1.2 Productivity

Based on our analysis, we notified that idle time takes the most time of the schedule. When refers to the industry partner's explanation, the Jaibot involved drawings and drawing approval. Without this in place and finalized, the work cannot continue, and since the Jaibot needs to be first in place, this also means that no other work can continue, which can cause major conflict between stakeholders. The work schedule overlap results in the current low level of efficiency. In the current practice, the schedule management framework is not yet generated by the project management team.

With a comprehensive structure of the schedule, it is easier to identify strategies to optimize the current workflow. Brosque et al. [3] analyzed the location-based schedule (LBS) and a 4D model to drill different areas and visualize how the robot impacted the continuity of crews working on production tasks, which successfully modeled the optimized schedule for robotic drilling.

Still, we figure out that with the long operation, the production rate seems to be at a higher level. This is because that continuous operation reduces extra effort to reset and calibrate the equipment, saving much time in the preparation stage.

4.1.3 Health and safety

The condition of the floor area greatly affected the drilling time and the safety of the operator and the robot. For example, when obstacles were present, "having to maneuver the robot around obstacles caused delays and [in some cases] collision, especially when navigating between different control points" (conversation with ALEC representative). Hilti, the robot manufacturer, also indicated that "Jaibot usually works in narrow corridors or spaces where there is heavy human traffic", and the "operator could have proximity to the robot during operation." Human activity on the job site could greatly influence the robot's stability, and in turn, the hazard could be brought to humans if the robot breaks at a certain distance from human beings. The project management framework should try to adapt to new regulations and rules for working with robots. Besides, a well-established

training program is needed. Continuous staff training can help address the various challenges and reduce false instructions because of human errors and mistakes

4.2 Human factor

4.2.1 Changing roles

Making the best use of humans and robots while keeping projects moving smoothly seems the biggest challenge when considering the changing roles in robotic adoption. Mossman [19] states that the on-site operation could greatly benefit from lean thinking, integrated project delivery (IPD), and BIM. The combination of such a strategy will support the just-in-time delivery of elements. It will improve productivity and efficiency via enhanced collaboration and integration.

4.2.2 Site culture

As defined in the site culture analysis, some construction companies face a shortage of technical workforce; thus, project managers should take a long-term view of workforce demand by simulating the future project pipeline. This forecast should be made on a granular skill-cluster level: it should consider, for example, future skills requirements in the digital space or the need for local market experts, but also expected productivity gains through technological advances. Companies should also engage constructively with the public sector to avoid misunderstandings, discuss the impact of regulations, and ensure good relations.

challenges and the optimization strategy identified in previous sections, a proposed framework was developed to assist owners, designers, CMs, and subcontractors to decide whether the new technology should be implemented or not and help with their future usage in other projects.

As shown in Fig. 6, CMs should develop the concept of the project first, and then by benchmarking the robotic applications, they need to define the activities where they would like to adopt robotic construction. In the planning phase, after initializing the contract, CMs will coordinate all parties to exchange technical profiles to understand the capacity of robots and overcome boundaries in specific tasks. CMs will also set up the work breakdown structure to allocate the tasks and develop an integrated management strategy to coordinate participants effectively. Designers and site managers can help with the schedule, budget, and quality management and develop reasonable ways for a robot to collaborate. All this information will be collected to generate an execution plan for a future test.

Before the actual implementation, digitalized models to simulate the robot's task can be used. Simulations are a cost-effective way to assess feasibility, safety, and cost risks in a real-world implementation. In the following step, during the testing phase, quantitative data such as task reports and qualitative ones such as people's attitudes could be gathered to test the feasibility of the robot. A comparison between robots and conventional working can help us better capture the efficiency of the robot. Information can then be used in the feasibility model. CMs' value on expectations of outcomes will help figure out what parameters to set up to evaluate the robotic system. Once the benefits and challenges are identified, all parties should work together to generate an optimization plan for further use or test. If the outcome is accepted, the robot application could then be adopted in a larger scope of the project.

5 Robotic management framework

Based on the lessons learned from this case study, we summarized the basic structure of an integrated robotic management framework (Fig. 6) to implement an innovative system on the construction site. With

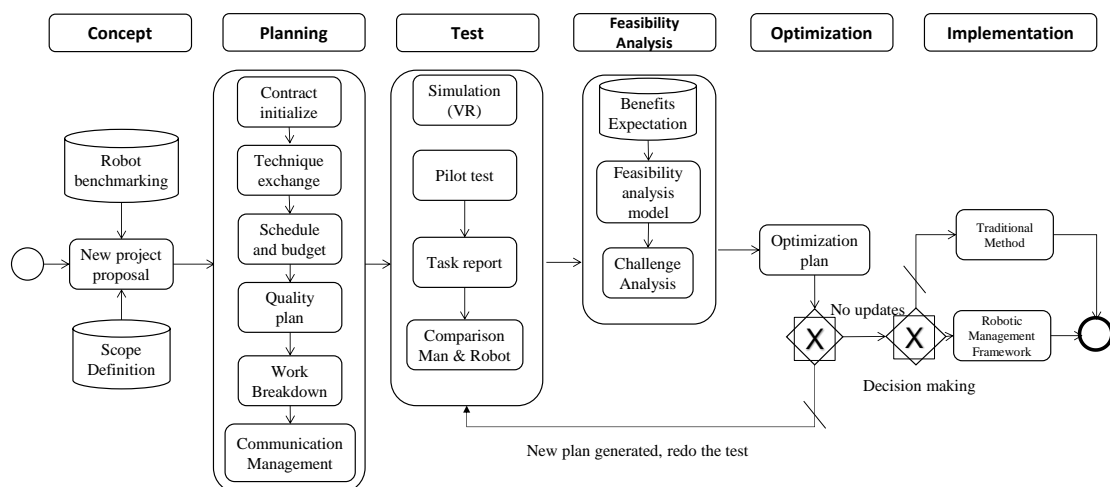

Fig. 6 Overview of the proposed robot adoption project management framework

6 Conclusions and Outlook

With the challenges identified in the previous feasibility analysis process, we proposed a framework to solve such problems and advance the current use of the Jaibot robotic system, which suggests the combination and integration of processes and technologies over the whole project management schemes to an advanced ecosystem of devices, equipment, resources, and workers.

Although the challenges are unique based on different robotic applications and different projects, the logic of using the feasibility analysis model to promote the framework set up a great foundation for investigating a generalized solution for robotic construction adoption. In the future, a more advanced framework with a state-of-the-art strategy will be added to push the future advancement of robotic construction applications.

For future studies, it is planned that the Jaibot might be used in other projects by ALEC; therefore, there could be opportunities for us to get firsthand data from the job site that could be used to further investigate the general management framework. Further studies could test the performance of this framework and advance it to a more general one. Besides, in future work, we will adopt a path correlation estimation and give different weights to the factors identified in the framework. That could help to understand how (and which) different factors influence robotic adoption.

Acknowledgment

The authors would like to thank Mr. Imad Itani from ALEC Engineering & Contracting and Mr. Hussam Droubi from Hilti Sub Region Gulf Countries for their support and feedback provided during this study. Thanks also to the individuals from ALEC and Hilti that participated in the questionnaire.

Abstract –

Quality inspection of existing buildings is a task currently performed by human inspectors. In general, these inspections consist of assessing the different elements of a building as they are being constructed, checking that they are within acceptable tolerances, and meeting industry standards. Typically, this process is carried out by doing a visual inspection, taking photographs, and using measuring tools to identify deficiencies for further comparison with the BIM model. The acquired data must be analyzed by different specialists such as civil, electrical, and mechanical engineers, looking for defects or substandard installations. This process is time-consuming and dependent on the human factor, leading to errors and inconsistencies.

To counteract that, we propose a methodology based on a multi-robot system that works synergistically to automatically collect data and analyze it for the further generation of a quality report. By automating the process, we are making the quality inspection more reliable, robust, and time-efficient.

The master robot will collect general data and identify specific regions of interest (ROI) (e.g., potentially defective areas). When additional information is needed, the master robot will command the slave robot to approach the ROI to collect more detailed data. This can be used to inspect some of the most prevalent defects in construction sites, such as cracks, hollowness in walls (i.e., lack of insulation or incomplete concrete fillings), surface finishing defects, alignment errors, evenness, inclination deviations, and possibly more.

Keywords –

Maintenance management; Quality assessment; Autonomous Robot; Master-Slave Robotic System.

1 Introduction

Automated processes have increasingly become more popular during the last decade in most industry-related fields. However, the construction field has not progressed at the same rhythm despite multiple studies proving that automation in construction would significantly improve the efficiency and productivity of the process [1]–[3]. Part of this slow adoption can be attributed to the unstructured nature of construction sites and their constantly transforming character.

Automation can significantly optimize tasks that need to be performed periodically and require repeatability. The construction progress monitoring and quality assessment are good examples of tasks that can be automated. Currently, those tasks are usually tackled by multiple experts that need to inspect the construction site visually, in most cases with the help of measuring tools. Unfortunately, this can lead to inconsistencies between consecutive reports because of the heavy reliance on the human factor.

In this study, we propose an automated construction inspection system (AutoCIS) for the quality inspection of buildings. The system consists of a multi-robot approach that, acquiring data from multiple sources (3D Scanners, visible and infrared cameras, environmental sensors, etc.), will provide, in an autonomous way, robust and reliable quality assessment during the construction progress. An overview of the proposed process is shown in Figure 1.

There are different quality assessment-related elements that could be automated. For this study, the focus will be limited to the task to identify specific elements, such as cracks, hollowness in walls (i.e., lack of insulation or incomplete concrete fillings), surface finishing defects, alignment errors, evenness, and inclination deviations.

The rest of the paper is structured as follows: Section 2 introduces the state-of-the-art on the two main areas of

this research (i.e., multi-robot systems and Automation in the construction field). Section 3 presents the details and main features of the autonomous robotic platform. Section 4 explains the methodology and the data processing. Finally, Section 5 summarizes the conclusions and provides an outlook for future work.

2 Previous work

2.1 Master-slave robotic approaches

Research has proven that developing a multi-robot system (MRS) is more cost-effective than developing a single costly robotic platform with all the capabilities [4]. When it comes to defining the taxonomy and architecture that different MRS can adopt, there are systems where the workload and task assignment are equally distributed between the different agents inside the MRS, and systems where there is a hierarchy between the different agents and one of them is acting in command [5]. With systems where the number of agents is minimal, the latter approach is more efficient and robust.

The master-slave denomination refers to systems where there are at least two agents with two different roles, one of them being in charge of assigning tasks (master) and the other one that would follow said commands (slave). This architecture has been widely used in the medical field, where surgical robots act as the slave component in a system where a human operator manually commands the movements through a master device. In the construction field, there are few approaches where MRS have been used for applications such as mapping the environment, block placing, or 3D concrete printing coordination [6]–[8]. Most of these approaches present an equally distributed task allocation between the different agents inside the MRS, making them suitable for repetitive and simple tasks.

The system proposed in this study uses a master-slave MRS, making it a robust system that can deal with the unpredictability and harshness present in the construction environment. To the authors' knowledge, this is the first study in which a master-slave MRS is considered for high-level tasks in the construction field.

2.2 Automation in the construction field

The current state of the use of robotic systems in construction sites is far from having autonomous robots performing specific task-oriented procedures, such as high-level construction assignments (e.g., bolting, painting, tiling, or bricklaying) [9]–[11]. This requires high precision and robustness to ensure that these platforms are safe working side-by-side with humans. However, this directly conflicts with the high complexity of the construction environment and the constant

movement of assets.

In contrast with the high-level construction assignments that require human collaboration, robots and autonomous processes can be integrated into tasks where no human interaction is needed, and there is not as much movement of assets across the site. Examples of suitable tasks are progress monitoring and quality assessment since these can be done when the construction works are paused. Automating these procedures can provide results with higher accuracy than those performed by skilled workers [10].

One of the steppingstones in the automation of construction is the BIM model. Many studies have shown that having a reliable and updated BIM model is the first step to increase efficiency and productivity in the overall construction process [12]. Therefore, a significant amount of research has been dedicated to creating as-built models from the data collected at the site [13], [14]. This process is commonly referred to as scan-to-BIM, and it is especially useful for both progress monitoring and quality assessment since the elements to be compared with the BIM model need to be segmented and identified.

2.2.1 Progress monitoring

Progress monitoring is usually based on the manual comparison of as-planned and as-built schedules. However, as-built schedules are often not maintained and updated throughout the entire life of the project but generated at the final stage [15].

Most of the progress monitoring approaches, even if they are updated during the construction process, do not consider the quality of the achieved progress [16], [17], which is something that can help prevent smaller problems from becoming bigger issues that might create rework, delay the construction process, and even affect the quality of the final product. By assessing the quality of the progress being made during the construction process, the generated report will be more accurate according to the current state of the construction and provide information for on-time actions to prevent defects in the final product.

2.2.2 Quality assessment

There is some research done regarding the quality assessment of construction [18]–[24]. When it comes to quality assessment of construction elements, there are two main approaches, namely destructive and non-destructive evaluation methods [25], based on the nature of the sensing element. Since this study aims to have an autonomous robotic system performing quality inspection during the construction process, a non-destructive evaluation method is preferred that allows for unsupervised and autonomous operation. The sensors used for non-destructive evaluation methods vary from 3D scanners to DSLR and RGB-D cameras to thermal

infrared cameras or sensing probes to measure temperatures.

In [18], they developed an autonomous platform for the quality assessment for some of the most common defects present in the construction environment (e.g., hollowness, crack evenness, alignment, and inclination defects). The proposed robot was equipped with a thermal camera, a color camera, a 2D laser scanner, and an inclinometer. The system was meant to be operated in finished buildings, and therefore is not suitable for a construction environment.

A semi-autonomous system was proposed in [19]. The approach used manually taken photographs in order to reconstruct a 3D point cloud from the environment. Measurements were taken manually from the point cloud to later be compared with the stats present in the BIM model. They present an improvement on fully manual quality assessment, but the process still relies on the human factor, and it is also meant for post-construction assessments.

Another post-construction quality assessment approach is developed in [20]. The authors proposed the robotic platform as an assistant to accelerate the process rather than performing the inspections on its own. The platform was equipped with a thermal camera and a 3D scanner. The acquired data was used to detect some of the most prominent defects present in floors, walls, ceilings, doors, and windows.

Some approaches focus on specific elements of the building, such as pipes [22] or cracks [25], to provide an assessment regarding the proper geometric position of said elements and the deviation they present concerning the BIM model.

As can be seen from the literature review, most progress-monitoring and quality assessment approaches do not deal with the quality and completeness of the collected data since it is usually not being processed in real-time. It has been proven that timely and accurate information collected from the construction site must have proper quality reports [26]. For the approaches that focus on quality assessment, all the current research revolves around post-construction assessment. In addition, most of the current approaches are not fully autonomous, relying in one way or another on the human factor for its normal operation. Therefore, the methodology presented here aims to fill in the gap for the current state-of-the-art, proposing a system that assesses the quality of the progress being made during the construction process autonomously and processing the data in real-time to collect accurate information.

3 The robotic system

The Automated Construction Inspection System (AutoCIS) proposed for this study consists of three

modules: (1) the Master Unmanned Ground Vehicle (M-UGV) robot, (2) the Slave UGV (S-UGV) robot, and (3) the Command Station. The UGVs (Figure 1) are equipped with different hardware with different capabilities. The reason for having two (or more) different UGVs is to distribute the responsibilities of the building inspection based on the capabilities of each robot. This architecture is scalable; therefore, additional robots can collaborate to perform inspection tasks (e.g., they can cover larger spaces or reduce the duration of the inspection).

Figure 1. Unmanned Ground Vehicle and sensors. Photo taken at the KINESIS lab at NYUAD

3.1 Command Station

The Command Station is fixed on-site or off-site. It consists of a server and a communication device responsible for collecting data from the UGVs and displaying them in a human-readable format. Therefore, the Command Station also serves as the main interface between human operators and the UGVs. For example, the operators give “high-level” commands, such as perform a 3D scan in a specific area of the construction site, start-stop the inspection, set a new inspection protocol, etc.

3.2 Master UGV

The M-UGV robot is responsible for allocating tasks and collecting the data from all the S-UGVs, merging 3D scans, creating 3D models of the construction, analyzing the collected data, and sending comprehensive reports to the Control Station.

The M-UGV is a four-legged robot capable of navigating in a dynamic construction environment, for example, obstacles, narrow pathways, stairs, etc. The payloads of the Master UGV robot include a high-performance Computing Unit based on x64 architecture CPU and a CUDA capable GPU. The main data collection instrument is a 3D scanner to acquire detailed 3D point cloud data with color information. The robot is also equipped with five short-range depth cameras needed for perception and a communication device.

3.3 Slave UGV

The S-UGV is responsible for creating a local 3D map of the current environment (which it shares with the M-UGV), navigating to predefined local coordinates by avoiding obstacles, interacting with the physical world (turn valves, flip levers, open doors, etc.), and collecting data from a variety of sensors.

The S-UGV is the same four-legged robot as the M-UGV but with different payloads. In order to interact with the physical world, the robot is equipped with a six DOF Robotic Arm with an end effector and a two-finger Gripper with a high-resolution Visible Camera. For navigation, a fusion of long-range LiDAR, five short-range depth cameras, and encoders are used to perceive the environment. For data collection related to the inspection, the S-UGV is equipped with a high-resolution double spectrum camera (visible, thermal) mounted on a three-axis gimbal. The robot is also equipped with a Computing Unit to run the local algorithms and a communication device.

3.4 Communication

All the modules of the AutoCIS are interconnected through a mobile ad hoc network (MANET) capable of transferring data with speeds up to 120 Mbit/s operating

in a Mesh topology. Through this network, the robots and Control Station exchange data for Telemetry, 3D maps, Sensors Measurements, etc. The Mesh architecture will allow for future expansion of the network when multiple robots are used, in both range and number of nodes.

4 Methodology

The main stages of the proposed system are shown in Figure 2. It consists of two basic elements: Data acquisition (for the M-UGV and S-UGV) and data processing. To effectively monitor and perform the quality assessment, the AutoCIS needs to autonomously navigate through the construction site, collect information from different sources, and process said information in real-time to ensure there is no missing information [27]. To simplify and facilitate the communication between the BIM workflow and the AutoCIS, we propose the BIM model as the only input to the process. Therefore, the M-UGV needs to fully understand the information present in the BIM model and interact with it to further retrieve the required data.

4.1 Data acquisition

The M-UGV and S-UGV fulfill an important part of the process as a whole. The data will come from various

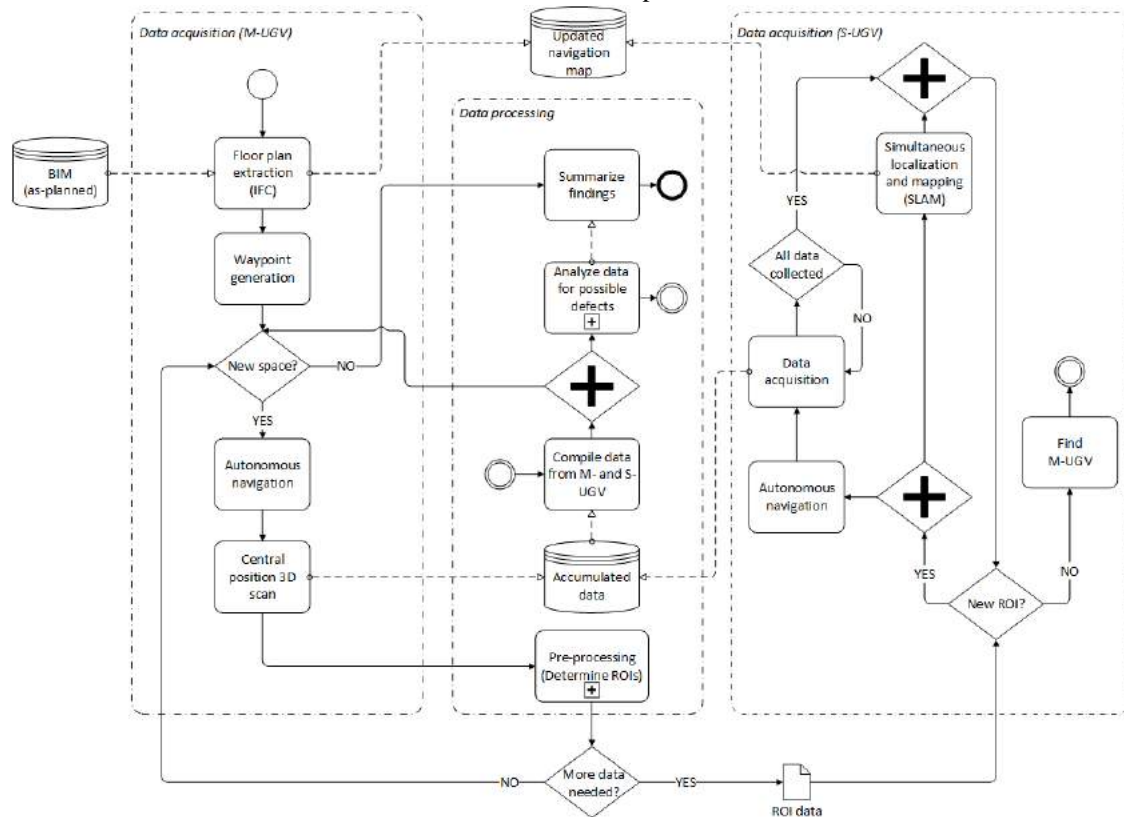

Figure 2. Flowchart of the overall methodology.

sources and sensors, mainly categorized in long-range and short-range, distributed between the M-UGV and the S-UGV, as indicated in Section 3.

4.1.1 M-UGV

The M-UGV is going to collect long-range data. The 3D scanner provides long-range information. The point cloud obtained will be used to build the general model of the construction site, obtaining the overall structure and geometry. The RGB information will help to determine regions where more data collection is needed. From now on, these regions will be called Regions of Interest (ROI).

In the proposed system, an initial floor map is extracted from the BIM model (using the IFC format). This floor map is used to generate a set of waypoints in each of the different planned spaces to ensure complete coverage of the scenario.

Waypoint-based navigation has been proven to be the most efficient way to collect as much data as possible from the construction site [28]. A set of waypoints located in the center of each space defined in the BIM model is automatically extracted from the initial floor map. The M-UGV will autonomously go from one position to the next, stopping on said waypoints to collect a 3D point cloud from the long-range 3D scanner. Plenty of solutions already exist for indoor positioning and autonomous path planning [29]. In this platform, we used an Adaptive Monte-Carlo Localization algorithm [30] and a Dijkstra-based planner approach [31].

4.1.2 S-UGV

The S-UGV is equipped mainly with short-range sensors, as indicated in Section 3. Although thermal information would be used as long-range to get an initial idea of the thermal characteristics of the different construction elements, it will also be used in a short-range approach whenever the S-UGV moves towards different ROIs to collect higher resolution images.

Before the AutoCIS moves towards the next waypoint in a different space, the S-UGV receives a set of local waypoints corresponding to the different ROIs detected in the pre-processing stage during the data processing part. The S-UGV then moves towards said waypoints in order to collect better quality data from those regions. The data collected is put together with the data taken by the M-UGV for further processing.

The constantly changing aspect of a construction environment makes it extremely hard for an autonomous robotic platform to navigate the construction site [32]. The presence of temporal obstacles and the rapidly evolving scenario requires a constant update of the maps used for autonomous navigation, making unreliable an approach entirely based on the initial maps obtained from the IFC file. That is why a multi-robot approach such as the one presented in this study increases the sources of

information and allows for a complete obstacle map updated in real-time. As the S-UGV moves around the construction site, it runs a Simultaneous Localization and Mapping (SLAM) [33] approach used to update real-time the maps generated from the IFC file. This information is being used by the navigation algorithms of both the S-UGV and the M-UGV.

4.2 Data processing

4.2.1 Pre-processing stage

A set of ROIs is generated in real-time after each 3D scan is taken. In order to do that, a mix of geometric, RGB, and thermal information is being processed before the AutoCIS moves to the next waypoint. Every time the M-UGV takes a scan, a pre-processing stage is being applied to the collected data. During pre-processing, data collected from different sources (3D geometry, RGB and infrared), discontinuities, and interesting features are used to detect two types of areas: 1) areas where not enough data has been collected, for example, due to occlusions or because they are hard to reach (Figure 3), and 2) areas in which data of higher resolution needs to be collected. These areas are tagged as ROIs for the S-UGV to explore.

Figure 3. Example of a cluttered part of the point cloud where not enough data was collected.

Regarding the first type of areas, these can be detected in the 3D point cloud by analyzing its density (i.e., amount of points per surface unit) and big areas lacking points.

The second type of area can be detected by inspecting the RGB and thermal images. The RGB orthoimages corresponding to each structural element segmented from the point cloud are processed to look for discontinuities and defects, such as cracks or finishing defects. Higher-resolution data could be collected from the S-UGV for further quantifying the extension of said defect. Lastly, the collected thermal images are studied to look for discontinuity patches that could indicate the presence of different defects, such as hollowness or lack of insulation

that could be properly detected with higher resolution data coming from the S-UGV.

4.2.2 Data analysis for possible defects

After the pre-processing stage and the data collection from the S-UGV have been done, all the information corresponding to each space is further registered with the accumulated point cloud using the localization data coming from the robot. An Iterative Closest Point algorithm [33] is then used in order to refine the alignment of these two data sets.

Some of the main defects to be identified in the processing stage are:

1. *Hollowness in walls, leaks, and insulation problems.* With the thermal information, the AutoCIS can detect incongruences inside the main structural elements. By studying the continuity of the structural element in the thermal space, a lack of insulation material or hollowness in the wall can be detected. The fact that the platform would be operating at the end of the working shift benefits the detection of these two features. This is because changes in the ambient temperature would be assimilated at different speeds by the construction elements, based on their structure behind the surface finishing. If there are noticeable problems with insulation, discontinuities in the thermal information can be expected due to how the internal structure follows the change of temperature, which would presumably decrease at the end of the working shift. Leaks would be difficult to detect in any of the two other data spaces, but the thermal information would provide a clear indicator of said defects by detecting the presence of humidity.
2. *Surface finishing defects.* By studying discontinuities in the RGB space, the system would be able to identify defects regarding the surface finishing of the construction element. Some of the most common defects regarding this category are surface roughness, paint discontinuities, and cracks. Cracks' overall position is being detected in the pre-processing stage from the RGB images using an Artificial Intelligence-based approach [34], tagging the location for further inspection. With the higher resolution images collected from the detected location, further image processing can be done to obtain quantitative data regarding the cracks. Some of the statistics obtainable from this stage are the cracks' length, width, and direction.
3. *Alignment, evenness, and inclination deviations.* Whenever two construction elements are concatenated with each other, the angle at which they join is measurable by studying the 3D geometry from the point cloud. When each

construction element has been segmented (Figure 4), a theoretical plane representing a continuous space of said element can be computed. The system can accurately compare the alignment with the BIM model by inspecting the angle at which those two consecutive planes intersect. This can be done by obtaining the relative orientation (θ) between the normal vectors of said planes, \vec{u} and \vec{v} using Equation 1.

$$\cos \theta = \frac{\vec{u} \cdot \vec{v}}{\|\vec{u}\| \|\vec{v}\|} \quad (1)$$

Finally, the inclination of the floor can be assessed through the sensors onboard the robot and by inspecting the 3D point cloud.

The evenness of the wall can be assessed by studying the geometric distance of the 3D points belonging to a wall with respect to the theoretical plane computed for said wall. By doing this, the bumps and depressions in the wall are clearly visible (Figure 5). The results show the areas of the wall that are not completely even with the plane approximation.

Figure 4. a) Original point cloud. Colors represent elevation (blue - low level; yellow - high level). b) Segmented point cloud. Colors represent different elements.

Once all data has been processed and assessed, it is presented in a structured and organized way to the user in the form of a quality report. This report will include a 3D representation of the space with color-coded information that will easily be accessible to the user. In addition, a list of all the discrepancies identified during the comparison will be available.

5 Conclusions and future work

Most of the research done regarding quality assessment focuses on the post-construction stage, where it might be too late to fix ongoing defects and would only imply additional work, time, and money to fix them. This study presents the preliminary work done to develop the AutoCIS, an automated construction inspection system consisting of a multi-robot approach for autonomous quality assessment and progress monitoring during the construction stage.

Figure 5 Left) Original point cloud. Right) Deviation of the wall with respect to the plane approximation of it.

The robotic system has been properly chosen to be efficient when navigating the harsh construction environment, collecting sufficient data to analyze some of the most common defects found in construction. With the M- and S-UGV onboard sensors, collected data from three different spaces (RGB, 3D point cloud, and infrared) can be processed, providing sufficient data to be analyzed and used to identify ongoing issues. Some of the current limitations of the proposed system rely on the presence of a complete and accurate BIM model. Segmenting each of the different elements in the construction site is not trivial. A wide variety of elements can be present (e.g., pipes, cables, columns of different shapes), and they can easily be mistaken by auxiliary elements such as scaffolding. Further robustness in order to prevent this is still needed.

Some individual parts have already been tested, but current work focuses on the scaling up of the experiment and validating the proposed AutoCIS as a whole. Once the platform is fully developed, the quality assessment can be easily extended into progress monitoring, including the 4D information from the BIM model.

Abstract

There has been a growing interest in adopting autonomous robots to perform routine tasks in facilities management. The goal of facility management is to ensure that the facility performs to design standards. Currently, the cost of maintenance and operations of a facility over its life cycle is often more than the initial cost of construction. One of the reasons for these phenomena is the cost of repetitive but necessary tasks. Particularly for power plants, such repetitive tasks like routine operator rounds to check for leakages, dripping, gauge readings and turning of valves require a significant number of personnel who are exposed to a certain amount of health risk due to the nature of the facility aside incurring basic costs for remuneration and health benefits. These tasks can be automated and carried out by autonomous robots in collaboration with humans to drive down the risk and incurred costs significantly. Our study proposes a solution to routine operator task of checking gauges of machines within a power plant to monitor performance using an autonomous robot-based system that can autonomously navigate to spaces by estimating the reading from gauges to monitor performance and give reports to basic operator round tasks using the Building Information Model (BIM), Robot Operating System (ROS), Computer vision algorithms, a mobile robot and our designed algorithm. Our proposed solution in this study can act as a blueprint for further research to provide more efficient solutions in the maintenance and management of a power related facilities.

Keywords – Robotics; Facility Management; Routine Operator Task

1 Introduction

With the advancement of technology, the need of robotics application in facility management has been increasing for human and work environment safety concerns. Tasks of facility management are different than the tasks generally done by industrial robots as the facility management environments are more dynamic, and less predictable (Parker & Draper, 1998). The objective of the use of robots in nuclear power plants is primarily to avoid human exposure to harmful environmental conditions such as high radiation, temperature, and humidity, in which autonomous systems are required to function. Automation in facilities management can be advantageous in nuclear industry for early detection of adverse conditions by routine surveillance and inspection, withstand extreme conditions to decontaminate radiation, and high efficiency in doing repetitive tasks. Some of the repetitive but necessary tasks are routine operator rounds to check for leakages, dripping, gauge readings and turning of valves. In a power plant facility, personnel doing such repetitive tasks are exposed to certain health risks, which demands basic costs for remuneration and health benefits. Application of robotics for routine operator tasks, whether fully automated or semi-automated, can significantly drive down the risk and incurred cost. Accidents based on human errors in performing day to day operations can be lowered with the use of robots. In addition, automation can also provide as a solution to labor shortages for jobs under radiation. All of these benefits of automated system for routine operated tasks factor to more cost-effective operation, increased overall productivity and improved performance of a nuclear power plant.

2 Robotics in Power Plants Facility Management

Nuclear facility operation and management system comprises of individual tasks and groups of tasks to be performed by either human, machine or a combination of both, in complex systems (IAEA, 1992). And, out of many activities, the area of routine operator task is one where a conjunction of robots and humans can be valuable. The key rationale of robotic applications in this realm is to enhance the operation of tasks which are routine, lengthy, require high accuracy & consistency, and involve high risk to humans (IAEA, 1992). A combination of human and automation can be beneficial in all three categories of routine operations- nuclear power reactor operation, power distribution & dispatch, and power plant operation-to make judgement, decision, and execution (Bureau of Labor Statistics, 2021). Some examples of these routine operator tasks include steam generator examination, tube leak plugging, dripping, gauge readings and turning of valves (IAEA, 1992). Robots, of various types, have been used in various applications in facility management to reduce the task completion time, to reduce health hazards, to improve safety, and to improve availability (Parker & Draper, 1998). Like, any specific task operation in the facility by specific human workforce, it is challenging but achievable in future to have robots with such intelligence to complete tasks in unforeseen situations (Iqbal et al., 2012). However, current practices in nuclear power plants are generally revolve around the idea to have a particular robot for a specific task. Suitable training for operators, and the development of multidimensional simulation models to operate robots on specific environment are the keys in achieving robotics implementation for facility operation and maintenance (Tochilin et al., 2021). This paper is focused on a specific scenario of nuclear facility routine operator tasks which is explained in the section 4.

3 Aim and Objectives

As developed and developing nations perfect plans to automate more tasks in response to the needed transformation into the digital age. More tasks are expected to be robotized freeing up humans from tedious activities and harmful job situations such routine operator tasks in power plants to increase productivity and efficiency. Our study aims to contribute to this body of knowledge by proposing an approach to robotize routine operator tasks using Building Information Model (BIM), Robot Operating System (ROS), Computer Vision, a mobile robot, and our designed algorithms. Specifically, our study will (1) create a robot-based system that

enables autonomous navigation, object detection, data collection and monitoring of power plant equipment, (2) autonomously monitor and estimate the gauge reading of power plant equipment at scheduled routines, (3) create an inspection report of estimated reading, and (4) test the performance of the system in a simulated environment of an educational facility using Gazebo and Robot Visualizer (Rviz). Our proposed solution in this study can act as a blueprint for further research to provide more efficient solutions in the maintenance and management of power and nuclear related facilities.

4 A Scenario of Routine Operator Tasks

There are different areas such as a nuclear reactor, auxiliary area, turbine generators area, fuel area, controls area, with multiple components in a nuclear facility management (Figure I).

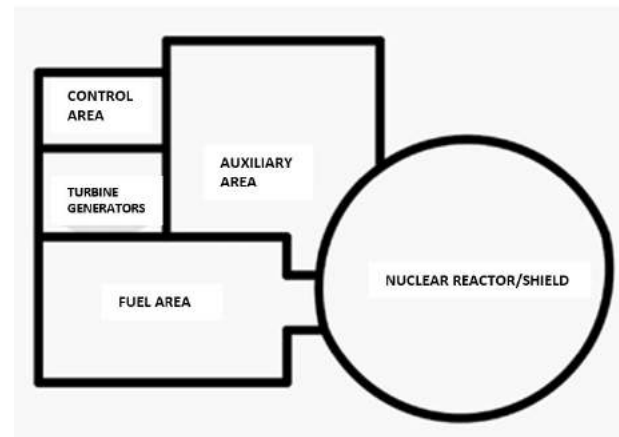

Figure I: A typical area plan scenario of a nuclear facility.

In this research, we have developed a scenario for our robot that can work on a specific room of turbine generators area that houses turbine, generator, condenser, condensate pump, and feed water pump. This room contains different valves and gauges that are directly connected to reactor building (Figure II). In this scenario, the general current practice of routine check of different pumps, their pressure, temperature, leaks, and vibrations is done by the field operators and they give feedback to the license operator who typically works from the control room. In the light of this scenario, performing these tedious routine tasks involves possible challenges of hazard risk, time inefficiency, inaccuracy, and large labor hours and cost. Therefore, in our proposed work model, a robot can work in conjunction with an existing operator to assist in daily gauge reading tasks. However, not all

judgements will be made by this robot. To perform the given task using a robot, it is an important ability to create autonomous navigation algorithms that is based on the information from the operating setting (Wang et al., 2018). We have envisioned a robot with vision capacity that can follow the assigned path remotely and walk into this area, capture images of the different gauges, post-process the image, determine the temperature and pressure of the values, and, finally, send to the control room where the ultimate decision will be made by the control staff. This robot, which will work in a loop with license operator, can also be useful in performing tasks in confined space and high radiation field. As the nature of operation in this scenario is also similar to other facilities, for example-water utility facility, this robot can be incorporated in such environment for everyday activities to achieve more overall efficiency.

Figure II: A scenario room inside a turbine generator area of a nuclear facility.

5 Methodology

The building used in this study for the simulation environment to replicate the scenario of a turbine generator area in section III is a laboratory of an educational facility with machines that require a gauge reading to monitor their performance during operation. Our set objectives were achieved by first recreating the model of the laboratory in Gazebo world from its Building Information Modeling 2D plan. A world in this context represents a space or environment created in Gazebo for simulation of real-world scenarios. This plan was passed through a Pgm_map_creator algorithm (https://github.com/hyfan1116/pgm_map_creator) to create a 2D map as shown in figure III containing the foot print of all objects and elements in pgm format readable by Adaptive Monte Carlo Localization (AMCL) algorithm (ROS.org, 2020) which is used for autonomous

navigation and localization of the robot and its environment features. Having successfully integrated the laboratory map into AMCL, an executable script was written to ensure our mobile robot navigates to predetermined coordinates with proper orientation within the map ensuring that the robot can capture the gauge of the machine in its view at every routine check from that position.

Subsequently, a machine (Ponjet Industries, 2020) and gauge (Cjanezich, 2014) models were downloaded from <https://3dwarehouse.sketchup.com> and attached to each other which is placed in an appropriate position in the Gazebo world. Through programming scripts, A fake pressure is then autonomously simulated in the machine and gauge forcing the gauge needle to imitate real world gauge needle movements. This is followed by spawning and localizing the model of the mobile robot in the simulated world and map generated earlier. Probabilistic-based guesses of the current position of the robot in relation to the map are continuously made during navigation using the AMCL algorithm, LiDAR information, odometry and inertial sensors. It is noteworthy to mention that errors from sensors measurements will accumulate if left unchecked during navigation hence the need for the continuous calculation of the robot's location during navigation in the world.

For the robot to perform monitoring task, a command is issued through a ROS node that contains preset navigation goals. A ROS node is an executable set of instructions contained in a file that runs within the robotic application. This command instructs the robot to avoid obstacles and autonomously navigate to certain positions and orient itself to a certain view of the world. This command can be manually issued by running the ROS node script or automated through launch files. The autonomous navigation ability of the robot is provided through a set of algorithms known as Navigation stack together with AMCL within the ROS ecosystem and the building floor plan. The process involves the robot accurately localizing itself and its target destination, which is followed by planning and mapping of the best route to reach the target destination with preference to the shortest distance to that target destination. The best route planning and mapping is continuously repeated by the robot to find a way around the obstacle for an alternative route in the event of an unforeseen obstacle suddenly appearing blocking the initially mapped route either permanently or temporarily like a standing person or object.

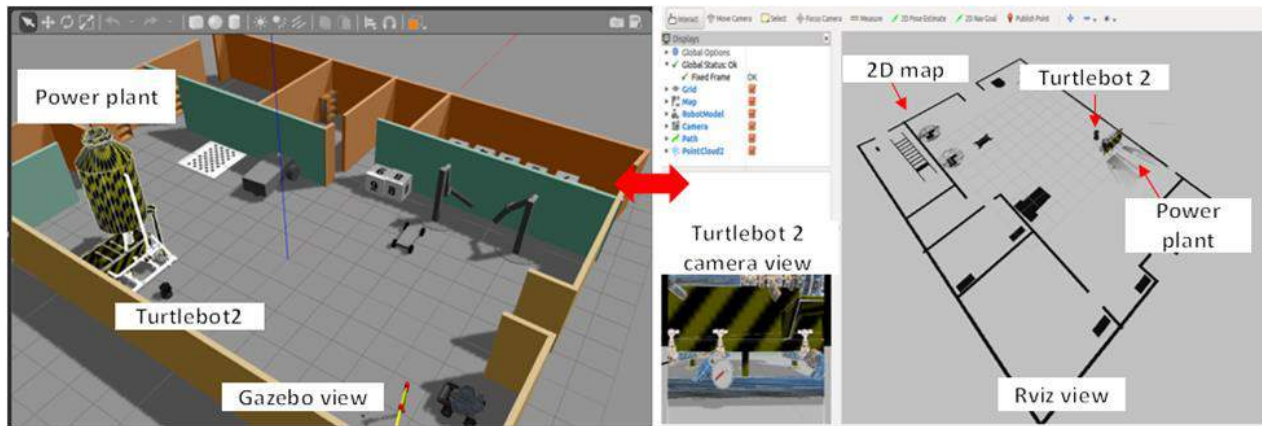

Figure III: Showing the case study set up and robot looking at the model plant machine.

On reaching the destination, the inspection activity begins with the robot taking a picture (image) of its view at the pre-set location and orientation through its camera which places the gauge at approximately the center of the robot's camera view. This image is then processed through Computer Vision (OpenCv) image detection algorithms to crop out predefined area of the picture that contains only the gauge (the body and needle position) face. The image recognition of the gauge face relies on the fact that the cropped image guarantees that the needle, which is colored red, will be approximately centered in the middle of the image and protrude through one of the four edges as shown in figure IV.

Figure IV: Side by side picture taken by robot and the cropped section for image detection.

This image is saved to disk, and the image recognition algorithm is called. The algorithm is written as a stand-alone application with the sole goal of calculating the pressure value from the gauge. The application is passed the file name of the image and loads this image during initialization. Once the cropped image has been loaded, the height and width parameters are obtained from the image. Nested for-loops are used to iterate over all the pixels in the image. A check is made to determine the pixel color, with all red pixels accumulated in a list.

The principal idea is to determine the angle of the needle by sampling the pixels that make up the image,

especially along the edge of the image. After all red pixels have been determined, the edges of the image (top, bottom, left, and right) are sampled to see if they are included in the red pixel list. These pixels are retained in a red-edge-pixel list. When an edge has been identified, the pixels at the opposite side of the needle are determined. They are the red pixels that are the farthest from the edge being examined. Knowing the coordinates of the pixels at the two sides of the needle allows a simple arc tangent function to be used to determine the angle of needle. Then an angle-to-pressure conversion is made to obtain the corresponding pressure value.

6 Case Study

In tandem with the study objectives, a part of the Peter Kiewit Institute (PKI) educational building in Omaha, Nebraska BIM model containing the laboratory was used to create the scenario environment envisioned in section III of our solution in Gazebo and Rviz packages from the ROS ecosystem alongside the AMCL algorithm. The BIM model created an underlay to recreate the world in Gazebo environment and infuse the machine plant model alongside other relevant objects to mimic the turbine generator area scenario. The Gazebo package in ROS provides a platform to simulate real world environment and scenarios ensuring that accidents and damages that may occur during real world testing is avoided while Rviz gives us more than a sneak peek at what is happening in the “brain” of the robot during task or command execution. Both are powerful visualizers that we employed in our work to checkmate and observe the performance of our design.

A model of Turtlebot 2 mobile robot was used in our simulation. We initiated the case study by spawning the robot in the simulated world and issuing a set of commands via ROS to the robot autonomously by running a launch script that includes all the necessary commands. This script is responsible for starting

previously described ROS nodes and other commands such as the navigation stack, AMCL algorithm etc. orientates itself both in Rviz and Gazebo by doing a couple of turns about its centroid to identify its position, map out its destination in relation to obstacles(objects) on the map, navigate to its target destination and orientates itself again to look at the gauge as shown in figure V, takes a picture and then run it through OpenCV algorithm

required for the robot to perform its tasks. On receiving the commands, the robot starts up Rviz and localizes and to crop out just the part containing the gauge as shown earlier in figure IV, apply color detection algorithm and calculate the position of the needle based on our algorithm to provide an output of the converted gauge readings.

Figure V: Showing the robot looking directly at the gauge to estimate gauge reading.

These readings are now presented inform of an inspection report (see figure VI for a sample of such report) with a clause in the system to issue warnings in case of anomalies such as beyond normal or poor performance of the equipment. This process is repeated thrice in this case study with one of the readings

purposely manipulated to test the occurrence of an anomaly. The report from this routine monitoring can be used by plant managers to make an informed on the go decisions about their facilities rather than waiting for personnel to report in the findings of their routine inspections.

7 Conclusion

Our study proposes a solution for a routine operator task, specifically, monitoring and checking the performance of machines in an ideal power plant setup through gauge readings. We developed and tested a robotic solution that can autonomously infer the performance of machines by the readings of its gauge in model power plants or facilities such as boilers, water, electrical and nuclear plants that require continuous routine checks of their machines. Our design by extension, has the potential to eliminate the extensive use of workers allowing a mobile robot to routinely navigate autonomously to preset locations with a predefined orientation to estimate the readings of machines or power plant systems and monitor their performance, providing report of inspections and warnings in the event of an anomaly in the readings.

This solution is ready for real world testing based on the performance from the case study. It buttresses our thinking that robotic systems have the potential to replace present systems used in power plants and related facilities which are cost and personnel intensive. This solution also provides an opportunity to reduce the safety and health risk of humans working in these facilities. In all, this study acts as an ice breaker ushering in innovative ways and application of using robots in power plants for day-to-day repetitive operations and management.

In the future, we hope to extend this work to accommodate probabilistic based approaches as well as dynamic scenarios of power plant operations. This will aid our plan to infuse more capabilities beyond gauge reading and estimation into our robotic system leading to an enhanced application that is more robust to perform other routine operator tasks

Abstract-

The mechatronic sliding formwork complex is a compound dynamic system, the quality of the structure being erected depends on the correct coordinated operation of its elements. The determining factor of the structure vertically is to ensure a constant formwork movement speed and compliance of its working floor horizontalness. To fulfil these conditions, it is necessary to ensure that all lifting jacks are in the same plane with a deviation of no more than 20 mm. Failure of one of the lifting jack's servos can lead to skewed of the working floor, jamming of the formwork and concrete stripping. To solve the lifting jack's technical condition monitoring problem can help its servo predictive diagnostics system.

The purpose of the research is to develop a method for mechatronic sliding formwork complex operating mode optimizing considering its servos technical condition predictive diagnostics results.

In the article, the authors propose a method for mechatronic sliding formwork complex operating mode optimizing considering the technical condition and external load on its servos. The additional load calculating and making decisions models are described. The results of experimental studies of this method on a fragment of the mechatronic sliding formwork complex are presented.

Keywords –

mechatronic sliding formwork complex, operating mode optimization, technical condition monitoring, predictive diagnostics system

1 Introduction

Monolithic construction is a *more common* method of high-rise buildings and structures. [1]. Technology this method provides a continuous supply and laying of concrete, installation of rebar, formwork hoist, regulation of project sizes and control settings of the building [2]. The modern method of automation of monolithic construction is the use of mechatronic sliding formwork complex (MSFC) (Fig.1),

which is a spatial form installed on the perimeter of the structures and moved up by lifting jacks (LJ) [3].

Figure 1. Arrangement of support columns with a electromechanical lifting jack

The position of the formwork panels is fixed by Jack frames that accept the loads of the laid concrete. Lifting of the formwork is carried out by Electromechanical lifting jacks based on DC or AC servo motors. Jacks should provide high load capacity, synchronous movement of the formwork, lifting speed regulation and ease of maintenance [4]. Important conditions for the quality of construction work are the continuity of the technological process and maintaining a constant movement speed of the formwork not less than 1 cm/min, as well as the need to strictly horizontal platform. To fulfil these conditions, it is necessary to ensure that all lifting jacks are in the same plane with a deviation of no more than 20 mm. To implement these requirements, it is necessary to ensure consistent operation of all servo motors

included in the complex. This problem can be solved by using methods and tools for predictive diagnosis of LJ and RMM servo motor [5-7] with its operation mode subsequent optimization. For this purpose, it is necessary to provide the technical condition control of all servo motors which are a part of the MSFC, information exchange between drives and decision-making for MSFC operation mode changing.

2 Mechatronic sliding formwork complex operating mode optimization

A necessary condition for ensuring the verticality of the structure is the observance of the horizontality of the working floor of the formwork by controlling the forces in the LJ, which are substantially non-linear and depend on the static and dynamic loads acting on the system. The lifting mechanisms of the MSFC are subject to the distributed weight of the platform with the formwork Q_{fw} , concrete (Q_{ct}), reinforcement (Q_{rt}), equipment (Q_{et}) and control system (Q_{cs}). The total static load acting on the platform can be calculated from the ratio:

$$Q_s = Q_{fw} + Q_{ct} + Q_{rt} + Q_{et} + Q_{cs}. \quad (1)$$

Also, in the process of lifting the platform with the formwork between the panels and concrete, adhesion occurs and friction occurs, which changes during the lifting process. Then the equivalent load on the platform will be a function of static load (Q_s), friction forces (F_{ff}) and adhesion (F_{an}) and will be written as follows:

$$N_{el} = f(Q_s, F_{ff}, F_{an}). \quad (2)$$

To fulfil the horizontal condition of the MSC platform, it is necessary to ensure load uniformity with the design (n) and current (n^*) number of jacks, which at any time can be

$$n^* \leq n. \quad (3)$$

Then the equivalent load on each working jack will be

$$N_{Lj} \approx N_{el} \cdot (n^*)^{-1} \quad (4)$$

To maintain the static stability of the jack during operation, it is necessary to fulfil the following ratio (5)

$$N_{Lj} \leq F_{CR} \quad (5)$$

where F_{CR} - the critical force according to Euler [9], calculated by equation (6)

$$F_{CR} = (\pi^3 \cdot E \cdot d^4) \cdot (64 \cdot S \cdot \mu^2 \cdot l^2)^{-1} \quad (6)$$

where E - the modulus of elasticity of the screw material; S - the safety factor; l - the length of the loaded portion of the screw; d - inner diameter of the screw; μ - the stiffness coefficient of a helical gear ($\mu = 0.5$)

Knowing the current platform load and critical force, it is possible to calculate the critical number of lifting jacks.

$$n_{CR}^* = \text{round}(f(Q_s, F_{ff}, F_{an}) \cdot F_{CR}^{-1}) \quad (7)$$

Then the boundary condition for static stability is the restriction on the number of simultaneously working jacks

$$n^* \in [n_{CR}^*, n] \quad (8)$$

Also, when choosing the of the MSFC jacks operating mode, it is important to prevent the servos from overloading. Hence the current boundary condition has the form:

$$I_c \leq K_C \cdot I_{nom}, \quad (9)$$

where I_c, I_{nom} - is the current and rated currents of the servomotor, K_C - is the overload capacity of the motor for current.

To ensure the high quality of formwork it is necessary to maintain the speed of movement of the platform at a constant predetermined level, which determines the boundary condition for speed:

$$v_p = \text{const}, \quad v_p \geq 1 \text{ cm/min} \quad (10)$$

In the process of selecting the operating mode, the technical condition of the servos is important, which can be unambiguously characterized by the number of periods of maintaining the working capacity T , determined using the methods of predictive diagnosis [7].

Then the boundary condition for reliability has the following form

$$T > 0 \quad (11)$$

If some servos are failure, the load on the lifting jack should be redistributed to the drives of serviceable jacks so that the total load difference tends to zero. Then the objective function of choosing the optimal operating mode of the MSFC will take the following form

$$\theta = \sum_{i=1}^n \text{Load}_{Lji} - \sum_{j=1}^{n^*} \text{Load}_{Lj}^* \rightarrow 0 \quad (12)$$

Since the load on the servo shaft n^* with simultaneously working jacks can be determined by the equation (13)

$$\text{Load}_{Lj}^* = \text{Load}_{Lj} + \Delta \text{Load}_{Lj}, \quad (13)$$

where Load_{Lj} - load on the drive with n working jacks; ΔLoad_{Lj} - additional load on the drive, the optimization function will depend on these two parameters and can be written in the following form (14)

$$\theta = f(\text{Load}_{Lj}, \Delta \text{Load}_{Lj}) \rightarrow 0 \quad (14)$$

Thus, to select the optimal operating mode of the MSFC, considering the technical condition of its executive

drives, it is necessary to determine the current ($Load_{LJ}$) and additional ($\Delta Load_{LJ}$) loads on the servos, followed by a decision [10] on choosing the operating mode of the MSFC.

3 Load determining model

As a research result [5-7], it has been established that the technical condition of the servo can be determined by the signs of the coefficients k of the straight lines, which approximate the envelopes of the wavelet transform values coefficients on the characteristic scales.

The servo motor is enabled if $k < 0$ and faulty if $k \geq 0$. The cause of the malfunction can be identified by the scale numbers [5-7].

To optimize the MSFC operating mode it is necessary to determine the loading mode of all lifting jacks. It is necessary to analyze all the parameters of the approximating straight line for a serviceable unloaded servo drive operating in the nominal mode.

The obtained data will be used as reference coefficients k_0 , b_0 with which the current values of the parameters k , b will be compared. The values of the maximum allowable coefficients k_{max} , b_{max} can be calculated from the overload capacity of the servo drive by current K_T :

$$k_{max} = k_0 \cdot K_T; b_{max} = b_0 \cdot K_T. \quad (15)$$

Then the approximating straight line coefficients k , b of the diagnosed servo will be in the range:

$$\begin{aligned} k_0 &\leq k \leq k_0 \cdot K_T \\ b_0 &\leq b \leq b_0 \cdot K_T \end{aligned} \quad (16)$$

Then the increments of these coefficients can be calculated from the relations:

$$\begin{aligned} \Delta k &= (k - k_0) \cdot (k_0 (K_T - 1))^{-1}, \\ \Delta b &= (b - b_0) \cdot (b_0 (K_T - 1))^{-1}. \end{aligned} \quad (17)$$

Based on this, the operating mode is permissible if

$$\begin{aligned} k &\in [k_0, k_{max}]; \Delta k \in [0, 1]; \\ b &\in [b_0, b_{max}]; \Delta b \in [0, 1] \end{aligned} \quad (18)$$

To check the possibility of increasing the load on the servo drives, it is advisable to use a fuzzy logical model *Sugeno*, the inputs of which are the relative coefficients Δk and Δb (Fig.2), and the output is the level of the load on the servo drive as a percentage of the maximum allowable.

The output parameter will be the corresponding coefficient on the interval $[0; 100]$ showing the percentage of load on the servomotor. If this parameter is zero, then the servomotor runs at nominal no load. If it is 100%, then the engine has maximum load and it is necessary to change its operating mode.

Figure 2. Input data of the fuzzy model for determining the load on the servo

The correlation of the entered sets can be written using the following fuzzy rules:

R1: if k is k_0 and b is b_0 , then $Load_{LJ} = l_1$;

R2: if k is k_{max} and b is b_{max} , then $Load_{LJ} = l_2$;

The *Takagi – Sugeno* fuzzy inference algorithm is used to determine the value of the output variable:

1. The input variables take some clear values k^* , b^* and the "truncation" levels for each rule are found:

$$\alpha_1 = \min[k_0(k^*), b_0(b^*)] \quad (19)$$

$$\alpha_2 = \min[k_{max}(k^*), b_{max}(b^*)]$$

2. The system output is calculated by equation (20)

$$Load_{LJ} = \frac{\alpha_1 \cdot l_1^* + \alpha_2 \cdot l_2^*}{\alpha_1 + \alpha_2} \quad (20)$$

The proposed model allows, based on the results of the analysis of the coefficients of the straight line, which approximates the envelope of the wavelet coefficients, to determine the current load on the servo as a percentage of the maximum allowable.

$$\Delta Load_{LJ} = Load_{LJ} \cdot (n - n^*) \cdot (n^*)^{-1} \quad (21)$$

The resulting ratio allows, knowing the total number of jack drives (n) and the number of currently serviceable drives (n^*), find the additional load on each drive.

The purpose of optimizing the operating mode of the MSFC is to ensure the possibility of continuing the technological process in case of failure of one or more LJ servos. To do this, it is necessary to develop a model for

making an optimal decision on the choice of an operating mode based on the predictive diagnostic results as well as calculating the current and additional load on the MSFC servo drive.

4 Intelligent decisions making model

After the current and predicted state of all MSFC servos has been determined, additional loads permissible for them have been calculated, it is necessary to decide on the choice of the mode of further operation of the complex and each group of its servos. For this, it is advisable to develop a mathematical decision-making model based on the methods of fuzzy logic.

To formalize the model, the following are calculated:

- average load on servo drives of the LJ group

$$Load = \left(\sum_{j=1}^{n^*} Load_{LJj}^* \right) \cdot (n^*)^{-1} \quad (22)$$

where $Load_{LJj}^*$ $j \in [1, n^*]$ is the load on each LJ drive.

- average additional load on servo drives of the LJ group:

$$Load = \left(\sum_{j=1}^{n^*} \Delta Load_{LJj} \right) \cdot (n^*)^{-1}, \quad (23)$$

where $\Delta Load_{LJj}$ $i \in [1, n^*]$ - additional load on each LJ servo

- the average predicted life of the LJ servos

$$T_g = \left(\sum_{j=1}^{n^*} T_j \right) \cdot (n^*)^{-1}, \quad (24)$$

where $T_j, j \in [1, n^*]$ - predicted service life of each LJ servo

The simulated fuzzy logical decision-making system will have three inputs and one output. To convert clear input values into clear output, the *Mamdani* fuzzy logic algorithm is used [7]. The fuzzy knowledge base that describes the relationship between the input term sets and the output sets is presented in Table 1.

The result of the decision-making model is the value of the decision $D \in [-1, 1]$.

If $D > 0$, then it is necessary to change the load on serviceable servos of the group by the value $\Delta Load$. If $D=0$, then the operating mode must be left unchanged. If $D < 0$, then the condition of the drives of the group is unsatisfactory and it is necessary to stop the process.

Based on this model, an intelligent decision-making method (Fig. 3) has been developed on the operation mode of each of the MSFC servo groups based on the technical condition of its servos.

To make the best decision on the MSFC operating mode choosing considering of the LJ servos technical condition. The following steps must be performed using the models of diagnosing and predicting the technical

Table 1 The truth table of the fuzzy decision-making model

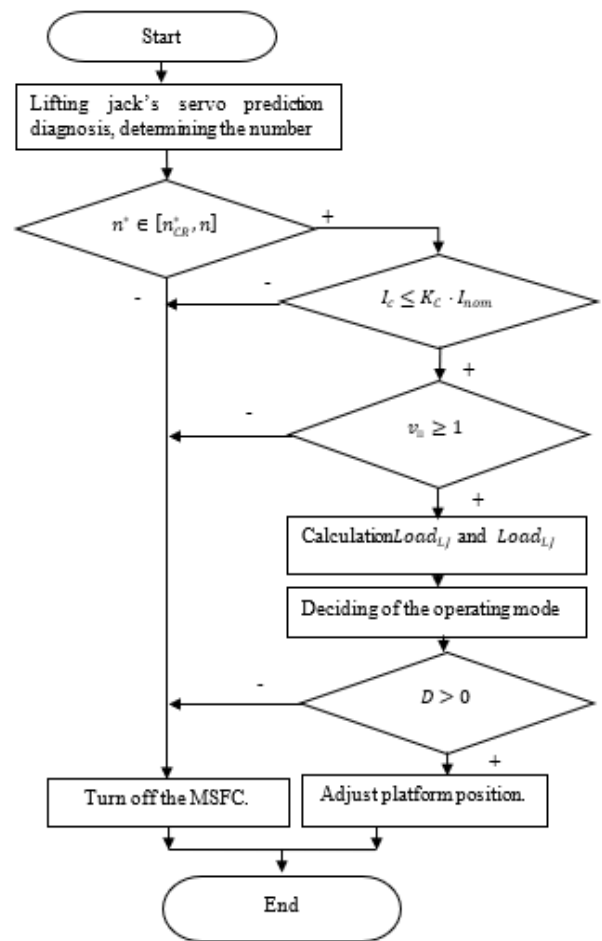

Figure 3. Algorithm of the intelligent decision-making method

condition, determine the current technical condition of each servo of the MSFC and find the number of serviceable drives for which the period of operability $T > 0$. Check the boundary conditions of the optimization function and, if all the boundary conditions are fulfilled, calculate the current and additional load on the servos. Next, using an intelligent decision-making model, determine the mode of further operation of LJ drives. If $D > 0$, send a signal to the control

system to level the platform. If it is impossible to fulfil any of the boundary conditions or $D \leq 0$, send a signal to turn off the MSFC.

5 Experimental research

A study of the prediction diagnosis methods of MSFC has been performed. The experimental stand was a fragment of a sliding formwork of four lifting jacks interconnected by formwork panels suspended on crossbars. This stand was put into step-by-step motion at a speed of 1 cm / min. As a result of the calculation, it was found that the average load on the drive is approximately the same and amounts to 29.52% of the maximum, which corresponds to the average statistical load on the formwork drives during operation. The health checks of the models for calculating the load change and the decision on the control of servo drives were carried out with the KY110AS0415-15B-D2-2010 formwork drive turned off. The objective of the experiment was to calculate the necessary change in the load on the three remaining drives and to study the behaviour of the system when working on three servos. To compensate for the failure of one of the drive jacks, it is necessary to increase the load on each of the three remaining drives by 9.84%. As a result of the calculation using a fuzzy decision-making model, it was found that the current load on the group drives can be increased by $\Delta Load = 9,84\%$. Based on the results of the calculation performed, the operating mode of the mechatronic sliding complex was optimized. For the three switched-on drives, the load on the calculated percentage was increased and the speed of the fragment of the sliding formwork was measured. The results of the study showed that the control system allows for uniform constant movement of formwork panels with a given speed of 1 cm / min with four drives with a load of 29.52% each, and with three motors with a load of 39.36%.

The nature of the movement of the mechanism remains almost unchanged when the load is redistributed within the motors group. This makes it possible to carry out repair work on replacing a faulty drive without stopping the process, reducing complex performance, and losing quality of the monolithic structure being constructed.

6 Conclusions

The article presents a method for MSFC operating mode optimizing considering it is LJ servos technical condition. The boundary conditions of the optimization function are formulated, considering the LJ static stability, platform speed, servos current of the and technical condition. A model for calculating the current and additional load on the servo drives is described. A model for deciding on the choice of an operating mode is described. An algorithm for making the optimal decision

on the choice of the operating mode of the lifting jacks depending on the technical condition of the servos is presented. The algorithm involves adjusting the servo current and platform lift speed depending on the number of serviceable jacks, as well as the current and predicted technical condition of their servos.

Abstract -

Having smart and autonomous earthmoving in mind, we explore high-performance wheel loading in a simulated environment. This paper introduces a wheel loader simulator that combines contacting 3D multibody dynamics with a hybrid continuum-particle terrain model, supporting realistic digging forces and soil displacements at real-time performance. A total of 270,000 simulations are run with different loading actions, pile slopes, and soil to analyze how they affect the loading performance. The results suggest that the preferred digging actions should preserve and exploit a steep pile slope. High digging speed favors high productivity, while energy-efficient loading requires a lower dig speed.

1 Introduction

Smart and autonomous earthmoving equipment may significantly improve energy efficiency, productivity, and safety at construction sites and mines. If the planning and control system can be made well-informed about the physics of earthmoving operations and the current state of the environment, then it can predict the outcome of an action and select near-optimal action sequences that are well-coordinated with other systems at the site. This motivates us to explore which wheel loading actions that maximize the performance over a task. The loading task is typically operated as a repeating cycle of sequential actions: heading into a pile, scooping, breaking out of the pile, carrying the soil, and dumping it to fill bodies of dump trucks [1]. Despite the repetitive task, adjusting the loading actions to the environment for consistent high-performance loading is challenging. The difficulty lies in the complex dynamics and variability in the wheel loader-soil interaction. It is impractical to address the challenge through physical experiments. Systematic and repeatable experiments appear possible only in simulated environments, but computationally efficient models for wheel loading with realistic

Figure 1. The typical loading cycle of filling a bucket and dumping the material in a receiver can be viewed as selecting a control action that transforms the system from one state to another with some performance that depends on the intermediate states.

soil dynamics have become available only recently.

In this paper, we introduce a method for exploring the sequential loading actions for maximum performance in a simulated environment. We view it as an optimization problem and analyze how the loading actions are expected to perform according to the situations. A simulator is developed, which combines contacting 3D multibody dynamics with a hybrid continuum-particle terrain model that supports realistic digging forces and soil displacements at real-time performance [2]. To show the ability of the simulator, we demonstrate how the loading performance depends on the pile and the loading action. In total 270,000 simulations are conducted with different action parameters for loading, pile slopes, and type of material. The performance is analyzed statistically, and some characteristic actions are compared in detail.

1.1 Related work

Some researchers have previously investigated strategies for maximizing the performance of wheel loading

in simulated environments. They especially focus on the bucket filling action, which is the most predominant action for fuel efficiency and productivity in the loading cycle [3]. Singh and Cannon [4] presented a planning algorithm to search for the best dig region and executed the planner by using a machine and pile model in 2D. Sarata et al. [5] proposed a method for dig planning, taking the 3D pile shape into account and avoiding undesirable stress by unbalanced bucket filling. Filla et al. [6, 7] investigated optimal bucket filling trajectories by using simulation based on the discrete element method (DEM), concluding that the “slicing cheese” motion, advocated by machine instructors, is indeed a good strategy. They also noted the need for fully dynamic simulation models, with the possibility to adapt the control to the changing environment as high-performing operators do, for developing optimal bucket filling strategies. The previous studies have been limited to either kinematic bucket trajectories or quasi-static soil models, often based on fundamental earthmoving equation (FEE) in combination with a cellular automata. This has several drawbacks. A kinematic bucket trajectory may not be realizable when the full dynamics and actuator force limits are taken into account. The FEE force resistance does not support situations when the vehicle or bucket is accelerating. The correct loading time and power consumption require a dynamic model. Furthermore, quasi-static soil models do not capture the actual soil displacement, around and into the bucket. This affects both the bucket fill ratio and soil spillage on the ground, which may significantly penalize the performance over time. For simulation results to be transferable to the control and planning on real sites, the dynamics of both the machine and the soil must be represented in the model. That is computationally very challenging, and few studies have been performed. Lindmark and Servin [8] explored a control strategy to maximize the loading performance using simulation based on 3D nonsmooth multibody dynamics. However, it was conducted for a load-haul-dump machine loading fragmented rock. Wheel loaders require a different strategy because of a lower breakout force than LHD:s [9] and the high-performing loading depends on the pile property [10].

1.2 Problem statement

During a loading cycle, the wheel loader typically performs a sequence of loading actions as illustrated in Figure 1. We assume that the wheel loader has a task planner and a controller for recurring actions $(a_i)_{i=1}^N$ during N sequential loading cycles. A loading action a_i starts with a machine state $x(t_i) \in \mathbb{R}^{N_1}$ and a pile state $p(t_i) \in \mathbb{R}^{N_p}$, which can be represented as a system state $s_i = [x_i, p_i] \in \mathbb{R}^{N_s}$. Then, a_i leads to some trajectory $x(t)$ and applied force $f(t)$, changing the pile state $p(t)$ over a

time interval $t \in [t_i, t_i + t_{\text{load}}]$. The system ends up with a new state $s_{i+1} = [x_{i+1}, p_{i+1}]$, where p_{i+1} may include material spilled in the working area. The loading cycle can be attributed to a performance $\mathcal{P}_i \in \mathbb{R}^{N_p}$. The performance depends on a state-action pair, that is, $\mathcal{P}(s_i, a_i)$. Examples of performance measures are the energy efficiency $\mathcal{P}^e = m_{\text{load}}/W$, productivity $\mathcal{P}^p = m_{\text{load}}/t_{\text{load}}$, and bucket fill ratio $\mathcal{P}^b = V/V_{\text{bucket}}$, where m_{load} is the resulting mass of the load in the bucket, $W(x, f, t_{\text{load}})$ is the accumulated work exerted by the actuators over the loading cycle of time duration t_{load} , V is the volume of the load in the bucket that has volume capacity V_{bucket} . The simulation process is illustrated in Figure 1. What is an optimal action sequence $(a_i)_{i=1}^N$ may depend on the initial pile state, p_1 , and the number of loading cycles, N . For example, an optimal action sequence for $N \gtrsim 1$ may transform the pile into a poor state. That would prohibit continued loading with good performance unless the pile is restored by additional actions optimized for improving the quality. On the other hand, an optimal action sequence for over $N \rightarrow \infty$ (terminated when the pile is empty) might start with a loading performance significantly worse than what is optimal for single loadings but can maintain a good average performance. From the perspective above, optimization of N sequential loadings correspond to finding $(a_i)_{i=1}^N$ that satisfy

$$\max_{(a_i)_{i=1}^N} \sum_{i=1}^N w^T \mathcal{P}_i \quad (1)$$

where $w \in \mathbb{R}^{N_p}$ are weight factors for the different performance measures \mathcal{P} . Note that optimization over sequential loadings is not carried out in the present paper but will be pursued in future work.

2 Simulator

A simulator is created using the physics engine AGX Dynamics [11], which supports real-time simulation of multibody systems with nonsmooth contact dynamics, driveline, and deformable terrain.

2.1 Terrain model

The terrain is simulated using a multiscale hybrid model presented by Servin et al. [2]. Resting soil is modeled as a solid, discretized in a regular 3D grid and a corresponding 2D height map for the free surface that mediates contacts with earthmoving equipment. The bulk mechanical properties of the soil are parametrized by the mass density, internal friction, cohesion, and dilatancy at the bank state. When earthmoving equipment comes in contact with the terrain, a zone of active soil is predicted and resolved with particles of variable size and mass. DEM is used

Figure 2. Overview of the wheel loader model with passive joints in blue and actuated joints in red.

for particle dynamics with frictional-cohesive contact parameters and a specific mass density that matches the bulk parameters of the soil. The earthmoving equipment experiences the active soil as a low-dimensional body with the aggregated shape and inertia of the particles and with frictional-cohesive contacts at its interfaces. This can be seen as an extension of the FEE to dynamic conditions, including also bucket penetration resistance and contacts between the bucket's exterior and the surrounding soil. The multiscale model allows for combined use of a direct solver for the vehicle dynamics at high precision, an iterative solver for scalable particle dynamics at lower error tolerance, and strong coupling between the vehicle and terrain dynamics that resist soil failure when the stresses do not meet the Mohr-Coulomb criteria.

2.2 Wheel loader model

The wheel loader is modeled as a rigid multibody system consisting of a front and rear frame, connected by a revolute joint for articulated steering, four wheels, and a parallel Z-bar linkage system [12] for controlling the bucket relative to the front frame. Bucket filling is the combined effect of thrusting the vehicle into a pile, by applying torque on the wheels, while raising and tilting the bucket. The driveline model consists of a revolute motor transmitting rotational power to the front and rear wheel pairs via a main, front, and rear shaft, coupled with differentials. Each wheel is connected to the frame with a revolute joint and consists of a tire-hub pair, with finite elasticity with respect to radial, lateral, bending, and torsional displacements. The parallel Z-bar linkage system is modeled using 11 revolute and three prismatic joints, with linear motors that represent the hydraulic cylinders for raising and tilting the bucket. In total, the assembled model consists of 27 rigid bodies and 23 kinematic constraints, whereof 18 are passive joints and five are actuated. The total operating weight is 15.59 tons, wheelbase 3.030 m, and the bucket has a volume capacity of 3.0 m³. Overall, the model roughly corresponds to a Komatsu WA320-7

Table 1. Actuators

name	type	speed range	force limit
drive	revolute	[0, 11] km/h	85 kNm
steer	revolute	[−0.1, 0.1] rad/s	100 kNm
lift	linear	[−0.2, 0.11] m/s	395 kN
tilt	linear	[−0.2, 0.1] m/s	530 kN

[13]. The actuators are controlled by specifying a momentaneous joint target speed and force limits, which are listed in Table. 1. The force limits are chosen to reflect that limited power can be drawn from the engine, which in reality supplies both the hydraulic cylinders and the driveline. In addition to the internal constraints, tire-terrain intersections give rise to frictional contact constraints, and bucket-terrain intersections cause soil failure and digging resistance. The wheel-terrain friction coefficient is set to 0.8. For clarity of the terrain dynamics, only the wheel and bucket are given visual attributes.

2.3 Comparison with field measurements

To verify that the simulator represents the real-world counterpart, we compare the trajectories and forces of the real and simulated a wheel loader conducting a loading cycle. Data was recorded from a manually operated wheel loader and control parameters in the simulation were selected to reproduce a similar, but not identical, loading cycle. The vehicle speed, traction force, and lift and tilt cylinder forces are shown in Figure 4, and the bucket tip trajectory is in Figure 5. The forces are normalized with a characteristic force for the wheel loader. The boom and bucket angles relative to the chassis pitch. The data in Figure 4 confirms that the model is representative. The forces and trajectories do differ, e.g., the swept area of the real bucket trajectory is about 60% larger than the simulated one. This agrees with the observed difference in loaded mass and the lift force after breakout. Presumably, the discrepancy is due to differences in pile shape and soil properties, which have not been calibrated.

3 Simulations

The purpose of the simulator is to support the development of high-performance wheel loading from different pile states. Therefore, we run a large set of simulations with different action parameters and analyze their performances in relation to the pile state. Piles with four different slopes are studied: 10°, 20°, 30° and 40°. The considered soils include gravel, sand, and dirt. Following the terrain library in AGX Dynamics, they have an angle of internal friction 44°, 39°, and 40°, and dilatancy 11°, 9°, and 13°, respectively. Gravel and sand are cohesionless, while dirt has cohesion 2.1 kPa. The soils are assigned the same

Figure 3. Image sequence from field experiment and simulation.

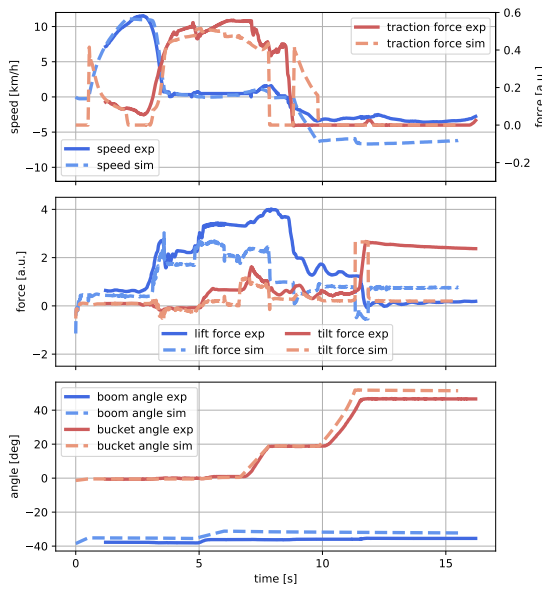

Figure 4. Comparison of the wheel loader speed and forces during a real and simulated loading cycle.

Figure 5. Comparison of the bucket tip trajectory during a real and simulated loading cycle. The pile surface is also indicated.

bulk density, 1400 kg/m^3 . For simplicity, the loading scenario is restricted to entering the pile head-on, with the bucket lowered to the ground and reversing straight out after completing the loading. The loading task is controlled using eight action parameters, α_i , listed in Table 3, and discretized to 45,000 parameter combinations per pile. In total, 270,000 simulations were run. Loadings on sand and dirt were carried out only for piles with 30° slope.

The loading is controlled with a simplified version of admittance control [14]. The approach drive speed is $v_d = \alpha_1 v_d^{\max}$, and the target speed during the penetration phase is $v_d = \alpha_2 v_d^{\max}$. When the digging force exceeds the set threshold values, $F_{\text{lift}}^{\text{dig}} = \alpha_3 F_0^{\text{dig}}$ and $F_{\text{tilt}}^{\text{dig}} = \alpha_4 F_0^{\text{dig}}$, the lift and tilt actuators start running with their respective target speeds $v_{\text{lift}} = \alpha_5 v_{\text{lift}}^{\max}$ and $v_{\text{tilt}} = \alpha_6 v_{\text{tilt}}^{\max}$. This continues until the boom and bucket angles reach their target, $\theta_{\text{boom}} = \alpha_7$ and $\theta_{\text{bucket}} = \alpha_8$, but is aborted in case of breakout or stalling. The brake is then applied for one second, letting the activated soil come to rest. After that, the vehicle is driven in reverse at the target speed $v_d = -0.6 v_d^{\max}$ and with tilt target speed $v_{\text{tilt}} = 0.6 v_{\text{tilt}}^{\max}$ until the end position $\theta_{\text{bucket}} = 50^\circ$ is reached. After the breakout, the lift target speed is $v_{\text{lift}} = 0.6 v_{\text{lift}}^{\max}$ until the end position $\theta_{\text{boom}} = -10^\circ$ is reached. The simulation is ended when the vehicle has reversed 5 m from the entry point. The following control constants are used: $v_d^{\max} = 11.0 \text{ km/h}$, $v_{\text{lift}}^{\max} = 0.11 \text{ m/s}$, $v_{\text{tilt}}^{\max} = 0.10 \text{ m/s}$, and $F_0^{\text{dig}} = 100 \text{ kN}$.

The simulations are run with 10 ms time-step, with the terrain discretized spatially to 0.2 m resolution, on a high-performance computer with Intel Xeon E5-2690v4 processors, each node enabling up to 28 simulations in parallel and roughly 10^4 loading cycles per CPU hour. During each simulation, the position, velocity, and force are registered over time for selected bodies, joints, and actuators. From this, the loaded mass m_{load} , dig time t_{load} , and energy consumption W are computed for each loading cycle, as well as the relative load spillage $s_{\text{load}} = V_{\text{spill}}/V_{\text{bucket}}$ of material on the ground, and the resulting pile shape. The energy efficiency and productivity performance measures, \mathcal{P}_e and \mathcal{P}_p , are computed for each loading also.

Table 2. Action parameters

	control	values
α_1	approach speed	[0.4, 0.6, 0.8]
α_2	penetration speed	[0.2, 0.4, 0.6]
α_3	lift-triggering dig force	[0.0, 0.3, 0.6, 0.9, 1.2]
α_4	tilt-triggering dig force	[0.0, 0.3, 0.6, 0.9, 1.2]
α_5	lift speed	[0.2, 0.4, 0.6, 0.8, 1.0]
α_6	tilt speed	[0.2, 0.4, 0.6, 0.8, 1.0]
α_7	lift angle	$[-40^\circ, -30^\circ, -20^\circ, -10^\circ]$
α_8	tilt angle	$[30^\circ, 45^\circ]$

4 Result

Figures 6 and 7 show the variations in performance over the 270,000 simulated loading operations. The distributions over dig time, load mass, and spillage, per pile angle and material, are shown in Figure 6. In general, the trend is that the load mass increase with the slope, and the dig time is positively correlated with the load mass. The nominal dig time is around 10-12 s, which can be compared to the 15 s for completing the experimental loading cycle in Figure 4. Higher load mass requires a larger pile slope, but it is harder to achieve a high load with gravel than for sand and dirt. Spillage is mostly below 2% of the bucket volume. It increases with the pile slope and is largest for sand and smallest for dirt, presumably thanks to its cohesive property. Figure 7 reveals that, to first order, loading efficiency, productivity, and load mass are linearly related, and they are positively correlated with the pile slope. However, many of the higher load mass cases are associated with poor productivity. The efficiency and productivity for dirt and sand have similar distributions, but higher load mass can be achieved with dirt. The efficiency and productivity are generally lower for gravel than for sand and dirt.

To study the sensitivity of action parameters, we select two performance points, $(\mathcal{P}_p, \mathcal{P}_e)$, in the gravel 30° data and extract the action parameter values that produce a similar performance. The performance of the identical set of action parameters on the five other sets of piles is then highlighted. The two performance points in gravel 30° are (150, 8.0) and (190, 9.0), and they are highlighted with (×) and (+), respectively. The corresponding performance points are not gathered narrowly in the distributions for other pile angles but more so for dirt and sand piles with 30° slope. This suggests that loading actions should be adapted to the slope of the pile, while high-performing actions may transfer to piles of different material but similar slope.

A selection of points of special interest (POI) is made for each pile slope and material. These points correspond to maximum efficiency (○), productivity (Δ), load mass (□), and a Pareto optimal point (◇). The Pareto optimal

point (◇) is chosen in between maximum efficiency (○) and productivity (Δ) arbitrarily. The action parameters and performance values for the POI:s for 30° slopes are presented in Table 3. We observe that a high entry speed (α_1) and medium-high dig speed (α_2) are beneficial for high productivity while high efficiency relates to low dig speed (α_2). For large load mass, it appears important to trigger tilting at a large digging forces (α_4) and to tilt at low speed (α_6). No obvious relations are found for many of the action parameters and performance values.

Although it is in general not possible to control the bucket to follow a prescribed path, it is interesting to analyze the trajectories of the POI loadings. This is presented in Figure 8 and 9 for different slope and material, respectively. Also shown are the initial and resulting pile surfaces as well as the initial position of the mass that is loaded or just displaced by the loading action. At lower slope, in Figure 8, we note a larger tendency for soil being pushed forward and not ending up in the bucket, negatively affecting efficiency, productivity, and load mass. In Figure 9, the trajectories for each type of POI (column) are shown for the different materials (row). The loadings of maximal mass (□) are characterized by digging deeper into the pile. For the other POI loadings, there are no obvious trends when comparing only the trajectories.

5 Discussion

Overall, the admittance-like control method seems to work well if adjusted for the pile slope. The results suggest that the preferred digging actions should preserve and exploit a steep pile slope. It appears more important to adapt the loading actions to the pile shape than to the soil type, at least among the materials tested in this study. High digging speed favors high productivity, while energy-efficient loading requires a lower dig speed.

Several delimitations have been made in the present study, and many questions are left for future work. The effect of more complex pile shapes and other materials needs to be studied. The reason for the moderate load mass for gravel is not understood. Possibly the virtual gravel represents a more densely packed and stronger material than what was used in the field experiments. Also, from field tests, one expects a larger difference in the high-performance trajectories between the materials, e.g., longer, and more shallow digging for dirt than gravel and lower and more deep thrusting motions for sand. These tendencies are present for the high-productivity trajectories in Figure 9, but the difference is expected to be larger. Digging actions can be represented and discretized differently than in the present study, and it is certainly possible that higher performance loading can be discovered within the present action space. The spillage and resulting pile surface can be observed in the results, but we have not

investigated how this penalizes sequential loadings.

6 Conclusion

We have developed a simulator to explore the sequential loading actions which maximize the performance of automated wheel loader systems. The simulator is based on 3D multibody dynamics and deformable terrain with real-time capability. A vast number of loading simulations demonstrates that the combined action and pile state significantly affects the performance. As the next step, we will study the sequential loading scenario and address the optimization problem.

Abstract -

In the autonomous excavation task, the real-time estimation of the bucket filling rate and the volume of the excavated mass are essential feedbacks to measure the excavation quality. In this work, facilitated by the LiDAR and inclination sensors mounted on an autonomous excavator, we introduce an online method to calculate the volume of the mass in the excavator bucket during digging process. The LiDAR is mainly used for acquiring the 3D point clouds of the excavated mass and bucket, and the inclination sensors are utilized for localization acquisition of the bucket. In specific, a pre-process is first used to obtain the empty bucket model by scanning it with LiDAR. Then, to reduce the influence of the noises of the inclination sensors in the digging process, a registration algorithm is employed to transform the real-time captured point clouds of the bucket and excavated mass to the empty bucket model (obtained in the pre-process). Finally, based on the height map construction and point clouds interpolation, volume estimation algorithm is utilized to obtain the final results. Note that our method is validated in real-world scenarios, and the experiment results demonstrate the accuracy and reliability of our volume estimation scheme.

Autonomous excavation; Volume estimation; Height map

1 Introduction

Recently, research and developments of autonomous excavation have seen increased popularity as it promises more efficient, more sustainable, and safer excavation operations (Zhang et al. [1], Jud et al. [2]). In the excavation process, important metrics to evaluate the excavate quality are whether the bucket is filled with excavated mass and how much it has been filled after each excavation. Previous methods, such as payload estimation [3], mainly utilize the measurement of hydraulic cylinder pressures and dynamic modeling for volume estimation by estimating the payload carried in a hydraulic excavator. However, these approaches usually require additional hardware sensors as well as sensor calibration, which limits the applications.

In this study, to relief the problem, we utilize visual strategies to directly measure the excavation quality con-

sidering current autonomous excavators are commonly equipped with cabin-mounted LiDAR and inclination sensors, while LiDAR sensors are mainly used for point clouds acquisition of surrounding environments, and inclination sensor for measuring the bucket pose. In this work, we address this problem by estimating the volume of the excavated mass in the bucket using LiDAR data on an autonomous excavator (Figure 1). Note that the data is acquired from LiDAR (e.g. Livox Mid100), which has an uneven distribution, and the volume estimation is especially challenging. Specifically, to estimate the in-bucket mass volume, firstly, the dense bucket point cloud is dynamically obtained by fusing multiple frames of bucket point clouds, and the bucket pose is acquired by the inclination sensors mounted on the excavator, simultaneously. We then align the real-time obtained bucket points with an initialized empty bucket model, and the height maps are generated and interpolated both on the real-time obtained bucket points and the empty bucket model. Finally, the mass volume is calculated based on the height maps.

In summary, this paper presents the following contributions:

- A dynamic bucket point cloud fusion method that allows obtaining the dense bucket point cloud while the bucket is moving, which is a base of real-time volume estimation.
- A height map interpolation method that makes it possible to estimate the volume from the height map on the uneven LiDAR data.

To the best of our knowledge, this is the first demonstration of the real-time in-bucket mass volume estimation on the uneven LiDAR data.

2 Related Work

A direct way to measure the excavation quality in real-time is to weigh the mass in the bucket. The method of payload estimation [3], which is based on cylinder pressures measurement and dynamic modeling, can estimate the payload carried by a hydraulic excavator. As we are in an autonomous excavator that can provide point cloud by the cabin-mounted LiDAR sensors and bucket pose by the

Figure 1. The autonomous walking excavator which is equipped with a cabin-mounted LiDAR(Livox Mid100) and a HIK web camera.

inclination sensor, it is possible to measure the excavation quality by visual methods.

Wulfsohn et al. [4] presented an estimator of the volume of axially convex objects from total vertical projections with the known position of the vertical axis. However, this approach needs to rotate the object around the known vertical axis and re-scanning it, which is not feasible in our task. Mayamanikandan et al. [5] presented a tree volume estimation method using terrestrial LiDAR data, based on the extraction of the tree diameter at breast height(DBH) using Random Sample Consensus(RANSAC) based circle fitting and the estimation of tree height. However, RANSAC based method is not suitable for the mass which has an irregular shape in the bucket. Be Wley et al. [6] presented a model and reconstruction based volume estimation method to measure the in-bucket payload volume on a dragline excavator. However, their approach focuses on bucket classification and reconstruction from the 2D scanlines, which is very different from LiDAR data.

3 Volume Estimation Pipeline

As the goal here is to dynamically calculate the volume of the mass in a moving excavator bucket, we are looking to get a dense and up-to-date bucket point cloud as well as the latest bucket pose in the LiDAR coordinate system. This section presents a dynamic bucket obtaining pipeline that uses the excavator's onboard LiDAR sensors and the joint states to fuse multiple frames of bucket point clouds incrementally. We first scan and initialize the empty bucket model, which is used to align with the real-time obtained bucket points and as a base of volume estimation. A height map and interpolation based volume estimation module is then presented. An overview of the different modules constituting the volume estimation pipeline is depicted in Figure 2.

3.1 Dynamic Bucket Obtaining

With the aim of providing a bucket point cloud as complete as possible, we intend to fuse multiple frames of bucket points to get a dense bucket point cloud. To this end, we initially acquire the bucket pose from ROS transformation tree(TF) corresponding with the current frame point cloud. We then segment the point cloud by the radius search to extract the bucket point cloud. After about 10 frames of the bucket point cloud are obtained, we fuse them by transforming them through the original pose. Thus, the dynamically dense bucket can be expressed as:

$$B = \{T_i^{-1} B_i | i = 1, 2, \dots, N\} \quad (1)$$

Where B is the dense bucket point set, N is the number of the frames, T_i is the current bucket pose, B_i is the segmented bucket point set in frame i .

3.2 Pose Initialization

It is easy to recover the bucket to the original pose by transforming it with the latest transformation matrix. Furthermore, it is necessary to initialize the empty bucket model to parallel to the axis for the convenience of bucket part removing and height map generation. We initialize the model with principal component analysis(PCA) results and fine-tune it by hand. The initialized empty bucket model is shown in Figure 3:(b) where the plotted grid represents the XOY plane. Thus, we got the transformation from the original pose to initialized pose T_p , and the initial transformation from scene to model can be expressed as:

$$T_{init} = T_p T_l^{-1} \quad (2)$$

Where T_{init} is the initial transformation, T_l is the latest bucket pose obtained from TF.

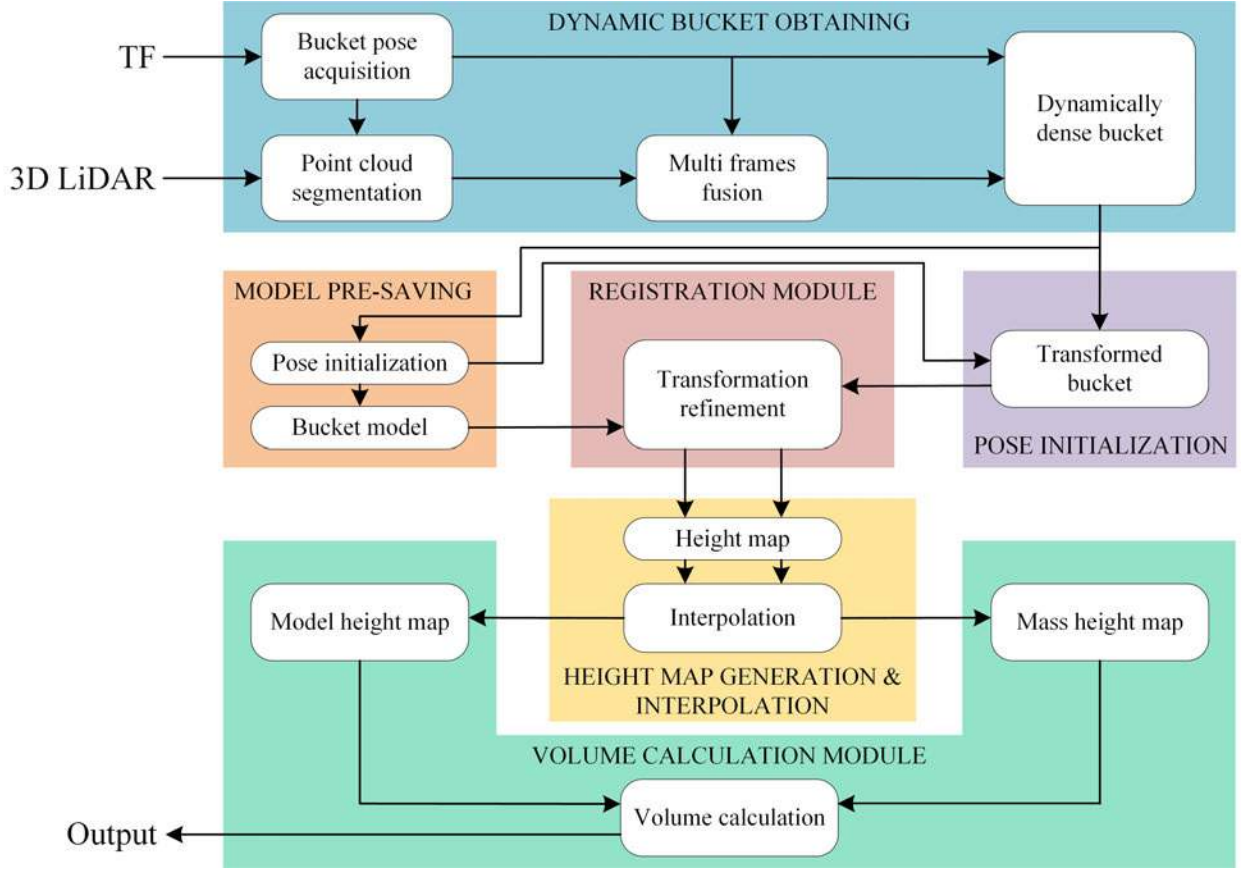

Figure 2. Overview of the volume estimation pipeline developed for the volume estimation of the mass in an excavator bucket.

3.3 Transformation Refinement

The registration module gives the volume estimation system the ability to align the real-time obtained bucket points with the model, which can improve the accuracy of volume estimation.

Our registration approach aims to find the transformation that minimizes the distance between the empty bucket model and the real-time obtained bucket points with an initialized pose provided by the inclination sensors. Considering this case, the iterative closest point (ICP) is suitable for the transformation refinement. As there is lots of noise produced by the moving bucket in the real-time obtained bucket points, the bucket point cloud is firstly filtered using a uniform down-sample, and then filtered by a statistical outliers removal. We retain the original bucket point cloud for the next height map generation step. Then, an ICP step is employed to refine the alignment of the empty bucket model and real-time obtained bucket points, yielding an improved transformation T_{icp} . The final transformation between the empty bucket model and real-time obtained bucket points is then computed as follows:

$$T_{final} = T_{icp}T_{init} \quad (3)$$

3.4 Height Map Generation and Interpolation

In our implementation, we generate the height map using the height of points on the z-axis directly, facilitated by the pose initialization step, and those values are stored in a plotted grids based on the minimum and maximum points on the x-axis and y-axis.

Before we generate the height map from the real-time obtained points, we first removed the most bucket part of the real-time obtained bucket points using a passthrough filter. The point cloud of mass in the bucket is then used for height map generation. We use the full point cloud to generate the height map on the empty bucket model (Figure 3:(b)), which is shown in Figure 3:(c).

As shown in Figure 3:(c), there are lots of holes in the generated height map produced by the distribution of LiDAR points. Those holes must be filled by the interpolation method, while each hole means an invalid value in

Figure 3. The height map generation and interpolation process: (a) the empty bucket image, (b) the initialized empty bucket point cloud, (c) the generated height map, (d) the interpolation area(white), (e) the interpolated height map.

the volume estimation module. The proposed approach of interpolation consists of the following steps:

1) Interpolation area selection: To interpolate correctly, the first step is to know which pixel needs to be interpolated, which is very important for volume estimation because false interpolation means reducing the accuracy. We firstly check the bordering points on every row and every column, which are shown in Figure 4, marked as red points. Then, the interpolating points are determined by judge whether it is within the bordering points and whether there are points in its adjacent region. We change the size of the adjacent region to fit the density variation. The interpolation points are marked as blue points in Figure 4. The selected interpolation area of the model height map is shown in Figure 3:(d).

2) Interpolation: As the interpolation area is selected, we compute the mean height of the valid points in the adjacent region of every interpolating points, and set the value of the interpolating point as h_{mean} , which can be expressed as:

$$h_{mean} = \frac{1}{N} \sum_{i=1}^N h_i \quad (4)$$

Where N is the number of the valid points, h_i is the height of i_{th} valid point in the adjacent region. The interpolated model height map is shown in Figure 3:(e).

3.5 Volume Estimation

The volume estimation module is based on the interpolated height map both on the empty bucket model and the real-time obtained bucket points(Figure 6:(e)). We compute the difference between the height maps of the empty bucket model and the real-time obtained bucket points on every pixel, where the values are valid on them at the same time, which can be expressed as:

$$d = h_s - h_m \quad (5)$$

Figure 4. The interpolation area selection, red: the edge points, black: the inside points, blue: the interpolation points.

d is the difference between the height h_m and the height h_s on the height maps of the empty bucket model and the real-time obtained bucket points on every pixel. The diagram of the difference is shown in Figure 5, which is a side-section of the empty bucket model and the mass.

Considering the size of the plotted grids, we compute the volume of the mass in the bucket as follows:

$$V = \sum_{d \in P_{valid}} (l_{grid}^2 \times d) \quad (6)$$

Where V is the calculated volume, P_{valid} is the valid pixels, l_{grid} is the length of the grid, d is the difference of the valid pixels.

Figure 5. The difference calculation in the side-section, red: the mass, green: the empty bucket model.

4 Experiments

To show the applicability and repeatability of the presented system, we implemented the different modules using the robotic operating system [7] and integrated them on the autonomous excavation system to perform the volume estimation of the mass in the excavator bucket, which is tested randomly in the field.

4.1 Bucket Obtaining and Pose Initialization

Figure 7 illustrates the process of multiple frames fusion of dynamic bucket point clouds and the initialized pose, which have been discussed in Section 3.1 and Section 3.2 respectively.

4.2 Transformation Refinement

With the bucket pose acquired by TF and a fixed transformation from the original pose to the initialized pose, we aligned the real-time obtained bucket points and the model with an error which is caused by the low accuracy of the sensors. After the down-sample and the outliers removal processes, an ICP step is then employed to refine the alignment. In our experiments, a large nearest point search radius leads to a false registration result while the mass entirely shades the bucket. Considering the maximum distance error is about 3 cm, we set the maximum correspondence distance to 3 cm to avoid false registration.

4.3 Height Map Generation and Interpolation

As 10 frames of bucket point cloud have been fused dynamically and the fused bucket point cloud has been aligned with the model successfully, we generate the height maps and interpolate them with the method discussed in Section 3.4 both on the real-time obtained bucket points and the empty bucket model. As it has been shown in Figure 6:(e), there are some not interpolated points which are resulted from the open form distribution of the points

on the height map. The most relevant parameters of the experiment are summarized in Table 1.

Table 1. Main parameters of the volume estimation pipeline

Bucket segmentation	
Search radius	1.5m
Down sample	
Voxel size	0.01×0.01×0.01(m)
Outliers removal	
Number of nearest points	100
Multiplier of the std. dev.	0.8
ICP	
Normal estimation radius	0.025m
Max. correspondence dist.	0.03m
RMSE threshold	0.01m
Height map generation	
Grid size	0.01×0.01(m)
Interpolation area selection	
Adjacent region size	8×8(pixels)
Height map interpolation	
Adjacent region size	5×5(pixels)

Abbreviations: ICP, iterative closest point; RMSE, root mean square error;

4.4 Volume Estimation

As the height map generated and interpolated, we calculate the volume of the mass in the bucket using the method discussed in Section 3.5.

Table 2. Mean computation times and standard deviations (in ms) of each step involved in the volume estimation pipeline, as computed on an Intel Core(TM) i7-10875H CPU

Submodule	Time
Bucket segmentation and fusion	46±11
Down sample	3±1
Outliers removal	286±7
ICP	
Normal estimation	20±6
Alignment	83±15
Height map generation	<1
Interpolation area selection	2±1
Height map interpolation	5±1
Volume estimation	<1
Total	539

For the sake of completeness, in Table 2 we report the computational times of the individual steps in the volume estimation pipeline, when executed in a single thread on a Core(TM) i7-10875H CPU. As it can be observed, the complete volume estimation routine is executed in approximately 0.5s in our experiments, which makes our approach suitable for online operation.

As there is not a convenient way to get the ground truth, we firstly generated a height map of the full bucket, which is shown in Figure 8, and calculate the full bucket volume

Figure 6. The height map generation and interpolation on the real-time obtained bucket points: (a) the bucket with mass image, (b) the mass point cloud (red) and the empty bucket point cloud (green), (c) the generated height map of the mass, (d) the interpolation area (white), (e) the interpolated height map.

Figure 7. Multiple frames of bucket obtaining, green: single frame of the background point cloud, red: the segmented bucket point clouds of 10 frames while the bucket is moving, blue: fused and initial-ized bucket point cloud of multiple frames.

Figure 8. Full bucket volume estimation, (a) the empty bucket height map, (b) the generated full bucket height map.

as V_{full} . In our experiment, $V_{full} = 1.71m^3$. Then, we compute the filling rate of the bucket comparing with the directly observed filling rate to measure the accuracy of our approach. The filling rate is computed as $R = \frac{V_{est}}{V_{full}} \times 100\%$, where V_{est} is the estimated volume of the mass in the bucket in Equation 6.

Figure 9 illustrates five times volume estimation processes, we compare the volume estimation results (in filling rate) with the directly observed filling rate, which is shown in Table 3.

Table 3. Volume estimation results comparison in filling rate

Experiments	Observed	Estimated
1	0%	0.93%
2	50%	47.51%
3	70%	72.16%
4	105%	107.35%
5	115%	110.86%

As it can be observed, our approach gets the expected results on volume estimation. In Experiment 1, the estimated filling rate of the empty bucket is 0.93%, caused by the alignment error and the noises. In Experiment 5(e), there is a not scanned area resulting a lower volume estimation result.

5 Conclusion

This article introduces an integrated in-bucket mass volume estimation system for the autonomous excavation quality measurement with a robotic excavator. The core of the volume estimation pipeline constitutes of a height map generation and interpolation module which is based on the dynamic bucket points obtaining and transformation refinement. And the experiment result shows the applicability and reliability of the presented system.

A limitation of the current system is that the model based volume estimation process always ignores the points outside the model on the height map. It means that the volume will not be calculated when objects are extended out the bucket side, such as the stones. As LiDAR collects the

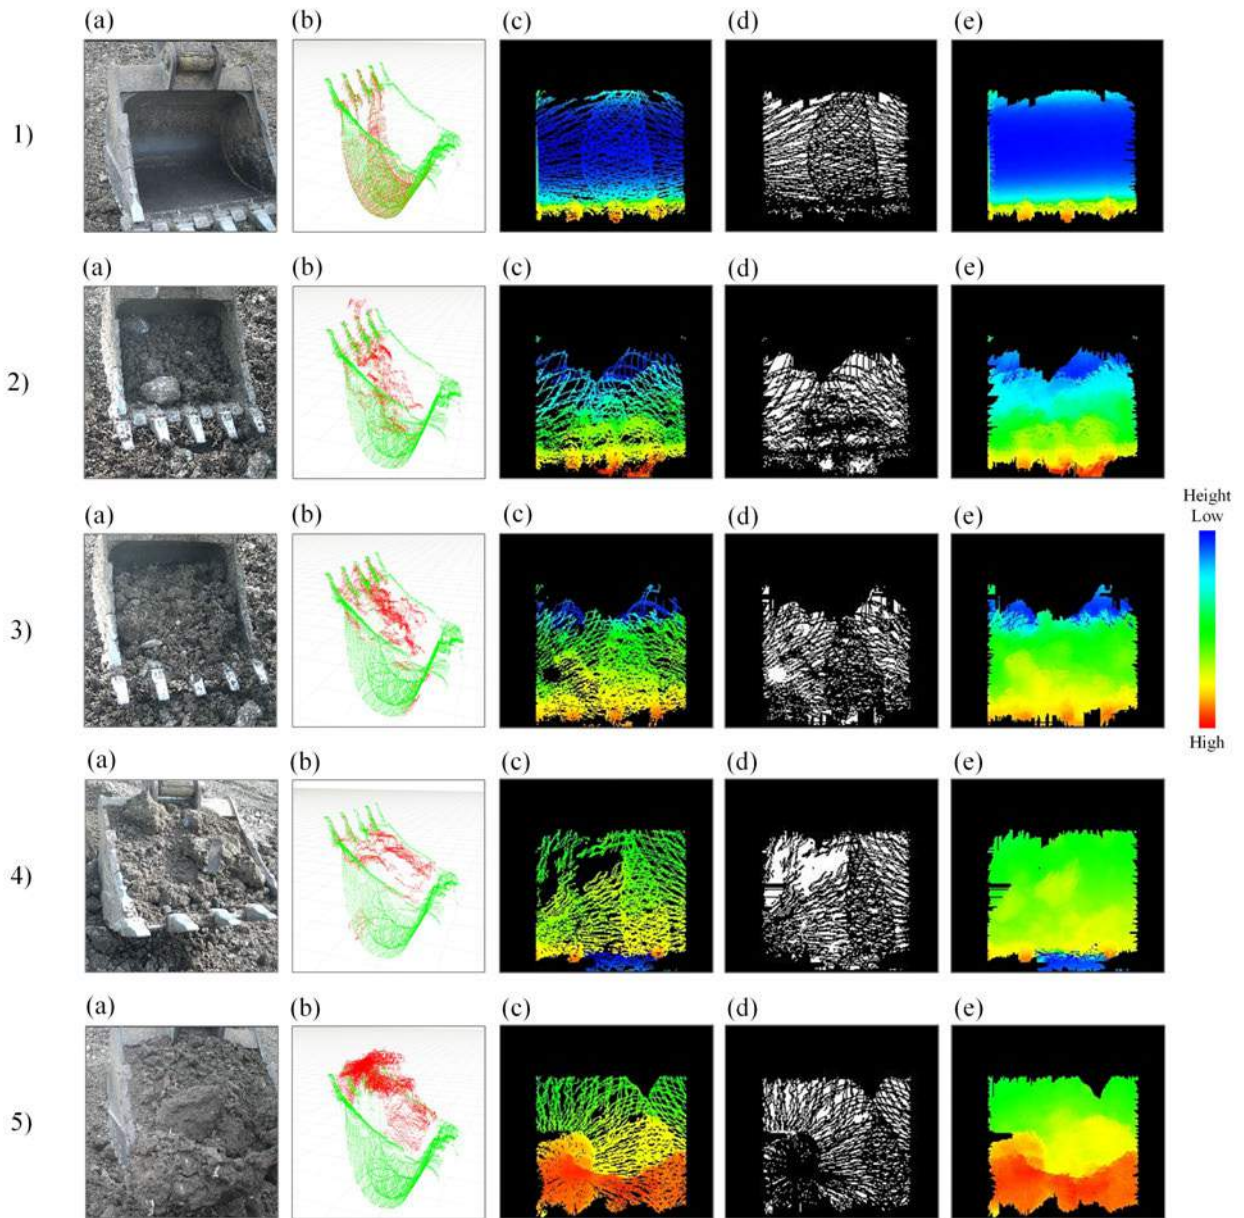

Figure 9. The generated and interpolated height maps on real-time obtained bucket points, (a) the bucket with mass image, (b) the mass point cloud (red) and the empty bucket point cloud(green), (c) the generated height map of the mass, (d) the interpolation area(white), (e) the interpolated height map.

data, another limitation is that the dynamically obtained bucket point cloud will be full of noises which are the flied-out points when the bucket is moving fast, especially when moving away from the LiDAR. As it can be observed in our experiments, the existence of noise leads to the reduction of accuracy, especially when ICP is employed. Thus, a future research direction of our approach is the noise suppression.

Abstract –

Although a shield tunneling machine should excavate a tunnel along its planned alignment, deviations occur between the planned alignment and the actual result. In this case, the deviating shield machine should return to the planned alignment gradually. However, because controlling the shield machine is difficult and time-consuming, and excavation managers and operators are aging, their skills may be lost in the near future. Artificial intelligence is expected to play an important role in automating the operation of shield tunneling machines, but the method proposed by Kubota et al. and the methods of related studies could not automatically calculate optimum operation parameters for curved sections of the planned alignment. Therefore, in this research, the purpose is to develop an autopilot model, which is a method to automatically calculate optimal operation parameters of the shield machine for straight and curved sections of the planned alignment, based on the method proposed by Kubota et al. Besides, as a result of applying the autopilot model to the data of a previously constructed tunnel, optimal operation parameters could be automatically calculated in the section where the tunnel longitudinal gradient is constant.

Shield tunneling; Shield machine; Automation; Machine learning

1 Introduction

Shield tunneling is a tunnel construction method using excavation machines called shield tunneling machines, and this method is often used for the construction of underground infrastructure, such as sewers and subways [1]. Although a tunnel should be excavated along the planned alignment by shield tunneling, deviations occur between the planned alignment and the actual result [2]. When this happens, the deviating shield machine should return to the

planned alignment; however, an abrupt direction change may cause meandering and cracking [3]. In order to gradually decrease the deviation without creating other problems, a target alignment should be generated (Figure 1). However, controlling the attitude and position of shield machines is difficult and time-consuming. Besides, as excavation managers and operators are aging, their skills may be lost in the near future [4]. Thus, it is necessary to automate the operation of shield machines with the same or better accuracy than that of skilled engineers and to improve the accuracy and productivity of tunneling.

Figure 1. Conceptual diagram of tunnel construction

In order to automate the operation of the shield machine, expectations have been increased for artificial intelligence (AI) to make predictions based on machine learning of huge amounts of data, and research on methods using AI has been conducted. On the other hand, the methods of Iwashita et al. [5], Zhou et al. [6], and Sugiyama et al. [7] have the problem that operation parameters for excavating along the target alignment are determined manually by repeated prediction and evaluation. In addition, Kubota et al. proposed a method to automatically calculate optimal operation parameters of the shield machine for straight sections of the planned alignment [8]. Although there are two types of the planned alignment, one is straight and the other is curved, the proposed method cannot be applied to curved sections of the planned alignment. Therefore, in this research, the purpose is to develop an autopilot model that automatically calculates optimal operation parameters of the shield machine for straight and curved sections of the planned alignment, based on the method proposed by Kubota et al. [8].

2 Literature review

To automate the operation of the shield machine, a method to predict the position and attitude of the shield machines using AI has been proposed. In this chapter, we summarize each method and show the position of this research.

2.1 Related works

In order to automate the operation of the shield machine, expectations have been increased for artificial intelligence (AI) to make predictions based on machine learning of huge amounts of data, and research on methods using AI has been conducted. Although there are two types of the planned alignments, one is straight and the other is curved, Iwashita et al. proposed a method for predicting the shield machined direction for straight sections of the planned alignment and applied it to actual construction data [5]. By repeatedly inputting optimum operation parameters and evaluating the prediction results, this method was able to determine optimum operation parameters without relying on the experience of the operator, and it was confirmed that the accuracy of the tunneling was improved. Zhou et al. proposed a method to predict the position and attitude of the shield machine and applied it to the previously constructed tunnel data [6]. They reported the prediction results of this method can be expected to be used by operators to manually adjust the position and attitude of the shield machine. Sugiyama et al. proposed a method for judging the timing of shield jack operations to propel the shield machine [7]. This method makes it possible to give operation instructions at the appropriate time according to the excavation conditions. The authors proposed a method for automatically calculating optimum operation parameters for straight sections of the planned alignment and have applied the method to the previously constructed tunnel data [8].

In order to improve the accuracy and productivity of tunneling, these methods are required to automatically calculate operation parameters of the shield machine that are predicted to excavate along the target alignment and to use the results in the preparation stage of excavation instructions. However, Sugiyama et al.'s method [7] could not calculate optimal operation parameters, and the methods of Iwashita et al. [5] and Zhou et al. [6] were determined by trial and error through repeated prediction and evaluation. The methods of Kubota et al. [8] and Iwashita et al. [5], as shown in Figure 2, constructed a machine learning model that predicts the amount of difference in the deviation between the planned alignment and the shield machine position, and the shield machine position is predicted by integrating the difference between the predicted deviations. On the other hand, in curved

sections of the planned alignment, the amount of difference in deviation differs depending on the curvature, even if the amount of difference in the shield machine position before and after an operation is the same. Therefore, these methods using the amount of difference in deviation as the objective variable has the problem that the shield machine position cannot be predicted accurately in curved sections of the planned alignment.

Figure 2. Conceptual diagram of the difference between deviation and predicted section

2.2 Objective of this research

In order to improve the accuracy and productivity of tunneling by using the method for preparing excavation instructions, the purpose of this research is to develop a method for automatically calculating optimal operation parameters for straight and curved sections of the planned alignment, based on the method of Kubota et al. [8]. The method uses a machine learning model that predicts the amount of difference in the position and the azimuthal of the shield machine before and after an operation and automatically calculates optimal operation parameters. Therefore, the method solves the problem of Iwashita et al. [5], Zhou et al. [6], and Sugiyama et al. [7] in automatically calculating optimal operation parameters of the shield machine and the problem of Kubota et al. [8] and Iwashita et al. [5] in applying proposed methods to curved sections of the planned alignment. In addition, the proposed method makes it possible to almost automate the creation of excavation instructions, contributing to the improvement of tunneling accuracy and productivity, and is considered to be a method leading to the automation of the shield machine operation.

3 Methodology

3.1 Autopilot model

In this research, the proposed method automatically calculates optimal operation parameters of the shield machine for straight and curved sections of the planned alignment and uses the prediction results in the preparation of the excavation instructions. The overall picture of the proposed method is shown in Figure 3.

The input data to the proposed autopilot model are sensing data as explanatory variables, and target alignment data. A total of 47 sensing data items were selected as explanatory variables, including operation parameters of the shield machine, items indicating the attitude of the shield machine such as jack stroke and pitching, and items indicating the ground solidity such as propulsive force, articulation pressure, and cutter power. Next, the autopilot model consists of a direction prediction model that predicts the shield machine position using machine learning methods, and an operation parameter optimization model that calculates optimal operation parameters of the shield machine. The predicted positions of the shield machine using the machine learning model are the horizontal, vertical, and azimuthal deviation. The horizontal, vertical, and azimuthal deviations are the deviations in the horizontal, vertical, and azimuthal directions between the tip position of the shield machine and the planned alignment, as shown in Figure 4. The output data from the autopilot model includes operation parameters that are predicted to excavate along the target alignment and the predicted position that the shield machine will achieve. This output data is used as the appropriate values for operation parameters in the excavation instructions.

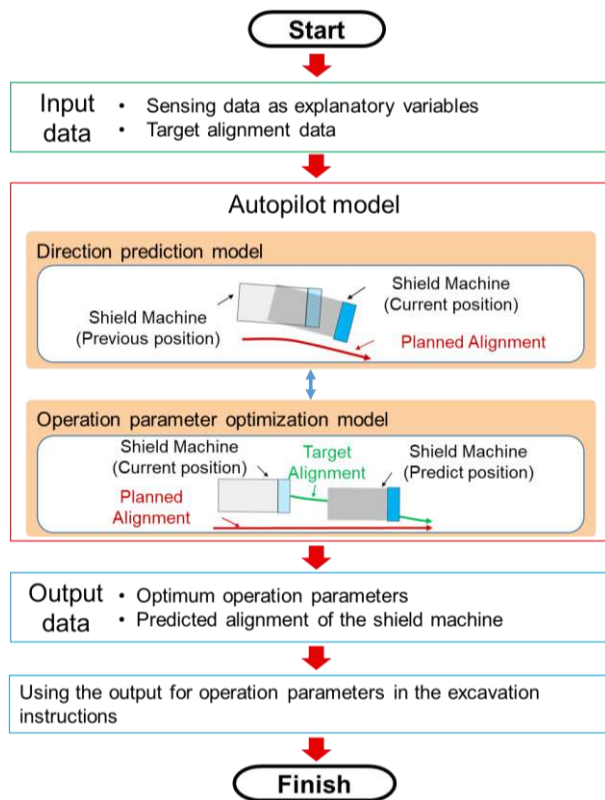

Figure 3. Conceptual diagram of an autopilot model

The autopilot model is intended to assist in the preparation of excavation instructions that include appropriate values for operation parameters. At the construction site, the operator controls the shield machine to get closer to the instructions by carrying out manual surveys for every 4-6 rings of excavation and preparing the excavation instructions based on the results. Therefore, it is assumed that the developed model will be applied to the next construction section, which is 1-6 rings ahead, as indicated in the excavation instructions.

Figure 4. Concept of deviation

3.2 Direction Prediction Model

The direction prediction model that predicts the difference in the position and azimuthal before and after the shield machine operation is proposed for application to straight and curved sections of the planned alignment. In the direction prediction model, a coordinate system is created based on the running direction of the shield machine in both plan and longitudinal views, as shown in Figure 5. The difference in the position of the shield machine at each coordinate is performed by machine learning. Next, the shield machine position can be predicted by integrating the difference in shield machine position after unifying the coordinate systems of the predicted points with the coordinate system of the map.

Figure 5. Conceptual diagram of the difference between deviation and predicted section

Machine learning is a field of AI that predicts the shield machine position using a regression method based on machine learning, which predicts a real-valued objective variable from the explanatory variable. Many machine learning regression methods have been developed, such as Support Vector Regression (SVR) [9] and Long Short-Term Memory (LSTM) [10].

The sensing data as explanatory variables in this research are time-series data measured during excavation that is assumed to be susceptible to disturbances. For this reason, we conducted a comparative verification using SVR, which is reported to perform well in the presence of noise, and LSTM, which is reported to perform better than Recurrent Neural Network (RNN) for predicting time-series data [11]. As a result of the comparative verification shown in Section 4, this study adopted SVR, which can predict the position of the shield machine with high accuracy.

When constructing a machine learning model, if the sensing data are used directly, the performance may be adversely affected by noise and the features may not be captured. Therefore, as preprocessing, we applied the processes of differencing and normalization. In the differencing process, the sensing data that represents the meaningful integration value of data difference are converted to a difference from the data obtained during the previous measurement. In the normalization process, a linear regression equation, which transforms the 5% and 95% values of each sensing datum as -0.4 and 0.4 , was used. To achieve a range of -0.5 for the lower limit and 0.5 for the upper limit, data below the lower limit of -0.5 were set to -0.5 , and data above the upper limit of 0.5 were set to 0.5 .

This model predicts the difference in the position and the azimuth concerning the running direction of the shield machine by inputting sensing data as explanatory variables at the current position of the shield machine. However, since the difference in the position is a value in the coordinate system at each predicted point, the coordinate system must be unified in order to obtain the position of the shield machine. Therefore, the shield machine position and deviation between the planned alignment can be predicted by integrating the difference in the shield machine position after unifying the coordinate systems of the predicted points with the coordinate system of the map.

For the developed model, the data measured for each 5 cm jacking stroke of the shield machine was used. This is based on the fact that the minimum height from the faceplate of the shield machine to the cutter bit is typically about 5 cm, which is the minimum height that contributes to directional control.

3.3 Operation parameter optimization model

The operation parameter optimization model

automatically generates operation parameters to excavate along the target alignment for each ring using an optimization method. The main optimization methods include genetic algorithms [12] and the particle filter method [13]. The characteristic required for the method to be adopted is the need to prevent delays in construction due to a large analysis time. This study adopted the particle filter method, which has low fluctuations in analysis time, depending on the experimental case, and high processing speed.

The particle filter method estimates the unknown parameters necessary for reproducing the observation data from among the candidate optimal values generated by approximating the shape of the probability distribution using multiple particles (Figure 6). This method can be applied to models where the relationship between the unknown parameters and the observation data is nonlinear. Although the accuracy improves with the number of particles, the amount of computation also increases with the number of particles.

Figure 6. Conceptual diagram of particle filter

Therefore, the unknown parameters are operation parameters and the observation data are deviations of the target alignment. Since it is common practice to use all shield jacks, we decided to use all of them in this model as well. Also, because azimuthal deviations of the target alignment are determined by horizontal and vertical deviations of the target alignment, the observation data are horizontal and vertical deviations of the target alignment. Optimal operation parameters are the one that comes closest to reproducing the horizontal and vertical deviations of the target alignment, which is the observation data, among the candidate optimal values.

On the other hand, in order to predict the shield machine position, explanatory variables other than operation parameters must also be input into the direction prediction model. In the case of calculating optimal operation parameters, the front of the tunnel face is targeted, it is necessary to complement the sensing data as explanatory variables. Among these, the jack stroke data was complemented based on the candidate optimal operation parameters and the data of

the jack stroke measured 1 ring earlier. The sensing data used as explanatory variables other than operation parameters and jack stroke were complemented with the same data measured 1 ring earlier, assuming that the influence of the ground was greater than that of operation parameters.

4 Evaluation of Prediction Accuracy

In this Section, in order to predict the arrival position of the shield machine with high accuracy, the machine learning model used to construct the direction prediction model is examined and the prediction accuracy is evaluated. In this verification, we used the data of the “A” project, which was constructed using a slurry shield machine to reduce the damage caused by flooding. There are two types of geology to be excavated in the “A” project. In general, it is known that the behavior of the shield machine differs depending on the ground conditions. Therefore, the direction prediction model was constructed for each geological feature, and the prediction accuracy was evaluated using sensing data measured during excavation of the same geological feature. As shown in Section 2, we used SVR and LSTM as machine learning models to make predictions and compare their accuracy. The sensing data used is shown in Table 1, and the analysis procedure is as follows.

Table 1. Sensing data used in the analysis

Category	Geology I	Geology II
Construction section	Ring Nos. 351-866	Ring Nos. 1117-1616
Geological classification	Alternating strata of diluvial layer, sandy soil and, gravel soil	Alternating strata of diluvial layer and gravel soil

First, the sensing data were divided into training and validation data sets, and the direction prediction model was constructed. Next, the validation data sets were input into the direction prediction model, and the calculated predictions were compared with the measured value. However, assuming the developed model management, the arrival position of the shield machine was predicted 1-6 rings ahead compared with the section where a manual survey was conducted in the section for validation data sets (Figure 7). As shown in Figure 8, 80 % of the sensing data were used as training data and 20 % as validation data, and the data were assigned roles so that both data contained data from straight and curved sections of the planned alignment.

We used the Root Mean Squared Error (RMSE) shown in Equation (1) as the evaluation index for prediction accuracy.

Figure 7. Outline of the section where the verification is conducted

Figure 8. Training data sets and verification data sets

$$RMSE(i, j, k) = \sqrt{\frac{1}{N} \sum_k (P(i, j, k, m) - M(i, j, k, m))^2} \quad (1)$$

where

$RMSE(i, j, k)$: RMSE aggregated under the conditions of i , j and k

N : Number of rings predicted

$P(i, j, k, m)$: Prediction value

$M(i, j, k, m)$: Measured value

i : Difference between the predicted ring number and ring number where manual surveying was conducted ($i = 1, 2, 3, 4, 5, 6$)

j : Type of deviation ($j = 1$ for horizontal deviation, $j = 2$ for vertical deviation, $j = 3$ for azimuthal deviation)

k : Geological classification ($k = 1$ for Geology I, $k = 2$ for Geology II)

m : Predicted ring number.

RMSE is an index of the difference between predicted and measured values squared, averaged, and then aggregated, and the smaller the values, the better the performance. RMSE was adopted because it has the same unit as the predicted value, making it easier to evaluate. Also, the shield machine is constantly excavating an extra 20 mm around the perimeter of the tunnel, which can have a negative impact on the prediction accuracy. Taking the extra excavation into account, the target value was to predict the RMSE within 20 mm for both horizontal and vertical deviations.

The analysis results of horizontal, vertical, and azimuthal deviations of 1-6 rings ahead are shown in

Figures 9 - 11. The smaller the RMSE, the better the performance. For the same experimental case, in most cases, the SVR models were found to be more accurate than the LSTM models in predicting horizontal, vertical, and azimuthal deviations. The SVR models were able to predict the horizontal and vertical deviations within 1-6 rings ahead with an RMSE accuracy of 20 mm or less.

Figure 9. Results of horizontal deviations

Figure 10. Results of vertical deviations

Figure 11. Results of azimuthal deviations

To consider the difference in prediction accuracy among the machine learning models, Figure 12 shows a conceptual diagram of the prediction methods of SVR and LSTM. SVR predicts the deviation based on the previously obtained sensing data, while LSTM predicts the deviation by maintaining a back-and-forth relationship between the sensing data. From these results, it can be concluded that the prediction accuracy of SVR exceeded that of LSTM in the sensing data of

the actual tunnel targeted in this verification because the influence of the previous sensing data contributed more to the prediction of the shield machine position than the influence of the back-and-forth relationship between the sensing data. Therefore, in this research, SVR was adopted as the machine learning model used to construct the direction prediction model.

Figure 12. Conceptual diagram of prediction method of SVR and LSTM models

5 Verification Experiment in Previously Construction Section

To show the effectiveness of the developed autopilot model, it was verified whether the deviation between the predicted position of the shield machine and the target alignment position was smaller than the actual measured deviation. The sensing data used is shown in Table 2 and the analysis procedure is as follows.

Table 2. Test data sets used in the analysis

Category	Geology I	Geology II
Construction section	Ring Nos. 867-1048	Ring Nos. 1632-1841
Number of manually surveyed section (longitudinal gradient to predicted section)	32 (Constant) 2 (Change)	49 (Constant) 0 (Change)

First, the direction prediction model was constructed using the sensing data as training data sets. Next, the position of the shield machine was predicted using optimal operation parameters, which were calculated by inputting horizontal and vertical deviations of the target alignment into the autopilot model. The developed autopilot model was applied to the next 1-6 rings compared with the sections where manual surveys were conducted in the prediction section. In the section used as test data, the tunnel longitudinal gradient from manually surveyed sections is constant in some sections and is changing in others. Therefore, the evaluation was divided into two sections: one where the tunnel longitudinal gradient is constant (Case 1) and the other where it is changing (Case 2). The RMSE results for horizontal and vertical deviations were evaluated because the input data to the autopilot model is the target alignment for horizontal and vertical deviations. The analysis results are shown in Figures 13 - 16.

Figure 13. Results of horizontal direction (Case 1)

Figure 14. Results of vertical direction (Case 1)

Figure 15. Results of horizontal direction (Case 2)

Figure 16. Results of vertical direction (Case 2)

In the section where the tunnel longitudinal gradient is constant (Case 1), the predicted RMSE is smaller than the actual RMSE. On the other hand, in the vertical results of the experimental case, where the tunnel

longitudinal gradient is changing (Case 2), the predicted values are larger than the actual values.

In the section where the tunnel longitudinal gradient is changing, it is necessary to change the pitching, which is the angle between the central axis and the horizontal axis of the shield machine shown in Figure 17. In actual practice, the angle of pitching is varied by changing the middle fold angle of the shield machine. In contrast, since the pitching data in the predicted section of the proposed method is complemented with the same sensing data measure 1 ring earlier, it is assumed that the angle of pitching needs to be changed according to candidate optimal operation parameters.

Figure 17. Pitching overview (longitudinal view)

In order to show the validity of this assumption, the results of Case 2 validation are shown in Figures 18 - 19, switching only the pitching data from the same data measured 1 ring earlier to data measured in the excavation of the predicted section. By using the measured pitching data, the RMSE of vertical direction was reduced, and operation parameters were automatically calculated to predict that the excavation would be closer to the target alignment than the actual results. Therefore, in sections where the tunnel longitudinal gradient is changing, correcting pitching data considering the impact of operation parameters may be effective in calculating operation parameters for excavating along the target alignment. In order to expand the method to apply to the section where the tunnel longitudinal gradient is changing, we consider that a machine learning model that predicts the amount of pitching change that occurs in the process of shield machine operation should be constructed and introduced into the proposed method to address this problem.

Figure 18. Results of horizontal direction (Case 2: revision)

Figure 19. Results of vertical direction (Case 2: revision)

6 Conclusion

This paper proposed a method to automatically calculate optimal operation parameters of the shield machine for straight and curved sections of the planned alignment and to use the prediction results in the preparation of excavation instructions by using machine learning and optimization method, in order to improve the excavation accuracy and productivity of tunnel construction and to contribute to the automation of the shield machine operation. In the section where the tunnel longitudinal gradient is constant, operation parameters for excavating closer to the target alignment than the measured alignment could be automatically calculated by applying the proposed method to the sensing data from a previously constructed actual tunnel. On the other hand, in the section where the tunnel longitudinal gradient is changing, operation parameters for excavating along the target alignment could not be calculated.

As future work, it is necessary to develop and introduce into the proposed method a method for predicting pitching data according to candidate optimal operation parameters and to extend the proposed method to apply to the section where the tunnel longitudinal gradient is changing. Besides, we need to apply the proposed method to unexcavated sections of tunnel construction in progress. The accuracy of the developed model will be improved in the future.

Abstract –

The advent of reinforced concrete (RC) at the beginning of the 20th century fostered the industrialisation of construction. Indeed, for the first time machines such as mixers appeared on the worksites. Strangely, RC construction is now probably more artisanal than steel or wood construction. Current technics raise questions about the security of workers, the quality and the control of the work carried out. Automation can, in particular, help tackle these challenges.

In this study, we developed a digital process for the fabrication of truss-like beams. Clay moulds are 3D printed and serve as a formwork for the cavities of the beam. The fabrication of a three-meter-long beam saving 30% of concrete and Eurocode-compliant is thoroughly described in the paper. A detailed evaluation of the process is then provided and future improvements are suggested.

Keywords –

Digital fabrication; Clay printing; Reinforced concrete; Structural optimisation

1 Introduction

Reinforced concrete (RC) is not only a material but also a construction technique and a building system. At the beginning of the 20th century, its rise fostered a paradigm change in the organisation of construction sites. Former highly skilled craftsmen like stonemasons are replaced by a greater but less skilled workforce working in a more industrialised environment [1]. Indeed, for the first time machines such as mixers appeared on the worksites. It is somewhat surprising to note that no major development has been made since then in the way we build with reinforced concrete. In particular, the shapes taken by concrete remain mainly driven by flat wooden or metallic formworks and straight rebars. And, compared to the current standards, RC construction is highly labour-centred. This raises questions in terms of productivity and quality of the work carried out [2][1], as

well as in terms of security for workers. Typically, the rebar workers tend to carry heavy loads with poor ergonomics. However, the shift towards a greater automation of tasks is not straightforward. Indeed, as observed by the authors in several factories of rebar cage or RC elements fabrication, there is no numerical continuity between the design offices and the factories. As such, a lot of time is lost due to a lack of efficiency in the management of information between the players at stake, namely the contractors and their subcontractors.

This paper presents an automated process for the fabrication of truss-like beams. By 3D printing clay moulds to form the hollow parts of the beams, one is able to address the challenge of mass customisation and geometric complexity without producing wastes as the clay is fully recyclable [3]. This process is part of a fully digital workflow that allows the efficient transmission of information between the design and the fabrication phases. Section 2 introduces the design of two three-meter-long optimised beams with 30% less concrete than in a traditional prismatic beam. The fabrication of the second prototype is described in Section 3. Eventually, we discuss about potential improvements regarding the fabrication process in Section 4.

2 Structural Design of Optimised Beams

The design of the three-meter-long beam prototypes is based on the struts optimisation approach [4], a Eurocode-based optimisation method [5]. By optimising the height of the concrete struts, the internal shear forces are carried more efficiently from the application points of the loads towards the supports. This methodology leads to the design of unconventional truss-like beams, enabling great concrete savings.

The prototypes presented in this paper were both designed as simply supported beams subjected to a uniform loading including appropriate dead and live loads representing typical office building loading. The geometries of the two prototypes are presented in ‘Figure 1’ and ‘Figure 2’. The main difference is the reduction of the width for manufacturing reasons which are detailed

in Section 3.3.

Figure 1. Design of the first prototype. The rebars are represented in blue.

Figure 2. Design of the second prototype. The rebars are represented in blue.

3 Design and Fabrication Workflow

3.1 Computational workflow

Every design and fabrication steps are integrated into a fully automated digital workflow. In this way, the shape complexity and unicity of the cavities of the beams can easily be managed at all point of the process. For instance, the shop drawings as well as the fabrication data, such as the robot's path, are automatically generated. With a view to an industrialisation of the process, it also facilitates the verification steps, reduces the risk for mistakes due to the digitisation of paper plans at the factory, and cuts the time spent in project management. Furthermore, this methodology is necessary to make mass customisation possible so as to fully take advantage of the struts optimisation method. The workflow is presented in 'Figure 3'.

The sizing of the beam elements (struts, ties, rebar cage) is performed with a custom C# library and results in a comprehensive model including key features such as the concrete type and volume, the rebars dimensions, shapes and position as well as geometrical outputs (height and inclination of the struts, width of the ties, concrete covers, etc.). Digital shop drawings are then automatically generated using Grasshopper software.

Although this data could also be leveraged to

automate the preparation of the rebar cage and of the formwork, this paper concentrates on the fabrication of the 3D printed moulds.

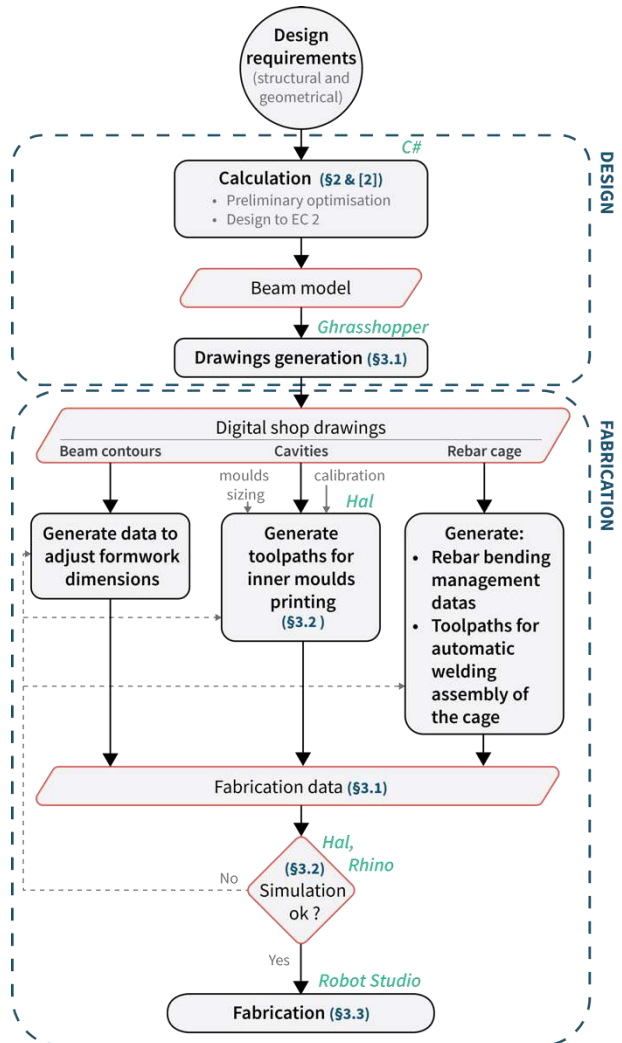

Figure 3. Fabrication-centred computational workflow

3.2 Developments around clay 3D printing

The fabrication of the first prototype, which is presented in 'Figure 4', has already been described in [4]. Key takeaways are that:

- Printing concrete moulds has no environmental interest using the current available technologies as the printing mix is mainly made up of cement.
- Manufacturing tolerances of all parts (formworks, moulds and rebar cage) must be consistent to ensure the insertion of the rebar cage and an even concrete pouring.
- Concrete cannot be vibrated. Indeed, it would displace the moulds which we cannot fix to lost

casing without complicating the demoulding phase.

To address the first shortcoming, a new process for 3D printing clay moulds has been developed. It uses a cartridge-based extruder [6]. The extruder is mounted on a 6-axes industrial robot. A pneumatic jack pushes a piston along a 4-L cartridge containing a clay mix in order to feed a 15 mm nozzle with this mix ('Figure 5').

Figure 4. Photo of a three-meter-long optimised beam prototype built with 3D printed concrete moulds.

Figure 5. Schematic representation of the cartridge extruder.

The extruded material is a mix between kaolin clay (Speswhite Imerys) and water with a water to clay mass ratio e/k equals to 0.58. With this ratio, the paste remains between the liquid and plastic limits. This is necessary to fulfil the compromise between the printability of the mix and its buildability, i.e. its capacity to support its own weight when extruded into layers.

3.3 Fabrication of the prototype

To assess the feasibility of the process, a second prototype was built following the design presented in 'Figure 2'.

It is important to note that, to ease the concrete pouring while maintaining an optimal design regarding shear forces, the width of the beam was reduced but the height of the struts was increased. The resisting section is thus kept but its shape is better adapted to the fabrication.

In chronological order, the fabrication includes the

following steps:

1. Preparation of the external formwork;
2. Assembly of the rebar cage;
3. Calibration of the robot's path for printing;
4. Printing of the clay moulds on the lost casing;
5. Filling of the moulds with sand;
6. Insertion of the rebar cage between the formwork and the moulds;
7. Concrete pouring.

The assembly of the rebar cage was done by Sendin in one of their factory. Special care was given to the bending of the rebar, to the spacing between the stirrups as well as to their inclination (perpendicular to the longitudinal rebars).

The robot's path (generated with Hal software) need to be calibrated to compensate for the non-planarity of the lost casing along the 3.2 m of the beam. This step is necessary to ensure a consistent height for the first layers of the 19 moulds. The moulds are then directly printed on the lost casing. Here, six cartridges were necessary.

Afterwards, the moulds are filled with sand in order to balance the pressure of the concrete at fresh state.

The rebar cage is inserted and finally the concrete is poured. No vibrating was required. In 'Figure 6', several photos of the fabrication process are shown.

4 Discussion

4.1 Benefits from a higher fabrication complexity

Table 1' presents the bill of quantities of both prototypes and 'Table 2' some metrics regarding their fabrication.

Table 1. Bill of materials (est.: estimation)

	Pr. 1	Pr. 2
Printed material (kg)	93	44
Poured concrete (m ³)	0.138	0.119
Steel ratio (kg/m ³)	77	156
Poured sand (m ³ - est.)	-	0.029

Table 2. Production data. In red, the number of people required to realise the task. (est.: estimation)

	Pr. 1	Pr. 2
Moulds fabrication (min)	80 (3)	210 (3)
Sand pouring (min)	-	15 (2)
Casting and finishing (min - est.)	120 (1)	25 (2)
Total time (min)	360	710
Slump flow test (mm)	-	730
Rebar cage assembly tolerance (cm)	2	0.5

Figure 6. Fabrication of the second prototype. From top to bottom: printing of the moulds, insertion of the rebars and filling of the moulds with sand, pouring of the concrete, demoulded beam.

The processing time for the second prototype took twice as much time as the one with concrete moulds. This

difference is mainly due to the time taken to prepare the clay moulds. The most time-consuming sub-process for the preparation of the clay moulds was the refilling and reloading of the cartridges whereas the printing time alone was very similar in both case studies. A continuous process avoiding cartridges would decrease highly this time step.

However, several parameters were leveraged to ease the concrete casting by allowing a smoother concrete pouring, especially regarding the coarser aggregates. The better manufacturing tolerance of the cage ensures minimal distances between the rebars and the moulds. The modification of the geometry of the struts also goes in that direction despite a higher steel ratio. This higher ratio is mainly due to the lack of availability of 8 mm diameter rebars in the second case. Lastly, the use of self-compacting concrete (SCC) instead of ordinary concrete, though requiring higher precision in the formulation, makes the pouring easier. To go further, robotic assembly of the rebar cage could also be leveraged to improve even better the precision. Shifting the complexity towards upstream tasks enables to ease the concrete pouring which is necessary to manufacture sound structural elements.

4.2 Complementarity of the formwork and the robot

The setup presented in this paper consists of a fixed wooden formwork and of a 6-axis industrial robot placed on a linear track. 6 axis are not required to print the moulds. Stiffer robots such as gantry robots or SCARA ones would be more relevant in an industrial environment: they are cheaper, more productive, and require less maintenance. Moreover, depending on the context i.e. prefabrication or on-site manufacturing, the moving part might not be the same. In a factory, to enable a continuous process from the preparation of the formwork to the steam-curing of the concrete and the demoulding of the beam, a conveyor is required. As such, a fixed robot should be used. On-site, a robot on a track offers a more compact printing unit. It thus better suits the tight space constraints of worksites in urban areas.

5 Conclusion and perspectives

This paper presented the fabrication of a three-meter-long optimised reinforced concrete beam. This beam, which contains 30% less concrete than a traditional one, displays a truss-like shape. Such beams are generally casted thanks to single-use wooden or polystyrene formworks. Here, the development of a 3D printing process enables the fabrication of fully recyclable clay moulds. This first realisation proved the feasibility of the process and allowed us to identify potential

improvements as stated hereinbelow:

1. Clay 3D printing was successfully implemented. As long as no cantilever shapes are required, it is easier to manage than concrete printing as there is no evolution of the material during the process.
2. Clay moulds are not able to withstand the lateral pressure of self-compacting concrete. One solution is to fill them with sand. Another would be to use a mix with a greater yield stress but this might require to use a more powerful pneumatic jack. Work is currently in progress for measuring the yield stress of the paste and characterize its extrudability. Yet another solution would be to print more complex geometries. Typically, topology optimisation could be used to design stiffeners for the moulds. Both these solutions would make the demoulding easier.
3. Introducing more complexity in all the preparatory tasks decrease the complexity of the most important one which is the concrete pouring. The durability of the manufactured elements is thus enhanced.
4. However, it also reduces the range of possibilities in terms of concrete formulations as the beams cannot be vibrated: only SCCs can be used. This requires greater control over the concrete mix preparation.

The automation of the construction industry can help solve some important challenges that it faces. It can improve the security of workers, it can increase the productivity, it can help build optimised structures. But it is important to look back at the evolutions brought by technological improvements. It often causes a polarisation of jobs, some requiring higher skills, some lesser skills. The advent of reinforced concrete construction at the beginning of the 20th century or the current development of prefabrication exemplify this. These aspects must also be studied from a social science perspective.

Acknowledgment

The authors are grateful to Mahan Motamedi, Hocine Delmi and Christophe Bernard for their help during the fabrication of the prototype.

This work was made during Mr. Maitenaz doctorate within the framework of an industrial agreement for training through research (CIFRE number 2018/1055) jointly financed by the company VCF TP IDF SA (Vinci Construction France), and the National Association for Research and Technology (ANRT) of France.

Abstract -

Timber construction and prefabrication are becoming increasingly important in the building and construction industry. The degree of automation in this area is low. Caused by the great variability of construction projects and building components, automation systems that can adapt flexibly to different construction projects are required. However, a system that fulfills these conditions does not yet exist. Downtimes for reconfiguration in between projects must be short. The use of robotics for the automation of prefabrication is constantly developing. Recent publications present a novel, flexible, reconfigurable, and transportable manufacturing platform using industrial robots. A system consisting of several of these modular platforms can be flexibly adapted to the changing requirements of different construction projects and set up on-site at local timber construction companies. To ensure the manufacturability of the timber components and to minimize downtimes between projects, the entire workflow from digital design to fabrication must be considered. The co-design approach makes this possible. It breaks up the currently existing sequential process from design to fabrication and considers all sub-steps holistically. Thus, enabling the consideration of the fabrication capabilities during building design. This allows the planning of building components and system layout so that fabrication is feasible. To achieve this, the fabricability of a given system layout has to be evaluated. This requires a digital twin of the fabrication system as a simulation model. The reconfigurability of the fabrication system must be reflected by the digital twin. The fabrication tasks and the system configuration are constantly changed in search of a valid combination. Therefore, with each iteration, the digital twin must be adapted or newly created. At present, this is mostly a manual process. This makes the whole approach unfeasible. To solve this problem, this work presents an approach for the automated, model-based generation of digital twins for the simulation of reconfigurable fabrication systems for timber prefabrication.

Timber Prefabrication, Digital Twin, Cyber-Physical System, Software Defined Manufacturing, Simulation

1 Introduction

The use of wood as a sustainable building material can help to reduce the emission of greenhouse gases from the construction industry [1]. In terms of recycling, wood as a building material also offers important advantages over building with mineral materials [2]. Prefabrication promises to at least partially solve current problems such as the high demand for affordable housing. The construction industry currently has lower productivity and degree of automation than the manufacturing industry. This important industry currently still relies strongly on the use of manual labor [3]. Certain branches of timber construction have already successfully adopted approaches from manufacturing [4]. However, this highly automated branch of timber construction is found almost exclusively in residential housing and accounts for only a very small share of the overall construction industry market [5]. The major part of timber construction has a strong project-based orientation [6]. Most projects are to some extent unique.

The mostly small [7] and locally based companies have to adapt flexibly from project to project and hence need flexible fabrication systems. Downtime between projects must be short. The wide variability of building components due to location-specific building codes and the strong dependence of the building design on the specific building location and the client is a challenge [8]. The wide variance in the requirements of project-based construction poses currently unsolved challenges for small and medium-sized timber construction companies in terms of automation. This is especially true for more advanced, higher-performance lightweight construction systems that use fewer resources but require more complex fabrication processes and higher fabrication accuracies. Existing automation solutions in timber construction are very inflexible. These often highly automated systems can be configured from a modular component system. However, later adaptations of these machines to specific project requirements are hardly possible.

1.1 Adaptive Fabrication Systems

Due to the lower requirements on machining accuracy compared to manufacturing technology, especially in subtractive machining, the use of industrial robots has become established in timber prefabrication [9]. Industrial robots offer the necessary flexibility that timber prefabrication requires [10]. Furthermore, the performance of industrial robots is sufficient for most timber building components with lower demands on machining accuracy and surface quality. Recent examples of the use of industrial robots in construction are the assembly of single timber frames [11] or the construction of successive roofs using ceiling-mounted industrial robots [12]. On the one hand, these examples show the potential for automating highly complex timber prefabrication tasks with industrial robots. On the other hand, these systems were developed specifically for this particular task and are not flexibly adaptable to other tasks.

In [8], a novel approach to the automation of timber prefabrication was presented using a modular, reconfigurable and transportable platform that was used to fabricate the building demonstrator from [6]. The platform is equipped with end-effectors for milling, nailing, gluing, and handling components.

A system consisting of several such platforms can be adapted to the specific requirements of individual construction projects by the arrangement and number of modules as well as their configuration. Since these modules are transportable, the fabrication system can be set up on-site at local timber construction companies.

1.2 Fabrication Planning and Simulation

Such a modular, reconfigurable fabrication system can be equipped with different tools and effectors as required. The system layout can be reconfigured by rearranging and replacing the system modules. To ensure minimal downtime between projects, this must be achievable in a short time and with minimal effort.

Several aspects play an important role in the operation and the successful, fast reconfiguration of such a fabrication system. A suitable control system is needed to operate the fabrication system. The adaptation of the control to a given system layout must be simple and as automated as possible. The same applies to the calibration of the modular system after a reconfiguration of the modules. Another important aspect is the planning of the layout and the transfer of the building design to the fabrication. To keep downtimes low, both the fabrication process and the system layout must be pre-planned and pre-validated. To efficiently ensure the manufacturability of the components with the existing fabrication capabilities that are available in the given fabrication setup, the usual sequential work-

flow from design to engineering to fabrication needs to be broken down. One such method is co-design [13]. In co-design, all involved stakeholders work in parallel and not sequentially. Their planning and calculation models interact via defined interfaces. The objective is to integrate manufacturability and machine skills into the design and planning process.

This can be done in parts on an abstract level, considering the workspaces, the payloads, and the manufacturing processes of the modules. Following on from this, the fabrication of the components must be simulated in detail. This requires a simulation model of the fabrication system. To reliably validate the manufacturability for a given system layout and task schedule, and thus to enable fast reconfiguration between projects, the simulation model must cover all relevant factors, such as path planning and execution, collisions, or reachability. This requires a digital twin of the entire fabrication system, which also includes the control system and incorporates it into the simulation. In this way, the later task execution can be pre-validated before the actual reconfiguration of the plant. To enable the rapid simulation of different system layouts and task schedules, a method that automatically generates the simulation models for a given system layout and manages the entire simulation process is needed. This paper presents the concept and early implementation of a method for automatic model generation and execution of digital twin models of the above described reconfigurable fabrication system for timber prefabrication. The concept is validated based on a simulation with different fabrication layouts and a simple tasks sequence.

The remainder of this paper is organized as follows. Section 2 discusses related work in the field of digital twins in manufacturing and construction technology. In Section 3, we discuss the problem definition and present our solution approach. This is followed by Section 4, where we describe the current state of implementation. The presented method is validated in section 5 We conclude and discuss our work in Section 6.

2 Related Work

Different definitions of digital twins are known in the literature. A general definition has been established by NASA as an "integrated multi-physics, multi-scale, probabilistic as-is simulation of a product, system, or process that can reflect the lifetime of the corresponding twin using available physical models, historical data, and real-time data" [14]. In principle, digital twins can be divided into online and offline digital twins. Online digital twins run in parallel with the system. These are used, for example, for the measurement of hard-to-measure conditions, predictive maintenance or life-cycle management. Offline digital twins run independently of the physical system.

Use cases include simulation or planning .

2.1 Digital Twin in Manufacturing and Construction

Different definitions of digital twins are used in manufacturing technology. It can be a virtual image of products, individual machines or machine components or even represent entire plants and factories. Depending on the application, these differ in the level of detail in which the physical instance is mapped. In manufacturing technology, the digital twin is often a model of a system or machine in which, in addition to kinematics and dynamics, communication via fieldbuses is mapped in real-time. In [15] the authors present a digital twin approach that allows the digital twin to be used as an deterministic, real-time environment for the reinforcement learning-based training of an agent for CNC based robotic manipulation of soft-tissue objects. In [16] an approach for real-time co-simulation of digital twin models is presented. In [17], digital twins for online optimization of the real fabrication system are discussed. The authors of [18] present a 3D reconstruction method for the exploration of SME environments with drones. The work of [19] discusses the construction of digital twins employing model-driven approaches. The authors of [20] present a method for the discovery and automatic generation of digital twins. The characteristics of manufacturing systems are derived from data. The authors find that the approach generates models that can correctly estimate the system performance. The work of [21] describes the automatic generation of digital twins for simulation. They use model generation techniques and generate a digital twin of the environment. The authors of [22] use a digital twin to evaluate the reconfiguration of an automation system. They find that their method can reduce reconfiguration times by up to 58%. A modular framework for digital twins of reconfigurable manufacturing systems (RMS) is presented in [23]. The work in [24] applies digital twins of reconfigurable machine tools for design purposes. Studies regarding different kinematics are conducted with the digital twin. The work of [25] presents an approach to reconfiguration planning of RMS based on digital twins. Similarly, the authors of [26] employ a digital twin-driven method for the reconfiguration of manufacturing systems. In [27], the authors discuss digital twin enabled reconfiguration for robotics-based manufacturing systems.

In contrast to manufacturing technology, digital twins in the construction industry are mainly used as a representation of a product like a building component or a building, rather than as a representation of the manufacturing resources used to fabricate it. The authors of [28] state that the use of digital twin technologies offers great potential for the transformation of the construction industry. Applications include structural system integrity, facilities management, monitoring, logistics processes, and energy

simulation. In [29], the digital twin of a building including its equipment is used for life cycle management and predictive maintenance. The authors of [30] aim to develop an integrated digital twin that can be used to update building information modeling. In [31], a digital twin is presented as a framework for combining computational design and robotic construction. The digital twin aims to represent the built structure, which is monitored using computer vision techniques. A detailed model of the robot and its behavior beyond its kinematics is not part of the digital twin.

In the field of manufacturing technology, work on the automatic, model-based generation of digital twins is known in the literature. In some cases, there are approaches for system reconfiguration based on digital twins. In the construction industry, digital twins are mainly considered as a model of a building or a construction system. In the field of robotic prefabrication, robot kinematics is used in component design and fabrication planning. However, an actual, automated simulation with the digital twin of the entire manufacturing system with its control system does not take place.

3 Methodology

3.1 Problem Formulation

Reconfigurable manufacturing systems offer a high degree of flexibility. However, reconfiguration planning is a very complicated and laborious process. During layout planning, it must be ensured that the resulting system is capable of fabricating the desired parts. This validation is of great importance, as the reconfiguration process involves a lot of time and effort. Since downtimes should be as short as possible, a reconfiguration due to an infeasible layout must be avoided. In the case of the robotic, reconfigurable fabrication system for timber prefabrication described above, further difficulties arise. First, the plant has to be reconfigured relatively frequently from project to project. Second, the system layout and the part geometries have to be planned synchronously so that an optimal combination that satisfies all requirements and constraints is achieved. In addition, the environment constraints change, since the plant is to be set up locally at the timber construction company in each case. Figure 1(a) and Figure 1(b) show examples of different system configurations with different modules and constraints.

The planning and validation of a layout for a given building system must be performed employing a realistic simulation based on a digital twin of the reconfigurable plant, showing an adequate level of detail. Since this is a complex planning problem and the manual creation or adaptation of the simulation models requires a lot of time, a suitable solution for the automated generation of the digital

Figure 1. Examples of Fabrication System Layout

twin is necessary. For each change in the development of the building system, the system layout has to be validated or planned again. The resulting amount of adjustments to the simulation model underline the need for this research.

3.2 Method

To solve the existing problems and hence enable fast, automated validation through simulation we automatically generate and manage the digital twin of the reconfigurable fabrication system. The generation of the digital twins is based on a descriptive model of the system. The level of detail of the digital twin must reflect the relevant behavior of the entire system from task execution to path planning. The 3D geometry, the kinematics, the dynamics, and the system capabilities as well as a description of the control components have to be part of the model. The path tracking behavior of the industrial robot control is excluded and assumed to be ideal. The reason for this is that the industrial robot control is a black box system. Based on a description of the system layout, the digital twin of the entire system is generated. This description holds the module configuration, the system layout with module poses, and the environment. A simulation management component is used to control initialization, simulation execution, and deinitialization of the generated models and enables automatic iteration over different configurations. After a successful start-up of the model, the execution of manufacturing tasks that are defined through a task graph is simulated. After that, the simulation is stopped and deinitialized. The simulation validates reachability, collisions trajectory planning, and task execution. A later extension of the simulation to include process simulation for handling and assembly or subtractive and additive fabrication is being considered and planned.

3.3 Model Structure

The digital twin of the reconfigurable, modular fabrication system is composed of several modules. The individual modules in the form of containers with robots and tools are referred to as fabrication units (FU). These are formed as a combination of the subcomponents platforms,

robots, and end effectors. The compatibility of the sub-components with each other is represented by interface descriptions.

Figure 2 illustrates this concept based on various FUs. The description model of the subcomponents includes not only the interfaces but also the required software components. These are for example responsible for path planning and I/O control. Depending on the tools and robots, CNC components or camera drivers for a simulated camera are also possible. This can be used to derive a dependency tree for the individual FUs or the overall system. As can be seen in Figure 3, each FU has a task controller. This controller is connected to the system controller. The system controller ensures the correct execution of the task schedule described in the graph. As soon as a task can be started, it is sent to the task controller of the corresponding FU, which is then responsible for its execution. In addition to the FUs, the model consists of ENV components that describe the environment, such as the workshop, and OBJ components that represent passive but not static objects. These can be, for example, pallets with material or working tables with components. Existing FUs and their components form a library that can be used for the reconfiguration of FUs and the fabrication system.

3.4 Model Description

Fabrication layouts are described in a text-based way. This description contains a list of FUs that are a part of the component library. For each FU the type and the pose is specified. Furthermore, ENV objects for the environment and OBJ elements for the interaction are included. The digital twin itself is described by XML-based files. These files are generated by the model generator and are started gradually during the ramp-up of the digital twin. They describe all subcomponents of the individual FUs and start them.

3.5 Model Generation

Based on the layout description and the component library, the digital twin is generated by the model generator. The layout description is retrieved and matched with the component library. Based on the FU description the dependency tree can be created. For each FU a Universally Unique Identifier (UUID) is created to uniquely identify the FU. This UUID serves as a prefix for the communication with the module. Identical FUs that occur more than once can thus be uniquely addressed. In a second step, the models of the FUs are adapted to the requirements of the simulation or it is checked whether an adaptation is necessary. Such an adaptation is for example the configuration of the collision monitoring so that occurring collisions can be registered. Furthermore, a bitmask must be generated that defines which collision pairs should not be reported.

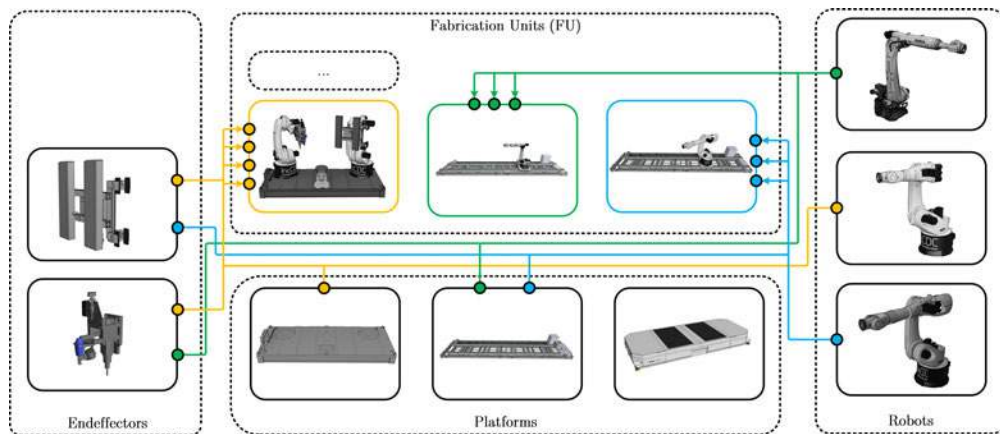

Figure 2. Composition of Modular Fabrication Units

This is necessary, for example, so that collisions of the module container with the ground are not permanently reported. A start file is created as an entry point for the launch of the digital twin. After the successful generation of the digital twin, this file is reported to the simulation manager.

3.6 Simulation

The automated simulation is managed according to figure 3 following model generation by the Model Composer. The Simulation Manager component is responsible for this. It receives pairs of digital twins and task descriptions to be simulated. The individual pairs are simulated according to their order. For this purpose, the digital twin together with the task description is automatically loaded into the simulation environment and started. During the simulation, monitoring data such as the movements of the robots or any collisions that occur are recorded. When the simulation is finished, the digital twin is stopped. The successful execution of individual tasks is reported by the task controllers of the FUs. If a task could not be executed successfully due to a collision or other errors such as reachability problems or too large tracking errors during path execution, the task is marked as failed. Using the monitoring data, errors such as collisions can be analyzed in detail and the component or system can be adjusted accordingly. If a task fails, the pair of the task description and system layout is marked as non-functioning.

Figure 4 shows the state flow of the Simulation Manager during automatic simulation. First, the digital twin is generated for a given layout (state 1). Then, the digital twin is started. After the successful model ramp-up phase (state 2) the simulation can be started (state 3). After the simulation is finished, the digital twin is stopped during the model ramp-down phase (state 4). In state 5, the generated data is deleted and the workspace of the model generator

and the simulation manager is cleaned up. In this step, the results of the simulation are saved.

4 Implementation

The above method was implemented as a proof of concept and is in an early stage of implementation. The implementation is based on the open-source robotics framework Robot Operating System (ROS) using C++ and Python. Gazebo is used as the simulation system. The individual fabrication units (FU) and their subcomponents are based on the IntCDC fabrication module library containing different containers and robots. The Unified Robot Description Format (URDF) is used as description the model for robot kinematics with the XACRO tool from ROS. For motion planning, the MoveIt path planning library is used. In the current state, digital twins can be generated model-based and started or stopped automatically. During generation, all FUs are configured with the required components. All configuration and launch files are generated. In the simulation, the robots can follow the paths described in the tasks. Any collisions that occur are detected. Based on the simulation data, the system configuration or the fabrication tasks can be adapted accordingly. The actual manufacturing simulation with handling and assembly processes or subtractive and additive processing is currently not integrated and will be realized in the next steps.

5 Validation

The validation of the described concept is realized using different system layouts of the fabrication system for testing. For this purpose, 4 different system layouts are used as use cases with a sequence of motion tasks. The individual tasks describe movements that have to be executed by the robots. Use Case 1 consists of 5 fabrication

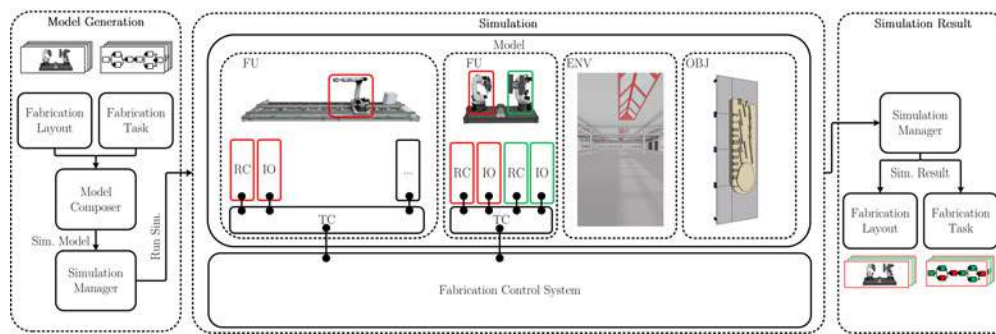

Figure 3. Simulation Workflow

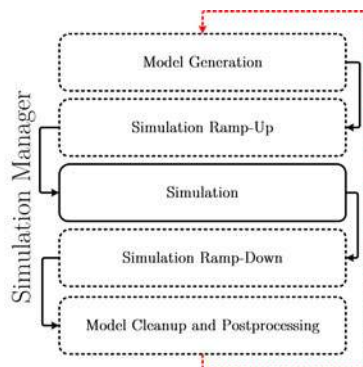

Figure 4. State Flow of the Simulation Manager

Figure 5. Use Case 1

modules with a total of 8 robots. The other use cases comprise 2 and 3 modules respectively. Use Case 4 is defined in such a way that collisions with the environment occur during certain tasks. The 3D model of the Large Robotic Construction Lab (LCRL) of the University of Stuttgart is used as a simulation environment.

The digital twin of use cases 1 and 4 can be seen in figures 5 and 6. The system layouts are defined in the configuration of the model generator. The generator iterates over the individual layouts. It generates the digital twin of the system according to the layout. The Digital Twin is then started and initialized. After the model is completely loaded, the simulation of the tasks is started and performed. After completion of the task simulation,

Figure 6. Use Case 4

the digital twin is deinitialized and stopped. The log data of the simulations are shown in Figure 6.

The log data shows the chronological sequence of the generation of the models. The models are first created (1). Then they are started (2) and the simulation is carried out (3). After the simulation is finished, the model is stopped (4) and the model generator is cleaned up (5). It can be seen that in simulation 4, as expected, collisions with the environment are detected. The validation shows that the implementation allows the automatic generation and simulation of digital twins for the described system. The automatic generation and simulation of a list of layouts are possible. The validation based on the current implementation shows that the presented approach works and that it provides a solution for the model generation and simulation for the described reconfigurable manufacturing platform for timber prefabrication.

6 Conclusion

This paper discusses the automatic generation and simulation of digital twins of a reconfigurable, robot-based fabrication platform for prefabrication in timber construction. The proposed method allows an easy and automated generation of these models. It allows the automated simulation of fabrication tasks described in a task graph for a given system layout. The primary objective of this approach is to enable co-design through integrated fabrication planning and fabricability analysis. Hereby it is

Figure 7. Simulation Log Data

possible to iterate quickly over different solutions. This permits efficient planning and validation of the fabrication and thus helps to keep downtimes for system reconfiguration between projects to a minimum. The next step is to extend the method to include an optimization procedure for the planning of a suitable system layout. In addition, the digital twin is to be extended to include a detailed simulation of manufacturing tasks such as handling, assembly, and subtractive and additive processes.

Abstract -

This paper introduces a new approach for extending the geometrical freedom of shotcrete 3D printing. Up to now, manual shotcrete manufacturing and the shotcrete printing process has been performed with a continuous material flow to avoid nozzle clogging, which is caused by the solidification of the fresh material within the printing system. However, this requires a continuous printing path for the entire component, which leads to considerable confines in terms of printable geometries. To overcome this restriction, potential factors to control the printing interruption process were determined and quantitatively investigated. Based on 3D specimen data, the most suitable parameter settings for realizing deterministic short term printing gaps without nozzle blockage were identified. For final validation, these settings served in the robotic fabrication of a test element and showed promising results.

shotcrete 3D printing (SC3DP), concrete construction, robotic fabrication, automation, process control, surface scanning

1 Introduction

The current 3D printing technology ranges from sophisticated and well-developed small-scale 3D printing with various materials [1] up to large-scale printing of steel, recycled materials, and concrete [2, 3, 4]. In particular, the production of constructive concrete components for the construction industry holds the prospect of increasing productivity and efficiency through more targeted use of materials. However, large-scale printing, especially with concrete, is still under development and presents new challenges relating to the fresh concrete characteristics and its handling [5]. One of these challenges is the control and supervision of the material flow during the printing process, caused by two opposing printing requirements. While good flow properties are essential during conveyance of the fresh material, high green strength is necessary immediately after the application to prevent the component from plastic collapse.

To address this conflict, a novel technique of shotcrete 3D printing (SC3DP) was designed at the Institute of Structural Design (ITE) at the Technische Universität Braunschweig [6]. In this process, the concrete is applied layer-by-layer with high kinetic energy, accelerated by pressurized air. The air flow is mixed into the concrete flow right at the end of the printing nozzle, thus the material is sprayed instead of extruded. Additionally accelerator can be added to decrease the curing time and improve the component stability. This technique is particularly used for the manufacturing of large scale, constructive concrete elements without formwork. In contrast to 3D extruded concrete elements [7], the shotcreted concrete elements obtain a monolithic structure with a much stronger inter-layer bond [8]. Consequently the initial risk of plastic collapse is reduced. This behaviour further enables printing of more significant overhangs and also on walls and ceilings.

Despite these advantages, the shotcrete 3D printing process is more susceptible to the risk of nozzle clogging during the printing. This is caused by the necessity of improved flow properties to ensure the sprayability of the material. Hence, the time window between pumpability and solidification must be narrowed to prevent elastic buckling, which will increase the chance of material solidification and nozzle clogging [9]. In this regard, ACI 506R-90 (*Guide to Shotcrete*) requests the material flow to be steady and uninterrupted during manual nozzle operation.

Additionally, the hose length, the pump inertia, and the valve lags avert a step response of the material flow to printing interruption or reactivation commands. For this reason, the temporary stoppage is not only accompanied by clogging [10] and material overrun but also unidentified idle times occur, when restarting the printing process. This clearly demonstrates that printing interruptions lead to reduced component quality.

For standard surface shotcrete manufacturing and basic 3D components, this can be bypassed through a continuous printing path [11]. Nonetheless, while investigating the manufacturing of complex geometries by SC3DP, the path planning becomes more complex as well. As result,

a continuous material flow is not suitable anymore and reduces the geometrical freedom along with increasing the material wastage. Solving this is essential to enter the next stage of geometrical complexity in SC3D printed elements. Thus, it is necessary to control the distribution of the material with an integrated system that determinately starts and stops the concrete flow.

Concerning this matter, the rheological properties and the system inertia are crucial for the deviation between as-planned and as-printed gap. However, in this study we will focus on the system. This given, the concrete valve status, controlling the concrete volume flow, and the pump actuation timing are most important for the inertia. Reasons for this correlation are the hose length and the accumulation of the material within the nozzle. While the hose length results in a severe delay between pump activation and material application, the residual material from the nozzle is distributed even after the valve is shutdown. To counteract this inertial system behaviour, the necessary setting of delay and lead times is identified and optimised in this work.

2 Background and motivation

Looking at state-of-art 3D printing processes, material application interruption is an integral part of all processes. This function is indispensable, especially for the production of complex parts, produced with 3 axis printers and 2.5D path planning algorithms. Thus, multiple methods for the realization of such interruption are available.

2.1 3D printing overview

In small scale Fused deposition (FDM) 3d printing with thermoplastic or other firm synthetic materials the option of retracting the material from the nozzle was established by changing the rotation of the extruder motor [12]. Hereby the pressure inside the nozzle is decreased and the molten material will not be extruded. A similar approach is used in the small-scale particle bed printing, where the adhesion substance is retracted from or not pumped further into the nozzle. In the process of large-scale concrete deposition, these solutions of material retraction are no longer feasible. Due to long pumping distances and time-dependent material processing the distribution can only be interrupted for a certain amount of time. In the case of contour crafting [13] and concrete extrusion it is possible to release the pressure from the end effector and the pumping system or use trowels to stop the concrete flow. Moreover, the material properties enable the idle mode of the concrete and let it stay inside the nozzle. However, this process becomes more complex when the material is deposited with a certain nozzle distance and additionally accelerated, such as in SC3DP.

2.2 SC3DP

The SC3DP Process was invented in the 1920s and is now being rediscovered as an additive manufacturing technique used in combination with precise robotic fabrication [14]. Through this combination it is possible to manufacture constructive concrete elements without formwork and with integrated reinforcement [4, 6]. The shotcrete 3D printing system used for our research is part of the Digital Building Fabrication Laboratory (DBFL) at the ITE. [15] In this setup a Stäubli TX 200 robot with 6 degrees of freedom is attached to a 3-axis gantry portal, provided by OMAG SpA. These are used in combination to carry the end effector, which is designed to mix the fresh concrete, the accelerator and the pressurized air. The concrete production and conveying line, which deliver the material towards the end effector, consist of a WM-Jetmix 125 Mixer by Werner Mader GmbH and a WM-Variojet FU Pump. The hose length between the pump and the end effector can be up to 25 m for large scale printing. The spray process itself is presented in figure 1. The material used for the printing of all components is a fibre reinforced plain cement concrete produced by MC Bauchemie Müller.

The control system of the entire plant consists of three sub-units. The major control is carried out via G-Code commands on a Siemens sinumerik 840D. For positioning, nine motion commands are mandatory, consisting of three parameters for the gantry portal and six values for the robot. The movement commands for the three-axis gantry are processed directly on the Siemens Sinumerik, while the motion commands for the robot are transferred to the Stäubli control unit.

Figure 1. Specimen production by SC3DP

For the control of the concrete, air and accelerator volume flows, G-code commands are forwarded to a Beckhoff industrial PC. To date, these commands are set in the beginning of each printing file and are not changed during the printing process. However, for realization of printing interruption it is necessary to interact with the concrete pump and the concrete valve while printing.

Considering the presented set-up, a wide range of process parameters can be identified which influence the material application. On the one hand, nozzle distance, nozzle diameter, printing speed and spray orientation will directly influence the strand geometry. On the other hand, concrete and air volume flow will suffer a delay due to the mentioned system inertia, before affecting the strand properties. Regarding the aimed printing interruption, the concrete flow will have a major influence on the applied material. Thus, the pump's on and off time, as well as the concrete valve timing are the main parameters for our research.

3 Experimental setup

To investigate the pump and valve timing in consideration of the applied material and possible clogging risks, our first experiment intends to achieve a printing gap with a defined start and endpoint. Another focus lies on the strand geometry itself, thus the investigation also focuses on the restoration of the initially intended path height and width. The amount of material at the set start and end point indicate the change of this geometry. For additional validation of the final parameter setting, a more complex structural element is chosen. The proposed column capital in figure 6 generates a printing path with multiple gaps and will confirm the integration in the existing control system.

3.1 Parameter settings

We choose the experimental setup for the delay and lead time investigations according to figure 2. The selected example distance of 500 mm serves as a basis for all short-term interruptions that do not result in any significant material hardening within the printing nozzle. While aiming for a suitable parameter setting to bridge the illustrated printing interruption, the strand height at the shutdown and restart points x_{stop} and x_{start} must not deviate from the average values prior to the interruption. Additionally, the amount of material within the printed gap should be minimized through the correct parameters.

Four operating points are available within the experimental setup to control the concrete pump and the pinch valve. In this regard, $t_{pv,close}$ and $t_{cp,close}$ mark the shutdown points. Since closing the valve interrupts the concrete volume flow \dot{V}_{con} independently of the concrete pump status and excess pressure must be avoided, de-

coupling the two actions from each other is not sensible. Therefore, the shutdown commands are combined into Δt_{stop} , which describes the delay between the shutdown process and the arrival at the targeted printing interruption x_{stop} .

In contrast to the shutdown process, a separation of the start-up process makes sense in that the pump must first build up the concrete pressure inside the hose before the material is conveyed through the nozzle. Thus, the start-up timing of the pump $t_{cp,start}$ and the timing of the pinch valve opening $t_{pv,open}$ are set separately within the test plan. Referring to this, $\Delta t_{cp,start}$ and $\Delta t_{pv,open}$ indicate the delay to the targeted restart x_{start} .

According to design of experiment standards we chose a three level design for the two restart factors $\Delta t_{cp,start}$ and $\Delta t_{pv,open}$. Due to the machine workspace we had to omit the central point, so no non-linear relations can be obtained. Since only one parameter is required for the shutdown process, repeat tests were carried out during our investigation. The detailed parameter settings are shown in table 1. For all tests, the nozzle feed rate, which is equivalent to the printing speed, N_{feed} was set to 4.500 mm/min, the concrete volume flow was kept at 0.4 m/h and the pressurized air ran at 30 Nm/h during the printing operation.

3.2 Software implementation

Looking at potential implementations of the interruption mechanism into the printing system, it is necessary to mention the holistic approach that is used for the printing process of concrete elements at the ITE. Here, complex printing paths are programmed using the programming interface Grasshopper for Rhinoceros3d in combination with "Robots" (a plugin developed by the Bartlett School of Architecture). This combination translates a designed geometry intuitively into G-Code which will run the printing system and serves to visualize the process control for robotic fabrication. Therefore, the identified feed forward times and printing interruption commands must be implementable into G-Code for use during the robotic fabrication process.

Hence the time offset primarily determines the interrelation between the applied material, and the pump and valve actuation, the settings for Δt_{stop} , $\Delta t_{cp,start}$ and $\Delta t_{pv,open}$ are specified in ms as can be found in table 1. However, due to the sequential processing of the G-Code, no time-based output of command signals is feasible. Thus, the time intervals were changed into travelling distances Δx taking into account the nozzle feed rate. Based on these distances, additional path points were included in the printing path, which serve as trigger points for the pump and valve actuation. Due to the sequential processing of G-code, the pump and valve commands must not be implemented di-

V8	1000	75.00	2000	150.00	500	37.50

rectly as this will cause feed rate interruptions and results in an inconstant material application. Therefore user defined marcos (UMACs) are implemented in the header of each printing files. So, when passing the respective trigger points during the printing process, the specified UMACs were executed to actuate the pump and valve commands. This process is providing a constant nozzle speed and an improved material application while printing.

3.3 Printing path

In order to ensure uniform ambient conditions throughout the investigation and to minimise the influence of external factors on the concrete volume flow, all parameter settings were merged into one single printing path. The complete path is shown in figure 2a). The specimen length was set to 2.200 mm in total to ensure volume flow retrieval after the interruptions. It should be noted that the change of the printing direction does not influence the result due to the circular nozzle geometry. This means that the results from linear tests can be transferred to more complex cornering.

3.4 Data evaluation

Changing the selected parameters directly impacts the as-printed gap. This can be obtained by visual inspec-

tion of the specimens presented in figure 3b) and c. For a significant comparison of the process parameters and their influence regarding the interruption, each probe was scanned with a 2D-Laser scanner (Keyence LJ-X8400). Matching the scanner feed rate to the printing speed of 4.500 mm/min while setting the scanning frequency to 10 Hz resulted in an evaluation every 7.5 mm. Figure 3c) presents an example of the processed measurement data set from V1. Within the scan data, the start and endpoints of the specimens were defined based on strand centre points of the transition regions. The specified transition regions are shown in figure 2b) and are defined by the printed material between to specimens. Both points allowed further identification of x_{stop} and x_{start} in the scans. For subsequent evaluation, the data sets were levelled to the printing surface and the width was set to 200 mm. Thus, all data sets contain the same amount of data points.

As marked in figure 3c) the raw 3D data sets were then separated into four areas, each 200 mm in length. The pre and post stop areas were placed around the desired printing shutdown x_{stop} and were used to evaluate the usability of the Δt_{stop} values. Analogously, the pre- and post-start areas surrounding x_{start} were used to evaluate $\Delta t_{pv,open}$ and $\Delta t_{cp,start}$. The purpose of this subdivision was to analyse the amount of the deposited material. Given the initial demands of producing the gap as planned, low

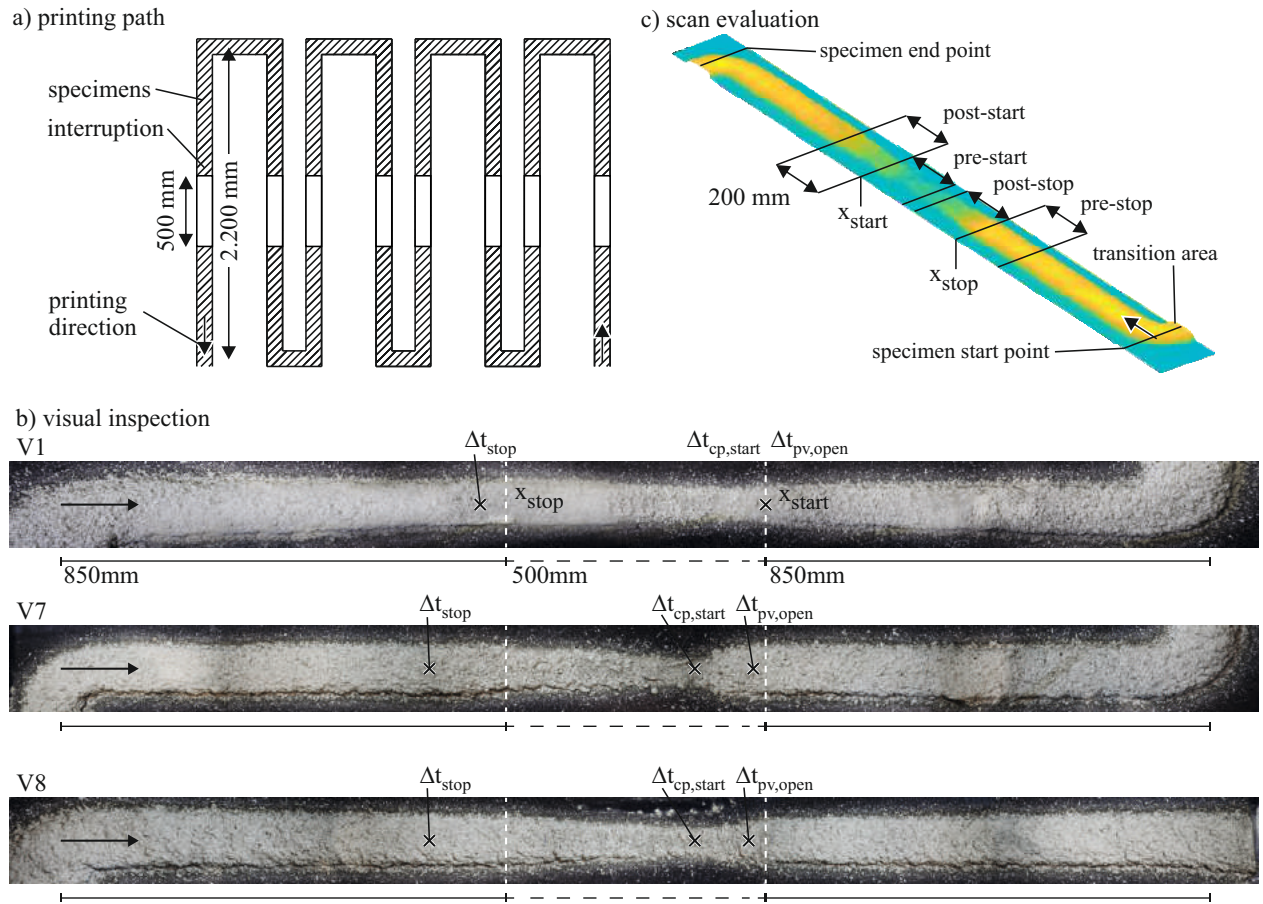

Figure 3. a) Printing path setup b) visual inspection and c) scan evaluation of the specimens

quantities of material in the post-stop and pre-start area are to be assessed as positive and low quantities in the other areas as negative. For a quantitative examination, the measured z-values in each area were accumulated. Since the scanned surfaces and the amount of data points are identical for each specimen, the comparison of the accumulated Z-values corresponds to the comparison of the amount of material. Thus, no additional volume calculation is required. The results of the height data evaluation can be seen in figure 4.

4 Results

Since the parameter settings for the investigation of Δt_{stop} were each examined twice, they were summarised for the evaluation. Figure 4a) and b) therefore show only four measuring points, each of which reflects the average value of the two specimens.

Specific evaluation of the pre-stop area in figure 4a) presents an almost constant value across all parameter settings. This confirms the constant material volume flow during the sample production. Therefore, further changes within the recorded data can be attributed to the effects of

the start-up and shutdown processes. Besides, the accumulated height value of 10^5 mm defines the target value for the post-start area.

There is no effect of the closed pinch valve on the applied material volume within the pre-stop area up to 1.000 ms lead time for Δt_{stop} . Source of this seems residual material within the nozzle, which is located on the application side of the valve and is still applied after the valve is closed.

In contrast, the accumulated height in the post stop area displays a decrease of 27 % when raising the pinch valve lead time Δt_{stop} up to 1.000 ms . Consequently, closing the pinch valve before reaching the planned printing interruption demonstrates an option to counteract the system's inertia and refrain the material from filling the gap.

Figure 4c) illustrates the results of the evaluation of the pre-start area concerning the valve reopening and the concrete pump restart. In line with the expectations, increasing the valve lead time $\Delta t_{pv,open}$ tends to raise the applied material. Since this is deposited within the printing gap, only low valve lead times for $\Delta t_{pv,open}$ can be recommended initially.

It should be noted that when low valve lead times are

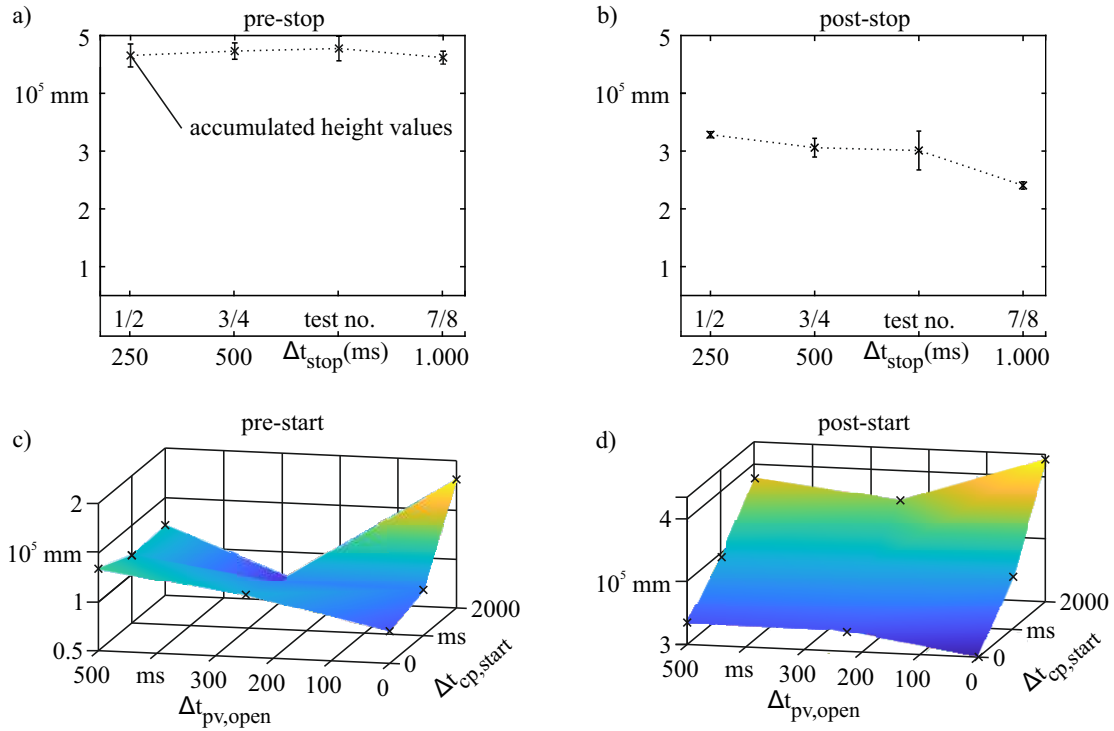

Figure 4. Accumulated height values of the scanned sample for evaluation of the sectional material quantity

combined with high pump lead times, which can be observed especially with the combination of $\Delta t_{cp,start}$ 2.000 ms and $\Delta t_{pv,open}$ 0 ms, the highest amount of material is deposited within the gap. This is due to the higher concrete pressure, which increases the material exit velocity after the valve opening resulting in a higher impact. This causes the material to shear and consequently flow into the undesirable pre-start area. Thus, lower valve lead times are unsuitable for the highest concrete pump lead time.

However, taking further into account the post start area, as presented in 4d), an increased pump lead time fosters the material quantity measured after the printing restart. This in turn leads to high contour accuracy after resuming the printing process and thus to a higher component quality.

Given the original requirement for an exact printing of the planned printing interruption, choosing a suitable value for Δt_{stop} is quite evident at 1.000 ms. However, for $\Delta t_{cp,start}$ and $\Delta t_{pv,open}$ the quotient formation according to equation 1 is necessary to determine an optimum in the opposing influences of the factors.

$$\zeta = \frac{\text{post start } [10^3 \text{ mm}]}{\text{pre start } [10^3 \text{ mm}]} \quad (1)$$

Hence, this will show a peak for minimal material in the pre-start and maximal material in the post start area. The resulting ratios are shown in figure 5. An optimal

Figure 5. Quotient of pre and post stop area

parameter setting is revealed at a pump lead time of 2.000 ms, and a valve lead time of 250 ms.

In addition, a first test of the presented approach to produce a more complex geometry was performed. A simplified column capital was manufactured to test the print interruption parameters including the automated concrete distribution. The produced component is presented in figure 6. This geometry is composed of eight strands which are combined in the center. The printing process for each layer started on the outer edge and was printed towards the center. The first 15 layers were printed horizontally

Figure 6. Column capital printed with printing interruption routine

and were the basis for the angled layers. The following layers were printed in a 30° angle to produce an overhang on the outside and to orient the layers perpendicular to the assumed force flow in the capital. Using the proposed coding it was possible to design the path planning without overlays or double printed layers. Although the overall quality of the printed geometry shows that printing interruptions are possible, post production process are still necessary to remove the lateral material overhang between the walls. The slight amount of excess material was distributed on the sides of each strand during the reorientation and dry phase of the endeffector due to material overrun. The most obvious solution to avoid this effect is to further delay the stopping time. It should be noted, however, that the increase will also causes the associated Δx_{stop} to rise further. This in return reduces the pump run time which, for short printing paths, may result in a stall of the concrete volume flow. Thus columns, beams and walls will serve as geometries for subsequent tests to analyse the minimal required path length. Given the minimum distance, additional research will focus on up-scaling and defining the maximal interruption time to consider both limits during the path planning of large-scale components.

5 Conclusion

This paper shows a method for realising and optimising short-term printing interruptions during SC3DP. Based on a systematic study, the effect of the systems' inertia could be reduced by implementing lead times for the pump and valve actuation, while avoiding nozzle clogging during the printing. Particularly 1.000 ms were embedded for the shutdown process Δt_{stop} , and 2.000 ms and 250 ms for the restart process of $\Delta c_{p,start}$ and $\Delta p_{v,open}$. A summary is given in 2.

While decreasing the material overrun by 27 %, the quantity directly after the interruption was increased by 25%. Although printing material is found in the acutal gap,

Table 2. Optimal process parameter settings

$\Delta t_{stop}(ms)$	$\Delta x_{stop}(ms)$	$\Delta t_{cp,start}(ms)$
1.000	250	18.75

this clearly shows the influence of the chosen parameters and their potential to precisely control the interruption. In particular, the position of the start and end point, as well as the shape of the resulting gap can be improved.

Evidently performing printing interruptions with SC3DP is possible and the precise application decreased the material wastage and expands the path planning possibilities for future components. For further reduction of material overrun, additional tests with increased lead times and printing idle times are scheduled.

Abstract -

The latest technological developments, especially in software, have made it possible to lower the barrier to entry for robotics, notably in fields that have typically been under-automated, like construction. Robotics in the construction industry is not new, but its acceleration has been marked in the last 10 years. This article presents the latest evolution of HAL Robotics' software, now called the *HAL Robotics Framework* alongside its associated concepts, its technical features, and its use in manufacturing and construction.

Keywords -

Framework; Robotics; Programming; CAD; Onsite; Offsite; Software; Simulation;

must be presented to, and understood, by their users alongside tools to simplify the creation of paths, simulation and communication, amongst others.

To address these requirements the *HAL Robotics Framework* is structured around four main features:

- a modelling: assembly of components required to virtually represent a robot cell.
- b programming: vendor-agnostic definition of where a machine should move, pause and trigger any events.
- c simulating: high-fidelity motion planning for one or more virtual machines to validate programs.
- d communicating: data exchange with physical, networked devices, be they robot programs being uploaded or sensor values monitored in real-time.

1 Introduction

Initially, the software was an academic initiative to simplify the programming of industrial robots for use in the teaching and research of architecture [1]. It was then developed and enhanced alongside several research projects primarily focused on the fabrication of complex elements, including concrete lattices and moulds [2], steam-bent timber [3] and hot-wire-cut foam for stereotomy studies [4], before being rewritten from the ground up from 2015 onwards to bridge the gap between R&D processes and industrialization.

This invariably led to several questions concerning the automatization of construction processes. First and foremost, what is required to have a seamless flow of data from design to fabrication? What kind of machines and mechanisms are sufficiently adaptable to various manufacturing processes, accurate and affordable enough to be appropriate for construction? And, given that robotics and programming are unlikely to be in the inherent skill-sets of architects and engineers, how can construction experts propose and experiment with new processes? With well proven economic and distribution models, easy adaptability for many processes, and a modular approach to their installation, six-axis arms, like those found in automotive factories, seemed to be a good starting point. Although flexible, these machines have constraints which

1.1 Modelling

Before programming any process a virtual representation of the robotic cell must be modelled. Typically (as shown in Figure 2) this cell model includes passive elements, such as fencing or other contextual items surrounding the robots, mechanisms that are controlled, such as robotic manipulators and positioners, process equipment, such as end-effectors or sensors, and controllers and PLCs administering all the equipment that will be programmed. We have developed software layers to help build these digital twins from the instantiation of virtual mechanisms and their controllers to the assembly of complex, bespoke, mechanical systems including the integration of these tools into the CAD environments and catalogues of prebuilt models that can be simply dropped in. These catalogues also offers basic research tools and allow sorting prebuilt mechanisms by payload, reach, names, or other criteria. This allows users to easily swap robots to find the best fit during cell specification, change or evolve processes for a new cell or test different robot brands to fit their needs.

The most complex catalogue is that of the robot controllers, each instance of which is configurable to match the options, e.g. communication protocols or language

Figure 1. Key feature categories of the *HAL Robotics Framework*

support, that are available on its physical counterpart and may be used to connect directly to it over the network. Several brands' controllers are currently supported, each of which propose subtly different implementations of similar capabilities. These option implementations are presented to users as *controller subsystems* which can be swapped to change how, among other things, a controller exports programs, uploads them to a remote controller (including authorization credentials and network details), starts or stops a running mechanism, monitors a mechanisms joint positions or I/O signals etc. As well as allowing a faithful representation of the equipment a user has at their disposal, this modular approach allows controllers to be extended and have new features added alongside manufacturers' updates without breaking existing uses or assuming that all users will invest in these latest packages. The graphical user interface (GUI) for configuring controllers from different manufacturers can be seen in Figure 3).

1.2 Program and Simulate

The prototypical workflow using the *HAL Robotics Framework* (shown in Figure 5) is built around linking process automation to CAD-based part descriptions and geometry. This approach, notably when the *HAL Robotics Framework* is integrated into CAD applications, ensures that trajectories are associative, that is to say that when the

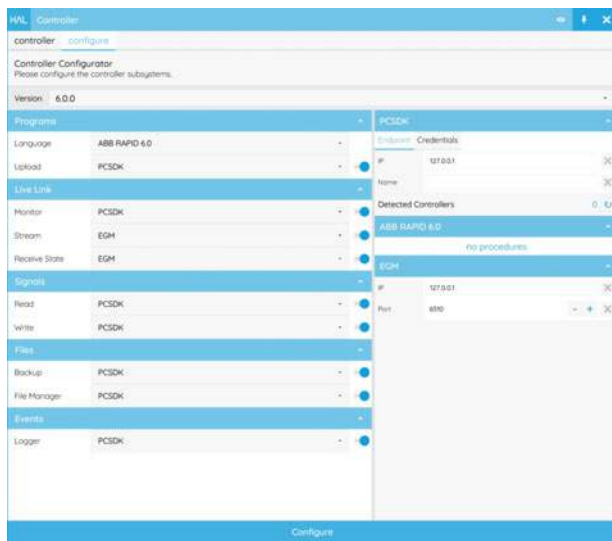

Figure 2. Core components of a model can be instantiated from catalogues of prebuilt items or manually modelled to create a digital representation of a cell ready for programming.

part is modified or moved, the trajectory will automatically adapt itself to match new revisions.

This flexible programming of toolpaths is built around *Actions*, the fundamental things a robot can do such as moving to a certain target, changing signal states or communicating with other devices like sensors, being parametrically linked to part geometry and subscribed to changes.

A sequence of *Actions* are combined into a *Procedure*. A *Procedure* can be "solved" by computing not only where a mechanism will move but *how* it will do so taking into account user-specified constraints like blends and inherent constraints like the maximum speeds and accelerations of each robot joint. From this solved state, we can run diagnoses, typically reachability of targets, collision checks, and kinematic singularities, any instances of which can be visualised help the user understand how to fix their issues (see Figure 7). These will help inform the user to optimise a robot's motion settings or even redesign a part if it cannot be processed with the given constraints, or could be fabricated more efficiently with minor modifications. This roughly follows the principles of Robot Oriented Design proposed by T. Bock [5] and expanded in Linner and Bock [6] by giving users, within their CAD environment, immediate graphical insights into how their design choices are impacting, and are impacted by, process and robot constraints. One of the major ramifications of this associative and parametric programming style is that many variants of a part can be swapped into the same *Procedure* and the robot programming is almost instantaneously updated, reducing the cost of programming additional variable parts close to nil and enabling mass customisation.

An important aspect at this stage is that all *Procedures* are "vendor-agnostic", meaning that they are not linked to any given manufacturer's language and can be translated

Figure 3. Controller subsystem configurator which allows users to change how capabilities are implemented in their virtual controller and how it may communicate with the real.

Figure 4. Procedures are associated to part geometry such that when, in this example, a hole is moved or modified, the toolpath will automatically adapt itself to the changes.

for any machine, making it possible to revise the design of a production cell, such as changing the robot(s), adding a positioner, changing the dimensions of the tool etc., all while still working on the part design.

1.3 Procedure Analysis and Debugging

Controlling a robotic manipulator, or any other mechanism, involves determining a set of appropriate joint positions such that the end effector(s) are moved to desired positions (also called "inverse kinematics") as smoothly, rapidly, and accurately as possible. This is generally termed "motion planning". To solve inverse kinematic problems, the *HAL Robotics framework* uses robust numerical approaches such as the *Jacobian pseudoinverse* [7], *damped least squares with singular value decomposition* (SVD-DLS) and *selectively damped least squares* (SDLS) [8].

These solutions are suitable for most complex mechanisms and offer real-time, adaptive control, thereby enabling the use of additional motion constraints to achieve secondary goals such as avoiding of joint limits, singularities or obstacles. The accurate modelling of robot kinematics provides users with advanced information about their real robot's behaviour. These details, such as speed, acceleration, position or torque of each joint, can be used to analyse motion behaviour and get a deeper understanding of mechanism's motion. For example, in a 3d printing process, one could examine the end effector speed to ensure it moves at a constant speed or determine that one joint's maximum speed is reached intermittently limiting end effector speed and leading to inconsistent material deposition.

A GUI dashboard and timeline, have been developed to easily represent the chronology of *Procedures*, which can often become complex particularly when dealing with multiple machines in parallel and constantly shifting between synchronous (robots moving at the same time) and asynchronous (robots moving separately or waiting for each other). The dashboard, shown in 7, also displays errors and warnings for each *Procedure* and allows the setting of "breakpoints" at which the simulation will automatically stop (useful for pinpointing the source of issues).

1.4 Linguistics, Communication and Interoperability

Once programmed *Procedures* have been validated in the virtual, they need to be executed on physical machines to undertake their processes. This is the stage at which our vendor-agnostic procedure gets converted into manufacturer-specific machine code, which can, in turn, be uploaded to the machine via an external medium like a USB key or, ideally, over a network. In the latter case we are directly connected to the controller and therefore, subject to support in the form of a *controller subsystem*, we can start to bring real-time data back from the machines which can be used to optimize process settings, evaluate tolerances, estimate energy costs, and/or we can store this data for traceability.

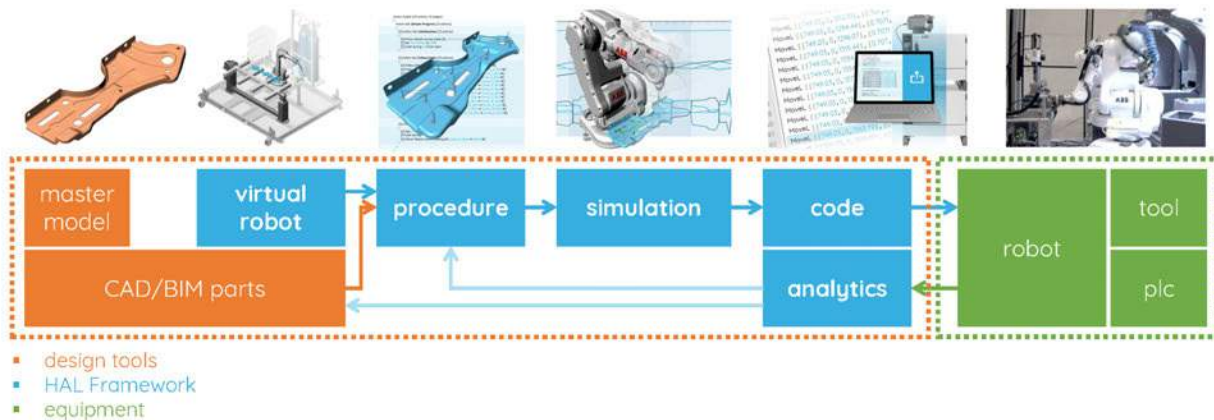

Figure 5. Typical HAL Robotics Framework workflow, from a CAD part to robotic execution and data feedback.

Figure 6. Timeline of a solved procedure showing the computed positions and speeds of each robot joint and the end effector.

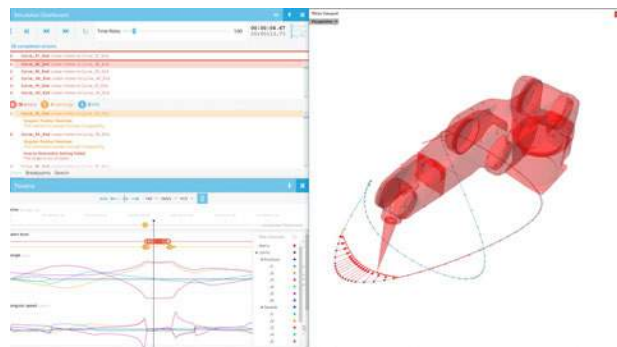

Figure 7. Dashboard showing the chronology of a Procedure alongside a robot in an error position highlighting the difference between its real and programmed toolpaths.

Adaptive Trajectories Once we can send data to a machine and read data from it then we can start to play with integrating sensors into the loop and create highly adaptive programs, combining sensed data from the real world with the digital data from the virtual world. This project at Carnegie Mellon University [3] involved steam-bending wood which, being a heterogeneous material, can't be easily simulated. An array of infra-red cameras (an OptiTrack motion capture system) and reflective markers on the wooden element calculated the current position of the real wood, compared it to the idealized digital model, and tweaked the trajectories of the two robots independently, and in real time, to create the exact shape

required.

These same principles can be used to operate a machine through human motion and gestures. In [9] and its related workshop, participants used their right hand to control the motion of a robot and gestures on their left to control I/O signals and thereby open or close a gripper to manipulate parts. Hand tracking and gesture recognition was handled by a Leap Motion and robot control through a combination of ABB's Externally Guided Motion (EGM) and custom protocols.

Embedded Software Combining this notion of one data transmission with the fact that the *HAL Robotics Framework* is lightweight and compatible with everything down to low-cost Linux hardware, means that the entire feature set of the *HAL Robotics Framework*, as well as any control logic that might be required, can be embedded within a production line or even a robot controller[10].

Figure 8. Monitoring welding data (joint positions, currents and voltages) through the HAL Robotics Framework running on a low-cost Raspberry Pi.

Figure 9. Robot following motion capture markers in 6 DoF using an OptiTrack camera array and ABB EGM.

2 Multi-process

The *HAL Robotics Framework* has been used by numerous academic, industrial and research and development institutions around the world to greatly reduce the development time of their novel manufacturing processes, including 3d printing concrete parts [11, 12], machining timber frames [13], prototyping plane components, non-destructive testing (NDT) [14] and even decorating cakes. Catering to, and receiving feedback from, this broad spectrum of processes ensured that the *HAL Robotics Framework* could handle, not only many different processes, but also multiple processes during the same *Procedure* (multi-process), greatly expanding the flexibility of these machines.

To approach multi-process programming, we start from the principle that we can use machines without knowing in advance what the users will do with them forcing the generalisation of robotic capabilities to primitives

such as motion, I/O changes and waiting. This approach clearly lacks the specificity, and simplicity, of process-dedicated software but lays a solid foundation upon which process-specific extensions can be added. These extensions, such as the slicer shown in 10, embed the semantics of process-dedicated users and variable user interfaces to cater for different skill levels in the field, reintroducing the simplicity lost by generalisation.

3D Concrete Printing 3D printing has been touted as a game-changing process but the toolpath programming and motion control required to successfully implement it, especially with robotic systems, remain obstacles to proliferation.

(a) Slicer and 3d printing

Figure 10. A 3D printing-specific extension to the HAL Robotics Framework simplifies toolpath generation for this complex process.

(a) Concreateive: industrial robotic (b) ENPC: R&D robotic 3DCP cell

Figure 11. Commercial and experimental 3D printing of concrete programmed using the HAL Robotics Framework.

HAL Robotics' software and solutions have been used to underpin groundbreaking R&D from the Democrite [11] project directly printing cementitious materials, to printing moulds in clays into which concrete can later be poured [15], all the way to enabling the creation of entirely new research departments like the Build'In co-innovation lab in Paris hosted by the École des Ponts, ParisTech, and, as 3D Concrete Printing (3DCP) has matured, so too have our solutions moving from powering pure R&D to underpinning industrial startups like XtreeE, and industrial production like Concreateive in Dubai.

Figure 12. Hindcon: milling freshly 3D printed mortar to improve tolerances change the finish.

Other interesting projects, like Hindcon or the 3D printed Truss developed at Navier's laboratory, demonstrate how 3D printing can be enhanced by combining it with other processes. In Hindcon a milling head is used in a post-printing step to change the surface finish of freshly printed mortar. For the spatial truss, on the other hand, the robot is first used to hot-wire cut (HWC) foam blocks which are then used as a formwork for the deposition of cementitious mortar by the same robot with a printing head now mounted. This process is explained in detail in [12].

Figure 13. A 3DCP spatial truss is built up by extruding onto HWC foam blocks.

Through collaboration with industrial partners, standardised tools can be tuned to meet the exact requirements of their process or operators. In 10 we see a slicer, derived from HAL Robotics' standard slicer which handles vase mode, infill patterns, concentric walls and most other industry standard features, tailored to the requirements of their engineers and operators leaving a

reduced set of parameters for their operators to use and some custom algorithms behind the scenes to fill in the gaps. This slicer retains the fully parametric approach to toolpath generation and the ability to take robotic constraints into consideration during the slicing, retaining rich metadata about the process for easy manipulation of the results, from the standard slicer.

Woodworking Through collaboration with LignoCAM, experts in woodworking software, HAL Robotics have had the opportunity to develop tools in wood machining for the manufacture of structural and architectural elements. To ensure ease of use for experts in the field, this included interoperability between the robotics, including all of their constraints, and trade-specific operations, CAD environments and standard formats (like BTL) to which carpenters are accustomed. Combining this with experience testing innovative processes, such as those carried out with the Navier laboratory [13], the know-how of this sector, and its robust ecosystem of tools, can be integrated into the *HAL Robotics Framework*.

On-site Robotics Moving from factories to construction sites brings a new set of opportunities and challenges which have been explored through projects like COSCR [16] which included work on:

- Integration into CAD/BIM software, allowing users to design and optimize work with integrated manufacturing constraints and to generate machine code directly from their model.
- Mobile platform enabling autonomous movement and access to height, via a hydraulic mast, between

Figure 15. COSCR can autonomously navigate construction sites and execute tasks as well as being controlled manually using various intuitive input interfaces.

tasks with sufficient accuracy to carry out drilling tasks.

- Automated simultaneous localization and mapping of the construction site to enable autonomous navigation and reuse of those sensors to detect humans. Maps from measurements via the moving robot, correlated with CAD drawings, determine where tasks need to be carried out.
- Ensuring safe human/robot interaction.
- Access to multiple tools increasing flexibility of the platform.

3 Conclusion: Towards Robot Task Orchestration

With the ability to run or connect to multiple cells or machines simultaneously, questions naturally arise about how best to distribute work to these cells automatically. This problem, referred to as "orchestration" in computing, could be distributing work between similar robots on the same construction site based on proximity and availability or between different factories around the world based on logistics and certifications. An orchestrator would optimize the utilization of multiple cells to minimize downtime, increase time in use, adapt to mechanical failures and improve the overall efficiency of multi-cell factories. HAL Robotics are working with Konica Minolta to extend their Platform as a Service (PaaS) orchestrator DCI to translate the advantages it provides for computational resources to mechanical devices. This means that robots can offload computation to more powerful devices, can communicate their status to a central orchestrator, and any faults can be compensated by other robots with the same capabilities. The classification

of capabilities is not a metric that is included in any existing container orchestrators and can be extremely varied including process-specific parameters e.g drilling with certain bit sizes, end shapes and compatible materials, or imaging with specific colour spaces, resolutions and exposure settings. This is further complexified as each capability translates into one or more applications that can be undertaken e.g. 2D imaging could be used for inspection, QA, and object detection. This collaboration will, therefore, create a new, extensible orchestrator that is able to incorporate the complexities and varieties of robotic capabilities for task distribution.

HAL Robotics have supported the development of many processes and projects over the past several years and will continue to do so by refining the tools made available to users and accelerate the deployment of R&D into industrial applications with packaged extensions to the *HAL Robotics Framework*. HAL Robotics will use their experience in manufacturing and construction to help advance both on and off site construction and fabrication from design all the way through to installation. The complexities and variety of requirements in construction make it the perfect sector for experimenting with advanced robotics and putting our developments to the test.

Abstract

Thinned wood, which is obtained as a result of pruning and thinning thick forests, is not widely used because of its small size and diameter. Thinned wood is not often used because conventional machines cannot leave enough cross-section for building materials. However, using computer vision technology to measure the shape of the wood and a fabrication machine that can adapt to the measurement results makes it possible to process the wood to retain a large cross-section and use it for construction. The developed workflow can be divided into three parts: 1) a database to handle wood inventory and shape data, 2) design of the desired shape, and 3) machining. Although it is difficult to reposition a discrete shape of raw wood during processing with the desired accuracy, the proposed method achieves repositioning of the wood with high accuracy. This research broadens the scope of raw wood processing and helps to utilize wood that was previously discarded and demonstrates a new processing method for irregular shapes.

1 Introduction

Thinned wood is wood generated in the process of forest management, such as pruning and thinning. Because the wood from thinning is small in diameter or crooked, it is not easy to utilize and much of it is left in the forest and overstocked. Overstocking of thinned wood occurs worldwide; it increases the risk of tree disease, insect damage, and wildfires [1]. Therefore, some of the thinned wood is being used for engineered wood and biomass; however, the market value is so low that it is often not worth the cost of recovery. The number of forest businesses that carry out pruning and thinning is decreasing because of the high cost and lack of commensurate income, and some forests are left unattended. In Japan, measures such as offering subsidies

to tree pruning companies have been implemented, but this problem has not yet been solved [2]. Construction materials account for a large percentage of the intended use of wood [3]. If small, thinned wood could be used as building material, the use of such wood could be promoted. Wood from thinning is not used because of its small diameter. Logs used for construction are usually cut into rectangular cross sections. When small thinned wood is processed into a rectangular cross section like standard lumber, it becomes too small to be used as a building material. However, three-dimensional (3D) CAD is now widely available, and it is possible to design posts and beams that do not have rectangular cross-sections. If the design retains as much of the cross-section of the thinned wood as possible, it will be sufficiently strong to be used as a building material. The processing of raw wood directly into the desired shape is good for the environment because there is no wasteful process of making standard lumber and then processing it, and the volume of cutting can be reduced. In this study, machining raw wood was realized by computer vision, shape-based design planning, and a machining machine with flexible motion. A staircase was made of raw wood as a practical application of the workflow. The parts that make up this staircase have parts to be machined on both ends and sides, making it difficult to machine without repositioning. However, machining an irregular surface by repositioning the material will cause a decrease in accuracy. A method was developed to estimate the position and orientation of the material to avoid the loss of accuracy.

2 Related Works

Design tools such as 3D CAD and arm-shaped robots have popularized fabrication projects that use wood to create complex shapes [4,5,6]. This high-mix, low-volume production is often fabricated from homogeneous wood products for process reasons. When dealing with non-homogeneous materials, the process is more difficult because the material needs to be handled more carefully than when dealing with homogeneous materials. However, if it can be processed from raw wood into the

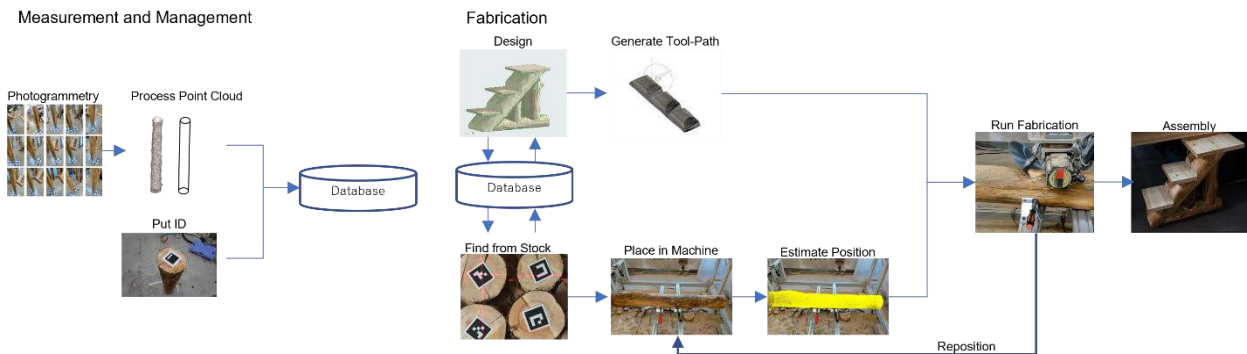

Figure 1 Workflow for registering wood measurement data and management IDs in the database (Left). Workflow for designing a staircase using raw wood to processing (Right).

desired shape without making it a homogeneous material, only one processing step is required, and cutting waste can be reduced. To process raw wood with an uneven surface, it is necessary to obtain raw wood shape data. Techniques such as laser scanners and photogrammetry have been used to measure shape.

The laser scanner measures the shape of the object using a system called time of flight (ToF), which measures the distance based on the time it takes for light to fly back from the measured object to the scanner. Siekański developed a system that can accurately acquire the shape of a log using six laser scanners [7]. Some projects use laser scanners to measure and process the shape of raw woods [8,9].

Photogrammetry is a technique used to obtain the shape of an object in images from multiple viewpoints. It can be performed with an ordinary camera, thus making the measurement relatively cost-efficient. Photogrammetry is also used in forked log processing projects because it is easy to increase the number of measurement positions needed to measure complex shapes [10,11].

In a project where raw wood is to be machined, the location of the shape data measured for design and the location of the raw wood when it is to be machined must be carefully handled. The simplest way to do this is to recreate the posture of the log at the time the shape data needed for the design was obtained.

This method is reliable, but it cannot change the fixed position; therefore, it can only be used in limited situations. To be able to change the posture, one solution is to add a fixture that can be tracked using optitrack [8] or Aruco markers [12]. These methods require the device to be attached to the wood, which may interfere with the fixing and cutting processes.

AR markers have a mechanism to estimate the position and orientation of the object from the features of the marker. In this study, focusing on the texture of a tree, a method to estimate the position and orientation of wood

like AR markers using the texture of the tree was investigated. Kei developed a method to obtain the position and orientation of a camera and an object by mapping image features to 3D data [13]. By applying this mechanism, the position and orientation of the raw wood can be obtained using a single camera.

3 Method

3.1 Machine

Figure 1 shows the workflow for log processing using the position and orientation estimation technique proposed in this study. To investigate the usefulness of the proposed workflow, a demonstration of the staircase fabrication was performed using this workflow. However, the proposed workflow for processing can be applied to both arm- and gantry-type machines. In this study, a self-made gantry-type five-axis machine was used for the fabrication. It has three main spindles and two rotary axes; the XYZ axes have a range of 1100 mm, 1100 mm, and 400 mm, respectively, and the rotary axes have a range of motion of 360° around the z-axis and 180° around the y-axis (Figure 2). The main axis is an auto tool change (ATC) motor so that the tool can be changed. The tools selected for this project were straight bits, dovetail bits, and circular saws. (Figure 3). Because the position and orientation estimation technique requires a camera, this machine is equipped with a camera. The camera must measure the position of wood in the machine coordinate system to use it for position and orientation estimation. The camera position is measured by solving the perspective-n-points (PnP) problem [14], which is a method for obtaining the camera coordinates by matching the UV coordinates with the 3D coordinates. We created 26 combinations of UV coordinates and 3D coordinates in the experiment and solved the PnP problem to obtain the camera coordinates (Figure 4).

Figure 4 Tip of the tool, which is the reference point on the 2D side needed to solve the PnP (perspective-n-points) problem (Left). The coordinate values of the tool tip, which is the reference point on the 3D side (Right).

3.2 Database

The database manages raw wood shape data, length, diameter, management ID, and feature point information mapped to the 3D data, which were obtained by photogrammetry. For photogrammetry, OpenMVG and Colmap were used, which can acquire not only 3D data but also the position of the camera that captured the picture. Photogrammetry, by itself, does not provide an accurate scale. Conversely, using the Aruco Board, the camera position can be obtained at a relatively accurate scale (Figure 5). In this experiment, by matching the distance between cameras obtained by photogrammetry to the distance between cameras obtained by the Aruco

Board, shape data were obtained at an actual scale. In addition, photogrammetry generates 3D maps of feature points during the process of creating 3D data. The 3D data of the feature points were stored in a database for use in estimating the position and orientation of the raw wood before processing. Photogrammetry includes not only the log but also the walls and the floor for processing reasons, but because the log is on the Aruco board, we trimmed the data to include only the top of the Aruco board, and the data of only logs was created automatically. The diameter and length of raw wood were obtained from shape data using Ransac Cylind, which was implemented in PCL. Aruco markers were placed at the cut end of the wood to link the acquired data to the logs. In this way, even if there is considerable stock, the camera can quickly find the raw wood to be used (Figure 6).

Figure 5 One of the photos for photogrammetry with the log on the Aruco Board (Left). Shape of the raw wood and the position and orientation of the camera acquired by photogrammetry (Right).

Figure 6 Application that finds logs to be used by Aruco Marker

3.3 Design

In the early stages of the design, a cylinder was used to study the shape. Once the shape is approximately determined, the diameter and length of the cylinder are used as inputs, and the appropriate wood is output from the database. The output wood shape data were reflected in the data designed with the cylinder. This application was developed as an add-on for ArchiCAD.

The staircase parts are designed to have joints in three directions on the sides and at the ends; hence, they need to be repositioned during machining (Figure 7,8,9).

Figure 7 Staircase designed with cylinders (Left). Staircase with cylinders replaced by the shape of a raw wood (Right).

Figure 8 Design of diagonally placed components in the staircase.

Figure 9 Enlarged view of the joint section.

3.4 Machining

3.4.1 CAM

The machining data is created in Fusion360; however, there is no function to generate the chip saw path. Hence, a plug-in was developed to generate the path for chip saw machining and to generate the machining path (Figure 10). The machining path was generated using the data designed in Section 3.3. The coordinate system used to generate the path matches the coordinate system of the raw wood shape data. Because the shape data of the raw wood are very uneven, a large distance is set for evacuation. This prevents unexpected contact.

Figure 10 Plug-in to generate processing paths for chip-saw

3.4.2 Position and orientation estimation

The method of estimating the position and orientation after fixation can simplify the fixation tools. In this experiment, only two toggle vises were used; no special jigs were used. The estimation procedure involves taking a picture of the raw wood with the camera attached as discussed in Section 3.1 after fixing it and inputting it into the estimation application. The estimation application extracts feature points from the image and matches them with the image features with 3D positions of the log to be processed in the database. By solving the PnP problem with a combination of the UV coordinates of the matched input image features and the 3D coordinates of the database, the 3D data of the raw wood and the positional relationship of the camera are output. Because the position of the camera in the machine coordinate system was obtained in Section 3.1, it is possible to derive the position of the raw wood in the machine coordinate system. The results are presented in Figure. 11,12.

Figure11 Images taken from a camera installed in a processing machine and overlaid with the feature points used for position and orientation estimation. From top to bottom: before processing, once repositioned, twice, and three times repositioned.

Figure 12 Images taken from a machine with shape data overlaid according to the estimated position and orientation. From top to bottom: before processing, once repositioned, twice, and three times repositioned

3.4.3 Machining

Because the machining path generated in Section 3.4.1 is associated with the data of the original raw wood, the coordinate transformation is performed according to the position of the wood obtained in Section 3.4.2. As discussed in Section 3.3, this shape cannot be machined without repositioning. After machining, it was repositioned, the estimation was redone using the system in Section 3.4.2, and machining was repeated.

This position and orientation estimation method using image features loses its accuracy as it is machined and loses its original surface. Therefore, in this case, the order of machining was such that the uncut area was mostly in the direction of the camera. As a result, it was possible to estimate the position and orientation even after three repositioning.

4 Conclusion

Because the position and orientation estimation was realized without the use of any specialized jig, the replacement in the log processing was simplified. It is necessary to consider the order of processing because processing reduces the number of feature points to be referenced, and the accuracy of the estimation decreases. Compared to methods that require equipment such as the Aruco Marker, this method can reference the entire shape and is, therefore, more robust to occlusions.

One of the disadvantages of this workflow is that people must make decisions about fixing and rearranging

materials. Owing to this drawback, full automation is difficult. However, as the repositioning of the materials, which was difficult in the past with fabrication using raw wood, has been realized, the amount of reworking in the workflow has been greatly reduced compared to the previous methods.

The applicability of the workflow proposed in this paper is not limited to raw wood; it can be adapted to all materials for which image features can be acquired and photogrammetry can be performed. It can also be said that the proposed workflow has a wide range of applications and is not limited to the processing machine used in this study, as long as it is capable of position control. In the future, we will conduct experiments on larger logs that are closer to the architectural scale.

Abstract -

Safely waking up a robot at an unknown location and subsequent autonomous operation are key requirements for on-site construction robots. In this regard, single-shot global localization in a known map is a challenging problem due to incomplete observations of the environment and sensor obstructions by unmapped clutter. In this work, we address global localization of sparse multi-beam LiDAR measurements in a 3D mesh building model, a typical setup for construction robots. Our solution extracts and summarizes planes from the LiDAR scan and matches them to the building mesh. We evaluate different options for the registration problem, and evaluate the system on simulated and real-world datasets. The best performing system uses a combination of the Randomized Hough Transform (RHT) and a modified version of the Plane Registration based on a Unit Sphere (PRRUS) algorithm. For sparse and noisy robotic sensors, our system outperforms contemporary systems like GoICP by a large margin.

Keywords -

Construction Robotics; Plane Extraction/Matching; Global Localization

1 Introduction

Localisation in 3D building models with onboard sensors is a necessary skill for autonomous construction robots, and it finds application even outside of construction tasks e.g. for indoor service robots. In this work, we consider a particular part of the localisation task, the robot wake-up problem: A robot has to find its location in a map without any prior knowledge, e.g. because its localisation routines diverged or it was just switched on. While it may be safe for a small household robot to blindly explore and risk collisions while performing the localization, this is too dangerous for e.g. heavy construction robots. Ideally, these could perform one-shot global localization at the location of wake-up. This is a difficult problem as the robot may only partially observe the environment and have incomplete information in its map, e.g. the building model only represent the raw state of a environment without equipment, temporary structures, or people. Fortunately, it is sufficient to find an approximate guess of the actual robot pose in a global map. Local methods (that

require such an initial guess) then enable fine registration.

In this paper we consider the problem of 3D global localization in meshes, which is a common representation for buildings in architecture and can be easily and automatically created from ubiquitous 2D floor plans. However, they do not contain any visual information, ruling out visual global localization such as [1], and also generally do not contain the necessary information for semantic localization methods [2]. Better suited for the presented problem are methods based on 3D geometry [3, 4, 5]. Unfortunately, as these were designed for localization on robot maps instead of building meshes, we found that they do not gracefully account for data mismatches due to clutter, have long processing times, or are prone to converge to (wrong) local minima. We investigate a solution to localize sparse LiDAR scans in meshes using a plane extraction and matching algorithm. We propose and evaluate different methods for the individual components of such a localization system, and show its superior performance against state-of-the-art methods operating on point clouds [3] and volumetric features [5]. Our experiments highlight in particular the difficulties of on-board sensors like sparse LiDARs, as opposed to e.g. dense 3D scanners used in surveying, and show a need to use specific methods for such sensors. Overall, we present the following contributions:

- Heterogeneous global localization system to localize sparse and noisy 3D point clouds in 3D mesh models
- A modified version of the PRRUS algorithm described in [6], which does not maximize the best alignment of two sets of planes by checking all possible assignments, but assigns three orthogonal planes in the scan to the map planes and checks this assignment for consistency
- An extensive ablation study of our design choices on simulated and real-world data

2 Related Work

The problem of globally localizing between 3D data is well studied in literature. Existing approaches can be categorised into local descriptor-based approaches, Iterative Closest Point Algorithm (ICP)-based approaches, Neural Network-based, object-based, and topological approaches, e.g., using plane-matching.

2.1 Registration based on Local Descriptors

Methods facilitating local descriptors typically aim to extract features of selected keypoints from point clouds to form correspondences and estimate transformations [7]. This is inspired by the 2D approach well studied in image-based place recognition, using local descriptors such as SIFT, SURF, FREAK, BRISK, BRIEF and ORB descriptors [1]. 3D approaches are e.g. (I)FSD, FPFH and (I-)SHOT, forming compact volumetric descriptors. However, these features perform best on dense point clouds and only to a limited extent on sparse point clouds [8]. The back-end for calculating the relative transformations is typically based on Random Sample Consensus (RANSAC) or defined as a cost minimization problem [4, 9, 10].

2.2 Iterative Closest Point Algorithms

Numerous variants of ICP exist for the local refinement of a localization given a good initial guess [11]. Furthermore, several extensions were proposed to apply the ICP algorithm to global localization. Fitzgibbon [12] use the Levenberg-Marquardt [13] optimizer to escape local minima which are the primary source of ICP failing on arbitrary global localization tasks. Boehnke and Otásteanu [14] perform a coarse-to-fine alignment to find a good prior for ICP. WP-ICP [15] pre-processes the raw data into sets of corner and surface points, which are aligned separately. GoICP [3], which we evaluate in our experiments, uses a branch-and-bound scheme to divide the space of all transformations along upper and lower bounds [3]. It also guarantees the finding of a global minimum given sufficiently long run-times.

2.3 Neural Networks in Registration

Ratz et al. [16] train a 3D Convolutional Neural Network (CNN) to globally localize sparse 3D LiDAR scans in dense point cloud maps. In general, trained descriptors or matchers may lead to strong dependence on the training data, with unpredictable behaviour outside of their trained domain. Scan2CAD [17] uses a CNN to match candidate keypoints between RGB-D scans and meshes.

2.4 Object-based Registration

Several object-based methods use registration of meshes for localisation. Feng et al. [18] match and align objects with a database of class-representative object meshes, but require multiple views. Further works match line segments extracted from a scan. He and Hirose [19] use information about the geometric relations between lines in an interpretation tree for matching, whereas Micusik and Wildenauer [20] match known structures of lines with known structures using efficient matching procedures. Wang et al.

developed a long-range localization procedure specifically for a shopping centers using names of visible stores [21].

2.5 Plane Extraction and Matching

Another approach involves the extraction of planes and the calculation of the relative transformation between the data by plane matching. To extract planes from a scan, [22] use a 3 dimensional version of the Hough Transformation. The authors also introduce various designs for the accumulator, which is crucial for the quality of the plane extraction. Fernández-Moral et al. [10] and Pathak et al. [6] use a region growing algorithm for the same task. Plane Sweeping [23], derives a transformation by constructing an axis of rotation through randomly selected points and generating a histogram from it. After extracting the planes, they are then interpreted by e.g. detecting and reconstructing openings [24], calculating plane features [10] or labeling occluded regions on the wall [25] to obtain a more descriptive representation of the planes. Fernández-Moral et al. [10] then construct a graph from the planes and the relative distances between two planes and match subgraphs with the help of a cost function.

We take inspiration from these works to develop a complete pipeline that includes plane extraction from the scan and matching to the mesh of the building model.

3 Method

The presented system (Fig. 1) localises sparse 3D LiDAR scans in 3D building mesh models. In the following, we describe how the LiDAR scan is preprocessed, planes are extracted from both the building mesh and the scan, subsequently matched to find a global localisation, which can finally be refined by local ICP based registration.

3.1 Point cloud filtering

LiDAR data from real environments is subject to different kinds of noise and outliers. We apply a voxel centroid filter that yields even density of the LiDAR scans, by voxelizing data in a fixed grid and merging points within each voxel into the centroid of all contained points.

3.2 Plane Extraction

Extracting the planes from the 3D mesh model is straightforward, i.e., merging neighbouring mesh cells based on parallel surface normals. However, for sparse 3D LiDAR scans, it remains a challenging problem. Due to the sparseness of the scans, the scene can no longer be completely reconstructed, which also makes it difficult to filter out clutter and noise. We evaluate different options, i.e., RANSAC-based [27], region growing-based [28], and

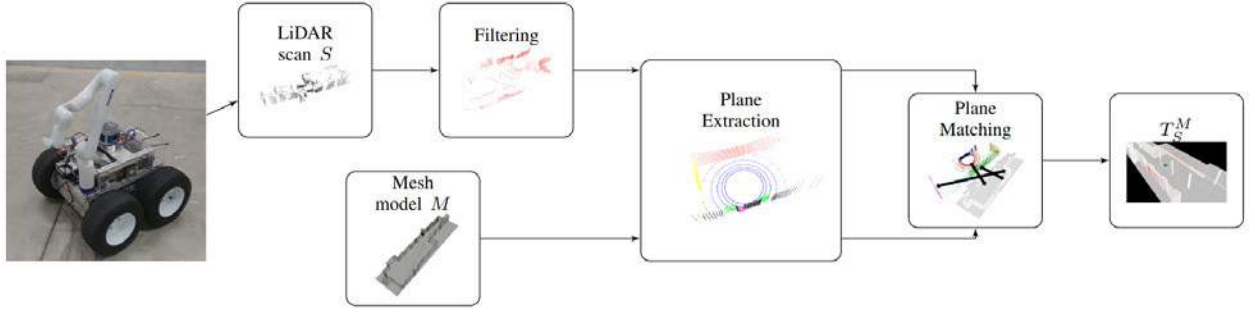

Figure 1. Software system overview of the global localization system: First the raw LiDAR scan input and mesh model are preprocessed in a filtering step and a mesh summarization respectively. On both data, planes are extracted using RHT, and consequently matched. Using the correct assignments, the system outputs the transformation between scan and model for the real robot [26].

RHT-based plane segmentation [22]. Our final choice is RHT, we therefore only briefly describe the other options.

In RANSAC-based plane extraction, hypotheses about the planes contained in the scan are made by considering only a small subset of the points and calculating the plane parameters from this. These are then checked for consistency with the remaining points in the scan. Several iterations are carried out and finally the solution with the most inliers returned. The run-time depends on the size of the considered subset that is used to derive the hypothesis, the inlier ratio and the number of LiDAR points [29].

Region growing is stated to show low sensitivity to noise [28], and is therefore an attractive option for the considered problem. Seed regions are determined, which are then checked for local coplanarity, e.g., by using RANSAC or areas of low local curvature evaluation. Then, points in the neighbourhood of the considered subset of LiDAR data points are checked for their association to the corresponding plane and added to the current subset as further plane inlier points. Efficient implementations facilitate a kd-tree for nearest neighbor search [28]. Planes can be further regularized comparing the calculated parameters of the detected planes to correct the found parameters towards parallelism, orthogonality or coplanarity.

RHT is a subtype of the 3D Hough Transformation and is characterized by single data points voting for single geometric primitives (in our case planes) instead of voting for all. Amongst different Hough Transformation variants, RHT is a good trade off for high efficiency [22].

3.2.1 RHT Voting Phase

RHT randomly samples three points p_i $i \in \{1,2,3\}$ from the point cloud and checks for their proximity. This proximity metric prevents detection of wrong planes lying crosswise in space. The plane defined by these three points is then found as

$$n_{plane} = \frac{(p_2 - p_1) \times (p_3 - p_1)}{|(p_2 - p_1) \times (p_3 - p_1)|} \quad (1)$$

The norm in the denominator is used to filter out sets of three points arranged on a line. Next, the plane parameters in 3D Hough space $\rho \in \mathbb{R}_{\geq 0}$, pitch $\psi \in [-\pi, \pi)$ and yaw $\theta \in [0, 2\pi)$ are determined. If the scalar product $p_1 \cdot n_{plane}$ is negative, the plane normal is flipped before calculation of θ and ψ . Votes for plane parameters are collected from the samples into an accumulator. The accumulator describes an arrangement of discrete bins, each of which represents a point in the 3D Hough space. After the plane parameters of the given sample p_1, p_2, p_3 have been determined, the bin representing the closest value in 3D Hough space is selected and its vote is incremented. Then, the next voting cycle starts with sampling three points. Since many points are discarded due to the requirements of the sampled points, good plane extraction results require a high number of voting cycles.

3.2.2 RHT Evaluation Phase

After several voting cycles, the bins with highest voting scores are selected from the accumulator. We assume a uniform distribution of reference points, therefore parameters associated with these bins correspond to the most dominant planes. We iteratively perform RHT, removing already detected planes, enabling detection of less dominant planes in subsequent iterations. Due to noisy LiDAR scans it may happen that reference points from the same plane can be assigned to different bins with similar parameters. Therefore, the same plane may be detected several times. To prevent this, a Non-Maxima Suppression is implemented, which is applied to the bins of the maximum values and their neighbors. The neighborhood of a bin A is defined as all bins B with $\max\{|\rho_A - \rho_B|, |\theta_A - \theta_B|, |\psi_A - \psi_B|\} < k$. Votes in the neighborhood are credited to the bin under consideration.

3.2.3 RHT Accumulator Design

Choice of the accumulator has a large effect on the plane detection performance due to the different quantizations of

the 3D Hough space. This choice is largely influenced by the LiDAR scan characteristics and the specific point sampling pattern. Here, we consider array and ball accumulator [22]. While array accumulators are easy to implement, they come with the downside of largely differently sized bins. Especially small bins at the poles lead to fragmented plane segmentation in θ , however, non-maximum suppression can reduce this effect. The ball accumulator on the other side counteracts this effect by applying a binning that couples θ and ψ resolution, according to:

$$\theta'_{\psi_i} = \frac{\max_{\psi} U(\psi)}{U(\psi_i)} \cdot \frac{1}{N_{\theta}} = \frac{1}{N_{\theta} \cdot \cos(\psi_i)} \quad (2)$$

where $U(\psi)$ is the accumulator circumference for a specific ψ and N_{θ} the number of bins of a comparable array accumulator in the θ -direction.

3.3 Plane Matching

After plane extraction, the extracted two sets of planes are matched. The algorithm developed in this paper is inspired by PRRUS [6] which aims to identify the geometrically most consistent assignment between two sets of planes. Our approach differs from the original PRRUS, i.e. restricting the plane assignments by a set of rules.

3.3.1 Assignments Generation

To generate the initial set of candidates, groups of planes are gathered from the model and the scan. These groups consist of three planes with approximately orthogonal normals. Then all possible combinations between the groups of the scan and those of the model are formed. Since the direction of the normals can be ambiguous, we also combine all (6) possible permutations of the groups. If no assignments of two groups of orthogonal planes are found, the algorithm fails to find the exact pose and terminates with a corresponding message.

3.3.2 Calculation and Consistency of Rotations

The set of candidates obtained from the previous step is further reduced by consistency checks with regard to rotational alignment. The rotation is determined by two scan plane normals and the corresponding model plane normals. This problem is known as Wahba's problem. Solving this problem generally requires matrix inversion, but since we only consider two vector pairs the problem can be solved efficiently [30]. We introduce the convention that plane normals in the plane extraction and the map planes point outwards with respect to the robot pose. Therefore, we check for consistency of the rotation determined above with the third plane normal of the group by rotating the third normal from the scan group $n_{scan,3}$. If $n_{scan,3} \cdot n_{map,3} > \delta$, the rotation aligns $n_{scan,3}$ well

with its counterpart $n_{map,3}$. Otherwise, the assignment is rejected.

3.3.3 Calculation of the Translation

Once a valid assignment and rotation between three orthogonal planes of scan and map has been found, the translation can be determined. The rotated scan planes are approximately parallel to those in the map. Thus, we find the translation as the mean distance of the plane centroids c_{map} , c_{scan} as $(c_{map} - c_{scan}) \cdot n_{map}$.

3.3.4 Cost function

After determining the transformation between scan and model, we calculate a cost of the assignment. For this purpose, the translation error $(c_{map} - c_{scan}) \cdot n_{map}$ between all scan and map planes is considered. We match planes between scan and map by the minimum error. If no corresponding model plane is found for a scan plane, its translation error is set to a fixed penalty. Finally, all errors of the individual scan planes are summarized into the overall assignment cost C_A (Fig. 2 and Fig. 3).

$$\begin{aligned} &\text{Initialize } C_A = 0, \delta = 0.8, \text{penalty} = 20 \text{ m} \\ &\text{for } i \in 1, \dots, N_{scan} : C_A += \\ &\quad \begin{cases} \min_{j \in I_i} | (c_{scan,i} - c_{map,j}) \cdot n_{map,j} |, & \text{if } |I_i| > 0 \\ \text{penalty}, & \text{else} \end{cases} \end{aligned} \quad (3)$$

Figure 2. Correct
 C_A : 0.3 m

Figure 3. Incorrect
 C_A : 14.5 m

The values of δ and penalty were chosen based on a series of experiments. I_i is the set of all map planes j which have a similar plane normal to scan plane i (i.e. as in 3.3.2) and on which the projection of $c_{scan,i}$ is within the known boundaries, except for i in the group of 3 reference planes that were used to determine the transformation and which therefore have a well-defined corresponding map plane. Finally, the algorithm outputs the transformation with the lowest cost. As the alignment from the plane matching phase is calculated based on groups of 3 planes and does not optimize over all the data available, the transformation yielded from our PRRUS variant can be further refined by ICP alignment after the global localisation.

4 Evaluation

We perform multiple experiments to validate the method for single-shot global localization. An ablation study of the presented algorithm on simulated data in several different environments validates our design choices. Finally, we

quantitatively and qualitatively evaluate the system in real-world experiments on a mobile robotic platform.

4.1 Experimental data

For quantitative evaluation, we generate simulated LiDAR data of various configuration. The model data is taken from real-world 3D building mesh models, i.e., a large parking garage of $\sim 62 \times 16 \times 3$ m (Fig. 4(a)), an open-plan office space of $\sim 14 \times 14 \times 3$ m (Fig. 4(b)), a utility building of $\sim 13 \times 4 \times 3$ m (Fig. 4(c)) and a synthetic object called *Construct* which consists of three stacked cuboids of $\sim 18 \times 9 \times 9$ m (Fig. 4(d)). The simulated LiDAR data is generated by sampling poses inside these models and then ray casting beams from this pose in different patterns analogous to real multi-beam sensors, e.g., a 16 beam LiDAR with an opening angle of 30 degrees. Since the LiDAR used in the real measurements had an inaccuracy in the range-bearing of ± 2 cm, we add Gaussian noise with a standard deviation of 0.01 in the same direction. Furthermore, we gathered data with a real robotic platform [26] equipped with a Robosense RS-16 LiDAR sensor. The robot is deployed in the parking garage and the utility building. The ground-truth position of the robot is tracked with a Multistation providing mm-accurate measurements. Note that it is not possible to resolve the ground-truth orientation of the robot with this sensor. In contrast to the simulated environments, the real data also contains both small and large clutter objects and dynamic obstacles that are not mapped in the models.

Figure 4. Overview of the building models.

4.2 Plane Extraction

Firstly, we perform an ablation study on the plane extraction method. Using a semi-automatic method, we create a data set of 30 simulated 16 beam LiDAR scans taken

Figure 5. Comparison of different plane extraction methods on simulated data (top row) and real LiDAR scans (bottom row).

method	clutter-free	cluttered	time [ms]
RANSAC	0.87	0.76	3.0625
RG	0.84	0.76	96.9688

from different positions in the garage map and a matching ground truth regarding the contained planes. In addition, three pillars and a mesh of an excavator are added in another set of experiments to assess the effects of clutter on the different methods. We compare array and ball accumulator for the RHT. Alternatively, we test a RANSAC-based approach and a region growing algorithm [28]. Quantitative results are reported in Table 1 and examples in Fig. 5. The fractional numbers correspond to the average of the correctly detected planes divided by the planes contained in the individual LiDAR scans. The results suggest that PCL RANSAC is the fastest algorithm. However, the measurements indicate that it reacts more sensitively to clutter and Fig. 5 also reveals bad performance on the real data. CGAL Region Growing produces better results in real data, but the method also finds fewer planes in case that clutter artifacts were not removed. Our experiments on the full localisation pipeline will show that RHT yield the best results on real data due to lower sensitivity to noise and clutter. Similar observations were reported in [22].

4.3 Full Localisation

We compare the different localisation methods based on accuracy A and true positive rate TPR of the yielded poses. We count as true positives all poses within 2 meters translation and 20 degrees rotation of the ground truth, if orientation is available. Higher errors are counted as false negatives and those scans where the algorithm returned that it cannot find a corresponding transformation are counted as false positives.

$$TPR = \frac{TP}{TP + FN} \quad A = \frac{TP + TN(=0)}{TP + TN(=0) + FP + FN} \quad (4)$$

Table 2. Localisation results (TPR / A) with different simulated LiDARs. LiDARs are simulated with different beam numbers and in either uniformly random (rand) sampled poses or poses simulating a ground robot (gr).

4.3.1 Simulated Data

We simulate LiDAR scans in a range of different configurations to evaluate the dependency of methods with respect to the density of the scans and the configuration with respect to the environment. The simulated scans do not contain random clutter or occlusions, but are generated directly from the building meshes. We test two LiDAR settings, a 16 beam LiDAR with 30° opening angle replicating the sensor used on the real robot and a dense 1000 beam LiDAR with even distribution of the beams over a full 180 degree opening angle. We test the different variants for 300 samples each. Our results are reported in table 2. We find a clear dependence between different plane extraction methods and LiDAR configuration. For GoICP and the 3D descriptor, we in general found very poor performance over all settings. Comparing the different LiDAR variants, we found that a randomly posed 16 beam LiDAR often produces ambiguous measurements that fit well to many different locations, impacting the performance of all methods. This is also illustrated in Fig. 7. Between the plane extraction variants, we find that while RHT provides less accurate plane parameters due to bin discretization, the localisation results of sparse 16 beam LiDAR scans, which is our target sensor, are better with this method. We also can observe an increased resistance of the RHT pipeline with respect to noise and clutter, in the form of a excavator and room pillars.

4.3.2 Registration of sampled point-clouds

In order to investigate the poor performance of GoICP above, we construct a less realistic experiment that may be better suited for classical 3D registration, to confirm that the poor performance is related to the characteristics of our robotic application. We run tests on the *Construct* object shown in Fig. 4(d) and do not simulate LiDAR scans but evaluate the registration of a uniformly sampled point-cloud against the mesh. We test the methods over randomly sampled transformations as before (Fig. 6). GoICP convinces in this test series by a significantly lower registration error and is able to find the desired transformation every time. Our PRRUS-based methods is less accurate, but can also coarsely localise nearly all poses. 3D descriptor based

localisation also fails for these more dense point-clouds, indicating that building models do not contain rich enough information for such descriptors. Fig. 6 shows the accuracy gained through the ICP refinement step, as reported above for PRRUS with RHT. Yet, we observe a large gap in the registration error between GoICP and our ICP refinement. Since there is no algorithmical difference, but different implementations, we conclude that the PRRUS registration errors could be further improved by fine-tuning of the used ICP implementation.

Figure 6. Accuracies of the different methods on the Map *Construct*.

Figure 7. Examples of failure of PRRUS

4.4 Robotic Experiments in Cluttered Environments

Finally, we deploy a wheeled robotic platform in the Utility and Garage buildings and take scans at various locations. The correctness of the obtained transformations depends on the position of the LiDAR system as can be seen in Fig. 8. PRRUS offers a fast algorithm to perform the plane matching, but it is highly dependent on the plane extraction and the number of planes contained in the scan

method	Utility	Garage	runtime
GoICP	0 / 0	0 / 0	12188
3D SHOT	1 / 2	2 / 2	405
PRRUS RANSAC	10 / 2	25 / 7	66
PRRUS RG	50 / 48	68 / 68	180
PRRUS RHT array	90 / 57	79 / 46	476
PRRUS RHT ball	77 / 77	75 / 57	387

Table 3. Localisation results (TPR / A) for 16 beam LiDAR scans from the robotic platform, captured in cluttered environments. The runtime was averaged over all scans from the Garage and is given in ms.

and map. In general, PRRUS fails if not enough planes could be detected to determine a unique pose. The PRRUS version with the RHT plane extraction yields the best results. The version with the array accumulator on both maps delivers higher values in the TPR and the ball accumulator in the A , which stems from the RHT version with array accumulator fragmenting the ground plane such that PRRUS cannot find an orthogonal set and does return an "unable to detect" message. The PRRUS version with the RANSAC plane extraction delivers lower values in A and TPR for the real data. GoICP not only required significantly more time, but also resulted in wrong localizations. Similarly, the localization performance of the 3D Descriptor approach is low.

Figure 8. Spatial distribution of localisation errors for our RHT ball based method [m].

5 Conclusion

This work proposes a new algorithm for global localisation of robots in mesh based maps of indoor environments. In our evaluation, established point-cloud based methods failed due to the sparse LiDAR scans and clutter even after filtering. Our proposed method based on plane extraction and PRRUS on the other hand achieved high TPR in localisation. The different plane extraction algorithms showed varying advantages and disadvantages, in either run time, precision or clutter-sensitivity. Overall, we found RHT a suitable method to detect static and coarse structures from scans, although other methods were more precise in clutter-free scenarios. Building mesh model based localisation has a huge potential for indoor robotics due to the large availability of floorplans, small memory footprint of the map, and because it is an intuitive representation

for operators. With the proposed algorithms, we achieved good performance in simulation and real-world experiments, with and without clutter, and in multiple building meshes.

Abstract -

This paper presents a localization system for mobile robots enabling precise localization in inaccurate building models. The approach leverages local referencing to counteract inherent deviations between as-planned and as-built data for locally accurate registration. We further fuse a novel camera-based robust outlier detector with LiDAR data to reject a wide range of outlier measurements from clutter, dynamic objects, and sensor failures. We evaluate the proposed approach on a mobile robot in a challenging real world site. In presence of clutter and model deviations, our system reduces the localization error by at least 32%.

Construction Robotics, Localisation, On-Site Robotic Construction

1 Introduction

Assistive mobile robots in building construction enable both higher degrees of digitized processes, and reduce risk for human workers [1]. Construction robots therefore pose a high potential to transform the building construction process and are important facilitators of the ongoing effort for higher digitization. To this end, mobile robots perceive the environment with digital sensors, offering ease of relating information from digital building models to robot perception. Localizing robots in these building models with high accuracies then enables them to perform building tasks with respect to these data, or accurately track construction progress.

Conventional methods for robot localisation in construction rely on using external sensing, e.g., total stations, or augmentation of the environment, e.g., with artificial markers, to achieve high accuracies. However, these solutions require line-of-sight to a manually placed total station or marker and therefore depend on time-consuming manual preparation for every site, thus limiting the ease and autonomy of such systems. Furthermore, accurately localizing model information with mobile robots is not straightforward, due to the following challenges:

Figure 1: Our proposed method localizes a LiDAR scan against reference surfaces (red) in the mesh of a building model. The scan of the LiDAR is fused with semantic information and points are colored according to their high (yellow - red) or low (blue) probability of belonging to building structure. Note that points visible through the transparent ground plane may also appear red. The visible mismatches between the LiDAR scan and the columns are not a localization failure, but highlight the challenge of localizing within a built structure deviating from a planned model.

- **Multi modality:** Robotic sensor data is recorded with exteroceptive sensors, e.g. cameras and LiDARs, while building models are typically manually created 3D mesh models, rendering data integration and registration between these domains difficult.
- **Deviations:** As-built environments typically deviate from the as-planned state by up to several centimeters (cm), rendering global references insufficient for accurate task execution.
- **Clutter:** Real construction sites contain numerous temporary artefacts (e.g. equipment, scaffolding), as well as dynamic actors, such as human workers. This clutter is not modelled in the building models and therefore disturbs registration.

In this work, we propose a robotic localization system that addresses these challenges by combining locally referenced sensing with a learning-based sensor fusion approach for robust outlier rejection. The system therefore requires only on-board sensing without any artificial preparation of the site. We address the multi-modality

aspect by converting the mesh model into a sparse point-cloud which is easily referenced to sensor point-cloud data using standard scan-matching algorithms. Furthermore, we propose a task-based referencing solution, yielding locally accurate localization. Finally, we fuse a novel learning-based robust detector for outlier rejection on image data with LiDAR data, able to reject clutter that is outside the training distribution. Our system is tested on a mobile robot in realistic construction environments, showing a reduction of localization error of at least 30%. In summary, this paper presents the following contributions:

- Fusing range sensing data with learned visual outlier filters, producing semantically annotated point clouds that can be leveraged in 3D floorplan localization.
- A referencing system that disambiguates deviations between as-planned and as-built and improves localization accuracies for locally referenced building tasks.
- Evaluation of the proposed methods in real-world experiments on a robotic platform.

This paper is structured as follows: In Section 2, we present related works on robotic floorplan localization and semantic localization. In Section 3, we present our proposed 3D architectural floorplan method. We then report experimental results on a mobile robotic platform in Section 4, where these results are also discussed. Finally, we conclude our findings in Section 5.

2 Related Work

While registration of scans to building models is a well-studied problem in surveying [3], the application was studied less extensively in robotics. The important difference between these applications is that 3D scanners used in surveying remain stationary while scanning an environment (usually for at least some seconds), whereas registration on robotic systems is especially important while the robots move around. This *registration* or in the robotic sense *localisation*¹ is part of the state estimation that is required to accurately control the robot's movement. Robotic LiDAR sensors therefore are in general much faster 3D scanners that however also yield more sparse and imprecise scans and therefore pose unique challenges.

2.1 Robot Localization in Architectural Plans

With the raise of LiDAR sensors, different works studied 2D robot localization within floorplans [4, 5]. However, to execute construction tasks, 2D localization is insufficient. Walls might be tilted or floors elevated such that

¹For the purpose of this work, registration and localisation are used synonymous.

water can run off. At higher levels of accuracy, the flat and rectangular world assumption therefore is no longer valid. [6] therefore studied the extension of conventional methods to 3D, but rely on a special measurement system to localize their robot's endeffector with respect to local reference walls. In this work, we study localization methods that do not require manipulators mounted on the robot. Bosché [7] shows ICP-based localization of 3D scan data within building mesh models under the assumption of negligible deviations between model and reality.

In case that LiDAR sensors are not available, research has made progress to extract floorplan-like information out of camera images [8]. Boniardi et al. [9] studied how such information can be used to localize a robot in 2D within a given floorplan. Mendez et al. [10] localize an RGB camera in floorplans based on semantic information and can show that their method does not benefit from range information.

2.2 Semantically Enriched Localization with LiDARs

Global localization techniques can be robustified by using semantic cues [11]. However, the considered semantics only considered distinct classes as information cue, while our approach is more fine-grained using semantic information for filtering and weighting measurements. Closest to our work is [12]. The authors propose to use a semantic segmentation network on LiDAR data and a semantic consistency term in a surfel-based map representation to filter dynamic objects over multiple observations. Furthermore, the work proposes to weigh associations of an ICP registration using semantic label classification scores. Our work differs in the used network that does not require pre-knowledge about semantic classes, and can generalise to reliably detecting outliers outside its training distribution.

2.3 LiDAR Registration

Among the first papers, [13] describe the use of ICP for registration of 3D shapes, i.e., an iterative error minimization over 3D point-correspondences. A multitude of variants were proposed since, including more generalized formulations also including probabilistic measurements [14], and variants that skip the re-association step [15]. A comprehensive overview is given in [16]. Further notable registration algorithms rely on feature extraction [17], or representing data as a probability density [18]. [19] demonstrate ICP for localization with respect to a known object in the environment using a LiDAR scanner, achieving sub-centimeter accuracies. [20] achieve sub-cm accuracies using 2D LiDAR localization in a reference scan of the environment. However, the authors also introduce clutter and dynamics to the scenes which heavily degraded

Figure 2: Overview of the proposed method: RGB images are segmented into foreground and background using a robust segmentation network [2]. These pixelwise scores are then propagated and fused with LiDAR scans. The classifications are then used as weights in the floorplan localization which performs a weighted selective localization in a 3D floorplan given local task references.

the achievable accuracies. Without modifying the principal ICP solution, our method proposes to use only partial data, i.e., local references for scan registration. Furthermore, we explicitly consider outliers.

More robust pointcloud registration such as TEASER [21] have been proposed, but rely on 3D Keypoint descriptors, which perform poorly in manhattan-world building plans.

3 Method

An overview about the proposed method can be found in Figure 2. In the following, we first describe the input processing pipeline for LiDAR scans and define the general problem of registering and aligning scans to building models. Subsequently, we describe how further information on the task references can be used to define the alignment more accurately. The whole method assumes a good initial guess for the robot pose to coarsely align the building plan with the initial pose of the robot. This initialization can be provided manually or with a global localization method.

3.1 Semantic Filtering

Classic semantic segmentation of images or pointclouds relies on large datasets to train networks to reasonable performance. Unfortunately, there are no such labelled datasets available for construction environments. Moreover, construction environments are highly dynamic with a lot of potential object classes appearing, whereas we are only interested in background-foreground segmentation, i.e., separating building surfaces from any other scene contents. Due to the limits of available datasets and the potential problems with training on a fixed set of classes, we use an alternative segmentation method described in [2]. The density estimation network from Marchal et al. is trained on the NYU Indoor Room Dataset [22], but able to generalize better than classical methods to new environments. In particular, we use their best performing model, which is a regression over density estimation at multiple layers of the feature extractor. Instead of a binary segmentation, the method returns a per-pixel score that is higher if the pixel belongs to background structure of a building. We

will hereafter refer to this score as density value d .

The proposed localization system relies on a multi-camera plus LiDAR setup with known intrinsic, extrinsic and timestamp calibrations. Whenever a new LiDAR scan arrives, we rectify the corresponding set of images $I = \{I_0, I_1, \dots\}$ and process them in the density estimation network [2].

From the scanned LiDAR points $P = \{p_1, p_2, \dots\}$, we project each point onto each image plane. For those points p_i within the field of view of a camera, we assign the density value d_i to the point. We reject all points that cannot be projected onto any of the images, but select camera lenses such that the amount of such points is negligibly small.

To localize within the building model, the scan P is aligned to the model with point-to-plane ICP:

$$T_{\text{icp}} = \text{ICP}(P, S) = \arg \min_T \sum_i w_i c[(p_i - m_i) \cdot \mathbf{n}(m_i)]$$

where $c()$ is a cost function, m_i is a matched point of p_i in the building model S and $\mathbf{n}(m_i)$ is the surface normal at that point.

For the weight w , we propose two variants:

$$w_i = \begin{cases} 0 & d_i < \delta \\ 1 & d_i \geq \delta \end{cases} \quad (1)$$

$$w_i = \max(0, a d_i - \delta') \quad (2)$$

Where a is a normalization factor such that $\max_i w_i = 1$. Equation (1) corresponds to a binary segmentation of the scan where only those points which belong to background structure are considered in the ICP problem (*masked clutter*) and equation (2) assigns higher weights to points that are more likely to belong to background structure (*weighted clutter*). The non-binary weighting does not rely on perfect predictions from the density estimation network and instead uses the prediction confidence in the ICP optimization.

3.2 (Selective) Localization to References

We define the mesh of the building model as a collection of closed surfaces $S = \{s_0, s_1, \dots\}$. In general, we can then

Figure 3: Illustrations for deviations between as-planned (solid) building model and as-built scan from the robot (dotted). In (a), the alignment of the horizontal walls is ambiguous and traditional ICP will align that wall with more points in the scan. In (b), any alignment will yield high errors and the solution in general depends on the settings for outlier filtering.

localize the robot with $ICP(S, P)$. However, building models are usually far from perfect maps of the actual environment, where during the construction phase walls might be missing, temporary structure such as scaffolding is not mapped and the relative positions of the final walls can deviate from the building model. Some of the typical deviations are illustrated in Figure 3.

To enable the robot to localize precisely in a building that deviates from the map, we define a subset of walls or surfaces $R \subset S$ with $\exists r_1, r_2, r_3 : r_1 \nparallel r_2, r_2 \nparallel r_3, r_1 \nparallel r_3, r_1, r_2, r_3 \in R$. The reference surfaces therefore define a (minimally) sufficient alignment problem for the robot to localize itself, but exclude all surfaces in S that are not relevant to a local task and would in case of deviations disturb the alignment. This is further motivated by most construction tasks being expressed in local reference frames. Within the case of approximately rectangular building structures that we study in our experiments, R is often the set of surfaces defining a corner in a room. Such references are part of the task definition and can e.g. be synchronised online with robot [23].

Initial experiments with our methods showed that in cases where the surfaces in R are only measured with a few points of the LiDAR scan P , the ICP alignment can fail with huge errors. We therefore propose the following localisation procedure:

1. Find the alignment $T_{\text{full mesh}}^{(t)} = ICP(S, P|T^{(t-1)})$
2. Refine the alignment to the references
 $T_{\text{references}}^{(t)} = ICP(R, P|T_{\text{full mesh}}^{(t)})$
3. Reject $T_{\text{references}}^{(t)}$ if $|T_{\text{references}}^{(t)} - T_{\text{full mesh}}^{(t)}|$ is too large.

4 Experiments

4.1 Experimental Setup

We conduct our experiments on the *supermegabot*² platform with a LiDAR and three cameras. The robot is further

²github.com/ethz-asl/eth-supermegabot

Figure 4: Sensor setup on the robot.

equipped with an IMU for smooth state estimation. The exact sensor configuration is shown in Figure 4.

We calibrate all cameras individually using Kalibr³ [24, 25] to obtain intrinsics and extrinsics with respect to the IMU. We then record a joined motion of LiDAR and cameras to find their respective transformations using visual-inertial odometry [26] with one of the cameras and optimizing the alignment of LiDAR scans with respect to that trajectory⁴. Time-synchronization is achieved with the VersaVIS [27] camera trigger board that synchronizes time between the host, all cameras and the IMU, while negligible time-offset is assumed between the host and the LiDAR.⁵

We supply the robot with a 3D mesh of the building that is generated from the available 2D floorplan. Because there are no information of the floor or the ceiling structure available, we add a planar floor to the mesh and give all walls the same height. Reference surfaces are specified as a subset of the same mesh.

To measure ground-truth, we attach a prism to the robot and measure the position with a total station referenced to the origin of the building plan that the robot is using as a map. We calibrate the prism position with respect to the robot frame by aligning trajectories of the robot moving around. In case that as-built reference walls deviate from the building plan in absolute coordinates, we measure this deviation and correct the ground truth position accordingly.

4.2 The Effect of Clutter

To verify the influence of clutter objects and moving workers on the general localization performance of

³github.com/ethz-asl/kalibr

⁴github.com/ethz-asl/lidar-align

⁵While complicated, this procedure is necessary such that the image segmentation is correctly propagated into the LiDAR scan.

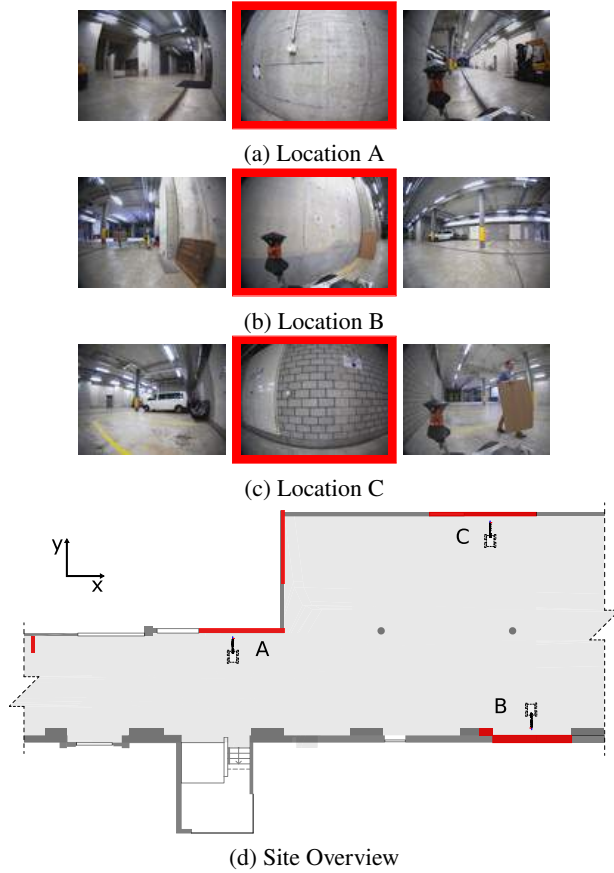

Figure 5: Selected locations and reference walls (marked red in d) for our experiments. All locations also have the floor as a reference surface. The red border around the images corresponds to the forward-facing camera.

a robotic system, we compare localisation at the same positions with and without clutter in Table 1.

We conduct experiments with a stationary robot while a construction worker is moving around the robot and clutter objects such as wooden boards and equipment boxes are placed to partially obstruct measurements to reference walls. For each location, we analyze a sequence of around 1 min. or 300 LiDAR scans.

The investigation shows that on-site clutter negatively affects the localisation accuracy and therefore confirms our initial hypothesis.

4.3 The Effect of As-Built Deviations

To simulate a severe deviation between as-planned and as-built, we move the upper and lower structure in Figure 5 apart by 0.3m in the mesh supplied to the robot. While the initial building mesh without this added deviation is already not an accurate representation of the environment, this further augmentation is used to compare localisation accuracy across higher and lower deviations.

clutter	Loc. A	Loc. B
no	157	74
yes	218	83

Table 1: Influence of clutter on the localization accuracy (RMSE in mm). For this comparison, the robot localizes the full LiDAR scan in the full building model. At location C, the clutter was fixed to the environment and therefore a comparison without clutter could not be done.

deviations	Loc. A	Loc. B	Loc. C
lower	218	83	87
higher	390	222	76

Table 2: Influence of deviations between as-planned and as-built on the localization accuracy (RMSE in mm). The robot localizes the full LiDAR scan in the full building model, in a cluttered environment.

The localisation results of this comparison are listed in Table 2. In two locations, the additional deviation severely worsens the localisation results, while it has little influence on location C. It is expected that particular deviations affect localisation at some locations more than at others. In general, the results confirm the suspected effect of deviations between as-planned and as-built on the localisation accuracy.

4.4 Accuracy of the Proposed System

Given the negative effects of deviations and clutter, we now introduce our robotic system to a cluttered environment with the stated deviations between as-planned and as-built. We then analyse the localisation accuracy to investigate to what extent our introduced mitigation measures can compensate for the added difficulties.

We compare all combinations of methods described in section 3 to a baseline of ICP alignment between the full building model and the full LiDAR scan. We measure repeatability by the trace and maximum eigenvalue of the covariance matrices for position and rotation. For accuracy, we compare the estimated position of the robot against the total-station tracked prism. This measurement therefore relies on the estimation of the full robot pose. The results are given in tables 3, 4 and 5 for the three different test locations respectively. Additionally, we report the fraction of LiDAR scans that could not be localized either because ICP did not converge or the solution was rejected (see section 3.2). To account for non-determinisms in the localization pipeline, all values are averages over three executions on the same input data.

From the results we see that in general, selective localization against reference walls constraints the localization very well in two dimensions. The trace and maximum eigenvalue for localisation against reference surfaces are very close, whereas there is uncertainty in more than one

Figure 6: Topview on position C of the distribution of localization outputs for the stationary robot. All points are transformed to the estimated position of the tracking prism. The ground-truth location is given by the output of the total station for the tracked prism.

Table 5: Stationary Localization Study Position C

direction for registration against the full building model. The same effect is illustrated in figure 6. This raises the question why the localization shows such a high variance in lateral direction in all three locations. A more detailed evaluation of the test site shown in figure 5 reveals that most of the walls in the building model are parallel to the x axis of the model and much fewer structures are parallel to the y axis. For all 3 locations, however, the lateral localization depends on the alignment of surfaces parallel to the y axis. The biggest available structure in this direction, which is also the reference wall for location C, is obstructed by a van parked in front of the wall. Therefore, for all three locations, the observable part of the lateral reference structure is small compared to both other directions and a higher localization uncertainty in x direction had to be expected.

Our experiments further show that semantic filtering is more important when localising against reference surfaces than when using the full mesh. Intuitively, localising only against references is more vulnerable to obstructions of these surfaces. While localisation in the full mesh is also worse in presence of clutter, as shown in table 1, our experiments show in two of three locations that without semantic filtering of the clutter, this impact is even more severe when localising against reference surfaces.

In all locations, the highest accuracy is achieved with a combination of semantic filtering of the LiDAR scan and selective localization to reference surfaces. The accuracy gain ranges from 32% in position C to 69% in position B. However, we could not find a single combination of methods that always worked. We found the performance of the semantic filtering method to be highly dependent on the location and the respective performance of the density estimation network. As we already describe in section 3.1, semantic classification in construction environments is difficult due to the lack of labelled data. The density estimation network from [2] showed reasonable performance for our test location, but still partially filtered out background structure that was too different from the training domain. In particular in location C, binary filtering of the pointcloud removed nearly all points on the lateral reference wall, resulting in high uncertainty and failure rate. We conclude that for precise localization of robots on construction sites, outlier filtering and selection of high quality measurements are key aspects. While learning-based solutions show promising characteristics in this regard, they require more domain-specific training data to further boost their performance.

5 Conclusion

In this work, we present a mobile on-board localization system for construction robots. In our experiments, we show that building deviations and clutter deteriorate

accuracy of traditional registration methods, and find that a combination of semantic filtering of LiDAR scans and selective localization to reference walls yields essential accuracy gains. Our findings show a need for semantic datasets closer to the construction domain and a need for more research to further close the accuracy gap between external reference systems and on-board sensing.

Abstract –

A static path, pre-calculated as the tool trajectory, cannot reflect potential changing states during the machining process. Therefore, adjusting to environmental differences between the assumed and actual conditions, such as variations in the physical properties of the material, is not possible. In this study, the path was dynamically changed by monitoring the load applied to the tool during processing. Furthermore, applying our method to processing with a chisel demonstrates that parts can be machined appropriately via dynamic path generation.

Keywords –

Robot processing; Dynamic path; Wood carving; Force sensor

1 Introduction

In architecture, numerically controlled machining is becoming widespread for manufacturing building members. When machining a member, a static machining path, in which the trajectory of the tool tip is calculated in advance, is generally used. The machining path can be obtained by calculating the three-dimensional (3D) shape of the member, and the member can be accurately machined by combining with numerical control machining. However, when using a static path, the state of the workpiece being machined cannot be considered. Proper processing requires processing conditions according to the physical properties of the material; however, there are large variations in the physical properties of workpiece materials, such as wood. If there is a difference between the assumed and the actual physical properties, the pre-set machining conditions may not be appropriate, and machining may ultimately fail.

Among indices used to determine the state of the workpiece during processing, the magnitude of the load/reaction force applied to the tool is one of the better candidates. When an excessive load is observed, it can be inferred that an excessive force is being applied to the

tool at that time and assess if it is within the range of appropriate processing conditions.

By using a force sensor, it is possible to measure the magnitude of the load and moment applied to the tool in real time. For example, when the tool overcuts a member, an excessive load is generated between the tool, which tries to follow a predetermined path, and shavings that oppose it. Furthermore, if the cutting amount exceeds the capability of the tool, the load applied to the shavings becomes excessive as the tool advances. If the path can be dynamically controlled while assessing the status during machining via load monitoring, a more appropriate machining can be realized.

In this study, by monitoring the load applied to the tool during processing using a force sensor and considering the logic for dynamic control that reflects the result in the path, we developed a dynamic path generation method. This method was verified via wood carving with a robot using a chisel.

2 Related research

In metal processing, in which the metal is a homogeneous material, there are examples of finishing techniques for the surface of parts, such as deburring and polishing, by robots using force sensors [1][2]. The force sensors are used for monitoring and fine-tuning the pressing force of the tool. In this study, we dynamically changed the path by using a force sensor to monitor the machining status.

There are also examples of using force sensors for wood carving using robots [3][4]. In such examples, to determine the parameters in wood carving, the movement and force during cutting by a human were recorded for machining using a vibration chisel. Furthermore, the machining path was optimized by modeling these data via machine learning. Based on this optimization, a cutting test was performed with a robot equipped with a vibration chisel and the machining parameters were determined. However, they targeted static paths as the processing paths, as opposed to the dynamic paths targeted herein. In this study, we aim to realize

processing in response to variations in physical properties and in the processing environment by monitoring the processing status via load monitoring using a force sensor and dynamically changing the processing path.

3 Experimental set-up

The robot used in this experiment is shown in Figure 1, left. The force sensor was attached to the tip of the robot flange (Figure 1, right). This sensor can measure the force in three axes and the moment around those three axes. The measurable range is ± 200 N for force, which is approximately the payload of the robot, and ± 20 Nm for moment. At the time of installation, the coordinate system set on the flange of the robot was aligned with the directions of the force sensor measurement axes, and the normal line of the flange and the Z-axis of the force sensor were aligned.

Figure 1. Robot (left) and tool set-up (right) used in this study

The tool held by the robot was a round-edged chisel with a width of 9 mm. A vibration chisel is an alternative tool for carving that can be machined with a relatively low load owing to the vibration of the blade. However, this vibration becomes a noise source for the force sensor measurement, which makes the load monitoring required for dynamic path generation impossible. Therefore, we did not adopt a vibration chisel. Instead, we built an adapter that enabled attaching a hand-held chisel to the robot and installed it at the tip of the force sensor.

4 Dynamic machining path

4.1 Machining path

The path required for machining consists of the

trajectory (path), through which the tip of the tool passes during machining, and machining parameters, such as the feed rate and rotation speed of the tool blade. Because the path determines the movement of the tool for processing the member's shape, it is mainly determined based on the 3D shape of the member and limitations regarding the moving direction of the tool.

In this study, machining paths are classified into static and dynamic machining paths. In the former, pre-set paths remain unchanged from start to finish during machining. In the latter, paths change during machining.

The machining parameters may be manually changed by the operator during machining depending on the user interface of the machine. For example, when cutting, it is possible to operate the controller to reduce the feed rate override and increase the rotation speed of the tool blade. Such machining parameters can be easily controlled manually via the user interface; however, it is difficult to change the path manually on the spot because it is calculated based on the 3D shape of the member.

4.2 Dynamic machining path overview

A simple dynamic machining path control involves changing the feed rate according to the load applied to the tool. This method is effective for tools such as circular saws, drills, and end mills, which rotate the blade for machining. If the feed rate is reduced, the amount of cutting per blade of the tool is reduced, and the load on the tool is reduced. Therefore, low-load machining is possible without changing the machining path.

However, in the case of chisels, this method may not be effective. After the tool enters the workpiece, the load continues until the shavings are cut from the workpiece. This tendency does not change even if the feed rate is reduced. In other words, if an excessive load is applied during processing, it is necessary to change the path itself to avoid it. If the machining path is not appropriate, it can lead to tool or machine damage due to overload (Figure 2). Accordingly, if a certain amount of load occurs, such damage can be avoided by changing the path.

In addition, wood, which is often used as a workpiece, has anisotropic physical properties, and when processed along the grain, it may be deeply scraped along the fiber direction.

By monitoring the machining status via load monitoring using a force sensor, it is possible to dynamically change the machining path and perform an appropriate machining.

Figure 2. Excessive workpiece carving with improper machining path

5 Dynamic machining path logic

The process under a load-based dynamic machining path is as follows (Figure 3).

1. Generate the original machining path for machining the member.
2. Command the robot the position and orientation of the tool based on the generated machining path.
3. Monitor the load on the tool during machining with a force sensor.
4. When the load exceeds a set threshold, the machining path is recalculated and registered as the path to be executed next.
5. Repeat steps 2–4 until the original path, that is, processing of the member surface, is completed.

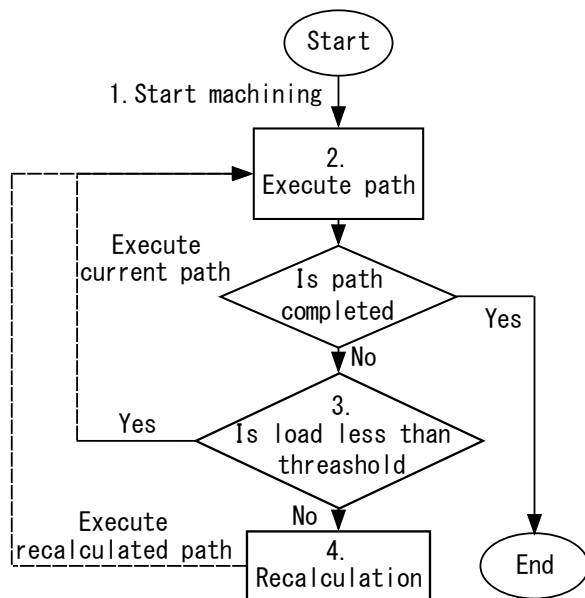

Figure 3. Machining flowchart under a dynamic machining path

In this study, the original machining path in step 1 was calculated based on the 3D shape of the member. The sampling rate of the force sensor was approximately 10

Hz, which is the execution cycle of steps 2–4.

The method of recalculating the machining path in the event of an overload may differ depending on the tool and the way to avoid overload.

For example, the machining with chisel in this experiment produces large shavings that are cut from the workpiece. Therefore, a method of processing a shallow position, that is, a position close to the workpiece surface, can be considered as a method of reducing the load. If the load is heavy, the path is recalculated and executed to handle a certain amount of the shallow part. If the recalculated path is still overloaded, a path to handle the shallower parts is calculated. This time, the depth, the position away from the target path, is managed, and the processing path completed when the original path could be processed without overloading.

If an overload condition occurs during machining, it is necessary to interrupt the machining path and correct the tool trajectory to reduce the load. This is easily realized by going back to the last processed path. The place where the tool passed is already machined and will not interfere with the tool, so it can pass safely.

In the processing with chisel in this experiment, when the load exceeded the threshold (step 4), the processing was set as follows (Figure 4).

- a. Return along the machining path until the load falls below the threshold.
- b. Recalculate the machining path. The recalculated path passes through a part shallower than the machining path that was being executed.

The above dynamic machining path logic was implemented as a robot control program. The control program determines the machining status while monitoring the force sensor measurement, and sequentially commands the robot to position and orient the tool according to the above algorithm.

Figure 4. Processing path recalculation for chisel machining

6 Machining experiments

6.1 Load measurement and threshold setting

To set the load threshold value to be referred to in the dynamic machining path, a trial machining was performed with a static path that passes through a certain depth in a straight line. The machining result was observed while recording the load. In the Z-axis (tool-axis) direction of the force sensor, the load due to the weight of the tool acts as tension, and the reaction force from the workpiece acts as compression. From the test processing, we found that if compression is applied up to approximately 60 N in the tool-axis direction, it is a reasonable machining (Figure 5). Conversely, if a larger load is applied, excessive digging (Figure 6, top) or cutting occurs. This force was used as the threshold value for overloading during processing (at step 4).

Figure 5. Low-load processing

Figure 6. Above-threshold-load processing

6.2 Planar processing

As an experiment using a dynamic machining path, we performed machining on the work surface. The workpiece used was a single-plate laminated material. This processing was performed along the grain of the wood. The processing area was set to 50 x 200 mm, and depth was set to 2 mm. This width range was divided in the width direction by 4.5 mm, which is half the width of the chisel, and linear paths were arranged to form the entire path. Using the logic described in Section 5, in the event of an overload, the path is returned and recalculated so that the next path is 0.2 mm shallower. The processed product is shown in Figure 7. By detecting an overload, to avoid the excessive excavation of the blade that may occur when machining in the grain direction and the machining that results in an excessive amount of cutting that exceeds the capacity of the tool, the path is dynamically changed when the threshold is exceeded. It was confirmed that processing that could not be executed using the original path can be executed using the dynamically changed path.

Figure 8 shows a linear path movement during machining. The top and middle graphs show the position of the tool in processing and depth direction, respectively, and the bottom graph shows the load measured by the force sensor over time. The threshold is shown by the solid red line in Figure 8, bottom, and the areas where excessive load occurs are shown as horizontal shaded strips. If an excessive load is applied, it will return by a certain amount in the direction opposite to the direction of travel along the path (such as the arrow in Figure 8, top), and the overload is repeatedly, the path will be recalculated to process the shallower position (Figure 8, middle). This operation is repeated until the processing of the original path is completed. Throughout the planar processing, the path was recalculated approximately 360 times.

Figure 7. Planar processing result

Figure 8. Tool movement under load. Top: tool position in the path direction; Middle: tool position in the depth direction; Bottom: sensor load in the Z-axis direction.

6.3 Bowl-shaped processing

Next, we conducted an experiment to process a bowl-shaped work surface. The work had a spherical dent with a diameter of approximately 120 mm and a depth of 8 mm, which was carved radially along the surface. In this experiment, lime wood was used. Considering the movable range of the robot, the path was divided into four, and the processing was performed while rearranging the workpieces. The calculated path moves the tool along the surface of the finished bowl. By monitoring the load and performing the machining while dynamically changing the path during overload, it was confirmed that machining can be performed without excessive cutting. The processed product is shown in Figure 9. The part orthogonal to the grain of the wood is slightly roughened, but it is generally well processed.

Figure 9. Bowl-shaped processing result

7 Conclusion

In this study, processing was performed using a chisel with a dynamic machining path. It was confirmed that the machining environment can be grasped via load monitoring using a force sensor, and that appropriate machining can be performed by dynamically changing the path. Furthermore, as a countermeasure against overload, we adopted a method in which the path is changed shallowly to reduce the load. However, it is also possible to change the posture of the tool according to the magnitude of the load.

It was also found that even a tool used by humans, not a blade dedicated to a processing machine, can be used by a robot with dynamic control. Because the cutting marks of the blade may be evaluated as a unique texture, we would like to expand the range of applicable blade types in future work.

Abstract -

As-built modeling using advanced visual sensing technologies (i.e., photogrammetry and laser scanning) provides an opportunity for a rapid assessment of construction performance, identifying deviations from 3D CAD/Building Information Modeling (BIM) models (i.e., as-planned model). For reliable decision-making, the accuracy and quality of the as-built model are critical. In particular, data collection techniques for image-based 3D reconstruction influence the quality of as-built modeling. In addition, manual data capture is time-consuming, error-prone, and infrequent, which impedes the assessment process. To overcome the challenges, this paper proposes a model-based planning system to automate image data collection for 3D reconstruction. The data collection system uses a camera-installed robotic arm. The locations of images to be captured are planned based on a given 3D CAD/BIM model using the camera parameters, distance away from the target object, and overlap ratio. The end-effector of the robotic arm, where a camera is installed, moves along the planned locations and captures images at each location. The complete image data set uses computer vision algorithms (i.e., Structure from Motion and multiple view stereo) to create the as-built model. The preliminary experiment produces an as-built model of the object successfully. Moreover, the quality of the as-built model can be improved by the presented method on the leverage of a camera-mounted robotic arm.

Keywords -

Image-based 3D reconstruction, automation image-data collection, robotic arm, as-built modeling

1 Introduction

The advanced visual sensing technologies (e.g., photogrammetry and terrestrial laser scanning) empower efficient visual-data collection in the construction industry. Efficient methods of as-built modeling enable a rapid assessment of progress, productivity, and quality, compared with the as-planned 3D Building Information Model (BIM) or computer-aided-design (CAD) model [1, 2, 3]. Despite the advantages, there is a challenge that many practitioners face when they first try image-based 3D re-

construction: difficulty in producing a high-quality and consistent as-built models [4].

To overcome the challenge, there are research efforts on the method of creating a high-quality as-built model. Two technologies are primarily used in construction applications: terrestrial laser scanning and image-based 3D reconstruction. The terrestrial laser scanner operates based on time-of-flight or phase shift measurements. Both techniques sweep laser rays and collect 3D coordinates of the points where the laser ray hit the object surface. The collection of points becomes a point cloud model of the scanned scene. The laser scanner has the advantage of speed and precise measurement in high resolution [5]; however, the high cost of equipment and labor turns down the benefits. By comparison, image-based 3D reconstruction uses the image processing algorithms, Structure from Motion (SfM) [6], and multiple-view stereo (MVS) [7] with a set of image data taken by the camera. The image processing algorithms estimate 3D structures from pairs of images and compute 3D dense points of the scene. Due to the cost-efficient and ease of data collection, image-based 3D reconstruction gained more attention to create the as-built model in construction [8].

For this reason, the research community has focused on the development of the visualization and analysis for construction performance using a as-built model that is reconstructed from daily photographs [9, 10, 11]. A set of the daily photographs taken by site engineers often are unordered, easily led to inconsistent point cloud quality. For modular or prefabricated components, a consistent and higher level of point cloud quality is required. Since the modular components are fabricated off-site, any deviations from design can lead to unexpected costs and schedule overrun due to the reworks, including re-shipping, re-fabricating, and repair. Thus, the quality of as-built model is critical to detect the deviation to secure cost and schedule in modular construction.

Since the performance of computer vision algorithms relies on the detection and matching of the features in different images, how images are collected (i.e., the number of images and data collection positions) greatly affects the accuracy and quality of 3D reconstruction. Without proper planning (predetermining camera locations), 3D

reconstruction may result in high measurement errors and incomplete and noisy point cloud.

To overcome these challenges, this paper presents a robotic arm path planning method for image-based 3D reconstruction. The presented method is designed to capture as-built models of fabricated building components. The result shows reduced errors in the 3D point cloud formation process. This paper also presents a research road map to build a reliable and practical image data acquisition method and improve as-built modeling using a robotic arm.

2 Related Work

The 3D reconstruction of real-world objects and scene has received great attention in many different applications, such as creating 3D model of heritage site [12], face recognition [13], detailed 3D spatial data for geoscience application [14], reverse engineering [15, 16], and quality inspection [17]. There are different vision sensors are explored for 3D reconstruction: stereo cameras [18], 3D depth sensors [19], monocular cameras [20], laser scanners and videos [21]. In addition to capturing technology, the image-processing algorithms are actively developed [6, 7]. Thus, the capabilities of data collection technologies and processing to create 3D models have been actively studied. Nonetheless, the quality of modeling is difficult to obtain without sensor planning for data collection.

Since image-processing techniques are robust in creating a 3D model from a set of image data, establishing the proper data collection methods and automation have a considerable potential to obtain the quality of the as-built model. The robotic system, such as unmanned ground vehicles (UGV), unmanned aerial vehicles (UAV), and robotic manipulators, is introduced to improve the data collection system. For image data collection, the UAV has been studied actively in construction applications due to the capability of extensive capturing ranges and avoiding occlusions [22, 23]. However, UAV operation is limited during construction, and the flight motion causes motion blur in captured images. The UGV has not been explored much for image-data collection since the fixed camera on UGV is not efficient in capturing multi-views in the construction site. A robotic manipulator with a high degree of freedom can be applied for data acquisition by installing the sensor on the manipulator. It allows the sensor to move to the ultimate position. Thus, the robotic arm can provide an opportunity to perform desirable motions to collect image data based on sensor planning.

The benefit of a robotic arm system is easily programmed and operates new scenarios [19]. The scenarios can be created based on sensor path planning. The current studies of sensor planning with a robotic arm focus on the small mechanical part [24] using a range sensor

or laser scanner. Their planning method is finding the set of required viewpoints and planning the sequence of the viewpoints [25] [20]. The sensor path planning with a camera has not been studied much with a robotic arm system. Since the 3D reconstruction principle is different between the camera and laser scanner, the sensor path planning method cannot be the same. The image data collection method to reduce reconstruction error has not been covered enough in the research community.

3 Method

The proposed framework aims to automate image data collection to reconstruct a complete and reliable quality as-built model. The automation of the data collection system uses an unmanned ground vehicle (UGV) integrated with a camera-mounted robotic arm. The robotics are programmable to move through the optimal path for collecting data. Thus, the overall system is associated with two motion plannings for a UGV and a camera-mounted robotic arm. In this paper, the study scope is limited to surface reconstruction to validate the robotic arm operation in image-based 3D reconstruction. Since a robotic arm has its allowable workspace, the study assumes that the camera installed on the robotic arm can cover a certain size of the surface. The study implements the model-based planning for the robotic arm to find camera positions from the given CAD model. The considerations for the image acquisition planning include capture distance and angle, field of view, overlap ratio, and robotic arm workspace to reduce a source of error for 3D reconstruction in the data collection step. The data acquisition with a robotic arm starts after a UGV stops. After a robotic arm finishes scanning one surface, the UGV moves to the other surface and starts taking image data of another surface. This procedure is repeated until collecting a complete image-data set for the object. The main focus of the paper is robotic arm operation for one surface data acquisition, not a complete object. The success of the surface reconstruction provides a promising conclusion for the 3D reconstruction of the complete building components as moving around the UGV. The overall study method is illustrated in Figure 1.

For camera sensor planning using a robotic arm, the following components, identified as a source of reconstruction error in the stage of data collection, are studied: camera distance, orientation, robotic arm workspace, and image overlap ratio.

3.1 Camera distance and orientation from the object surface

The constant distance between the image plane and capturing object surface is an important element to assure 3D point cloud quality. It minimizes the error finding corre-

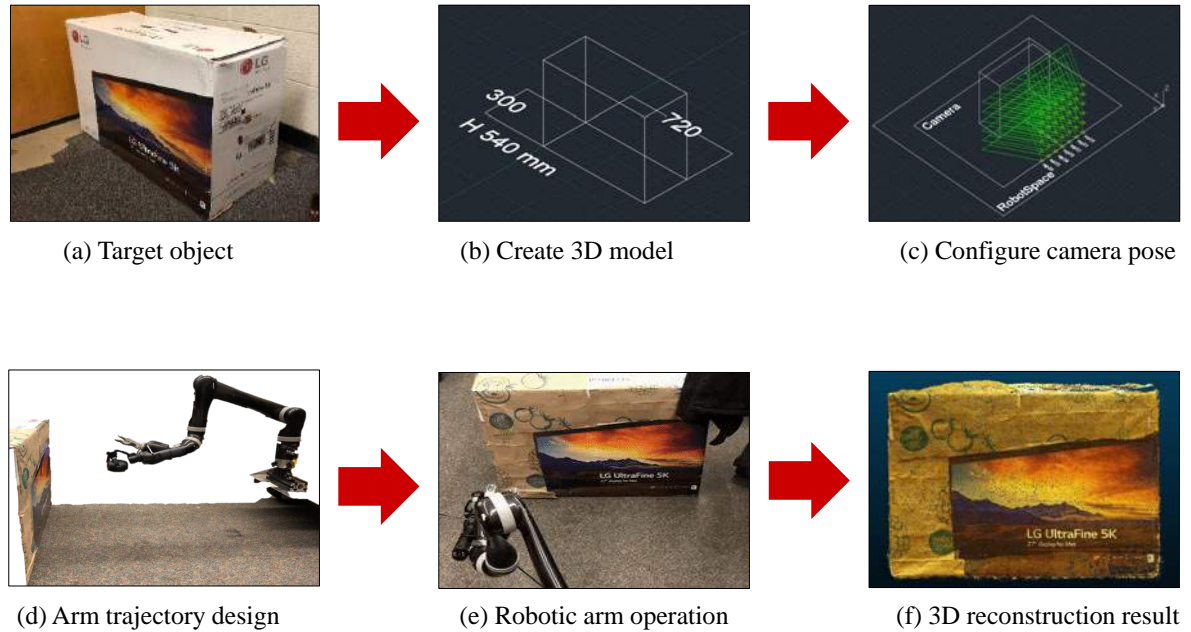

Figure 1. Research method overview - Image data collection for 3D reconstruction

sponding 3D points from two different images. According to Yousfi et al. [26], the images used for 3D reconstruction from difference distances cause an error in matching corresponding points. Although the image processing structure-from-motion and multiview stereo (SfM-MVS) algorithms are robust to images at different scales, the images taken from significantly different distances cause to be rejected [14]. The minimum focus distance of the camera was considered to maintain the distance for image capture. Camera orientation remains constant along the surface to maintain the distance between object and image plane.

3.2 Robotic arm (end-effector) workspace

Before determining the image collecting locations, the end-effector workspace is determined. The end-effector workspace refers to the 3D space that the end-effector can reach without joint collisions. Defining a workspace preserves the quality of images since it reduces the failure of the arm trajectory and improves the accuracy of end-effector positioning.

From the Kinova robotics user manual, the maximum reachable robotic arm distance is given as 1260 mm in the z-direction and 984 mm in x,y direction when the arm is placed on the ground, as shown in Figure 2 [27]. However, the actual reachable space for this study is different from the maximum because of the constraint due to the end-effector's fixed orientation and distance. The constraint

Figure 2. JACO robotic arm usable workspace in mm [27]

limits the robotic arm motion planning space on the yz-plane (Figure 3); i.e., the workspace for this data collection task only needs to be defined in the yz-plane.

Therefore, the maximum camera reachable space maintaining a fixed angle and distance of end-effector is identified. Based on the maximum, the range from the arm base is determined. Between the range, the robotic arm

Figure 3. Robotic arm coordinate system

motion is tested at each 3D point location every 0.05 m. For example, if the identified maximum space in the y-axis is +0.3 m from the arm base, then the minimum space is -0.3 m. Each space point every 0.05 m from -0.3 m to +0.3 m was tested. The test is conducted by commanding the move distance through a python script and compares the arrival position based on the publishing data from the encoder. The position errors compared with the command are less than 0.02 m, then include the 3D point into the workspace.

3.3 Image overlap ratio

The importance of image overlap ratio is image-based 3D reconstruction process starts with feature detection and matching in the different photographs by the Scale-Invariant Feature Transform (SIFT). Insufficient feature overlap attributes to the failure of the scene reconstruction [28]. For this reason, the different overlap ratio has been studied, changing the spacing between waypoints.

4 Experimental Setup

The experiment setup of the research is shown in Figure 4. The target object was placed in front of the robotic arm installed on UGV. The visual sensor, a camera (OSMO Plus from DJI), was mounted on a six-degree-of-freedom manipulator's (Jaco robotic arm from Kinova robotics) end-effector as shown in Figure 5.

The test object was selected and its size was 0.3 m (width) x 0.72 m (length) x 0.54 m (Height). For the model-based approach, the 3D CAD model of the object was created (Figure 1(b)). The field of view of the OSMO Plus camera is a minimum 35 ° maximum 92 ° based on

Figure 4. Experimental setup, including target object, camera attached robotic arm, and unmanned ground vehicle (UGV)

Figure 5. Camera mounted robotic arm end-effector

the focal length. Assuming the camera operating field of view is 60 °, data acquisition positions were decided and drawn on a 3D CAD model (Figure 1(c)). The camera candidate positions are tested with the robotic arm to make sure that no joint collision occurs during the end-effector movement to the candidate positions (Figure 1(d)). The image data was taken when the robotic end-effector stops at the capturing positions (Figure 1(e)). The robotic arm was programmed to stop every waypoint and capture images. After robotic arm operation is completed, a set of images run dense cloud algorithms (i.e., SfM-MVS) to create an as-built model [29].

5 Experimental results

- **Robotic arm workspace:** The test result of the workspace was that from -0.3 m to 0.3 m in the y-axis and from -0.15 m to 0.6 m in the z-axis from the center of the arm base. These spaces are the robot arm able to operate spaces maintaining the fixed camera angle and distance. All planned waypoints are inside of the defined workspace.
- **Sensor trajectory and operation:** The sensor tra-

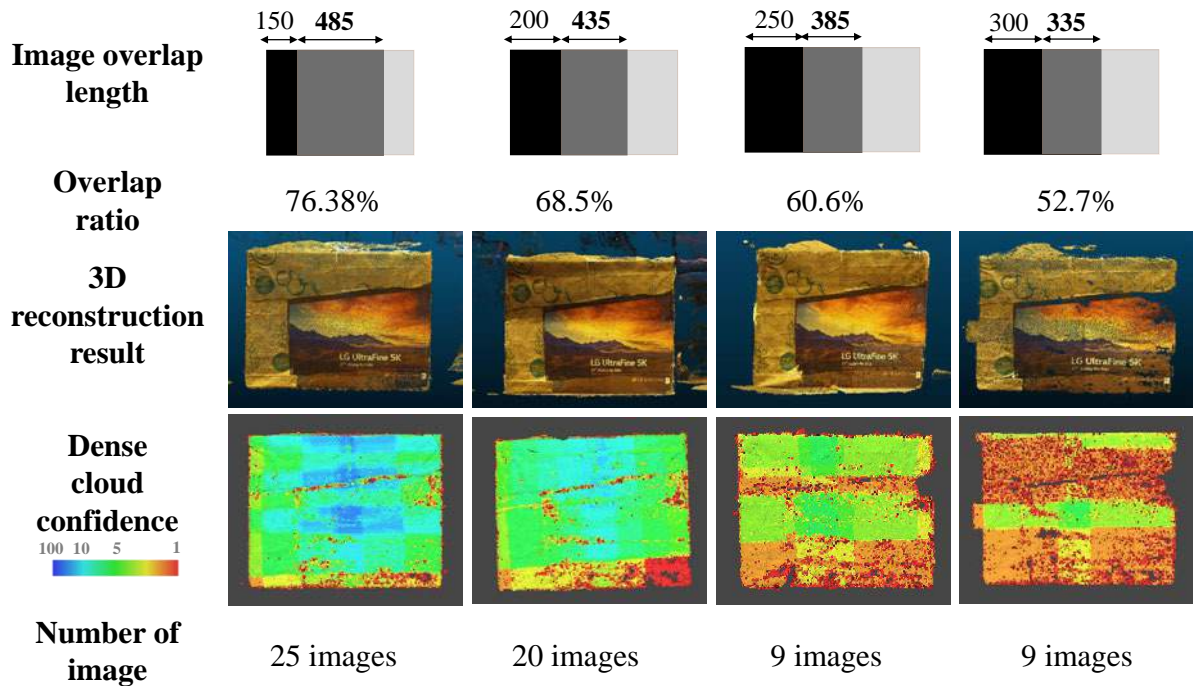

Figure 7. 3D reconstruction results based on overlap ratio

jectory is shown in Figure 6 (a). The camera moved along the designed trajectory and stopped at the planned positions to take photographs. The images (in blue boundary) created as-built models are shown with image-taken positions. Figure 6 (c) shows the surface reconstruction result.

- **Image overlap ratio:** The 3D reconstruction results with different overlap ratios are shown in Figure 7. The maximum tested overlap ratio was 76.38 %, and the minimum was 52.7%. The more overlap ratio

achieves a better to complete 3D point cloud model, the least model with nine images was not able to completely reconstruct, especially on the edge of the object. The comparison of the dense cloud confidence result shows that a small number of images creates the lower confidence level of dense cloud (Figure 7) since the lower number of images is associated with creating an as-built model, which reduces the accuracy of the as-built model.

- **Construction object:** The designed camera trajec-

tory was tested on the concrete object located in the Construction Facility Laboratory (CFL) at North Carolina State University (NCSU). The successful 3D reconstruction is shown in Figure 8.

6 Conclusion and future research

This paper presents a sensor planning method for image-based 3D reconstruction using a robotic arm. The planning method is to minimize the source of errors from data collection. The preliminary results show a great potential that the quality of 3D reconstruction can be improved by the presented method. Moreover, this research can be extended to complete as-built modeling, installing a robotic arm on the unmanned ground vehicle (UGV). The sensor planning method will be automated regardless of the object shape in future studies.

The automation of data collection with a camera or a laser scanner installed robotic arm can be applied to various applications in construction. The high degree of freedom operation allows placing a sensor in desirable locations depending on the object's shape. Therefore, the leverage of robotic arm data acquisition enables efficient data collection methods for the construction building components with diverse complexity of shape and a wide range of quality requirements.

Abstract

Featuring manual-intensive labor as the primary source of productivity, the construction industry is plagued with low efficiencies and high safety risks. Increasing ground robots have the potential to address these shorting comings. However, the complicated indoor sites result in many barriers for adopting unmanned ground robots (UGR), especially in path planning. As the basis for the robot movement, reliable indoor path planning is often unavailable due to the lack of up-to-date maps and reliable path planning algorithms. This paper presents a BIM-integrated indoor path planning framework for UGRs. First, robot information is integrated into BIM as a knowledge base. Second, an IFC-based layered mapping is proposed to build a robot-centric prior map. After extracting necessary robot properties from the BIM base, an improved A* path planning algorithm is introduced to be adaptive to UGRs with different mobilities. Final simulation results have proven the value of this framework.

Keywords –

Building information modeling, ground robot mobility, layer mapping, Adaptive A* path planning

1 Introduction

The architecture, engineering, construction (AEC) industry is one of the main economics worldwide, but with various problems due to the limited automation, such as inefficiency and high safety risks. With the rapid development of computers and sensors, robotic system has become a promising method to automate the AEC industry. Among various robotics, unmanned ground robot (UGR) achieves the most attention in the indoor environment. It can provide not only reliable control in cluttered space but also high payload capacity to carry multiple sensors. Previous studies have proven UGR's advantages in AEC-related projects. For instance, [14] used a UGR for automatic data collection in hazardous areas, which reduced potential safety

problems. Another UGR was proposed for removing materials to reduce labor costs [3].

Efficient path planning is crucial for UGR's navigation, aiming to find an optimal and robust path in different indoor environments. However, two main hindering factors still exist. First, buildings are becoming increasingly complex due to irregular geometries, diverse space functions, and dynamic changes [9], which poses a significant challenge for UGRs to acquire the knowledge of building data. Simultaneous localization and mapping (SLAM) is the classical mapping approach adopted by UGRs, but expensive sensors and manual inspections are required for constructing highly accurate maps [22], especially in complicated environments. Recently, reinforcement learning (RL) is proposed as a map-free method for UGR's navigation [7]. Although without the mapping requirement, RL requires costly real-world training, since models trained in the simulation are not guaranteed to be transferred for a real robot [22]. Second, UGR's mobility systems are not fully studied with previous path planning algorithms, while general ones (e.g. A*) may fail due to certain kinematic constraints. Generally, only one kind of UGR mobility system will be considered in each path planning algorithm, like the Ackerman system [11] or the skid-wheeling system [8]. A comprehensive framework that takes different UGR's mobilities into account is still in lack.

As a central database for the AEC industry, BIM contains not only geometric, semantic information of indoor elements, but also other project-related resources, like schedule, cost, equipment, etc. Thus, BIM could be extended to an N-dimensional platform for different purposes. In addition, BIM outperforms other computer-aided-design (CAD) tools in its object-oriented data format, namely "Industry Foundation Classes" (IFC), which advances the data exchange due to its high interoperability [21]. Due to these advantages, this study aims to propose a BIM-integrated framework to realize comprehensive indoor path planning for UGRs. The method initially integrates robot information (e.g. 3D

models, properties) into BIM as a knowledge base. Then, the IFC-based layered mapping is executed to construct a robot-centric prior map, which also establishes the relationship between BIM and the map of path planning. After extracting necessary robot properties from BIM, an adaptive A* path planning algorithm is introduced to improve the efficiency for UGRs with different mobility systems.

This paper is organized as follows: Section 2 reviews related studies about indoor environment mapping and path planning algorithms. Section 3 illustrates the proposed methods on the integration of BIM and robot information, the IFC-based layered mapping, and an adaptive A* path planning algorithm, followed by the validation design and results in Section 4. In closing, the conclusion and future work are presented in Section 5.

2 Literature Review

2.1 BIM-based indoor mapping

While not widely used in the robot domain, BIM has already been a popular resource for path planning mapping of other fields. Geometric information of BIM element is the basis for indoor mapping, which indicates its size and location. Follini, et al. [8] extracted the bounding box of physical objects from IFC files to get the lowest height, only those lower than height of moving object was considered as obstacles. For complex elements, Xu, et al. [26] proposed to use Boundary-representation (B-rep) to represent shapes, where a face is a bounded portion of a surface, and an edge is a bounded piece of curve. In addition, Brown, et al. [4] suggested that topological information should be extracted for indoor mapping, which could create an abstract and simplified network. Semantic information is what makes BIM different from other CAD software, generally including standard properties (e.g. name, construction phase and material) and other customized properties. For example, the construction data was parsed from IFC files by Follini, et al. [8], leading to a 4D dynamic BIM. Besides, Property Definition mechanism of BIM allows users to attach user-customized properties with Property Sets [17]. To express the status of BIM elements, Xu, et al. [26] added the property of public or private for *IfcSpace* and the property of locked or unlocked for *IfcDoor*. Li, et al. [15] linked indoor sensors into BIM to develop a real-time path planning platform for fire evacuation. Cheng, et al. [5] used CCTVs to measure the real-time congestion degree of a corridor to get a dynamic path for fire evacuation.

BIM offers not only valuable built-in information but also access to expand additional information.

However, previous studies mainly focus on the BIM-based indoor mapping of facility management or safety planning, while a specific BIM environment for robot path planning is still lack.

2.2 Robot path planning

After constructing the indoor map, a path planning algorithm needs to be implemented for the optimal path. Firstly, the objectives of path planning should be determined, which are generally the components of the path's cost function. Boguslawski, et al. [2] optimized the path planning based on three criteria: hazard proximity, distance/ travel time, and route complexity. Similarly, Soltani, et al. [23] suggested a multi-objective framework for path planning at construction sites, which considered the transport cost, safety, and visibility to automate the routing analysis of people and vehicles during construction. In the context of robotic studies, mobility-related factors are drawn attention by researchers. Jun, et al. [12] and Jeong, et al. [11] considered the robot's stability during path planning on uneven ground surfaces. Zhou, et al. [27] used the control input of the robot and traveling time to construct a straight but efficient cost function.

The path planning algorithm is then adopted to find the optimal path based on above-mentioned criteria. Sampling-based methods are efficient in large environments, which generate random samples and connect to a search graph. Rapid-exploring Random Tree (RRT), RRT* and Probabilistic Road Map (PRM) are common sample-based examples [20]. Search-based methods, A* algorithm, developed by Hart, et al. [10], is also frequently used. Variants of A* algorithms have been developed for variable needs. Weighted A* was designed by Pohl [19] to adjust the weights of the heuristic function to reduce the planning time but easily getting into the local minimum. Aine, et al. [1] introduced MHA* to explore the optimum solution by using multiple heuristics simultaneously, while is time-consuming. Some studies also considered motion constraints. Lin, et al. [16] used straights and right/left turning as motion primitives of the RRT algorithm, while Dolgov, et al. [6] put forward Hybrid A* that considers the nonholonomic constraints of unmanned vehicles.

Turning back to the topic of UGR's indoor path planning, it could be found UGR's properties are usually ignored or partially considered in path planning. A UGR-centric algorithm deserves to be developed to fully cover the whole path planning process, including primitive generation, collision checking and cost setting.

3 Proposed Methods

This section describes the proposed methods. An

Figure 1. Workflow of the proposed methods

overview of the framework is illustrated in Figure 1.

3.1 Integration of BIM and robot information

As mentioned in section 2.1, BIM plays as an integrated platform to combine different object-related information. It can not only organize information more clearly but also provide interconnection and interoperability for decision makings. Referring to [24], the *IfcBuildingElementProxy* entity is a proxy definition with the same functionality as an *IfcBuildingElement* (i.e. walls, doors), so that it is herein adopted to represent robot models. Three IFC property sets are customized for the UGR by *IfcPropertySet*, namely Robot-Kinematic, Robot-Task and Robot-Dimensions. Further, specific properties are defined for each set by *IfcPropertySingleValue* (as shown in Figure 2). The final content of UGR’s IFC entity is provided in Table 1.

the restriction that all faces are planar and bounded polygons, is used as the shape representation method to integrate external robot model resources (i.e. from SolidWorks or 3DMax) with BIM.

3.2 IFC-based mapping

The grid-based map is a well-known spatial model for path planning, which tessellates the indoor 3D space into a finite number of square cells. However, a single grid map is hard to clarify different information, where various data sources share a common map [18]. Thus, a multi-layered grid map is proposed to separate the processing of BIM data into semantical layers (Figure 3), which is suitable for the project's whole life cycle. Details of each layer and its corresponding BIM sources are as follows:

[illegible]

Figure 2. Part of IFC definition for robot's dimensions

Table 1. IFC-based robot properties

Property Type	Property	Units
Robot-Kinematic	MaxSpeed	(km/h)
	MaxTurningAngles	°
	MaxBrakeTorch	N • m
	MaxTorch	N • m
	Mobility	Text
Robot-Task	Weight	Kg
	SafetyBuffer	cm
	StartingPoint	(m, m)
	StartOrientation	°
	EndPoint	(m, m)
	StartingTime	yyyy/mm/dd/ HH/MM
Robot-Dimensions	Height	cm
	Length	cm
	Width	cm
	PivotToFront	cm
	PivotToFrontWheel	cm
	PivotToRealWheel	cm

Finally, *IfcFacetedBrep*, a manifold solid brep with

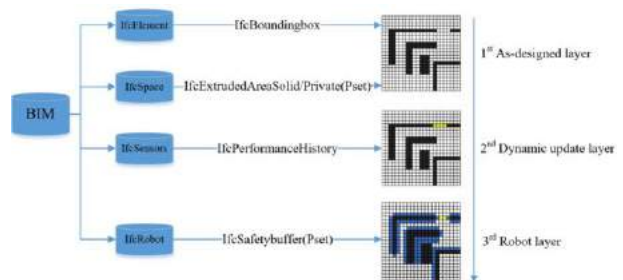

Figure 3. IFC-based layered mapping

1st layer: As-designed layer. The As-designed layer is a shared map for each robot originated from the BIM design plans, indicating physically passable areas. First, the current phase of the project should be determined to identify related indoor elements. This study selected the facility management phase for the demonstration, and floors, walls, doors and columns are included as the relevant building elements. However, our method is insensitive to other phases, like the construction phase which contains temporary facilities like formwork, scaffolding. Second, the *IfcExtrudedAreaSolid* of *IfcSpace* is extracted from the BIM models, which indicates the localization and the size of the space element. *IfcSpace*'s extended property "public/private" is also required, where public space is constructed as the free space and private space is grouped to the obstacles. Finally, the *IfcBoundingBox* of *IfcWall*, *IfcDoor* and *IfcColumn* is drawn, composed of the world coordinates of each element's the lower-left corner and the upper

right corner. The areas covered by the *IfcBoundingBox* are considered as obstacles. Due to the trade-off between accuracy and computation load, the minimum width of *IfcBoundingBox* is taken as the unit grid size of the map, while the size of the map is decided by the boundary of *IfcSlab*. Hence, a preliminary 2D (x, y) grid cell map could be established, where an object's world coordinate (X, Y) should be connected to the cell coordinate (x, y) it arrives.

2nd layer: Dynamic updates layer. Path planning can also be affected by different dynamic factors, such as crowds, fire, locked doors. Dynamic updates refer to changes to the as-designed layer with real-time variations, mainly originated from sensors or construction schedules. Previous studies have demonstrated how to integrate real-time information with BIM [8,25], but such operations are out of the scope of this study. Hence, only the real-time status of door-related *IfcSensor* is considered in this article for the demonstration. In specific, the “locked” status of *IfcSensor* indicates cells covered by the door remain as obstacles, while cells covered by “unlocked” doors are turned to free space.

3rd layer: Robot-based layer. As the last step, this layer enables us to realize robot-centric mapping based on the robot data extracted from the IFC file. Each robot can obtain a unique map after customized refinements. Firstly, the robot's height will be compared with the bottom height of each building element, cells covered by elements higher than the robot will update their cost to 0. Besides, inflation sets cost value at the cells around obstacles according to the robot's SafetyBuffer.

3.3 Adaptive A* path planning

Our path planning module is a variant of the well-known A* algorithm that is adaptive to different kinds of UGR mobility systems. As shown in Alg.1, the searching loop is similar to the standard A* algorithm, where O and C refer to the open and closed set. Continuous motion primitives respecting the UGR's mobility are used as graph edges during *PrimitiveExpansion()*, resulting in a structure *node* recording the pose information (Section 3.3.1). Then *CollisionChecking()* checks the feasibility of generated nodes (Section 3.3.2), only those with the smallest total cost (*PrimitiveCost*, *HeuristicCost*) will be saved (Section 3.3.3). This process continues until any primitive reach goal.

Algorithm 1: Adaptive A*

```

Initialize();
while  $\neg O.empty()$  do
   $n_{current} \leftarrow O.PopMin()$ ;  $C.insert(n_{current})$ ;
  if ReachGoal( $n_{current}$ ) then
    | return RetrievePath();
   $nodes \leftarrow PrimitiveExpansion(n_{current})$ 
  for  $n_i$  in  $nodes$  do
    if  $\neg C.contains(n_i) \cap CollisionChecking(n_i)$  then
       $g_{temp} \leftarrow n_c.g_{current} + PrimitiveCost(n_i)$ ;
      if  $\neg C.contains(n_i)$  then
        |  $C.add(n_i)$ ;
      else if  $g_{temp} \geq n_i.g_{current}$  then
        | continue;
       $n_i.parent \leftarrow n_{current}$ ;  $n_i.g_{current} \leftarrow g_{temp}$ ;
       $n_i.f_{current} \leftarrow n_i.g_{current} + HeuristicCost(n_i)$ ;

```

3.3.1 Mobility-based primitive expansion

UGR's mobility should be discussed before primitive expansion, as it determines UGR's capacity to execute the movement. UGRs can be generally categorized into omnidirectional, all-steering, corner-steering, skid-steering and Ackerman-steering. The omnidirectional system is the most capable, whose holonomic wheels can make instantaneous translation in any direction (Figure 4. a). While restricted by nonholonomic constraints, the all-steering system composed of steering wheels also allows any direction's translation (Figure 4. b). With the outstanding mobility for following any shaped path, omnidirectional and all-steering systems are grouped into “**Unlimited UGR**” system, which adopt straight primitives of conventional A* algorithm (Figure 4. c) to visit the centers of eight neighborhoods. In addition, a set of quadrant rotations should also be added into each expansion (0° , 45° , 90° , 135° , 180° , 225° , 270° , 315°) to represent unlimited UGR's self-rotation capacity (Figure 5 a).

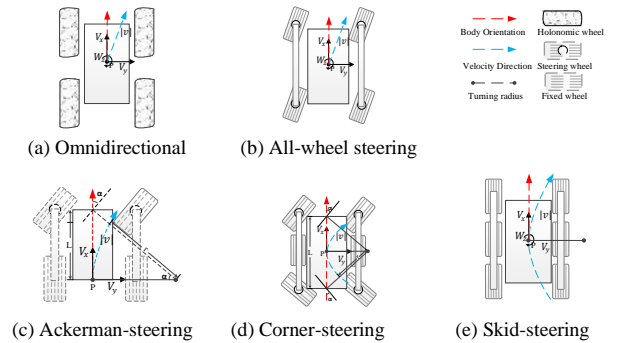

Figure 4. The mobility system of the UGVs

The linear velocity of Ackerman-steering, corner-steering, skid-steering, and is constrained to lie along the forward x-axis of the body (Fig 4, c-e). Hence, they are grouped into “**Limited UGR**” system, whose feasible primitive sets are curves generated based on their steering angles, while the straight extension is a special case of zero steering angle (Figure 5 b). Both skid steering and corner steering make turns by steering

wheels with a maximum steering angle α_{max} , while the latter generally has a better steering ability due to the smaller distance from the pivot \mathbf{P} to the front axle. To keep the balance between efficiency and accuracy, the choice set of these two UGVs' radii are determined by dividing the steering range into six parts (Formula 9). Skid-steering UGV's turning is supported by the speed difference between two-side wheels, freeing itself from the turning radius limitation. Similarly, we used a uniform distributed set $[\pm 20^\circ, \pm 40^\circ, \pm 80^\circ]$ to represent its outstanding steering ability.

Fig 5. Primitive of the UGVs.

As a result, new nodes will be generated at the end of each primitive, and the 2D map (x, y) will be extended into the 6D map (X, Y, x, y, θ, m) by additionally recording the world coordinates (X, Y) , heading θ and move direction m . The new world coordinates of “**Unlimited UGR**” could be easily calculated by converting the cell coordinates, while that of “**Limited UGR**” should be updated based on the drive distance d and max steering angle α_{max} (Formula 1-4). Besides, UGR's heading can be updated by adding rotation degrees to the former heading status, while m is denoted as +1 for forwarding, and -1 for reversing.

$$X' = \begin{cases} X + d\sin\theta, & \text{straight} \\ X + r \left(\cos\theta - \cos\left(\theta + \frac{180d}{\pi r}\right) \right), & \text{curved} \end{cases} \quad (1)$$

$$Y' = \begin{cases} Y + d\cos\theta, & \text{straight} \\ Y + r \left(\sin\left(\theta + \frac{180d}{\pi r}\right) - \sin\theta \right), & \text{curved} \end{cases} \quad (2)$$

$$\theta' = \begin{cases} \theta, & \text{straight} \\ \theta + \frac{180d}{\pi r}, & \text{curved} \end{cases} \quad (3)$$

$$r \in \begin{cases} \left[\pm \frac{L}{\tan \alpha_{max}}, \pm \frac{L}{\tan \frac{\alpha_{max}}{2}}, \pm \frac{L}{\tan \frac{\alpha_{max}}{4}} \right], & \text{Ackerman - steering} \\ \left[\pm \frac{L}{2 \cdot \tan \alpha_{max}}, \pm \frac{L}{2 \cdot \tan \frac{\alpha_{max}}{2}}, \pm \frac{L}{2 \cdot \tan \frac{\alpha_{max}}{4}} \right], & \text{Corner - steering} \\ \left[\pm \frac{L}{\tan 80^\circ}, \pm \frac{L}{\tan 40^\circ}, \pm \frac{L}{\tan 20^\circ} \right], & \text{Skid - steering} \end{cases} \quad (4)$$

3.3.2 Collision checking of the primitive

The moving object is usually considered as a particle in traditional A*, which ignores its actual shape. However, this method may lead to the failure of primitive extension in indoor environments, where corridors are highly likely to be narrower than the robot

length (e.g. case in Figure 6). To ensure both the primitive feasibility and the success rate of path planning, a three-stage **CollisionChecking()** is proposed, including “Axis-Aligned Bounding Boxes Intersection” (AABBI) checking, “Line-Line Intersection” (LLI) checking, and “Point-in-Rectangle Intersection” (PRI) checking. The basic idea is to detect if the rectangle covered by the robot is intersected with the rectangles covered by other obstacles, and we use the world coordinate for the following calculations.

Figure 6. Robots in a congested corridor

AABBI checking is a fast method to test if two no-rotation rectangles intersect in 2D space, and intersection happens if their corners satisfy Equation (5) and (6). Since either obstacle or robot's bounding box is not always axis-aligned, AABBI checking here serves as a speed-up process. The collision between rectangles will not exist if their bounding boxes are not intersected with each other (as shown in Figure 7. a).

$$a.minX \geq b.maxX \parallel a.maxX \leq b.minX \quad (5)$$

$$a.minY \geq b.maxY \parallel a.maxY \leq b.minY \quad (6)$$

Figure 7. Three-stage collision checking

Secondly, LLI checking should be executed for better accuracy, each line of the robot's rectangle should be checked with all lines of obstacles' rectangles pairwise (Figure 7. b). Two segments (e.g. $[(x_1, y_1), (x_2, y_2)]$, $[(x_3, y_3), (x_4, y_4)]$) meet the requirement of Equation (7-9), with the idea that the intersection point should be between two endpoints of each segment.

$$(y_4 - y_3)(x_2 - x_1) - (x_4 - x_3)(y_2 - y_1) \neq 0 \quad (7)$$

$$0 \leq \frac{(x_4 - x_3)(y_1 - y_3) - (y_4 - y_3)(x_1 - x_3)}{(y_4 - y_3)(x_2 - x_1) - (x_4 - x_3)(y_2 - y_1)} \leq 1 \quad (8)$$

$$0 \leq \frac{(x_2 - x_1)(y_1 - y_3) - (y_2 - y_1)(x_1 - x_3)}{(y_4 - y_3)(x_2 - x_1) - (x_4 - x_3)(y_2 - y_1)} \leq 1 \quad (9)$$

One special collision case that will escape from LLI checking is that a rectangle is inside another one. As the

final checking step, PRI checking will divide the rectangle of the obstacle into two triangles. Then it will check if any corner of the robot rectangle can be expressed as a linear combination of either triangle's corners, which satisfies Equation (10-12) (Figure 7. c). After repeating for the case that the obstacle is inside the robot, the primitive that passes all the checking is considered as a feasible expansion.

$$0 \leq \frac{(y_2 - y_3)(x - x_3) + (x_3 - x_2)(y - y_3)}{(y_2 - y_3)(x_1 - x_3) + (x_3 - x_2)(y_1 - y_3)} \leq 1 \quad (10)$$

$$0 \leq \frac{(y_3 - y_1)(x - x_3) + (x_1 - x_3)(y - y_3)}{(y_2 - y_3)(x_1 - x_3) + (x_3 - x_2)(y_1 - y_3)} \leq 1 \quad (11)$$

$$0 \leq \frac{x(y_1 - y_2) + x_1(y_2 - y) + x_2(y - y_1)}{(y_2 - y_3)(x_1 - x_3) + (x_3 - x_2)(y_1 - y_3)} \leq 1 \quad (12)$$

3.3.3 Improved cost setting

We aim to find a path that is optimal in energy and time, so the actual cost g of a path is defined as:

$$g = \sum_{n=1}^N d(n) + \alpha|\theta(n) - \theta(n-1)| + \beta|s(n) - s(n-1)| + \gamma * m(n-1) \oplus m(n) \quad (13)$$

Specifically, the **PrimitiveCost()** is composed of moving distance, orientation difference, steering angles, and motion difference. Thus, a UGR should travel with the least distance $d(n)$, changes of orientation $|\theta(n) - \theta(n-1)|$, changes of steering angle $|s(n) - s(n-1)|$, and switch of motion direction $m(n-1) \oplus m(n)$. α , β and γ are coefficients decided by users. The **HeuristicCost()** is measured by Euclidean distance between the robot's current position and goal position as the basic A*.

4 Validation

In the validation section, the fully integrated professional game engine Unity3D is selected to validate the whole path planning framework. Due to the integration of a powerful physical engine PhysX, Unity3D has shown great performance on the simulation of kinematics and dynamics. Particularly, previous studies [13] have proven Unity3D's ability to validate the efficiency of robot path planning algorithms. In addition, as Unity3D offers us significant flexibility to simulate different environments and robot mobility systems, it could be highly time-saving and economical.

4.1 Experiment setting

The fifth floor of Cheng Yu Tung Building, a laboratory and office building of Hong Kong University of Science and Technology, is selected as the environment (shown in Figure 8 with its BIM model). It is a representative place for robot applications, where many tedious works (e.g. material handling, cleaning) could be taken by robots.

Figure 8. Cheng Yu Tung Building of HKUST

While five mobility system has been discussed, an Ackerman-steering transport robot is herein selected for validation, which is a very common method to delivery objects in indoor areas (shown in Figure 9). And the starting point and ending point are selected in a laboratory (Figure 10).

Figure 9. Ackerman-steering transport robot

Figure 10. Start and goal of the path

4.2 Results

4.2.1 IFC-based integration and mapping

Following the method in section 3.1, the robot model and its relevant information is integrated into BIM, and an overview of its BIM model is shown in Figure 10. After extracting the necessary information from IFC files, a layered grid map is constructed (Figure 11), where the robot's safety buffer (blue) and dynamic update of *Ifcdoor* (yellow rectangle) are included. All space is considered public in this study, and grey ground/cells indicate the free space.

Figure 10. IFC model of the transport Robot

Figure 11. IFC-based indoor map

4.2.2 Performance of adaptive A* path planning

To evaluate the performance of adaptive A* algorithm, IFC information of the robot is extracted to develop the robot model in Unity3D. Its physical properties and kinematics are all considered to guarantee the fidelity of the robot. In addition, a PID controller is designed to simulate its movements.

Tradition A* and its integration with our improvements are selected for comparison. According to metrics, computation time is used to test how efficient the algorithm is, while steering jerk and speed jerk are used to test the energy-efficient performance. Trajectory time and success rate are the other two metrics that are commonly considered. We run 20 runs for each scenario and the average values are used for final evaluation. As shown in Table 2, our adaptive A* outperforms others in all the metrics except the computation time, which is expected as more calculations are executed during the path planning process. The demonstration of the failure case of adaptive A* without kinematic primitive and success case of adaptive A* is provided in Figure 12.

Table 2. IFC-based robot properties

	Computation Time (s)	Steering Jerk (rad/0.2s ²)	Speed Jerk (m/0.2s ²)	Trajectory Time (s)	Success Rate (%)
Ours without kinematic primitive	/	/	/	/	0
Ours without collision checking	/	/	/	/	0
Ours without improved Cost	2.031	1926.38	740.5	114.4	100%
Adaptive A* (ours)	2.703	1466.6	707.35	97.72	100%

5 Conclusion

This paper presents a BIM-integrated framework for unmanned ground robot. Integrating robot into BIM results in a useful knowledge base for UGR's indoor path planning. In addition, an IFC-based layered method is proposed to establish the relationship between BIM and indoor map, followed by a mobility-based A* algorithm that adaptive to different kinds of UGRs.

However, there still exist some limitations to be improved in the future. Firstly, this study uses an Ackerman-steering robot for the validation but does not have a demonstration for unlimited UGRs. The future experiments will try to cover this part. In addition, only a laboratory scenario is considered during path planning, while scenarios with different complexities should be explored in the future.

Abstract –

Many of the fatalities and injuries in the construction industry occur in scaffolding accidents, and monitoring the scaffolding process and checking compliance are critical. However, monitoring scaffolds is labor-intensive and inefficient because it is done manually. To address this issue, we propose an advanced 3D reconstruction method for detecting and monitoring scaffolds. Deep learning-based RandLA-Net architecture is used to perform scene segmentation. RandLA-Net is trained based on transfer learning, using the knowledge of the model learned with the Semantic3D dataset. RandLA-Net uses 3D point cloud data that are matched and registered by LIO-SAM, a laser slam algorithm. By attaching a LiDAR to a quadruped robot, it is possible to obtain data frequently in a manner suitable for construction sites. The proposed methodology has demonstrated good performance in monitoring scaffolds.

Scaffold; Mobile Laser Scanning (MLS); Robot Dog; 3D Semantic Segmentation; Transfer Learning

1 Introduction

According to the Korea Occupational Safety and Health Agency, 292 fatalities occurred at construction sites in 2019, in which 162 workers died during work related to temporary structures [1]. The main factor among the causes of fatalities and injuries is scaffolds, one of the representative temporary structures. To secure the safety, guidelines for installation and use are provided, and they check the spacing, angle, presence, etc. of the scaffold members. However, the process of checking the regulation of scaffolds is done manually by humans and takes a very long time.

Previous studies have attempted vision-based safety monitoring [2, 3] and sensor-based monitoring such as strain gauge or accelerometer [4, 5] to perform automated management of scaffolds. Wang [6] classified the point clouds of scaffolds acquired by

Terrestrial Laser Scanning (TLS) using histogram of data, M-estimator Sample Consensus (MSAC), and Random Sample Consensus (RANSAC) algorithm. Xu et al. [7] proposed a reconstruction procedure for scaffolds using a 3D local feature descriptor, Linear Straight Signature Histogram of Orientations (LSSHOT), for the photogrammetric point cloud. For effective safety management of scaffolds, the actual geometry of the scaffold should be checked. However, not much research has been done on point cloud data containing geometric information of scaffolds. Moreover, the recognition method of scaffolds via a deep learning-based 3D segmentation model has not yet been proposed.

To address the above issue, this paper proposes a point cloud data reconstruction method of scaffolds acquired with a robot dog, as shown in Figure 1. In general, acquisition and post-processing of point cloud data take a lot of time. However, this study uses the robot dog and a Mobile Laser Scanning (MLS) method with a Simultaneous Localization and Mapping (SLAM) algorithm to improve the efficiency of data collection.

Figure 1. Overview of the proposed method

2 Methodology

2.1 Data acquisition system using robot dog

A data collection system using a robot dog (A1 robot dog of Unitree) was developed for this study. An Inertial Measurement Unit (IMU) sensor and Velodyne VLP-16 are mounted on the robot dog; the robot dog provides power for the sensors. Figure 2 shows the overall hardware configuration of the robot dog. The software development kit provided by Unitree, drivers for scanning instruments, and customized teleoperation code were installed on the on-board computer (NVIDIA Jetson

TX2). Main computer and on-board computer communicated via Secure Shell (SSH) using the robot's internal Wireless Access Point (WAP). By manipulating the on-board computer through SSH, control, scan, and data transmission became possible remotely.

Since the robot dog's field of view was limited when collecting data, this study developed appropriate scan motions and used them for data acquisition. The robot dog's maximum pitch and roll angle were 20 degrees, respectively, and the maximum yaw angle was 28 degrees. Therefore, the combination of angles of roll, pitch, and yaw has made the robot dog's field of view as wide as possible in the scan position. A few examples of posture at the scanning point of the robot dog are shown in Figure 3. Depending on the relative position of the scaffold, the robot's scanning posture was changed, and data were continuously acquired by wandering around the structure.

Figure 2. Hardware configuration of robot dog

Figure 3. Examples of robot dog scanning postures

2.2 Mapping point cloud data

To create the point cloud map and estimate the odometry of the robot dog, a SLAM algorithm called LIO-SAM [8] was used. The LIO-SAM algorithm uses high-frequency IMU data to predict tightly-coupled lidar

inertial odometry and enables precise and fast mapping in complex environments [8]. The SLAM algorithm was implemented with IMU data and LiDAR data. The data acquired from the robot's on-board computer were transferred to the laptop, the main computer. Figure 4(b) and Figure 5(b) show the registered point cloud data acquired at Site A and Site B, respectively.

Figure 4. Site A dataset; (a) photograph of Site A, (b) registered point clouds

Figure 5. Site B dataset; (a) photograph of Site B, (b) registered point clouds

2.3 Transfer learning and 3D segmentation

To achieve high learning performance from less training data, we propose a transfer learning-based semantic segmentation method for training a new model using a pre-trained model. The Semantic3D dataset [9] was used to obtain the pre-trained model. Semantic3D is one of the typical datasets used in 3D classification, 3D object detection and tracking, and 3D segmentation. This dataset was chosen because it is similar in size to our dataset, acquired outdoors, and is a registered data unlike SemanticKITTI [10].

The registered 3D point cloud data were segmented by RandLA-Net [11]. It achieved the best performance for 3D segmentation method on the Semantic3D benchmark [12]. RandLA-Net uses random sampling and

local feature aggregators to classify large-scale point cloud data in a short period of time. The network follows the commonly used encoder-decoder structure and consists of five encoder-decoders. In this study, we attempted a fine-tuning method through changing the frozen layers of encoders and decoders of the pre-trained model. Consequently, the training performance was best when re-training three encoders and decoders in the middle of the network.

3 Experiments and Results

3.1 Dataset

Point clouds were acquired at Site A and Site B as shown in Figure 4 and Figure 5. Point cloud data acquired at Site A were used to train the model, and data acquired at Site B were used for testing and validation. Of the four structures at Site B, only the second structure was the validation data and the others were the test data. On Site A, point cloud data were acquired through the robot dog and a handheld method. Sensor data were stored in a Robot Operating System (ROS)-based bag file format, with 16 files acquired in the handheld method and 20 files acquired using the robot dog.

3.2 Implementation

RandLA-Net was trained with a batch size of 4 and there were two class labels: background and scaffold. Epoch was set to 100 by default, early stopping was used, and learning rate decay was implemented. The training process of the 3D segmentation model on data acquired by the robot dog is as follows: 1) Find the most suitable modified structure through fine-tuning using training and validation data acquired by the handheld method; 2) Train the model using the found structure in the above step with the training data acquired by the robot dog.

3.3 Evaluation metrics

The performance of the semantic segmentation model was computed by Eqs. (1), (2), and (3). Precision (P) indicates how many actual positive points are included among the positive points predicted by the model. Recall (R) calculates the proportion of points that are predicted to be positive properly among the points that are actually positive. F1-score (F1) is the weighted average of Precision and Recall.

$$P = \frac{\text{True Positive}}{\text{True Positive} + \text{False Positive}} \quad (1)$$

$$R = \frac{\text{True Positive}}{\text{True Positive} + \text{False Negative}} \quad (2)$$

$$F1 = 2 * \frac{P * R}{P + R} \quad (3)$$

3.4 Results and Discussion

Table 1 demonstrates the performance of a model trained through transfer learning using data acquired by the robot dog. The model achieved an 84.96% F1-score on scaffolds. The F1-score of the scaffolds is always relatively lower than that of the background, because the number of points corresponding to the scaffolds is small. Figure 6 shows the worst and best examples of scaffold prediction. In Figure 6, pink is true positive, cyan is true negative, yellow is false negative, and orange is false positive. In the figure, the white area is caused by cropping the point cloud data corresponding to the validation data.

Table 1. The performance of the 3D segmentation model trained with the robot dog dataset

	Precision	Recall	F1 score
Scaffolds	97.15%	76.45%	84.96%
Background	98.56%	99.86%	99.20%

Figure 6. Examples of semantic segmentation results (top: F1 score is 63.16%; bottom: F1 score is 96.31%)

Overall, the lower parts of scaffolds were poorly predicted, as shown in Figure 7. It is assumed that this is due to the effect of noise caused by the surrounding environment or people, or to the difficulty of distinguishing between scaffolds and ground. In future studies, we will systematically compare the results of the

data acquired by the handheld method with those of the data acquired using the robot dog. Furthermore, we will analyze the cause of poor prediction on the data acquired by the robot dog. Although the point cloud data of scaffolds were not perfectly classified with the proposed method, they were segmented more effectively than when using the RANSAC or histogram-based method attempted in previous studies.

Figure 7. Examples of failure of semantic segmentation

4 Conclusion

This study proposed a novel pipeline to segment 3D point cloud data acquired from a robot dog through transfer learning. The LIO-SAM-based data acquisition system was implemented and tested using a robot dog with various patterns of scanning postures. By the proposed data acquisition system, point cloud data can be effectively collected by the robot moving around the scaffold. With the transfer learning, the RandLA-Net algorithm was efficiently trained on the scaffold data of the two sites for scaffold segmentation. In the experiment, the F1-score from the handheld method (97.31%) was relatively higher than that from the robot dog (84.96%). The cause of this phenomenon will be analyzed in future

research. The scaffold point clouds classified by the segmentation model can be used for 3D modeling through post-processing steps. Using the 3D model, safety managers can monitor the scaffolding installation and dismantling procedure and automatically check compliance with safety regulations. If the proposed method is further developed, it is expected to efficiently monitor scaffolds and reduce mortality and accident rates at construction sites.

Abstract -

Robotic solutions for the construction industry are attracting the attention of researchers and of the market. Among the various technologies, robotic bricklaying promises to become a disruptive technology. However, most of the solutions proposed so far resulted to be inefficient and did not pass the prototype status. One of the main problems is that most proposed solutions adopt the classic assumption of 'rigid robot' which results in large weight of the robots *w.r.t.* the loads it is able to manipulate. In this paper we propose and analyze an innovative bricklaying concept based on two robotic sub-units: a 'non-rigid' crane which cooperates with a lightweight rigid robot. The correct cooperation between the two robotic sub-units poses a series of control challenges that must be studied in the context of cooperative manipulation of a object. In this paper we will first derive the mathematical model of this robotic system during the positioning of the block. Then a control law will be proposed. The goal of the control is to move the common payload (*i.e.* the block to be placed) to the desired position while making sure the robotic arm is never overloaded. The corresponding stability and convergence analysis is proved using the *LaSalle's invariance principle*. A physical and realistic CAD-based simulator of the overall system has been developed and will be used to demonstrate the feasibility of the concept.

1 Introduction

With the constant technological advancements, we are assisting to the progressive robotization of many labor-intensive and repetitive human activities. In the current historical phase robots are "leaving" the factories to assist humans in an increasing number of activities. In particular, in the last few years, mostly thanks to the development of new technologies, the use of robotic solutions for the

construction industry has grown rapidly [1]. Among the various technologies, robotic bricklaying have in recent years attracted the attention of the public and of the experts and promise to become disruptive technologies. However, very few of the prototypes built in these years have reached the market and can be considered successes.

Most authors [2, 3] agree that the low level of success of robots for bricklaying is due to the fact that developers tried to replicate the solutions developed for the manufacturing industry into the construction context. A major issue is that most solutions are based on rigid arms. In the manufacturing industry robots tend to be much bigger and heavier than the components they manage. This allows the robot to be rigid and to have a very good dexterity in managing the components to be assembled. However since construction materials are often large and heavy themselves, using the same approach results in unreasonably bulky and heavy robots. In [4] a long-range/high payload hydraulic 6-DOF robot for brick assembly named ROCCO was proposed. This machine was able to handle nonstandard and standard blocks with a maximum weight of 350 kg. The prototype of ROCCO weighed 3t and its dimensions were 2.5 x 1.7 m. Given its dimensions and weight, it was nearly impossible to use it on a ceiling slab. Therefore, the prototype was abandoned. Following the same concept of ROCCO, in [5] the robot BRONCO was proposed. Conceptually ROCCO and BRONCO were very similar. However, BRONCO was much smaller but every single pick and place operation was very slow. Like ROCCO, BRONCO did not pass the prototype status and, at the best of our knowledge, this concept was abandoned. Due to the lack of success of robots able to manipulate large and heavy blocks, the market and the scientific publications have turned their attention to robots capable of building with small bricks. SAM100 is the first (and currently the only) commercially available bricklaying robot for on-site masonry construction [6]. SAM100 is based on a standard industrial manipulator with a gripper mounted on a large mobile base. The robot is a very typical industrial rigid robot able to work only with small bricks. DimRob [7] is a prototype mobile construction unit developed in the early 2010s consisting of a standard industrial robot

*This research has been funded by The Brussels Institute for Research and Innovation (INNOVIRIS) of the Brussels Region through the Applied PHD grant: Brickiebots - Robotic Bricklayer: a multi-robot system for sand-lime blocks masonry (réf : 19-PHD-12)

arm attached on a mobile base. As SAM100, DimRob was specifically thought to work only with small bricks. Recently the design of DimRob was further refined giving rise to the "In Situ Fabricator" prototype [8]. However, the use of small building bricks has limited use in practice and the global trend (especially for large civil buildings) is to go toward larger and heavier blocks which speed-up the construction process and have better mechanical and insulation characteristics.

In the remainder of this paper we will propose a new concept for the automatic laying of large blocks that we believe has the potential to overcome the main limitations of the designs proposed so far. The solution consists of two robotic sub-units: a 'non-rigid' crane and a rigid robot. This system exploits the characteristics of the crane (and in particular the presence of the lifting cable) to perform the macro-movement of the block and hold most of the weight of the block. The use of the rigid robot allows to obtain the desired precision during the fine placement of the block. The control of the two robotic units poses a number of co-operation challenges that must be studied in the context of cooperative manipulation [9] with the aim of: i) ensuring that the robotic manipulator is able to precisely manipulate large and heavy blocks without being overloaded; ii) carrying out the bricklaying in a fast, reliable, and safe way. From the control viewpoint, the main cooperative challenge concerns the final activity of block placement. In fact, the laying activity of a block can be divided in two main phases. The first phase is the macro-movement performed by the crane. In this phase, the crane lifts the block from the pallet and brings it near its final position. The main difficulty of this first phase concerns the oscillations of the payload which must be counteracted with a proper handling of the crane by the operator. As demonstrated by the authors in [10, 11, 12], for boom cranes this problem could be dramatically mitigated by properly controlling the crane. The second phase is the precision placement, in which once that the robot has grabbed the block, the crane and the robot must be controlled in a cooperative way to carry out the fine-positioning of the block on the wall. In this paper we focus on this second phase. Note that the problem of grasping the swing block has already been addressed in [13], where the authors propose a crane with three wires lifting mechanism to control both the position and the orientation of the block.

Cooperating manipulator systems appear to be a case study of growing interest in the recent literature [14]. This interest is mainly due to typical limitations in applications of single-arm robots. It has been recognized, in fact, that many tasks that are difficult or impossible to execute by a single robot become feasible when two or more manipulators are employed in a cooperative fashion. Such systems are capable of performing a wide range of tasks

that include, for instance, carrying heavy or large payloads. Several cooperative control schemes have been proposed in the literature, including motion control [15] and force-impedance/compliance control [16] schemes. Other approaches include adaptive control [17], task-space regulation [18] and joint-space control [19]. To solve the problem of robotic bricklaying, in this paper we address the problem of modeling and control of an heterogeneous robotic system composed of a 'non-rigid' robot, such as a crane, in charge of the macro-movement and of holding most of the weight of the block, and a rigid robot to achieve the desired precision during the fine placement of the block. In the first part of this paper, a mathematical model of the proposed robotic architecture will be derived. On the basis of this model a nonlinear control law will be derived which will allow to control the whole system correctly and safely. A proof of asymptotic stability of the resulting closed-loop system is provided making use of the *LaSalle's invariance principle*. At the end of the paper, a physical and realistic CAD-based simulator of the overall system was developed to demonstrate the feasibility of the concept.

2 Dynamic Model

The proposed robotic solutions is composed by two sub-units: i) an industrial robotic manipulator, and ii) a boom crane. The manipulator used in this paper is a standard 6-axis industrial robot like the one in Fig.1a. The robot configuration is described by the joint variables vector $q_r \in \mathbb{R}^6$, with $q_r = [q_{r1}, q_{r2}, q_{r3}, q_{r4}, q_{r5}, q_{r6}]^T$, see Fig.1a. The crane selected for our analysis is a small boom crane (like the one in Fig.1b) which is among the most common types of small cranes used for bricklaying. For the modelling we consider the block to be placed as part of the crane system. For the sake of simplicity, we will also consider the following reasonable assumption.

Assumption 1. All the links and joints of the crane are considered rigid. Moreover, the cable is supposed to be massless, rigid, and always taut, thus the lifting mechanism can be described as a prismatic joint.

Note that this assumption is quite reasonable in most practical applications. In fact the deformations of cranes due to the load are typically negligible w.r.t. overall dimensions of the crane. Furthermore the mass of the payload is usually much bigger than the mass of the cable, which together with the small swing angles that are typically used when operating cranes, makes the assumption on the cable reasonable [20]. The validity of this latter assumption will be verified in Sec.4 where a realistic model of cable based on the Finite Elements Method will be used for the simulations.

The configuration of the crane+block is conveniently described by eight variables, $q_c \in \mathbb{R}^8$, with $q_c = [\alpha, \beta, \theta_1, \theta_2, d, \theta_3, \theta_4, \theta_5]^T$, Fig. 1b. Where α is the slew angle of the tower, β is the luff angle of the boom, d is the length of the rope, θ_1 is the radial sway due to the motion of the boom, θ_2 is the tangential pendulation due to the motion of the tower, and $\theta_3, \theta_4, \theta_5$, are the orientations of the block w.r.t the cable.

Figure 1: Robotic Arm and Boom Crane

The dynamic model of the system can be obtained using the *Euler-Lagrange method* [23] considering as set of generalized coordinates q_r for the robot and q_c for the crane+block. Firstly, for both systems we need to define the *Lagrangian function* as the difference between the kinematic and potential energy. In particular, let the kinematic energy, potential energy, and Lagrangian of the robot be

$$T_r = \frac{1}{2} \dot{q}_r^T B_r(q_r) \dot{q}_r, \quad U_r = U_r(q_r), \quad \mathcal{L}_r = T_r - U_r, \quad (1)$$

while the corresponding quantities for the crane+block system are

$$T_c = \frac{1}{2} \dot{q}_c^T B_c(q_c) \dot{q}_c, \quad U_c = U_c(q_c), \quad \mathcal{L}_c = T_c - U_c, \quad (2)$$

where the matrices $B_r(q_r) \in \mathbb{R}^{6 \times 6}$ and $B_c(q_c) \in \mathbb{R}^{8 \times 8}$ are the robot inertia matrix and the crane+block inertia matrix, respectively.

The Lagrangian function of the entire system is

$$\mathcal{L}_t = \mathcal{L}_r + \mathcal{L}_c = T_r + T_c - U_r - U_c. \quad (3)$$

To derive the dynamic model of the system we need to introduce a set of closed-chain constraints that come from the interaction between the robot and the crane during the last part of the laying activity where the robot has already grabbed the block that needs to be placed in the final position (see Fig.2). For the sake of simplicity, we assume that the robot grasps the block with a two finger-end

Figure 2: Interaction between the Robot and Crane

effector and that the grip is tight enough so that no sliding nor rotational movements can occur. In this situation, the interaction between the two systems can be model as *holonomic constraints* [24].

To define these constraints, let p_e be the end-effector position, while a minimal representation is used for its orientation, o_e (e.g. Euler angles). The robot end-effector pose can be expressed by means a 6-dimension vector

$$x_e = \begin{bmatrix} p_e \\ o_e \end{bmatrix}. \quad (4)$$

Accounting for the dependence of position and orientation from the joint variable, the direct kinematics equation can be written as $x_e = k_r(q_r)$, where $k_r(\cdot)$ is in general a nonlinear function. However, when the robot grabs the block, the robot end-effector pose can also be seen as function of the crane joint variable $x_r = k_c(q_c)$, where $k_c(\cdot)$ is the crane direct kinematics.

This leads to the following *holonomic constraints*:

$$k_r(q_r) = k_c(q_c) \Rightarrow k_r(q_r) - k_c(q_c) = 0. \quad (5)$$

In presence of (5), the constrained model dynamics can be derived using the *augmented Lagrangian*

$$\mathcal{L} = \mathcal{L}_t + \lambda^T [k_r(q_r) - k_c(q_c)], \quad (6)$$

where $\lambda \in \mathbb{R}^6$ is the Lagrangian multipliers vector that can be interpreted as the generalized forces that arise on the contact interface when attempting to violate the constraints. The equations of the motion of the constrained system are derived using the *Euler-Lagrange equations*

$$\begin{aligned} \frac{d}{dt} \left(\frac{\partial \mathcal{L}}{\partial \dot{q}} \right)^T - \left(\frac{\partial \mathcal{L}}{\partial q} \right)^T &= \frac{d}{dt} \left(\frac{\partial \mathcal{L}_t}{\partial \dot{q}} \right)^T \\ - \left(\frac{\partial \mathcal{L}_t}{\partial q} \right)^T - \left(\frac{\partial (\lambda^T h(q))}{\partial q} \right)^T &= u + F \dot{q}, \end{aligned} \quad (7)$$

$$\left(\frac{\partial \mathcal{L}}{\partial \lambda} \right)^T = h(q) = 0, \quad (8)$$

where $q = [q_r, q_c]^T \in \mathbb{R}^{14}$ is the system state vector, $h(q) = k_r(q_r) - k_c(q_c)$ are the constraints expressed by

(5), $F \in \mathbb{R}^{14 \times 14}$ represents dynamic friction, and $u = [u_{r1}, u_{r2}, u_{r3}, u_{r4}, u_{r5}, u_{r6}, u_{c1}, u_{c2}, 0, 0, u_{c3}, 0, 0, 0]^T \in \mathbb{R}^{14}$ is the control input vector. It is worth noting that while the robotic arm is fully actuated (*i.e.* the number of input is equal to the number of DOFs to be controlled, $u_r \in \mathbb{R}^6$), the boom crane is an under-actuated system (*i.e.* $u_c \in \mathbb{R}^3$). In fact, the crane system has only three inputs for 8-DOF as the actuated DOFs are the first two rotations (*i.e.* α and β) and the length of the rope (*i.e.* d).

Substituting (1)-(3), and (6), into (7)-(8), the dynamic model of the constrained mechanical system can be compactly rewritten as the following *descriptor system*

$$B(q)\ddot{q} + C(q, \dot{q})\dot{q} + F\dot{q} + G(q) = u + A(q)^T \lambda \quad (9)$$

$$\text{s.t.} \quad A(q)\dot{q} = 0, \quad (10)$$

where $A(q) = \frac{\partial h(q)}{\partial q}$ is the *Jacobian* of the constraints.

In (9), the matrices $B(q) \in \mathbb{R}^{14 \times 14}$, $C(q, \dot{q}) \in \mathbb{R}^{14 \times 14}$, and $G(q) \in \mathbb{R}^{14}$ represent the inertia, centripetal-Coriolis, and gravity term, respectively. To simplify the next analysis we introduce the auxiliary variables: $m(q, \dot{q}) = C(q, \dot{q})\dot{q} + F\dot{q} + G(q)$. Matlab® code that contains the dynamic model is released as open-source on GitHub: <https://github.com/MikAmb95/RobotModel>.

The Lagrange multipliers in (9) can be eliminated by differentiating (8) twice *w.r.t* the time

$$\begin{aligned} h(q) = 0 \Rightarrow \dot{h} &= \frac{\partial h(q)}{\partial q} \dot{q} = A(q)\dot{q} = 0 \Rightarrow \\ \Rightarrow \ddot{h} &= A(q)\ddot{q} + \dot{A}(q)\dot{q} = 0. \end{aligned} \quad (11)$$

Substituting in (11) the expression of the joint acceleration (*i.e.* \ddot{q}) of (9), one obtains

$$A(q)B(q)^{-1}(u + A(q)^T \lambda - m(q, \dot{q})) + \dot{A}(q, \dot{q})\dot{q} = 0. \quad (12)$$

Solving (12) for the multipliers λ , we obtain

$$\begin{aligned} \lambda &= (A(q)B(q)^{-1}A(q)^T)^{-1}(A(q)B(q)^{-1}m(q, \dot{q}) \\ &\quad - A(q)B(q)^{-1}u - \dot{A}(q, \dot{q})\dot{q}). \end{aligned} \quad (13)$$

Replacing (13) into (9), the constrained dynamic model can be rewritten as

$$\begin{aligned} B(q)\ddot{q} &= (I - A^T(q)A^*(q))(u - m(q, \dot{q})) \\ &\quad - B(q)A^*(q)\dot{A}(q)\dot{q}, \end{aligned} \quad (14)$$

where $A^*(q)$ is the inertia-weighted pseudo-inverse of the constraint Jacobian A defined as

$$A^*(q) = B^{-1}(q)A^T(q)(A(q)B^{-1}(q)A^T(q))^{-1}. \quad (15)$$

Although the equation of motion (14) is quite complicated, it has several fundamental properties that can be exploited to facilitate the design of the control law. The main property that will be exploited in the next section is:

Property 1.

$$\frac{1}{2}\dot{B}(q) - C(q, \dot{q}),$$

is skew symmetric which means that

$$\eta^T \left[\frac{1}{2}\dot{B}(q) - C(q, \dot{q}) \right] \eta = 0, \quad \eta \in \mathbb{R}^{14}.$$

2.1 Control objective

The goal of the control scheme is to ensure: *i*) the correct cooperation between the robot and the crane in order to move the payload to a desired position; *ii*) the safe cooperation between the two sub-units so that the robot will never be overloaded.

To reach these control objective, the first step is to define a desired reference q_d that makes sense. For the problem in hand, in this paper we consider the following properties for the desired reference

Property 2. The desired reference belongs to the workspace of the robot and the crane.

One of the goal of the control scheme will be move the common payload (*i.e.* the block) to a desired position. The constraints (5) imply that once the robot has grasped the block, the desired position and orientation of the block can be seen as a desired pose for the robot end-effector (4). This means that by controlling the six robot joints so that the robot end-effector can follow a desired trajectory, the block can be positioned correctly. Concerning the crane, to limit the forces on the robot, the control scheme must ensure that the crane follows the movement of the payload in the horizontal plane by controlling the two actuated angles (*i.e.* α, β) so that the two oscillations (*i.e.* θ_1, θ_2) are ideally zero. Furthermore, exploiting the cable length (*i.e.* d) the crane control scheme can move the payload along the z-axis (*e.g.* keep the altitude of the block constant, release or lift the block). Concerning the block orientations (*i.e.* the angles $\theta_{3,4,5}$), when the robot has grasped the block *a priori* each robot end-effector orientation could represent a feasible block orientation. However, it is reasonable to think that in the desired position the first two angles (*i.e.* the angles $\theta_{3,4}$) must be equal to zero both for correct

alignment with the pre-existing wall and to avoid high torque at the robot wrist due to gravity. Instead the angle θ_5 can be whatever so as to reach the desired block orientation in the final position.

Accordingly to these consideration we will hereafter assume that all desired references are in the form

$$q_d = [q_{rd}, \alpha_d, \beta_d, 0, 0, d_d, 0, 0, \theta_{5d}]^T. \quad (16)$$

3 Control design and stability analysis

The control strategy proposed in this paper consists of a nonlinear control law based on energy consideration. The corresponding stability and convergence analysis is proved by using the LaSalle's invariance principle.

In order to develop our control law, we start from the following energy function

$$E(t) = \frac{1}{2} \dot{q}^T B(q) \dot{q} + mg(d - dC_{\theta_1}C_{\theta_2} + l_p - l_pC_{\theta_3}C_{\theta_4}), \quad (17)$$

where the first term is the kinetic energy of the system, whereas the second term represents the payload potential energy in which m is the mass of the block and g is the gravitational acceleration. In (17) l_p is the distance along the z-axis between the cable-block attachment point and the block Center of Mass (COM), C_i and S_i are the abbreviations for indicating the *sine* and *cosine* function of the angle i .

Based on (17), we can define the following Lyapunov function candidate:

$$V(t) = \frac{1}{2} \dot{q}^T B(q) \dot{q} + mg(d - dC_{\theta_1}C_{\theta_2} + l_p - l_pC_{\theta_3}C_{\theta_4}) + \frac{1}{2} \tilde{q}_r^T K_{pr} \tilde{q}_r + \frac{1}{2} k_{p\alpha} e_\alpha^2 + \frac{1}{2} k_{p\beta} e_\beta^2 + \frac{1}{2} k_{pd} e_d^2, \quad (18)$$

where \tilde{q}_r represents the error between the desired and the actual robot posture, K_{pr} is a (6×6) symmetric positive definite matrix. $k_{p\alpha}$, $k_{p\beta}$, and k_{pd} are positive gains, and e_α , e_β , e_d are the crane error between the desired and the current values.

Differentiating the equation (18) w.r.t the time and using (14) we obtain

$$\begin{aligned} \dot{V}(t) = & \frac{1}{2} \dot{q}^T \dot{B}(q) \dot{q} - \dot{q}^T B(q) A^*(q) \dot{A}(q) \dot{q} \\ & + \dot{q}^T ((I - A^T(q) A^*(q))^T) (u - m(q, \dot{q})) \\ & + mg\dot{d} (1 - C_{\theta_1}C_{\theta_2}) + \dot{\theta}_1 mg d S_{\theta_1} C_{\theta_2} + \dot{\theta}_2 mg d C_{\theta_1} S_{\theta_2} \\ & + \dot{\theta}_3 mg l_p S_{\theta_3} C_{\theta_4} + \dot{\theta}_4 mg l_p C_{\theta_3} S_{\theta_4} - \dot{q}_r^T K_{pr} \tilde{q}_r \\ & - \dot{\alpha} k_{p\alpha} e_\alpha - \dot{\beta} k_{p\beta} e_\beta - \dot{d} k_{pd} e_d. \end{aligned} \quad (19)$$

Using the Property 1 and considering (10) we obtain

$$\begin{aligned} \dot{V}(t) = & \dot{q}_r^T (u_r - G_r(q_r) - K_{pr} \tilde{q}_r) \\ & + \dot{\alpha} (u_{c1} - k_{p\alpha} e_\alpha) + \dot{\beta} (u_{c2} - G_\beta(\beta) - k_{p\beta} e_\beta) \\ & + \dot{d} (u_{c3} + mg - k_{pd} e_d) - \dot{q}^T F \dot{q}, \end{aligned} \quad (20)$$

where $G_r(q_r)$ and $G_\beta(\beta)$ are the gravity term of the robot and of the boom crane arm, respectively.

In order to cancel the gravitational terms and keep $\dot{V}(t)$ non-positive, the following controller is designed:

$$u_r = K_{pr} \tilde{q}_r - K_{dr} \dot{q}_r + G_r(q_r), \quad (21)$$

$$u_{c1} = k_{p\alpha} e_\alpha - k_{d\alpha} \dot{\alpha}, \quad (22)$$

$$u_{c2} = k_{p\beta} e_\beta - k_{d\beta} \dot{\beta} + G_\beta(\beta), \quad (23)$$

$$u_{c3} = k_{pd} e_d - k_{dd} \dot{d} - mg, \quad (24)$$

where K_{dr} is an (6×6) symmetric positive definite matrix, $k_{d\alpha}$, $k_{d\beta}$, and k_{dd} are positive control gains.

Substituting (21)-(24) into (20), one obtains

$$\begin{aligned} \dot{V}(t) = & -\dot{q}_r^T K_{dr} \dot{q}_r - k_{d\alpha} \dot{\alpha}^2 \\ & - k_{d\beta} \dot{\beta}^2 - k_{dd} \dot{d}^2 - \dot{q}^T F \dot{q} \leq 0. \end{aligned} \quad (25)$$

The following theorem describes the stability property of the system under analysis using the control law (21)-(24).

Theorem 1. Consider the system (14), the controller (21)-(24) makes every equilibrium point (16) asymptotically stable.

Proof: As already seen, the derivative of the Lyapunov function candidate (18) is (25) which is negative semidefinite. At this point let Φ be defined as the set where $\dot{V}(t) = 0$, i.e.

$$\Phi = \{q, \dot{q} | \dot{V}(t) = 0\}. \quad (26)$$

Further, let Γ represent the largest invariant set in Φ such that:

$$\begin{aligned} \dot{q} = 0, \dot{\tilde{q}}_r = 0, & \Rightarrow \ddot{q} = 0, \ddot{\tilde{q}}_r = \phi_r, \\ \dot{e}_{\alpha,\beta,d} = 0 & \Rightarrow e_{\alpha,\beta,d} = \phi_{\alpha,\beta,d}, \end{aligned} \quad (27)$$

where $\phi_{r,\alpha,\beta,d}$ are constants to be determined. Combining (27) with (21)-(24) and (9), we obtain

$$\begin{aligned} K_{pr}\tilde{q}_r &= 0, \\ k_{p\alpha}e_\alpha &= 0, \\ k_{p\beta}e_\beta &= 0, \\ gmdC_{\theta_2}S_{\theta_1} &= 0, \\ gmdC_{\theta_1}S_{\theta_2} &= 0 \\ -gmC_{\theta_1}C_{\theta_2} &= -mg + k_{pd}e_d, \\ gml_pC_{\theta_4}C_{\theta_3} &= 0, \\ gml_pC_{\theta_3}S_{\theta_4} &= 0 \end{aligned} \quad (28)$$

Considering that all the control gains are strictly positive, from the first three equations of (28) we obtain

$$K_{pr}\tilde{q}_r = 0 \Rightarrow \tilde{q}_r = \phi_r = 0 \Rightarrow q_r = q_{rd}, \quad (29)$$

$$k_{p\alpha}e_\alpha = 0 \Rightarrow e_\alpha = \phi_\alpha = 0 \Rightarrow \alpha = \alpha_d, \quad (30)$$

$$k_{p\beta}e_\beta = 0 \Rightarrow e_\beta = \phi_\beta = 0 \Rightarrow \beta = \beta_d. \quad (31)$$

From the other equations of (28), one can be obtained that:

$$\begin{aligned} C_{\theta_2}S_{\theta_1} &= 0, \\ S_{\theta_2}C_{\theta_1} &= 0, \\ C_{\theta_4}S_{\theta_3} &= 0, \\ C_{\theta_3}S_{\theta_4} &= 0. \end{aligned} \quad (32)$$

The following conclusion can be achieved:

$$\theta_1 = \theta_2 = \theta_3 = \theta_4 = (k\pi) \vee \frac{(2k+1)}{2}\pi, \quad k \in \mathbb{Z}. \quad (33)$$

However, the only acceptable solution will be:

$$\theta_1 = \theta_2 = \theta_3 = \theta_4 = 0. \quad (34)$$

By inserting the (34) in the sixth equation of (28), one can conclude that:

$$k_{pd}e_d = 0 \Rightarrow e_d = 0 \Rightarrow \phi_d = 0 \Rightarrow d = d_d. \quad (35)$$

Note that none of above equations depends on the angle θ_5 . However, the final value of this angle is defined by the final orientation of the robot. Then, choosing q_{rd} so that the robot reaches the desired orientation, we can conclude that due to (29), $\theta_5 = \theta_{5d}$, which concludes the proof. \square

4 Simulation Results

In this section we will demonstrate in simulation the effectiveness of the proposed approach. In particular we will show that this solution allows a relatively small industrial arm to manipulate a large and heavy block. To ensure realistic simulations a detailed CAD simulator (see Fig.3) was developed in Simscape™ making use of sub-units already available in the market. In particular the following devices have been selected:

- Crane: NK 1000 Mini Crane produced by NEEMASKO [22], see Fig.5.
- Robot: the ABB IRB 1200 produced by ABB Robotics Fig.6, [21] was selected. This robot weights approximately 50Kg, and it can carry a payload of up to 7kg.

In addition, a realistic wall model is included in the CAD simulator to analyze the possible impacts between the block to be placed and the existing wall. The block to be placed has dimension $0.6m \times 0.8m \times 0.2m$ with a weight of 120kg. The mechanical properties of the cable are reported in Tab. 1. The cable is modelled using 10 Finite Elements.

Material	Elastic Modulus	Poisson's Ratio	Mass Density
Galvanized Steel	$2^{11}[N/m^2]$	0.29	$7870[kg/m^3]$

Table 1: Crane cable material characteristics

Figure 3: CAD simulator enviroment

The parameters for the control law (21)-(24) are

$$\begin{aligned} K_{pr} &= 1 \cdot 10^3 I_6, & k_{p\alpha} &= 100, & k_{p\beta} &= 100, & k_{pd} &= 1 \cdot 10^4, \\ K_{dr} &= 3 \cdot 10^2 I_6, & k_{d\alpha} &= 50, & k_{d\beta} &= 50, & k_{dd} &= 7 \cdot 10e^2. \end{aligned}$$

Figure 4: Sequence block placement

The simulation results are reported in Figs.7-8. The desired references are designed in such a way that the block

is moved to its final position. Snapshots of the placement are shown in Fig.4. As expected, Fig.7 shows that the robot joints reach the desired values. Fig.8 shows that the crane actuated states reach the desired configuration. It is important to notice that for the block orientations, the first two angles (*i.e.* θ_3 and θ_4) remain almost equal to zero since the robot is able to damp this oscillations, while the third angles θ_5 rotates according to the robot end-effector trajectory. In Fig.9 the torques applied by the robot motors at each joint during the operation are reported. Most notably, these torques are well within the typical limits of the joint actuators. This means that the mass of the block is sustained almost entirely by the crane and the robot is never overloaded. However it is important to notice that in Fig.9, when the block touches the wall (at around 20 second), there are sudden changes in the torques. Even if their values are reasonable, this suggests that a mechanism for the manage of the impacts should be foreseen. This aspect will be the subject of future studies.

5 CONCLUSION

This paper proposes a new concept for the robotic brick-laying of large and heavy blocks based on the crane currently used in the manual bricklaying operations and a rigid robot. This new robotic concept opens to a number of challenges regarding the development of cooperative safety control of this multi-agent system. In the first part of this paper a mathematical model of the overall system is derived. On the basis of this model, a nonlinear control law has been developed which is able to perform position control of the robotic system. The stability properties of the scheme have been proved using the LaSalle's invariance principle. A realistic CAD-based simulator of the overall system was developed to demonstrate the feasibility of the concept. As emerged from the simulations the robot is able to manage quite easily a block that weights the double of its weight.

Abstract –

Broad research concepts are usually developed in different phases where advances are carried out separately. That is the case of the automated and robotic façade renovation with modules. In this case, solutions were developed independently in the context of two research projects. In order to offer a holistic vision, analyze the current state, and solve gaps, a conceptual framework was defined. This conceptual framework contained three main subcategories: a) Information Flow, b) Off-site Manufacturing, and c) On-site Installation. Within this conceptual framework, four Novel Solutions were achieved: 1) Semi-automated Primary Module Layout Definition, 2) Partial routing and novel assembly sequence, 3) Robotic Installation of Modules, and 4) the Matching Kit Concept. These Novel Solutions were assessed depending on the working time per square meter and the accuracy of the attached façade modules. In order to have a general overview of the results, these were compiled and evaluated, which offered a perspective for future challenges.

Keywords –

renovation; evaluation; time; accuracy

1 Introduction

This paper is a part of a broader research named “Study on Automated and Robotic Renovation of Building Façades with Prefabricated Modules” [1]. The paper consist on an assessment of diverse technologies that are part of broader research projects.

Automation and robotics may be able to help with productivity issues. When it comes to marketing robotics for construction, productivity is a major concern. During the asset price bubble in the 1980s, the field of robotics in construction was achieved, primarily in Japan. [2]. Some robotic systems have remained in use since then, primarily in the prefabricated industry and less in the on-site construction. [3]. When developing robotics for

construction, there are significant financial implications. Skibniewski [4] and Balaguer [5] already made approaches for quantifying that. The key, according to Warzawski [6], relies on the adoption of robotics and automation in the lifespan of the building, and on the economic viability of the established techniques. This requires a greater level of productivity when using robotics. To develop technology in such complex contexts, matrix-based decision-making methods were defined [7–9]. Besides, more specifically on the field of robotics, several criteria were specified to develop robots in construction [10–12]. Finally, specific problem-solving methods are common in engineering development [13–17].

“Façade renovation with prefabricated modules and its automated and robotics solutions” is a complex and multidisciplinary task that needs to consider multiple aspects [18–20]. For this reason, a conceptual framework was created to organize different issues. The reminder of this paper is to explain how this conceptual framework was used during the analysis, development and assessment of different solutions. Moreover, the conceptual framework was used as a basis for the compilation of the results.

2 Conceptual framework

Following the structure of previous research [21], the subcategories of the conceptual framework were defined as in the next points:

- SC1 Information or Data Flow:
 - SC1.1: Measuring the geometry and acquiring the state of the building façade.
 - SC1.2: Processing the acquired data.
 - SC1.3: Defining the layout of the modules.
 - SC1.4: Create the necessary data for the manufacturing process.
 - SC1.5: Mark the necessary data for the installation of the modules on-site.
- SC2: Off-site Manufacturing of the modules:

- SC2.1: Prepare (Cut/machine) the elements.
- SC2.2: Assembly elements.
- SC3: On-site Installation of the modules:
 - SC3.1: Setting up the robotic device.
 - SC3.2: Fixing connectors.
 - SC3.3: Placing the module.

2.1 Current procedures with modules

Based on the aforementioned list, an analysis was carried out regarding the time spent during each of the subcategories and the accuracy of the installed modules [1]. In Table 1, the operator working time per square meter of the lowest and highest records of several cases is shown.

Table 1 Lowest and highest records

	Working time h/m ²	
	Lowest	Highest
Data flow (SC1)		
Data acquisition	0,09	0,15
Defining the layout	0,17	0,34
Data marking	0,04	0,13
Manufacturing total time (SC2)		
Cutting and routing	0,21	0,45
Assembly	0,40	1,74
Installation (SC3)		
Connector fixation	0,03	0,08
Installation of modules	0,34	0,71
TOTAL	1,28	3,60

Regarding the accuracy, standards such as the DIN 18202 [22] specify the accuracy requirements of external walls depending of the segment size, which, in normal conditions is up to 25mm (see Table 2).

Table 2 Tolerances in external walls according to DIN 18202

	Wall segment size				
	0,1 m	1 m	4 m	10 m	15 m
Normal condition	3	5	10	20	25
Restricted conditions	2	3	8	15	20

The DIN 18203-3 specifies the maximal deviation at 5 mm for timber walls, in any case. However, these data needs to be updated or checked in real projects. For instance, a demonstration was carried out during the early stages of the BERTIM research project [23], which consisted of the installation of three 2D modules onto an existing test building. In this case manufacturing and installation processes caused visible accuracy issues. On one hand, the modules were not manufactured to the specified level of precision (+/- 1 mm). Stud's location

reached tolerances of up to 8 mm once the process was completed (see Figure 1 top). In the other hand, the final coordinates of the 2D module placement deviated by more than 20 mm from what was planned. This necessitated additional rework once the 2D modules were installed on the wall by overlapping the waterproof layers. For this reason, the DIN 18203-3 was not fulfilled (see Figure 1 bottom).

Figure 1: Top: deviations due to assembly inaccuracies. Bottom: deviations during installation.

2.2 Research Gaps

Following the quantitative analysis on previous section, the next research gaps of the manual methods were defined:

- **RG1:** Lack of automated data flow. Automation is required for the data workflow. It is necessary to save time and eliminate redundant measuring and marking. The data and information must flow easily from the existing building's data acquisition to the installation of the façade modules. Two points

should be addressed:

- RG1.1. The need for an automated module layout definition.
- RG1.2. Facilitate the connector fixation of the modules by transferring data to the existing facade.
- **RG2:** Lack of Automated Manufacturing modules. It is vital to save working time while improving accuracy and the proper placement of module pieces. The more routed the pieces are, the more precise the modules are, but manufacturing time increases. A balance between precision and production consumption is required. Two points are outlined:
 - RG2.1. Reduce routing and manufacturing time.
 - RG2.2. Lack of fully automated assembly.
- **RG3:** Lack of automation in the installation of façade modules. To reduce installation time, a precise and automated robotic technique for the installation of façades is necessary. A focus on the following two subtopics is necessary:
 - RG3.1: Lack of automation installation of the connector.
 - RG3.2: Lack of automation installation of the Module onto the connectors.

On the next section, the solutions to these research gaps are explained.

3 Developed Novel Solutions

The experiments presented are diverse and focus on different issues. Moreover, the solutions solve different research gaps. The four different Novel Solutions are presented on the next points:

- **Solution 1:** Semi-automated Primary Layout Definition with a “Point Cloud”. One of the most significant impediments to commercialize the usage of prefabricated modules for façade rehabilitation is the lengthy time required for data processing and module design. This solution provides, with the only input of the current building facades’ Point Cloud, a novel method that enables a semi-automated definition of the module layout. [1]. The solution developed here facilitates a semi-automated generation of the shape of the modules that will be installed on top of the existing building (see Figure 2). Because of this solution, time was saved.
- **Solution 2:** Partial routing and novel assembly sequence. Currently, the precision routing, machining and calibration of the pieces that are part of the module determine the accuracy of robotic assembly. The approach given in this solution is based on a minor increase in the machining of the current timber

frame module's pieces by using dovetailed unions, as well as a design that makes robotic assembly unidirectional [1]. Thanks to this solution, the working time was reduced while the accuracy was gained (see scheme in Figure 3).

Figure 2. Generation of the module-layout from the Point Cloud coordinates.

Figure 3: Unidirectional assembly of timber frame by dovetail joints thanks to a partial routing.

- **Solution 3:** Robotic Installation of Modules with a cable-driven parallel robot (CDPR). The solution is based on the on a CDPR that hosts a solution of tools on its platform named Modular End Effector (MEE). The MEE is based on a robotic arm with different changeable end-effectors, a Stabilizer, and a Vacuum

Lifting System. [24]. This solution provided an automated fixation of connectors on top of the building slab as well as the installation of CWM. Even though this solution was initially foreseen for building renovation, the tests were carried out in new building construction sites (see Figure 4).

Figure 4: Robotic Installation of Modules with a CDPR.

- **Solution 4: Matching Kit Concept.** The Matching Kit (MK) is a set of components that includes a bespoke interface to correct the deviations occurred during the placement of the connectors in the wall [25]. The initial test carried out with the Matching Kit reveal a reduction of time compared to current strategies based on an initial accurate localization of connectors in the existing buildings (see Figure 5).

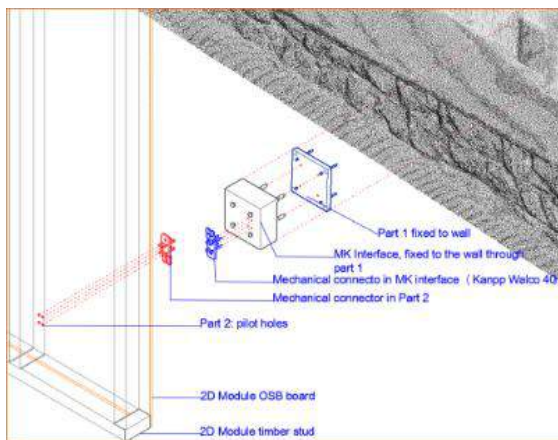

Figure 5: Installation process of the Matching Kit.

4 Compilation and evaluation

The aforementioned Novel Solutions focused on the working time and the accuracy for achieving a task. However, in terms of how the Novel Solutions should be evaluated with a holistic perspective of the renovation process, that is, the aforementioned conceptual framework. For this reason, the solutions developed in the previous chapters need to be compiled and combined to set up a comparable result. A compilation of results regarding working-time per square meter (h/m^2) of all the solutions defined was considered first (see Table 3)

Table 3: Time spent in the selected Novel Solutions.

	Solutions			
	1	2	3	4
SC1:Data flow				
SC1.1: Data acquisition	0,012			0,05
SC1.2: Data Processing	0,002			
SC1.3: Layout definition	0,002			0,05
SC1.5: Transfer On-site data			0,02	0,18
SC2:Manufacturing		0,18		
SC2.1: route elements				
SC2.2: assembly				
SC3:Installation				
SC3.1: Setting up device			0,3	
SC3.2: brackets fixation			0,05	0,18
SC3.3:module installation			0,06	0,084

Some notes on the data in Table 3 include the fact that the SC1.4 is not considered since the creation of the CAM is a task that is already solved almost automatically with current software [26]. Besides, the data need to be considered in different contexts.

- **Solution 1.** This solution is fast at defining the layout of the module but it requires a considerable effort around acquisition to generate reliable and accurate data.
- **Solution 2.** The data gathered in solution 2 shows a significant reduction in working time. It needs to be pointed out that the time for assembling the timber frame is only around 20% of the whole module manufacturing process. However, it shows a strategy, albeit further CNC machining of elements that might be a solution to some issues in the future.
- **Solution 3.** Regarding the installation robot presented, the biggest handicap is the set-up of the robotic system (173 hours that for an optimal workspace,

0,36 hours per square meter in the analyzed case). The rest of the operations are work-time efficient and accurate enough according to the first tests. For the calculation of solution 3, the following remarks were considered:

- The data transfer to the CDPR and the MEE of the robot takes 0,05 hours for each bracket. Considering that two brackets are necessary for at least one curtain wall of 4,8m², then 0,0208 hours are necessary per square meter.
 - The bracket installation takes 0,13 hours, excluding the aforementioned data transfer. Similarly, considering that two brackets are necessary for at least one curtain wall of 4,8m², then 0,0542 hours are necessary per square meter.
 - The CWM installation takes 0,33 hours, therefore, 0,06875 h/m² are necessary.
 - **Solution 4** requires higher consumption time in the initial phases but it provides a smooth connector fixation and module installation because there is no need of adjustment.
- The solutions explained before do not offer a complete façade renovations process, which is why they should be combined. Three combinations were drafted with the data of each of the sets:
- **Combination 1:** It combines the Solution 1 (Semi-automated Primary Layout Definition with a Point Cloud), 2 (Partial Routing and Novel Assembly

Sequence) and 3 (Robotic installation of modules with a CDPR).

- **Combination 2:** It combines Solution 2 (Partial Routing and Novel Assembly Sequence) and 4 (Matching Kit concept).
- **Combination 3:** It combines Solution 1, 3 and 4. In this case, the Matching Kit concept is combined with the robotic installation of the modules. Combination 3 overlaps different solutions since the robotic installation with the MK was not approached.

In all combinations, for the manufacturing subcategory (SC2), the data achieved in solution 2 is multiplied by 5 (as the data gathered is only 20% of the module manufacturing process) to represent the manufacturer of the whole prefabricated module. This is only an estimation.

Data shows that combinations 1 and 2 have a very similar performing result (1,05 h/m² for Combination 1, and 1,08 h/m² for Combination 2), as shown in Table 4. In both cases, less time is necessary than the combination of the lowest records in the analysis in Table 1, which is 1,28 h/m², specifically 18% and 19% less time, respectively. The sum in Combination 3 is slightly higher than the lowest records but considerably lower than the combination of the highest records. These results show a significant reduction of working time in regards to the manual processes specified in Table 1(3,60 h/m²).

Table 4: Time of the combinations

	Combination 1	Combination 2	Combination 3
SC1:Data flow			
SC1.1: Data acquisition	0,0127	0,05	0,05
SC1.2: Data Processing	0,0021		
SC1.3: Layout definition	0,0021	0,05	0,05
SC1.5: Transfer On-site data	0,0208	0,18	0,18
SC2:Manufacturing			
SC2.1: route elements	0,108*5	0,108*5	0,108*5
SC2.2: assembly			
SC3:Installation			
SC3.1: Setting up device	173h=0,36		173h=0,36
SC3.2: brackets fixation	0,054	0,18	0,054
SC3.3:module installation	0,068	0,084	0,068
TOTAL	1,06 h/m²	1,08 h/m²	1,30 h/m²

But are the results in Table 3 enough for assessing if a combination of the set of solutions is an optimal choice or whether further development is even worth it? Accuracy needs to be part of the evaluation as well. In the case of selecting the best solution, how to decide which of the combinations has further development and success possibilities? A Multi-Criteria Decision Making [18,27] that includes the accuracy parameter is necessary. In other words, accuracy needs to be evaluated within a

weighting equation that includes the working time.

In the next paragraphs, an evaluation of the Combinations 1 to 3 is explained. The evaluation range is measured on a 0-100 scale, where 0 is the worst case and 100 is the best case. The highest record stands for 0 and the lowest record stands for 100 on that scale. The indicators are explained as follows:

- **Indicator A:** Working time of the combination (A in Table 5) which is based on the lowest and highest

records and the combinations from Table 1. The benchmarked lowest record is 1,28 h/m² and the highest record is 3,60 h/m². The weight (W) of this indicator is considered as 50% (or half, 1/2).

- **Indicator B:** Manufacturing accuracy (B in Table 5). As mentioned in section 2.1, the initial objective was that fabrication tolerances must be lower than 1 mm, and that is considered as the lowest record. For the highest record, section 2.1 shows a maximum deviation of 8 mm, which has been considered as highest record. For all Combinations 1 to 3, the experiments in solution 2 showed a maximal deviation of 1,5 mm. The W weight for this indicator is considered as 25% (or a quarter, 1/4).
- **Indicator C:** Installation accuracy (C in Table 5). The initial objective of this research was that installation tolerances must be lower than 5 mm, as the DIN 18203-3 specifies. This value will, therefore, be taken as the lowest record. On the other hand, in the analyzed cases in BERTIM, deviations were bigger than 20 mm (see section 2.1), and this value is taken as the highest record. For solution 3 and, therefore, Combination 1, the installation accuracy showed an absolute deviation of up to 11,66 mm in regards to the planned position. For solution 4 and, therefore, Combinations 2 and 3, the installation showed absolute inaccuracies of up to 7,2 mm. The W weight for this indicator was considered as 25% (1/4).

In Table 5, all the indicators of the Lowest (L) and the

Highest (H) records and the three combinations (C1, C2, and C3) are shown. To normalize the value of the indicators, Equation 1 is used and applied for getting Normalized Indices (\bar{I}_{ij}).

$$\bar{I}_j = \frac{I_j}{(\sum^j I_j)} * W \quad (1)$$

By applying Equation 2, the Normalized Indices' \bar{I}_{ij} values are summed and the Combination's significance R_j is achieved (see R in Table 5)

$$\bar{I}_{ij} = \frac{I_j}{(\sum^j I_j)} * W \quad (2)$$

By applying the Normalized Indices' \bar{I} values are summed and the Combination's significance R_j is achieved by Equation 3 (see R in Table 6). Finally, the Combination's degree of efficiency in 0-100 scale is achieved by applying Equation 4 (see N in Table 6).

$$R_j = \sum^j (\bar{I}_j) \quad (3)$$

$$N_j = \frac{R_j - R_{min}}{R_{max} - R_{min}} * 100 \quad (4)$$

Table 5: Indicators.

	W	L	\bar{I}_L	H	\bar{I}_H	C1	\bar{I}_{C1}	C2	\bar{I}_{C2}	C3	\bar{I}_{C3}
A	1/2	1,28	0.08	3,60	0.22	1.06	0,063	1.08	0,065	1.3	0,076
B	1/4	1	0.02	7	0.14	1.5	0,030	1.5	0,030	1.5	0,029
C	1/4	5	0.02	20	0.10	11.66	0,057	7.2	0,035	7.2	0,035

Table 6: Final assessment.

	Lowest	Highest	C1	C 2	C3
Sum of normalized indices (R_j)	0,12	0,45	0.15	0.13	0.14
Degree of efficiency (N_j)	100	0	90.57	96.73	93.49

The results show that the objectives have not been reached 100%. Future research should solve the remaining issues. The future needs (FN) are compiled and their numbering re-adjusted as in the next points:

- FN1.1.1: Accuracy of the measuring device. One of the issues in solution 1 was the inaccuracy of the Point Cloud itself.
- FN1.1.2: Potentialities of online data for the initial

measurements of the building should be explored, in order to avoid excessive visits to the existing building.

- FN1.1.3: Recognition of the Matching Kit automatically. One of the issues regarding the Matching Kit concept was that the connectors placed on the wall had to be measured manually. Photogrammetry can be useful for these cases.
- FN1.3.1: Accuracy of the selected segments of the

Point Cloud. The solution 1 relies still in designers' criteria that might tend to errors.

- FN1.3.2: Recognition of slab. The solution 1 is based on the localization of the slab of the building. If the building doesn't show the slab, the solution 1 is useless.
- FN2.1.1: Adjustment in design to facilitate assembly process. The design needs to facilitate a robot based assembly.
- FN2.1.2: Design should consider rigidizing during the assembly. During experiments it was noticed that a key point that facilitates the assembly is a rigidizing union between elements. This future need might be in contradiction with the FN 2.1.1.
- FN2.1.4: Adjusted Robot Oriented Design [28] depending on Assembling Tolerances. Depending on the robotic accuracy, the assembled module's tolerances should be adjusted accordingly.
- FN2.2.1: Adjust the manufacturing line, depending on the most suitable configuration.
- FN2.2.2: Agile robot path adjustment depending on CAD of the modules. It is of a vital importance to generate a parametric adjustment of the robot path depending on the CAD file of the module.
- FN3.1.1: Faster set up of the robotic device is necessary. In Solution 3, the main burden for a rapid installation is the need for a fast set up of the robotic device.
- FN3.2.1: A leaner production of the Matching Kit interface is necessary. In Solution 4, the manufacturing time of the interface was time consuming.
- FN3.2.2: Consider uneven surfaces. The robotic device in solution 3 did not consider the unevenness of the façade of the existing building.
- FN3.3.3: Accurate Recognition of the modules. The robotic device in solution 3 will be more accurate if the device would recognize the modules from its picking rack.
- FN3.3.4: Recognition of the connector. As in the previous point, the robotic device in solution 3 will be more accurate if it recognized the connectors on the slab while installing the modules.

5 Conclusion

The results show that the different combinations of options might depend on the automation level and different strategies for reaching high accuracy. On the one hand, automation in all subcategories is still needed. On the other hand, learnings from the experimentation show that reaching absolute accuracy in a façade workspace leads to time-consuming setting up of the robotic device.

The data gathered in this research can be used as a basis for future business plans. However, the Technology Readiness Level (TRL) of the Novel Solutions is still around 5 or 6, which means that there might not be sufficient data for accurately calculating the cost of the automated and robotic solutions presented in this paper. However, some approaches have already been made [29]. The question of how to manage technology and make it ready for the market must also be addressed. This topic has been approached in two different research projects, namely BERTIM and HEPHAESTUS [30], where this research has been contextualized and several deliverables have been reported. Once the latest points highlighted in this chapter are properly improved, a potential reduction in time with necessary accuracy can be achieved by applying automation and robotics in the field of Automated and Robotic Renovation of Building Façades with Prefabricated Modules. Projects like ENSNARE [31] will address some of the aforementioned needs.

Acknowledgements

This project has received funding from the European Union's Horizon 2020 research and innovation programme under grant agreement No. 636984 and 732513.

Abstract

The paper is devoted to robotic in the construction field based on industrial robotics. The main focus is made on a proper modelling of a robotic system stiffness and identification of their parameters for work on vertical walls. The robotic system is composed of a vertical lift system that can carry a 200kg load including a Doosan cobot (45kg), equipment for tasks to do, and a human operator (80 kg) for working at a height up to 8-10m. Particular attention is paid to the robot's accuracy while working operation (painting, insulation spraying, facade cleaning, etc) and evaluation robot capacity to perform the task with desired precision regardless of the height of the vertical work. In contrast to other works, the robot stiffness is evaluated using a protocol that is based on the deformation of the vertical lift system. The developed approach is applied to find the best geometrical configuration of the scissor lift next to the vertical surface to be worked and the best position of Doosan cobot on the platform lift taking into account the robot working space. The efficiency of the proposed technique robotic solution for the vertical task is validated by experimental study.

Keywords: *Robotic System, Construction robotics, Stiffness model*

developed a method to assess the effects of human-robot collaboration on automating a construction task and examined the method using an interesting multi-purpose robot, named TAMIR, for block laying and wall painting.

Here, we develop a new robotic architecture proposed and studied to work on vertical walls with a manipulator composed of a cobot Doosan which is a poly-articulated arm fixed on a moving vertical lift mechanism. Doosan M0617 is a cobot with a maximum reach of up to 1700mm and a payload of about 6kg. And also has torque sensors at each joint so that it will be safer for the human operator to share work-space alongside the robot and also prevents damages to the work environment or to the robot itself from collision against wall surfaces. The vertical lift mechanism is commercially more desirable compared to other types of lift mechanisms as it is cheaper and lighter weight, with a greater weight-to-strength ratio. Vertical scissor lifts can support larger weight and move to greater heights. The main objectives of this robotic system (Fig.1) are to reduce working time, get consistent quality and free the workers from making dangerous or repetitive tasks

1) Introduction

In recent years, the construction field is looking for new ways to perform complex tasks on a large surface in buildings for a task like cleaning and polishing façade as new robotic architecture systems are emerging. Robonaut by NASA was one of the first robots capable of collaborating for space construction applications [1]. Roboclimber is an automated drilling system with a remote-controlled Human interface that is hosted onto a semi-autonomous climbing platform [2]. The reconstruction of buildings, facades, and maintenance tasks can be much more safe, fast, and cheaper with the deployment of robots. Finishing services for productivity improvement on the construction sites were initially studied by Rosenfeld et al. [3], and Warszawski and Rosenfeld [3] [4]. Later, Kahane and Rosenfeld [6]

(a)

Fig.1. Developed robotic solution (a), Vertical building Tasks with Doosan (b).

The Doosan robot is positioned on one side of the structure, and counter-weights are employed to return the structure's center of gravity to its original location. The stability of this system is critical to ensuring that the precision of vertical jobs is improved by decreasing stress and position inaccuracy of the end-effector for spraying insulation, as shown in Fig.1. The goal now is to assess the accuracy of the robot's accuracy under stress.

2) Stiffness modeling of robotic system

The positioning of the robot end-effector in the Scissor Lift reference with a set of frames. The positioning of the Tool Center Point (TCP) i.e. R_{Eff} regarding R_{rob} is not considered. Our objective for vertical task focuses on the positioning of R_{rob} regarding R_{Lift} . Therefore, the frames are represented in Fig. 2.

Fig. 2. Positioning of the reference frames

In this section, the stiffness of the scissor lift will be studied with the elements in the fully extended configuration. The vertical force applied by the hydraulic cylinders is very low due to the low slope between the lift's scissor legs. Consequently, the cylinders will have to apply a high amount of force to rise up to escalate to the desired height. Also, the weight distribution in the lift platform may not be always uniform but we assume the weight is uniformly distributed on the lift platform. In our case, we try to analyze the distortion of the GENIE GS-1932 scissor lift using a Laser telemeter.

$$\sigma = F/A$$

$$K = F/U$$

where,

F is force applied (N),

A is the area of cross section (mm^2)

K is Stiffness (N/m)

U is change in Displacement (Position in our case) (m)

$$D = \frac{n(L + W)}{200}$$

where,

D = Maximum allowable platform edge deflection

n = Number of vertically stacked panto-graph leg sections (Scissor Legs)

L = Platform Length

W = Platform Width

Stiffness and Displacement Calculation of Standard Scissor lift (Analytical method):

Beam element with vertical force F_{1y} and F_{2y} acting at nodes 1 and 2 with a moment m , rotation ϕ and vertical displacement v .

$$\begin{bmatrix} F_{1y} \\ m_1 \\ F_{2y} \\ m_2 \end{bmatrix} = \begin{bmatrix} 12 & 6L & -12 & 6L \\ 6L & 4L^2 & -6L & 2L^2 \\ -12 & -6L & 12 & -6L \\ 6L & 2L^2 & -6L & 4L^2 \end{bmatrix} \begin{bmatrix} v_1 \\ \phi_1 \\ v_2 \\ \phi_2 \end{bmatrix}$$

Table.1.Beam Stiffness Matrix

Frame Element is 2D problem forces along x and y direction of the frame. So along with elastic slope θ_1

$$\begin{bmatrix} F_{1x} \\ F_{1y} \\ m_1 \\ F_{2x} \\ F_{2y} \\ m_2 \end{bmatrix} = \frac{E}{L} \begin{bmatrix} A & 0 & 0 & -A & 0 & 0 \\ 0 & 12\left(\frac{I}{L^2}\right) & 6\left(\frac{I}{L}\right) & 0 & -12\left(\frac{I}{L^2}\right) & 6\left(\frac{I}{L}\right) \\ 0 & 6\left(\frac{I}{L}\right) & 4 & 0 & -6\left(\frac{I}{L}\right) & 2 \\ -A & 0 & 0 & A & 0 & 0 \\ 0 & -12\left(\frac{I}{L^2}\right) & -6\left(\frac{I}{L}\right) & 0 & 12\left(\frac{I}{L^2}\right) & -6\left(\frac{I}{L}\right) \\ 0 & 6\left(\frac{I}{L}\right) & 2 & 0 & -6\left(\frac{I}{L}\right) & 4 \end{bmatrix} \begin{bmatrix} u_1 \\ v_1 \\ \phi_1 \\ u_2 \\ v_2 \\ \phi_2 \end{bmatrix}$$

Table.2. Frame Element Stiffness Matrix

Considering the Rotational Matrix while moving from local coordinates to Global Coordinates along x and y direction with rotation around ϕ

$$\begin{bmatrix} u_1' \\ v_1' \\ \phi_1' \\ u_2' \\ v_2' \\ \phi_2' \end{bmatrix} = \begin{bmatrix} \cos\theta & \sin\theta & 0 & 0 & 0 & 0 \\ -\sin\theta & \cos\theta & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & \cos\theta & \sin\theta & 0 \\ 0 & 0 & 0 & -\sin\theta & \cos\theta & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} u_1 \\ v_1 \\ \phi_1 \\ u_2 \\ v_2 \\ \phi_2 \end{bmatrix}$$

Table.3. The Global Coordinates Matrix

So, we add the rotation matrix with frame element stiffness matrix:

$$[K] = \frac{E}{L} \begin{bmatrix} Ac^2 + \frac{12Is^2}{L^2} & sc\left(A - \frac{12I}{L}\right) & -\frac{6Is}{L} & -\left(Ac^2 + \frac{12Is^2}{L^2}\right) & -sc\left(A - \frac{12I}{L}\right) & -\frac{6Is}{L} \\ sc\left(A - \frac{12I}{L}\right) & As^2 + \frac{12Ic^2}{L^2} & \frac{6Ic}{L} & -sc\left(A - \frac{12I}{L}\right) & -\left(As^2 + \frac{12Ic^2}{L^2}\right) & \frac{6Ic}{L} \\ -\frac{6Is}{L} & \frac{6Ic}{L} & 4I & \frac{6Is}{L} & -\frac{6Ic}{L} & 2I \\ -\left(Ac^2 + \frac{12Is^2}{L^2}\right) & -sc\left(A - \frac{12I}{L}\right) & \frac{6Is}{L} & \left(Ac^2 + \frac{12Is^2}{L^2}\right) & sc\left(A - \frac{12I}{L}\right) & \frac{6Is}{L} \\ -sc\left(A - \frac{12I}{L}\right) & -\left(As^2 + \frac{12Ic^2}{L^2}\right) & -\frac{6Ic}{L} & sc\left(A - \frac{12I}{L}\right) & \left(As^2 + \frac{12Ic^2}{L^2}\right) & -\frac{6Ic}{L} \\ -\frac{6Is}{L} & \frac{6Ic}{L} & 2I & \frac{6Is}{L} & -\frac{6Ic}{L} & 4I \end{bmatrix}$$

Table.4. The Global Stiffness Matrix

In addition to the analytical analysis, we analyzed the scissor lifting system with finite element method with elements such as platform and base plate were on the extended configuration for the simulation analysis. The system was fixed in the base platform which was attached to the base plate of the scissor lift. The load acting on the platform is a Uniformly distributed Load of 1000N acting all along the length of the standard scissor platform and 500N point load acting on the extended side of the scissor lift, respectively. These loads were applied vertically on the scissor lift platform to study the system for Stiffness.

Platform Material and Scissor Material			
Material	Plain Carbon Steel	Material	6061 Alloy
Yield Strength	2.20594e + 08 N/m ²	Yield Strength	5.51485e + 07 N/m ²
Tensile Strength	3.99826e + 08 N/m ²	Tensile Strength	1.24084 + 08 N/m ²
Elastic Modulus	2.1e + 11 N/m ²	Elastic Modulus	6.9e + 10 N/m ²
Poisson's ratio	0.28	Poisson's ratio	0.33
Mass Density	7,800 kg/m ³	Mass Density	2700 kg/m ³
Shear Modulus	7.9e + 10 N/m ²	Shear Modulus	2.6e + 10 N/m ²

Table.5. The characterization for the numerical simulation

The stress distribution and quantity of deformation following mesh creation in each scissor element of the lifting system were studied using numerical simulation. The maximum strain energy hypothesis was used to calculate the system's stress distribution (Von-Mises Stress). On the extended scissor platform, a point load of 500N is operating, and a 1000N evenly distributed load is acting on the remaining scissor platform. The equivalent stress was observed to rise linearly with the applied load on the platform. A scissor lift in extended form with point load (weight of the robot operating on it) demonstrated a maximum Von Mises Stress of 17.63MPa on the system is shown in Figure (3). In planning for design and Model analysis, a minimum stress of around 3.695e-17 Mpa operating on the scissor lift is suggested. The amount of deformation in the components of the scissors lifting system was shown in (Fig:3) owing to point load (p)s, where the center of gravity with no point load is generally the maximum deformation (13.43mm) found at the extended scissor lift platform.

Fig.3. Numerical simulation to analyze the stress distribution and the displacement

Placing a robot on the lift extension platform leads to a change in center of gravity moves 600mm along y-direction and 227mm in x-direction which clearly shows this will lead to tip over criteria or other system failures where the trajectory of the robot must include varying correction factor to maintain good trajectory. With this configuration, we performed the numerical simulation illustrated in figure 4.

The system was considered to be in full functioning height of around 5.4m for this investigation. The center of gravity of the scissor lift changes to $x = 64.7\text{mm}$ and $y = 2510\text{mm}$ which would result in tipping of the scissor lift, before which the center of gravity is acting on the center of the scissor lift platform was the same for each connection point as shown in Figure 4. This shows the deformation and the COG of the scissor lift. We also see that the deformation results of the scissor lift are closer to that of the Experimental value detailed in the experimental paragraph and this also shows the validation of the structural analysis.

Von mises Stress : Maximum = $1.814 \text{ e}+07 \text{ N/m}^2$
Minimum = $2.053 \text{ e}+02 \text{ N/m}^2$

Fig.4. Numerical simulation with another configuration of the Doosan robot

3) Experimental Setup

We design an extended frame setup to mount the Linear Tracker on the Nacelle lift (scissor lift) platform. The standard design of the extended platform frame is fixed onto the Genie GS-1932 with a modified L-joint and screwed rigidly in the hole on the lateral side of the lift. The remaining parts of the extended setup are welded together rigidly except the robot. This extended frame is where the robot will be mounted to work on the vertical wall. Now to understand/study the stiffness of the lift system we use a winch to replicate the payload which would be acting on the real-time in the lift system. In the experimental setup, a rope from the winch is hooked onto one end of the lateral rail on the lift platform and

pulled using the winch's pulley handle, which is utilized to create the equivalent force (200kg) operating on the lift system in our desired direction. The winch rope is pulled in two directions, one along the platform's y-axis and the other along the z-axis, to generate a dynamic pulling force.

The study is carried on two different wheel configuration of the scissor lift (SL1) and (SL2) at two different heights $H_1 = 3\text{m}$ and $H_2 = 7\text{m}$ along the building floors (Fig.4)

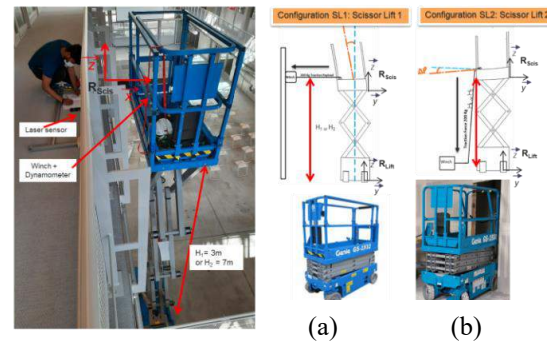

Fig.5. Experimental setup: Scissor Lift Configurations 1 (a) and Scissor Lift Configurations 2 (b)

The study is carried on two different wheel configuration of the scissor lift at three varying heights along the building floors.

- Wheel aligned along the direction of the mobile platform (Configuration: WC1)
- Wheel aligned at 90° steering angle the direction of the mobile platform (Configuration: WC2)

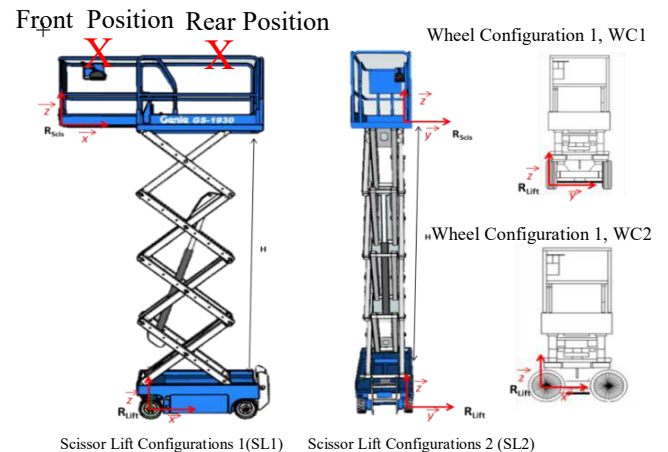

Fig.6. Scissor Lift Configurations (SL1 and SL2) and Wheel Configurations (WC1 and WC2).

For scissor lift configuration 2, wheel configuration 2 at a height of 3m, the stiffness remains high in general throughout the experiment from a minimum force of 88 N to a maximum of 557N. However, for the rear wheel, the stiffness drastically increases in magnitude from 100N/mm to 600N/mm from 295N to 588N.

For scissor lift configuration 2, wheel configuration 1 at a height of 7m, the stiffness remains high in general throughout the experiment from a minimum force of 88 N to a maximum of 557N. However, for the rear wheel, the stiffness drastically increases in magnitude from 100N/mm to 600N/mm from 295N to 588N. For scissor lift configuration 2, wheel configurations 1 and 2, at a height of 7m, the stiffness gradually increases from 20N/mm (front) and 10N/mm (rear) at 80N to 53 N/mm (front and rear) at 588N. Stiffness is almost identical for the front and rear at higher payloads.

Figure 7 shows the displacement and stiffness along the global Y-axis received for configuration 2 measured at two points "Front point" and "Rear point" at two heights 3m and 7m.

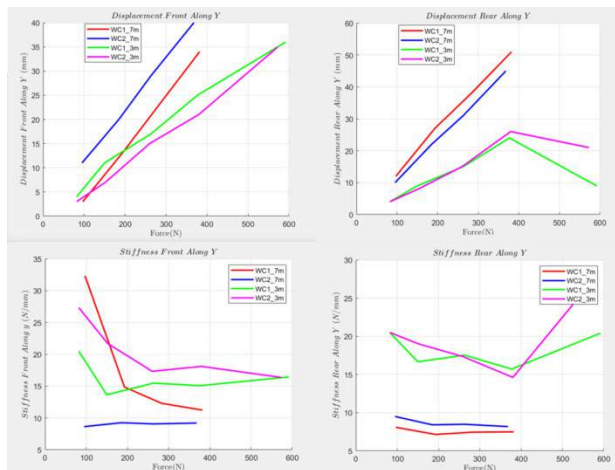

Fig.7. Displacement and Stiffness (Front and Rear) along Y axis:

Figure 8 shows the displacement and stiffness along the global X-axis received for configuration 2 measured at two points "Front point" and "Rear point" at two heights 3m and 7m.

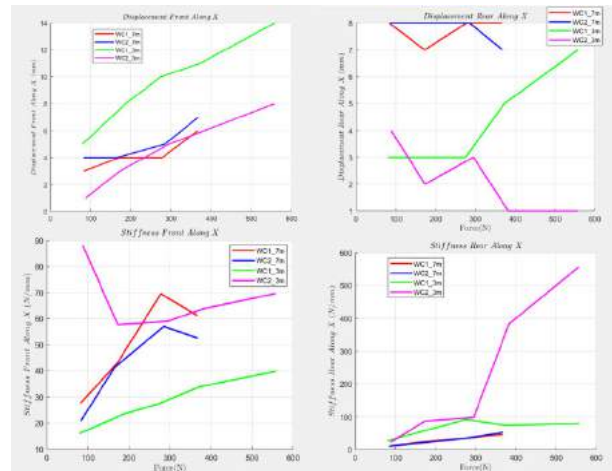

Fig.8. Displacement and Stiffness (Front and Rear) along X axis

When the scissor lift wheel is parallel to the platform, the displacement is large at 3m height in the Y-axis direction in the Front Position, as illustrated in fig. 9. However, at 7m, the x-axis displacement in the Front or Rear positions is relatively minimal.

Fig.9. The global displacement of the robotic system in X and Y axis.

4) Conclusions and Perspectives

We offer a new identification approach in this work for a more accurate assessment of the stiffness of a robotic solution for a vertical job. We used a metrological measurement with a physical meaning as the foundation for our approach. For both wheel configurations 1 and 2, the scissor lift configuration 2 offers more rigidity to the system. It increases the stiffness of the system, which results in less displacement. Furthermore, for configuration 2, the system's stiffness values on the back and front sides of the platform are almost similar. As a result, the entire scissor lift will be more isotopically rigid as a result of this. Scissor Lift Configuration 2 as well as any wheel configuration with a fixed robot base would be the optimum solutions for our Task.

The robotic lift system is designed in such a manner that it can accommodate both a robot and a human operator in a collaborative environment, thanks to the optimum platform size.. The deformation and change in the center of gravity of a scissor lift with a robot and a robotics frame arrangement is also investigated, with results that are very close to theoretical and analytical ones.

The stiffness, deformation, and responsiveness of the lift system at various heights and payloads have been calculated, enabling us in determining the optimal configuration for the robotic system. In future study, we will enhance the robot's trajectory planning and optimization to work on complicated wall surfaces in order to fully use the robotic system's workspace on the wall.

5) Acknowledgments

The authors are grateful to Hall6Ouest of Nantes University for provided possibility to carry out experiments with robot Doosan and the Lift Scissor. The work presented in this paper was funded by Nantes University and ROMAS team in LS2N Laboratory, France.

Abstract –

Additive Manufacturing allows for high geometric freedom and the fabrication of non-standard building components. This new-found flexibility results from the fact that no formwork is required with additive manufacturing and thus each part can be different at no additional cost. One drawback however is that the geometric freedom comes at the price of non-verified geometric precision, requiring methods to determine and possibly counteract deviations and ensure building component's quality. Within this paper we present an "Lean-based Production Approach" for an off-site production of concrete components. Therefore, firstly lean construction is introduced and its synergies with additive manufacturing are shown. Shotcrete 3D Printing is used as a case study and illustrates the approach and unveils current potentials and challenges. Our approach is mainly based on an on-demand production, bi-directional digital workflows and quality checks. Current methods for geometric and surface quality as well as for predicting production (and process) times for varying components still need to be developed further. We conclude with forecasting a new and more intelligent production system in construction.

1 Introduction

In the context of a social rethinking and political ambitions to produce in a climate-neutral and resource-friendly way, the construction industry, as one of the largest industrial sectors in the world, is of particular importance. The construction industry is mostly confronted with the challenge of the "large scale" of the structures to be built [1]. Additional challenges result from typical construction industry peculiarities, such as

one-off production, on-site production, or engineer to order production [2]. Furthermore, construction is usually done on a project basis, where a considerable number of independent companies are linked only by the goal of delivering building. These construction peculiarities are often blamed for the construction industry's poor project delivery, i.e., construction delays and exceeded budgets as well as the contribution concerning waste and value loss [2].

To counteract stagnant productivity and inefficient construction processes, comparisons are often made with stationary production like the automotive sector [3]. It is assumed that similar improvements in the construction can be achieved by adopting established processes and methods from that sector. The goal of a "lean" and value-added production is also increasingly targeted in the construction industry. The traditionally more conservative construction industry has so far found it difficult to implement innovative and, above all, digital and sustainable solutions. However, advances in the field of additive manufacturing (AM) with concrete are opening up new construction process options and production principles [4]. In particular, Shotcrete 3D-Printing (SC3DP) as one method of additive manufacturing has the potential to lead to significant improvements in productivity and - hence - to a sustainable production process. Due to the avoidance of formwork as far as possible, a high degree of form flexibility and efficiency gain is achieved, accompanied by new challenges in production with regard to geometric and surface quality accuracy.

The aim of this paper is to show how high-quality precast concrete parts can be produced on the basis of lean principles and to emphasize existing challenges. For this purpose, we will first introduce the basics of lean production and additive manufacturing. Using the SC3DP as an example, an approach is outlined which attempts to solve current production problems.

2 From Lean Production to Additive Manufacturing in Construction

In recent years, the construction industry has developed a greater awareness for the need for a holistic view of the value chain and a process-oriented way of thinking. These developments are driven by several factors, especially current shortcomings such as an extreme fragmentation (of knowledge and project structure) and lack of collaboration within projects. Currently, Lean Construction principles and methods are increasingly being used to restructure (manual) construction processes.

2.1 Lean Production and their principles

The origins of Lean Construction can be traced back to the design and orientation of production (principles) of the Japanese car manufacturer Toyota. During an MIT-study (1985-1991), Womack/Jones/Ross had revealed significant differences from the predominant "buffered production" at that time [5]. The five key lean principles are: (1) define value as what a customer is willing to pay for, (2) map and reduce waste of any kind along the value stream, (3) create a continuous flow for all value-adding steps, (4) produce only on customer demand (pull) and (5) pursue perfection wherever possible. Lean Production aims to produce goods solely in response to demand, rather than mass-produced "in stock." Whereas in the automotive industry high volumes were usually produced based on one (producer-specific) prototype design, buildings have so far and will continue to be unique in most cases based on customer-demand design. Regarding these differences, Lean Production has to be carefully adapted as Lean Construction (LC) within the construction industry.

2.2 Lean Construction

The construction industry is characterized by process instabilities, low added value and waste of various kinds, where the application of different Lean Construction principles and methods promise significant improvements. Due to the traditional project delivery systems and fragmented structures, LC-methods like production cycle planning as well as the "last planner system" are often used, but primarily to improve handcraft production processes. Replication and collaboration are of high relevance for the successful implementation of those two methods to generate stable (but manual) construction processes. In contrast to conventional in-situ construction, prefabrication pursues a higher added value by shifting construction processes to a controlled environment. In order to be economically competitive, avoiding long changeover times and achieving high added value, components and/or their

underlying building processes are often standardized on the price of form and production flexibility.

2.3 Towards a Lean-based Production through the integration of Additive Manufacturing in Construction: Lean Construction 4.0

The integration of lean production principles is accompanied by a production "on demand" in an organizational perspective (pull principle). In order to avoid that materials or semi-finished products for subsequent work steps are generated or produced "on stock" contrary to the principles of lean production, components are only supplied just-in-time and only when required. While producing components only on demand and to specific customer requests, generally warehousing and inventory can be minimized. However, the construction industry has produced in nearly all cases only on customer request ("on-demand-production" in a design perspective on the building scale, e. g. unique customer-related building design). Only in specific segments, certain standardized components (e. g. precast concrete girders, columns or walls) have been produced, placed at storage areas outside the factory waiting to delivery to construction site (component scale).

Additive Manufacturing is defined as the "process of joining materials to make objects from 3D model data, usually layer upon layer, as opposed to subtractive manufacturing methodologies" [6]. Hence, Additive Manufacturing seems perfectly suitable to enable a new level of Lean Production on construction sites: Lean Construction 4.0 [7]. The limitations of current standardization approaches could be overcome by AM with concrete since any form can be produced. With AM not the component is standardized but the process, allowing for more freedom of form and a short-term production (hence production on demand in two perspectives). Lean-based additive manufacturing could make it possible to customize every product (flexibility of AM) and to produce without any changeovers in the production line only on demand, as the combination of lean principles and characteristics of additive manufacturing shows:

- **Defining Value.** Value is only what the customer is willing to pay for. Changeover times (of machines and formwork) and the resulting (manual) effort are currently unavoidable to produce different component types (no value-added processes). By using AM, a new level of form flexibility is gained since formwork is no longer necessary resulting in customized or even individualized components based on customers value.
- **Mapping the value stream.** Process analysis of the value chain aims at identifying waste and

unnecessary tasks. Due to additive manufacturing especially formwork as a crucial non-value-adding task can be eliminated. AM makes it possible to produce individually designed components (wall, columns, slabs) without long changeover times focusing on mapping the value stream.

- **Create a continuous flow.** Not only material but also information must be provided in correct order to create a continuous production flow. AM enables both due to a direct transformation of the virtually designed into a physical object making it possible to create a continuous production flow.
- **Establish a pull production.** AM is a fully digitized design-to-construction workflow where the actual production tasks are reduced to “printing”, allowing to produce components promptly on demand (pull), but with a high level of flexibility in form and production eliminating a push production and long inventory times.
- **Pursue Perfection.** Based on necessary 3D-Models for production, robotic-guided concrete deposition prohibits mistakes due to the integrated information flow. Since geometric quality and tolerance aspects are very important, permanent as-planned and as-built comparisons are essential to identify divergences immediately and hence offer a way to pursue perfection of customers value.

3 Additive Manufacturing

Additive Manufacturing is predominately applied in Construction (AMC) for concrete components [4]. Concrete is the most commonly used building material in the construction industry. Considering the climate change and the CO₂ emissions caused by cement production, the efficient and economical use of concrete is of utmost importance [8].

3.1 Methods of AM in Construction

Additive Manufacturing in Construction (AMC) is suitable both for on-site or off-site application [4]. As known from prefabrication approaches, the desired component quality can be achieved the best, when it takes place within controlled environments [4]. Additive Manufacturing with cement-based mortars, often also referred to as 3D concrete printing (3DCP), means that a component is firstly 3D modelled, sliced into multiple layers and digitally build up layer-wise.

One of the most commonly used AM methods for in-situ application is based on extrusion [9]. In this method, material layers are either extruded from the nozzle in a controlled manner or they flow out of it. This process has a high geometry resolution, but at the expense of a fast application rate [9].

In processes using a particle bed (also referred to as particle bed-based 3D printing (PB3DP)), dry base material (particle or mixture) is placed on a platform (the particle bed) and binder or activator is applied at the required locations according to the desired geometry [10]. The selective application of binder/ activator creates the concrete matrix. This is followed by the build-up of a new layer, starting with the renewed application of the base material to the particle bed. This process is repeated until the component has the desired geometry. After a defined number of printing processes (and layers) the component can be freed from excess, unbound material. The mainly applicable off-site PB3DP process achieves very high resolution and shape accuracy [10].

Shotcrete 3D Printing (SC3DP) is another AM technology mostly suitable for off-site application that offers access to an increase in speed and productivity and in component quality (extra surface finishing needed, see below) [11].

AM allows more freedom of form because it doesn't need formwork or support structures. However, due to the lack of precision that formwork brings to the traditional process, AM requires advanced methods of quality control, which can be solved through bi-directional (or feedback-based) production workflows. To exemplify this, Shotcrete 3D Printing is described as a case study.

3.2 Shotcrete 3D-Printing

SC3DP has been developed within an interdisciplinary research project at the Digital Building Fabrication Laboratory (DBFL) at the TU Braunschweig [12]. Unlike other additive manufacturing methods, concrete components are built up layer by layer but with the controlled addition of compressed air [18]. It is characterized by high printing speed and varies significantly compared to other additive manufacturing methods with the following aspects [12]:

- **Integration of reinforcement:** Concrete can be sprayed around structural reinforcement and hence integrate it.
- **Surface finish (visual and functional):** After the core printing process, shotcrete can be applied robotically as a levelling layer to obtain a higher surface quality. The surfaces can be finished with formative methods if required.

In order to improve manufactured components in the shotcrete 3d printing process – i.e., to produce complex elements with high accuracy in addition to the required surface treatment - the combination of additive and subtractive manufacturing tasks to form a hybrid manufacturing process is a suitable option.

To achieve a decent component quality, the initial printed core is covered with multiple applied secondary layers of shotcrete and in a next task processed with subtractive tools (Figure 1). Compared to common hybrid manufacturing, for example in metalworking, an AM process is combined with a subtractive process here, but additional integration of sensor technology for tolerance and dimensional control is missing. Sensor technology is needed to monitor and validate the increased complexity of the production process [13].

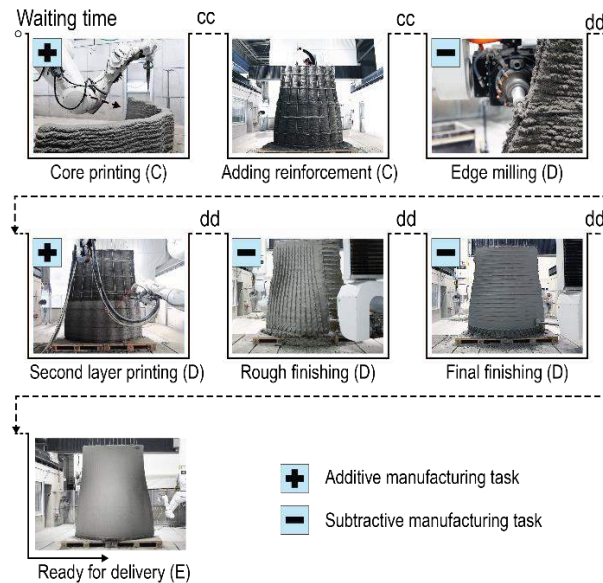

Figure 1: Multiple fabrication tasks for a fully-reinforced double curved concrete component

3.3 Challenges within the SC3DP Process

During these tasks, predicting the behaviour of the printing material is a major challenge. Due to the complex interaction of temperature, forces, material properties, the printing system setup and external circumstances, inaccuracies or even critical errors can occur. The success of the SC3DP and the quality of the component are determined by a large number of parameters to be controlled, such as nozzle distance, spray angle or conveying speed [12] just to name a few.

These parameters have a major influence on the printing quality. Incorrect parameters can lead to a reduction in concrete quality, concrete rebound, varying layer thickness or low early strength. Thus, printing layers can sag over time. Furthermore, the geometrical freedom of the robot tracks is limited due to the low printing resolution. For example, the production of sharp geometric edges is currently not possible using the SC3DP process alone.

Therefore, for high-precision shotcreted parts, a component improvement process consisting of the multiple interlocking tasks (edge milling and surface finishing) and quality inspection (measuring) will be critical in most cases. These interlocking tasks can in turn lead to unpredictable and long cycle times due to repair/finish work or due to insufficient task control.

Currently, SC3DP is characterized by the following challenges [19]:

- Compensation of inaccuracies due to unintended parameter variations during the fabrication process.
- Process validation of different production tasks must take place in order to optimize these tasks.
- Compensation of inaccuracies must be integrated into the manufacturing process. An automated finishing process with subsequent quality control for the surface must be developed to minimize process times.

In order to improve the component quality multiple tasks are needed, which increases the level of process complexity. However, each additional process task may increase the error rate.

Nevertheless, a variety of challenges are correlated with the quality control process as well. Acquiring data for a well-established quality control/check (QC) approach depends on a variety of aspects that could affect the acquisition strategy or the quality. The SC3DP manufacturing environment is in general contaminated. Dust emissions during the production process, coupled with high levels of humidity that occur in the production room, can lead to insufficient data quality (noise) during the data acquisition process. The size and the shape of the object could add another factor for the selection of the sensor as well as the data capturing strategy thus the data does not suffer from occlusion [15].

The material properties of the captured object play a crucial role in the quality of the captured data. After the SC3DP process, the object is saturated. Therefore, for example in case of TLS, infrared wavelength would not penetrate the water surface while green wavelength would have penetration properties through the water column [16]. Moreover, for rough surfaces, the received signal intensity depends on many factors: the distance; the incident angle of a laser beam; environmental and system factors; the value of material reflectance. This material reflectance is influenced by the colour and roughness of the object [17].

In conclusion, selecting an adequate sensor for capturing complete and reliable data depends on inter-correlated factors which have to be investigated thoroughly in order to satisfy the project's requirements.

4 Lean-based Production Approach

It is the aim of research in the project C06 of the Transregio 277 to investigate and develop a production approach for additive manufacturing methods that overcomes current drawbacks such as geometric and surface quality as well as hardly predictable production (and process) times. Therefore, SC3DP is used as a case study for prefabricated components with high-quality (geometric accuracy or surface). The five principles of Lean production are applied as followed resulting in a “lean based production approach (for SC3DP)”.

The proposed methodology is shown in Figure 2.

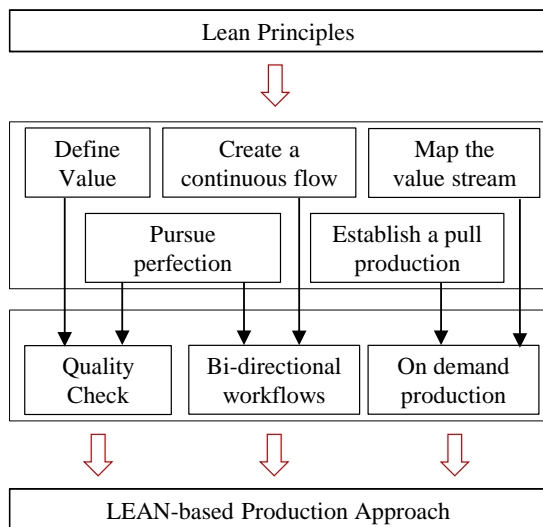

Figure 2: Derivation of the Lean-based Production Approach from Lean Principles

1. **On demand production.** Since with SC3DP technology components can be produced without any long lead time, pull production gets within reach for construction industry. In the context of SC3DP prefabricated components, the construction site (“customer”) could communicate the demand concerning individually designed components. This message defines the starting point and the production process begins immediately. Therefore, an on demand production of SC3DP produced concrete components is set up and being discussed.
2. **Bi-directional workflows and quality check.** Short cycles of quality control help to achieve the desired component quality. Due to the lack of formwork and hence lack of precision of AM processes, bi-directional information workflows provide the framework to ensure component quality. Therefore, short continual improvement processes at different stages are presented, e. g. (1) making sure that the core is printed accurately and that reinforcement (if existing) is placed correctly,

- (2) making sure that the edges are cut precisely and
- (3) the surface has a high quality.

By applying lean principles to the production and quality control processes, a higher component quality is expected as well as a significant reduction in waste during production and hence a higher productivity. In the following, those parts will be focused in detail.

4.1 On demand production

With the help of a simplified representation of a value stream mapping (Figure 3), the significant production tasks of the SC3DP can be visualized in the context of an on demand production from a holistic point of view [18]. Based on customers demand and a 3D-Model (or a Building Information Modelling (BIM) – Model in the near future) the production of concrete components can be initiated. The SC3DP Process consists of five main tasks: Material Supply (A), Material Production and Handling (B), Core Printing (C), Component Improvement (D) and Delivery (E) to construction site (Customer). Component improvement plays a major role in this process chain since quality control, both of surface and geometric, is crucial for high-quality concrete components as it remains the latest task before the delivery to construction site can start. Hence, it will be discussed further in the following sections.

Value Stream Mappings is a lean production method often used to analyse the production processes. In the context of SC3DP, this technique is confronted with various adaptations. Value stream mappings are very useful to calculate production and process times as well as inventories. However, since with the SC3DP method no geometrical standardized components are produced in series, but rather serialized individual parts, the design-to-construction workflow is nearly the same, but production times vary in each case and every time. The SC3DP method is not limited to one component type (e. g. walls or columns). Therefore, a continuous flow might be difficult to create as long as measure times for production and other important process parameters (e. g. printing speed) are not collected within a production database. It becomes obvious that a process and parameter database is a decisive factor of a successful SC3DP Production system. Production and process times (especially of component improvement) heavily depend on targeted geometry and surface quality as well as on curing time. Concrete curing is an important natural process to ensure load-bearing qualities and to allow the transport to the construction site. Aiming a direct design-to-construction-to-assembly workflow, curing times need to be investigated and should be reduced to a necessary minimum. Currently, digital-supervised placement or automated integration of reinforcement is another unsolved challenge.

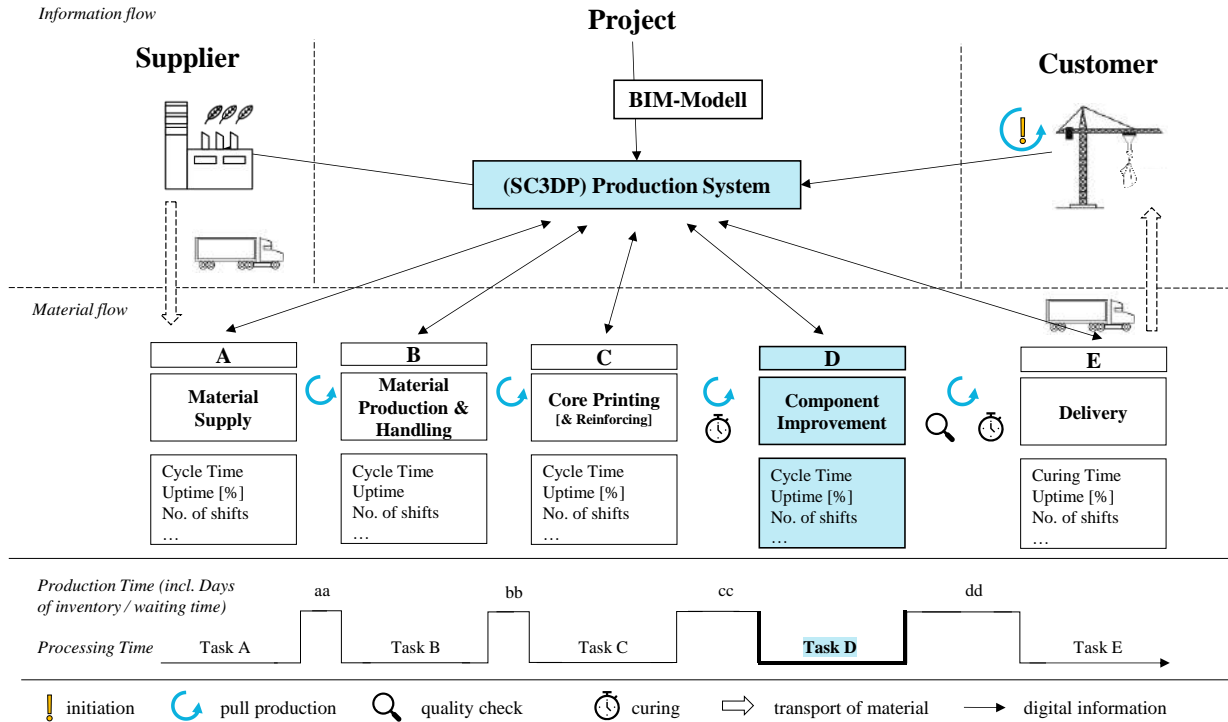

Figure 3: Lean-based Production Approach based on a value stream mapping

4.2 Bi-directional workflows for Component Improvement

Even in the field of digital fabrication, the possibilities of process-controlled component improvement are still limited and often depends on the skills of experienced workers and is labour-intensive [19]. To ensure the continuous quality control of surfaces as well as of the deposition process during the fabrication process and material damages during post-processing, the entire process must be monitored and validated. This can be done using a bidirectional workflow [20].

During the printing of the core structure in the SC3DP process, the required dimensions and tolerances must be observed and the previously shotcreted concrete has to be post-processed within the early phase of the curing concrete [21]. A delay can lead to defects such as cracking or other deficiencies in structural integrity. If the aging process is too advanced, it can lead to the damage of the formation and subtraction tools used or even to the failure of the fabrication system.

To create a hybrid manufacturing workflow for the shotcrete 3D printing process, a bidirectional workflow must be implemented. Feedback and quality inspections of the produced component must be established between

each task of the process (see Figure 4).

In this workflow, a fabrication model is created from the as-planned design model, which includes the path planning along the fabrication parameters. After the transition to fabrication and the actual execution of the process, the process is validated by a data acquisition and a subsequent analysis. This can lead to a task iteration in the production process. Depending on the measured geometry of the actual produced component and previously produced components, the process parameters can be adjusted after each validation step. For example, material must only be applied where insufficient material deposition has occurred. These adjustments can be executed locally to minimize the production time of the actual component.

In order to control the various tasks of the manufacturing process, quality control must take place. This raises the question which requirements of the produced component are important and should be measured. Robot-assisted additive manufacturing of prefabricated building components with complex geometry involves more than visible large-area surfaces. Should the objects be joined, the contact surfaces may complex geometries for dry joints. The following chapter addresses some important aspects in this context.

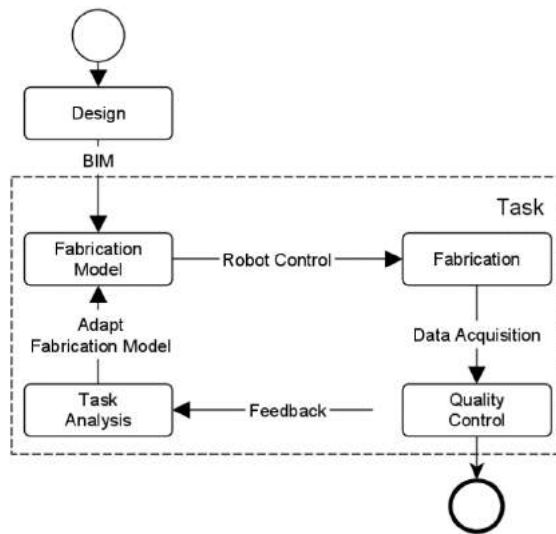

Figure 4: Bi-directional workflow for component improvement

4.3 Quality Check

To step forward towards the demands of industry 4.0 and meet the aspects of Lean-based production, as stated here as “value”, not only the printed specimen’s geometry must be checked, but also the existence of deformation on its surface.

Through the printing process, we have two main stages of the printed object. In the early printing process stage, especially in the core structure, the object is still in the forming process. In this step data capturing and processing speed are the major factors. However, in the surface finishing phase, the printed object reaches its final shape and develops to its digital twin. Therefore, at this stage, the accuracy of the process has to be treated with caution and be defined properly [22]. Accordingly, the need for having an integrated quality loop for every step is required.

An overview of different geometric aspects that could be controlled through the quality assessment process was given by [23]. The dimensions of the object and its tolerances are also two crucial parameters whose deviations from the as-designed model must be checked. This quality control guarantees a straightforward construction process and ensures that the original vision of the designer comes to light.

The integrated loop of QC in AMC adds another degree of freedom and establishes a bridge between construction and design. As an illustration, in the case of a printed specimen with a deviation from its digital twin, the modification needed for the deviation correction can be performed either on the printed object directly or on the designed model if the deviations are still in the acceptable range regarding the structural design.

5 Conclusion and Outlook

Bi-directional information flow provides the framework for the integration of additive manufacturing in construction and remains a necessary requirement for our Lean-based production approach. In addition, this a production approach can only get intelligent and truly efficient when it is actually based on building parameters (e. g. printing rate, layer thickness or curing time) as wells as on as-built geometry (by real-time measurement). Therefore, digital tools are required for a continuous and uninterrupted quality control throughout the entire construction process. Sensor feedback, data collection and interpretation play key roles here. Unforeseen issues during fabrication and construction that lead to deviations (as-built) from the design (as-planned) can be corrected instantly, the project’s goals or the defined value can be fulfilled more efficiently compared to the current situation.

Applying LP principles and methods is playing a key role here. A holistic process understanding ensures that not only a multitude of relevant building parameters can be integrated right at the beginning (ex ante) of the design phase (e. g. structural requirements, fabrication constraints, logistic restrictions, etc.), but also allows data to be collected after design completion (ex post) and during the fabrication and the assembly process on site. Those can be subsequently fed back into a centralized BIM model. Therefore, a database of AM production processes and parameters is of major importance. It would allow it to choose the best productions properties for a specific project/ production step. To analyse patterns or correlations in complex data sets, artificial intelligence such as machine learning can create a fully automated production. Hereby, it would be possible to identify trends and modify deviations between the production steps and various building parameters. This would finally lead to a new and truly “intelligent” production system merging current trends of lean (production) and construction.

Abstract -

Machine control systems are advancing side by side with the adoption of 5G and growing trends of the internet of things (IoT) has made autonomous excavators more ubiquitous. The autonomous excavators have gained significant interest in the earthworks area, due to their enhanced productivity for long hours, safety, space exploration, mining and construction work. However, A great amount of effort is required to address many existing challenges such as adaptive movement and control, task planning (digging, moving debris, etc.), collaborative work with other machines and humans. In this study, we review the state of the art and provide artificial intelligence (AI-) driven road map for implementing a complete autonomous framework for the earth-moving machine to our test platform ‘Smart Excavator’. Furthermore, the challenges and required effort to implement the framework are also discussed in comparison with existing literature.

Keywords -

construction engineering;mining;excavation;smart excavation;artificial intelligence;data collection; machine learning; excavator

1 Introduction

The automated and autonomous excavators can be seen as a logical outcome, or at least enabled by, engineering mega-trends namely AI, automation and , IoT, and Space exploration. In one sense we can classify an excavator as a manipulator that is working on the field, using IoT and 3D models and control hydraulics for digging; however, if this would be the case self-moving excavators would already be plenty in the field. What is lacking from this is a simplified view of the complexity of the always-changing work environment where the excavator needs to smoothly operate. All this still while maintaining safety and fleet capabilities with machines and humans.

Makkonen et al. suggested that road designer’s design models (3D surface) can be used as a source for path generation for excavators [1]. High usage of machine control systems in earth-moving machinery gives effortless access

to target 3D surfaces, real-time localization, and kinematic positioning of the excavator. Given that this kind of excavator is also part of IoT, that makes the autonomous excavator is already capable of updating the information about its activities and processes to the network.

The operational performance of excavators is continuously being improved. As it holds a great potential market for construction engineering area, where earth-moving machines require planning and precise control [2] to execute various tasks from trenching to larger-scale operations. For example, founding and constructing the supporting layers of the highway. The effective operation time of the excavators in construction is maximized in the majority of cases to cut down the cost of building, which holds a potential challenge and opportunity for automation-based excavators.

The automation level for excavators have been categorized into various types, the most common are, i) human-controlled machines, ii) remote-controlled machines, iii) semi-autonomous machines, iv) fully-autonomous machines [3, 2]. . The automation and autonomy traits in excavators can however be increased, considering the ongoing challenges in construction engineering and earth moving machines area. Apart from the heterogeneous and circumstance-dependent characteristics of the terrain, ensuring the safety and efficiency of these machines is a great challenge toward fully autonomous excavators [3].

In this study, we propose a framework to implement AI-driven autonomous excavators using the data streams from the excavator itself in real-time. The study is one of the first attempts, to consider both edge and cloud-driven challenges and solutions for implementing an autonomous excavator system. Considering, the low latency and real-time processing challenges, a hybrid approach is proposed, see Section 4. First, we identify the requirements to implement AI-driven autonomous framework from existing literature, following that, a framework is proposed. In addition, the system will be capable of handling drifting scenarios and the occurrence of concept drift while modeling, which can affect the learning of models and decision-making.

The rest of the paper is structured as Section 2 details

the state of the art, Section 3 lists the requirements to implement the autonomous framework. Section 4 describes the framework and Section 5 presents a use case for the framework. Finally, we discuss the limitations and concrete challenges along with the conclusion.

2 Literature Review

2.1 Methods for autonomous excavators

In previous years, various toolboxes and methods were introduced for autonomous excavators. Back in 1998, the Robotic Institute at Carnegie Mellon University, USA, created an excavator model capable of finding and filling up the intended truck without any human interaction [4]. Similarly, Lancaster University's intelligent excavator (LUCIE) [5] demonstrated several automated robotics features in the excavation process e.g. controlling motion of the bucket. Unlike traditional excavators, autonomous excavators now have become perceptive, as they are equipped with cutting edge sensors, cameras, a global positioning system (GPS), lidar, radar, and laser beams mostly [3, 6]. Such equipment enhances the autonomy of the excavators, as they can collect raw data, and analyze the data using machine learning to develop an understanding of the designated environment.

A study by [6], proposed a real-time multi-frame Long Short-Term Memory (LSTM-) based method with a You Only Look Once (YOLO)-v2, as the main backbone to accumulate useful information from image frames for more robust image detection, with decreased computational effort. The developed approach resulted in near human-level accuracy to detect different types of objects under varying light conditions, lots of dust, etc. However, the performance of the method decreased in low light conditions.

Another study by [7], focused on the soil excavation operation of autonomous excavators, to maximize the performance of the digging process like an expert human. With the varying soil dynamics, capturing soil characteristics by adaptive models can be challenging. Dynamic Movement Primitives (DMP), was adopted to tackle the complex soil dynamics. In particular, DMP uses virtual dynamics approach to structure and preserve the true trajectory shape to the finishing point i.e. transition to move and dump excavated material [7]. The implemented algorithm effectively learns the best position trajectories, ensuring excessive adaptation to changing soil properties with additional safety and robustness.

There are different ongoing challenges to operate excavators autonomously such as, variable environmental conditions, weather, changing lighting conditions, dropping piles of materials to a place or truck, digging of the material with its natural integrity, and avoiding collisions with the objects in construction site [8]. In this regard, a

new architecture and algorithms were proposed by [8] for autonomous excavators. The system was built by a central perception module, integrating perception, planning, and control. The perception module fuses the information from equipped 3D-Lidar and camera outputs, to perceive 3D models of material, dumping site, obstacles, and others. The system was also capable of handling sudden changes in the environment to provide safety e.g. movement of animals on construction sites.

2.2 Applications of autonomous excavator

So far automation is used to streamline the earthworks on infrastructure and construction sites in most commercial solutions [9, 10, 11] using GNSS localization and boom-mounted IMU sensory to pinpoint the bucket or blade of the machinery. This allows the operator to measure grades and slopes with the machine itself and removes the need for laborious marking the site with physical signs as the operator can view the plans besides the machine from the system monitor. Now gaining popularity are also cloud-based management services like [12] which are already widely in use on Finnish public construction sites to manage the full project. Cloud services enable flexibility as any changes made and uploaded to design models or other information are immediately available to everyone involved including the excavator operators. It also helps to reduce material and fuel expenses as well as labor costs and machine hours as the service eases machine management on a whole scale.

The machine manufacturers [9] and automation system providers [10, 11] are also introduced grade control to semi-automatically excavate grades and slopes with improved precision. The operator controls the joystick and automation keeps the bucket on grade. Semi automation controls also include depth control for preventing over-cutting. A study by [10], have also showcased safety functions to limit the working area by virtual walls to prevent collisions, when working on tight construction areas and weighting system for the bucket to have better material management on truck loading in construction or for example in gravel pits.

Japan institute [13] stated that automatic and unmanned construction machines could be used to sort debris in reconstruction sites to remove or restore broken roads or structures or demolish or rebuilt damaged houses in places that cannot be safely accessed by humans after disasters. Also, automation could be used in highly repetitive job sites in construction on tasks like truck loading to let human operators focus on more challenging tasks.

The Space programs [14] introduced plans to send unmanned construction machinery to explore the surface and build lunar and Mars stations before sending manned flights. Automatic excavation of possibly unknown soil

materials is a crucial task to establish any buildings and efficient usage of the local materials would greatly reduce the payload of the flights.

3 Requirements for AI driven autonomous excavators

3.1 Intelligent Control

An autonomous excavator requires adaptive and robust control procedures to be able to operate with full control along with an understanding of its surroundings that is in constant change. The remote-controlled excavators in past have used feedback linearization technique, impedance controller, non-linear proportional-integral controlled for optimized interaction.

Usually, for self-operation, the source of movement is hydraulic power, but lately, electric machinery like [15] are on the rise. The base excavator can move and rotate reasonably freely on the work area using tracks or all-wheel drive. The end-effector also has 4 degrees of freedom as the cabin rotates and the boom, arm, and the coupler for the bucket are all linked together with a rotational axis and have actuators to manipulate them. When an excavator is used as a multipurpose tool a rototill adds versatility by adding 2 more DOFs for the end-effector. To fulfill the requirement for control of its movements, all kinematics links from the base to end-effector should be measured and the movements performed in a precise and accurate method enough.

Understanding the surroundings is mandatory for autonomous machines in general and can even be the key difference between AI-controlled machines and normal machines as humans have limited situational awareness and cognitive load. Typical sensor solutions for this are 2D cameras with various sensor types like RGB, heat, and multi-spectral; for scanning and modeling the environment 3D stereo cameras and lidars are typically used. For localization on the work site GNSS-location systems are most used, with two antennas they provide heading and angle measurements in addition to location data. In larger job sites, local fixed reference stations provide correction signals to the localization to achieve centimeter-level preciseness.

Specific to autonomous construction work machines like an excavator, a dynamic site-wide plan to follow is provided and AI needs to be able to full fill the plan. Typically this plan comes from humans like road designers, but there is no reason that this plan is also from AI in the future. The plans are typically presented in CAD models, but the surge of structured digital information in the forms of building information modeling (BIM) is fast gaining ground also outside the Nordic countries.

3.2 Motion Planning

The earth moving machines in general for earth cutting and standard movements require force feedback to sense the surrounding environment especially the processed soil. Force control also would help to have more advanced loading and other movements as skilled human operators also use wide haptic feedback from the machine. The force feedback could be also used in tandem with vision sensors in events, where continuous movement and digging is performed with a high chance of collision with static objects in excavation site e.g. collision with another machine, falling to a ditch or a dump, hitting a tree or a rock, or others. The force feedback in excavation sites can be provided using sensor-based data collection adjoined with real-time sensing and AI-driven learning methods.

Several scientific studies have tried to address the challenges of nominal motion planning in excavation sites. A study by [4] proposed an autonomous loading system using a perception engineering-based approach, using laser scan to detect truck model and soil without change of texture. Similarly, a study by [16] introduced a framework for each work machine to minimize human involvement in the excavation site. In addition, different approaches and algorithms have been experimented to optimize the process of planning and perception for earth-moving machines.

3.3 Simulation Environment

The major reason to use simulation and virtual environments is safety and real-time tests, mapping, and learning in continuously changing environments. In a study by [17], excavator Menzi Muck M545 simulated the excavation process using a planning and control approach. The excavator was able to reliably fill buckets using force trajectory-based dig cycles. [17]. In another study, a co-simulation framework was developed based on MATLAB-SIMULINK for modeling controller and OPNET to simulate communication network and optimize the remotely controllable excavator [18]. Simulation-based methods are also prominent to understand the landscapes and changes in the environment using sensor data [2].

The simulation environments integrated with the complete autonomous excavation system are useful to demonstrate the fieldwork virtually, along with planning and monitoring. As the earth moving machines are equipped with sensors like IMUs, a global positioning system (GPS), pressure sensors, and possible weather sensors, and others. The sensor data can be utilized to develop perception-based autonomous excavation systems using artificial intelligence approaches. Therefore, developing and integrating simulation tools or environments with an autonomous excavation framework can help in planning and monitoring data in real-time. Lastly, the simulation environment can

be effective for monitoring the sensor feeds continuously for detecting the possible drifts in streaming data [19].

3.4 Tools and Frameworks

Construction work-specific autonomous excavation machines require dynamic technology solutions to adapt to diverse characteristics of soil and building materials, accompanied by a coherent modeling plan. Typically, this plan comes from expert individuals in the respective field such as road designers, civil engineers, and urban planners. Therefore, it should be possible that future AI-driven intelligent solutions could learn from historical plans and construction sites, and do minor adjustment to the construction plans such as mass swap, layer thicknesses with minimal or no human intervention. In this regard, the autonomous earthwork machines require dynamic and light computational tools and frameworks, which can be used in both cloud and edge architectures for effective excavation solutions.

The excavation plans are typically presented in CAD models, but the surge of structured digital information in the forms of building information modeling (BIM) is fast gaining ground both in Nordic countries and outside as well. The equipped sensors with earth machines are configured using CAN bus and other platforms. The sensed feeds from sensors are often further pre-processed and explored using MATLAB/Simulink, standard python libraries, and different simulation tools. With cloud and edge-based platforms low latency computing and analysis tools are also gaining prominence for generating insights e.g. at cloud end Apache Spark, Apache Kafka, Kibana, and others [20]. However, as with increasing trends of IoT and implementation of 5G, the earthwork machines would need more edge computing capabilities. Therefore, light computational tools and frameworks with the ability to handle low latency data streams are needed.

4 Theoretical Framework

4.1 Framework of AI driven Autonomous Excavator

The proposed framework will be implemented on hybrid cloud and edge architecture, considering the ongoing trends of IoT and the implementation of 5G. In this regard, we propose an abstraction level hybrid architecture that constitutes both edge and cloud-based solution requirements, please see Figure 2. and Section 4.2.

The first block of the AI-driven framework is "Sensing and Planning", which is designed based on the idea of sensing and adaptive learning in real-time, please see Figure 1. It first utilizes the sensors to make model adjustments in both local and global aspects. Then, the tasks are created by the task planner based on the work maps and building information models. The data from sensors such as laser

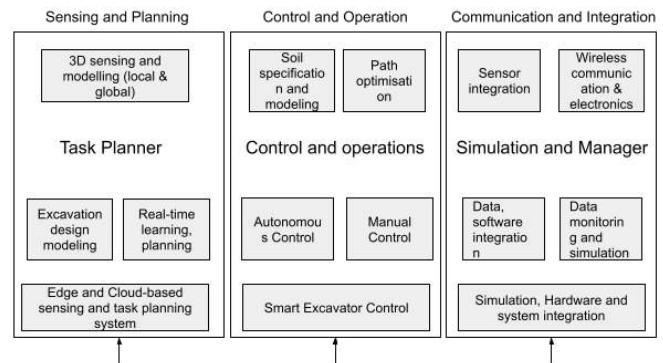

Figure 1. Framework for AI-driven Autonomous Excavator, adapted from [21]

sensors and 3D Lidar sensors will be used for developing adaptive learning methods for intelligent movement. In addition, as data from sensors is continuously changing and real-time in nature, therefore, due to changes in statistical properties of data, a concept drift can occur [19]. The drift is often due to the malfunction of the sensor or actuator. Such changes in the data stream can result in ineffective predictions from learners e.g. less efficient object detection for collision-free movement. Therefore, concept drift detection and adaption methods are also a key requirement for learners operational in real-world settings.

The second block "Control and Operation" in the framework incorporates and implements the sensed feeds and knowledge from learners to perform excavation operations in a real environment. In this regard, the requirements described in Section 3. to adapt and characterize the dynamic nature of excavation terrain is handled by using the control procedures from implemented models. Furthermore, collision is possible on excavation sites due to animal movement, object movement, truck movement, and debris., which requires collision detection and path planning methods. All previously mentioned procedures are controlled and managed in this layer. Additionally, the likelihood of device and machine failures is possible, which can make the autonomous operation by excavator impossible. Therefore, a hybrid approach is implemented for controlling the excavator i.e. in case of failure or system shutdown, an administrator on site can flexibly take over the machine. For such cases, an alarm system will be implemented using the sensed feeds from the machine that can be enabled to receive alerts and view the performance of the machine using a tablet or other mobile device, please see Figure 2.

The third block "Communication and Integration" constitutes control and monitoring tasks during the excavation operations at a respective site. We propose to integrate and continuous monitoring and simulation system with the pre-

vious two mentioned technology stacks. Keeping in view the new methods of communication aided by 5G support and simulating sensor feeds can make the operations of excavators more efficient. Additionally, the integration of developed intelligent packages for adaptive control and movement of excavators is executed in this block. This creates the possibility to monitor and simulate the operations before going to the excavation site, as well as allows continuous monitoring facility during real-world operations.

4.2 Edge AI architecture for Autonomous Excavator

As the world is rapidly moving towards IoT and advance communication paradigms. With the increased number of interconnected physical devices, developments are being made in edge computing to handle the sheer amount of data being shared. There are several application areas from edge computing assisted IoT, which includes household IoT, industrial IoT, autonomous vehicles, and 5G networks [22].

In industrial IoT, there are several opportunities available which include the capability to continuously monitor production lines in real-time using sensing feeds from a multitude of sensors [22]. For example, the data produced from equipped vibration sensors from an excavator's pump can help in distinguishing safety levels using mechanical vibrations. Similarly, the multitude of sensors can also be used for collision-free movement, identifying the position of excavators, and acquiring the movement routes of other vehicles in the vicinity.

The overall approach to implement AI-driven autonomous excavators using edge computing approach is illustrated in Figure 2. The excavator machine is equipped with a myriad of sensors that are continuously producing and pushing data to the database at cloud and edge. The data stored in the cloud is further used to simulate and generates insights to better monitor and control the excavators in exceptional situations. Additionally, the data at cloud is used to model and train learners for adaptive control and collision-free movement, as described in Figure 1. The sensed data can however further be utilized to ensure security and for prompt administrative response in case of malfunctioning or hazardous situations. For example, if the autonomous module of the excavator goes offline and at the excavation site their exceptional circumstances (falling of debris or other vehicular movements etc), before going offline the system will send an alert to the mobile or tablet device of the administrator, and the excavator can be switched to manual mode. Following that, the learned knowledge is then transferred to an edge network that stays persistent with excavators, reducing the latency issues. However, if a concept drift occurs in drawn predictions, then the new information is pushed at the edge

from the cloud to retrain the learners. The architecture is further extended by providing command and control using smart devices such as mobile phones and tablet devices.

Figure 2. Basic Edge AI driven architecture for autonomous excavator

5 Use Case

In our developed model-based autonomous control, Machine Control Model (MCM) is used for the trajectory generation for the Smart Excavator. In these examples, the models are in LandXML file transfer format saved using Finnish Infra model standards. For adaptive development and testing purposes, the visual programming language Grasshopper included in Rhinoceros CAD software is used to model the digital twin of the Bobcat E85 Robotic Excavator and to load and partition the lines and triangulation from the Inframodel for the trajectory generation.

The use of Grasshopper allows easy high parametrization of the trajectories. The software includes various ready function blocks from basic calculations to graphics computation. Also, own custom blocks can be written with custom expression or C sharp script, python script, or VB script. The visual preview of the digital twin in Rhinoceros is useful for examining the trajectories for errors before testing them with the actual robotic excavator. A major drawback is that there seems not to be a quick workaround to convert created grasshopper code to the standalone program to the Smart Excavators control system since code often contains blocks with various scripting languages. The Grasshopper itself is rather dependent on Rhinoceros because its core product uses many geometry functionalities provided by the CAD software.

The design lines from the Machine Control Models are used to define the working area and to compute cartesian-space paths to cut the model surface. Adjacent and parallel lines are filtered and when necessary, divided according to working region. The bucket paths are then computed between those lines to excavate the designed surface. We also use the lines from the model to create surfaces with Rhino's loft tool instead of using the triangulated surface from the model to avoid imprecision and confusion in the edges of the triangles. Alternatively, para-metrically controlled Bezier curve-shaped shoveling paths are created in grasshopper and the endpoints are linked to soil surface for mass excavations.

To define the trajectories, the path's curve or line is divided into segments which are then evaluated with the associated surface. The evaluation gives a surface normal vector for each segment. Every path point is translated to the excavator's local coordinates. The formed frame for each path segment is yet compared to the excavator's mainframe to compute Euler angles. The path is then converted to joint space using inverse kinematics. After that, with information from the surrounding environment and cooperating vehicles such as a dumpster, additional joint space movements are generated to complete the workflow and to dump the excavated material to the defined location. For example, onto a truck bed.

The trajectories are tested and analyzed with the 8,5-ton Bobcat Smart excavator. The excavator has retrofitted electric valves to control the hydraulics. An on-board PC is in charge of controlling the valves and forwarding signals from joysticks and other controls and data from boom IMU sensors. It is connected to an industrial PC with a CAN bus over a local 5 GHz wireless network. The industrial PC runs Matlab/Simulink controller program which has a separate controller for each actuator with online adjustable tuning. The controller has three modes: remote control, teach-in to record and repeat workflow, and automatic control for executing the model-based trajectories. So far the automation tests have included different special-shaped surfaces like stairs and various slopes to iterate and tune the trajectories and controllers to better precision. Experiments to compare excavation aboard, remote controlling, and automation have been also planned.

6 Discussion

Artificial intelligence has been identified as a driver for sustainable development [24]. Within the autonomous vehicle community and industrial IoT, the main considerations of sustainability are resource optimization and safety [24]. Intelligent automation saves resources when optimal real-time planning can be made through intelligent algorithms for enhanced fuel efficiency, leading to fewer emissions. We can recognize different layers of planning:

Figure 3. Smart excavation in progress at test site in winter conditions[23]

1) construction site planning 2) fleet intelligence 3) individual vehicles. The construction site planning could optimize material movements on-site to maximize material re-usage and minimize unnecessary loading, transport, and other material manipulation. Connected vehicles operating in fleets can optimize their cooperation to maximize activity and reduce wait time and overall work duration. For example, excavators and front loader can synchronize their operations to optimize piling or truck loading.

Automated monitoring of vehicles can be used in improving vehicle maintenance schedules. Environmental measurements like emission particles, temperature, and moisture can also be used to create climate-friendly earth moving machines by studying data generated from sensors and operational insights of existing excavators. Additionally, cloud computing and edge computing can play a pivotal role in produce climate-friendly and sustainable machines. As we know, the data generated from IoTs, and data from vehicular sensors becomes larger each day, therefore, generating insights and modeling the respective data can aid in achieving sustainable societal goals. In this study, we proposed a hybrid approach that includes both edge and cloud computing paradigms to retain historical information and help in quick real-time decision making for smart and autonomous excavators machines, please see Figure 2.

The operation of individual vehicles can be optimized for efficient and energy prudent trajectories. Accuracy is to be improved where needed. Few centimeters of improvement on preciseness can save a lot of work and material on a bed of kilometers long highway but does small-scale landscaping need such accuracy? To be able to complete a complex planning task with multiple agents, task decomposition and task distribution need to be modeled. The edge architecture designed in this paper is designed to be used to leverage the high-volume data produced by these intelligent agents.

The construction machinery is increasingly equipped

with various sensors to increase situational awareness of the operator. However, as mentioned earlier, presenting for example raw images from multiple different cameras could swiftly overwhelm the cognitive capacity of a human operator. Therefore handling of the sensor data should be somewhat automated and fused to form more clear and intuitive presentation using for example means of extended reality (XR). Also, adaptive AI control methods can be overwhelmed by too wide data streams. First and foremost irrelevant data or concept drift can slow down and even completely stall or mislead possible learning solutions [19].

The edge computing provides capabilities to access stored data, computing resources, and access with low latency, finding the closest available resources to the machines e.g. database at edge at the roadside unit, a database of an edge machine (car, truck, etc.) using a vehicle to vehicle communication [25]. Moreover, the infrastructure solutions which are used in edge computing can collect local resources efficiently in lesser time when compared with traditional computing paradigms. However, the concept itself is relatively new and has received prominent attention from both academia and industry as well as in transportation e.g. intelligent vehicles [25], therefore still requires exploration.

7 Conclusion

Industrial IoT has gained prominence in past decades, especially when it comes to construction engineering, the concept of "smart excavators", "intelligent excavation system", and "autonomous excavators" is on the rise in both academia and industry to produce industrial-grade earth moving machines. This article presents a approach to implement AI-driven intelligent framework for autonomous excavators after conducting a state-of-the-art review. Considering the ongoing advancements and challenges in ICT concerning autonomous and intelligent vehicles. A hybrid architecture is proposed along with three main technology blocks to implement AI-driven autonomous framework for smart excavation, Figure 1 and 2.

The work presented in this study is still at its initial stages and shortcomings are expected. At the moment, the presented framework for AI-driven autonomous excavators has some limitations, e.g. the aspects to ensure the effectiveness of the system are not well covered, privacy and security concerns still require great effort. As with the implementation of 5G and new generation hardware, privacy and security constraints will also take a shift and will require advanced efforts.

In the future, we plan to move forward with development and present a fully implemented AI-driven autonomous framework with rigorous tests.

Abstract -

Autonomous excavator develops rapidly in recent years as a result of the shortage of labor and hazardous working environments for operating excavators. We present a novel hierarchical planning system for autonomous excavators. The overall planning system consists of a high-level task planner for task division and base movement planning, and general sub-task planners with motion primitives, which include both arm and base movement. Using the proposed system architecture, we experiment the trench and pile removal tasks in the real world and experiment large-scale material loading tasks in a simulation environment. The results show that the system architecture and planner algorithms are able to generate effective task and motion plans which perform well in autonomous excavation.

Keywords -

Task planning; Autonomous excavator; Planning architecture; Material loading

1 Introduction

Excavators are widely used for many different applications such as moving earth, rock, or other materials. As one of the most versatile heavy equipment, it has a vast market over the world [1]. However, a skillful excavator human operator needs much training [2]. At the same time, many operation sites are located in remote areas with less convenient infrastructures. Moreover, hazardous work environments can impact the health and safety of the human operators on-site [3]. The autonomous excavator has the advantage of addressing these challenges and improving the overall working condition. In recent years, researchers in both academia and industry put more and more effort into developing autonomous excavators [4].

A major challenge for developing autonomous excavators is to design a general planning architecture that is suitable for a wide range of real-world tasks, such as material loading, trench digging, truck loading. In most of the literature, the authors focus on developing key individual components for autonomous excavators, including high-level task planner design, excavation trajectory generation algorithms, and control modules.

As for the high-level task planner design, some research has covered autonomous excavation in task division or base move route planning. In [5], Seo et al. devise a task planner to create optimized work commands for an automated excavator. The key components of the excavation task planner are the modules for work area partitioning and excavation path generation. In [6], Kim et al. present the intelligent navigation strategies, which are essential for an automated earthwork system to execute excavation effectively. In [7], Kim et al. present a complete coverage path planning (CCPP) algorithm by considering the characteristics of earthwork. Also, a path similarity analysis method was proposed to test the effectiveness of the CCPP algorithm.

Other research has contributed to developing the excavator arm motion generation and controller design [8] [9]. In [10], Jud et al. present a planning and control approach for autonomous excavation in which a single dig cycle is defined with respect to the end-effector force-torque trajectory. Compared with the position trajectories for the bucket motion, it has the advantage that it can overcome the limitations of that soil interaction forces, which are dominant and immensely hard to predict or estimate. In [11], Son et al. propose a novel excavation trajectory planning framework for industrial autonomous robotic excavators, which emulates the strategies of human operators to optimize the excavation of different types of soils while also upholding robustness and safety in practice.

Despite these advances, there is less research focusing on the planning architecture that connects the high-level task planner, sub-task planners and motion planning for autonomous excavators. In [12], Elezaby et al. present an event-based finite-state machine strategy model which selects different motion primitives for the wheel loader task cycle. It provides a promising system architecture design, but the motion primitive definition is based on a wheel loader and does not fit the excavator very well. Furthermore, no related sub-task definition exists in the published work and within which the architecture of the task planner is general. Most research mentioned above mostly focuses either on the high-level task planning, or the motion primitive's design. Overall, there is no from top to bottom planning system architecture design for autonomous

excavators.

To address the limitations, in this paper, we present a novel hierarchical planning architecture for autonomous excavator systems. We first handle the issue of the vast variety of excavation task types and design a high-level task planner for excavation task division and base move planning. Then we abstract out two types of sub-task planners with good portability and generality, including material removal sub-task planner, and base move sub-task planner. Next we encapsulate the motion primitives and furnish them with suitable controllers for both joints control and base control. Finally, we implement our approach and further validate it in both real-world experiments and dynamic simulation environments with a range of excavators. The results show that the system architecture and planner algorithms are able to generate effective work plans that could be fed into the autonomous excavation system in a general way.

This paper is organized as follows: In Section 2, a novel general planning system architecture is presented. In Section 3, a high-level task planner is proposed in terms of excavation task division and base move planning. We first give our definition of the local task region. Then three common tasks and their planning schemes are introduced in detail. In Section 4, we focus on the implementation of sub-task planners, which include both arm movement and base movement. Their related motion primitives are covered there as well. Both real-world experimental results and simulation result is presented in Section 5. In Section 6, conclusions are drawn, and potential future work is discussed lastly.

2 Planner Architecture

In our approach, we propose a hierarchical planner architecture regarding the general applications. There are two levels of task planners plus one level of motion primitives. From top to bottom, they are high-level task planner layer, sub-task planners layer and motion primitives layer. In most scenarios, the excavator alternates between the motion of its arm to perform excavation operation and the moving of the base to the desired position. Based on this characteristic, our planner separate the material removing and base moving into two planning pipelines.

Generally, there exist a variety of user-defined tasks and it causes the high-level task planner to be highly customized. In our design, we define two types of sub-tasks. And the high-level task planner, being closest to the user interface, only needs to take the user task as input and then divide the whole task into these types of sub-tasks, namely material removal sub-tasks and base move sub-tasks. As a result, the planner plays the role of determining which location the excavator needs to move to and which region of material the excavator needs to dig. For each excava-

tion task, it will determine the sequence of excavator route points first, and at each excavator route point, a sequence of digging regions (sub-task regions) is determined. Once all sub-tasks are done by following the generated sequence, the task assigned by the user is considered finished. For the arm movements task, the high-level task planner assumes the excavator base is stationary, and calculates the sub-task region (the material region) that can be reached by the excavator's arm at that fixed position. For the base movements task, the planner requires the excavator to reach the desired route point with a given heading angle.

Given this high-level task planner and its result of sub-tasks, sub-task planners provide the solution to achieve the short-term goal. It guides the excavator to reach the target route point through waypoints planning. Meanwhile, it helps the excavator complete the sub-region excavation efficiently and accurately at a fixed base position. For simplicity, we name material removal sub-task planner as MRSP, and name base move sub-task planner as BMSP. MRSP receives sub-task region from high-level task planner, then decides the motion primitive and calculates the relevant parameters. BMSP receives the excavator route points from the high-level task planner, and outputs the waypoints between two route points and the relevant constraints.

We abstract the motion primitives as the result of sub-task planner, instead of direct motion control, mainly because there are many repeated and modular operation actions in excavation job, which simplifies the complexity of sub-task planners. Currently, we have designed dig motion primitive, dump motion primitive and base move motion primitive. Besides the task planning results, these primitives will use several external excavation parameters to generate the feasible trajectories. For example, the excavation parameters can be the length of each excavator link, bucket volume, material remove sub-task region size, desired dig depth, and bucket teeth position constraints. The generated trajectories will be the output of the entire planning system, but the input for the controllers to follow.

In summary, we have the high-level task planner to calculate the global stop route points, local task regions, and local task goals of each stop station. And sub-task planners MRSP and BMSP will handle these sub-tasks by calling the encapsulated motion modules, which are the motion primitives we design. The motion primitives will finally generate the trajectories for controllers. The overall architecture of our planner is shown in Fig. 1.

3 High-level Task Planner

The high-level task planner takes the user-defined task as input and divides the task for the sub-task planners. Thus, in this section, we will cover about this division in terms of local task region. Also, for better understanding

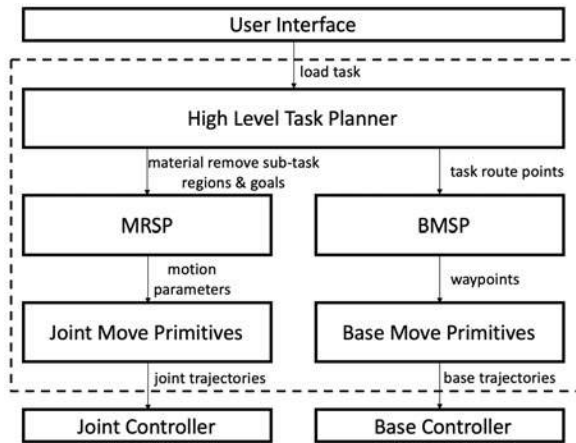

Figure 1. Planner architecture. Components are drawn inside the dashed box.

the use of high-level task planner, three common tasks in real constructions are developed, which are the trench task, pile removal task and large-scale pile removal task.

Here we define two different types of excavation task based on the moving direction and the requirement of the material residue: forward-movement tasks and backward-movement tasks. For forward-movement tasks, the target material is above the surface ground, which means that the goal height of the material removal is the same as that of the surface ground. Only after the material in front of the excavator is removed, can the excavator forward to continue. On the other hand, for backward-movement tasks, the goal height of material is below surface ground, after closer materials are removed, the excavator moves backward to continue. Apparently, the trench task is a backward-movement task, while pile removal and large scale pile removal are forward-movement tasks.

For a given excavator kinematic model, the local safely reachable range is pre-determined. We denote the maximum reachable distance as r_{max} , the minimum reachable distance as r_{min} . To fully cover the global task zone, we set a local task region overlap area, denoted as r_o .

3.1 Local Task Region

Before introducing the three specified common tasks, this section gives the definition of the local task region for MRSP. The task region of MRSP is defined locally in the excavator's base coordinate frame. The local task region is defined using four parameters: 1) area center swing angle α ; 2) area angle range or width β ; 3) near end distance r_{min} ; 4) remote end distance r_{max} . Two types of local task region are provided. The high-level task planner can select sector area or rectangle area as local task region. The parameter β has two definitions. Angle

range definition corresponds to sector area, while width definition corresponds to rectangle area. Fig. 2 shows the local task region definition using the parameters.

Figure 2. Local task region definition.

There are two points worth noting about the local task region. First, the selection of r_{min} and r_{max} should be based on excavator size to make sure the local task region is reachable by the bucket. Second, during the dig and dump loop, the excavator base pose may have a small change compared to the initial base pose. If the local task region is not updated, the global task zone in the map coordinate frame will change. To solve this problem, MRSP records the task region center in the map coordinate frame initially. Before each dig dump loop, MRSP will check the current excavator base pose in the map coordinate frame, and then adjust the local task region parameters to ensure the local task region does not shift in the global task zone.

3.2 Trench Task

Suppose the desired trench has a length of l , and width of w . The initial route point of the excavator is located along the trench direction, r_{max} meters from the trench beginning. After each sub-task finishes, the excavator base moves backward for the next sub-task. The backward distance $d = r_{max} - r_{min} - r_o$. The total number n of material remove sub-task execution is $n = \lceil l/d \rceil$. To meet the trench length requirement, the near end boundary distance of the last sub-task is $r_{min} + n \cdot d - l$.

In general, the desired trench width w is relatively narrow. We choose rectangle as the sub-task region shape. Fig. 3 shows the high-level planning for trench tasks.

3.3 Pile Removal Task

Pile removal task and trench task share similar definitions and have the same notations to describe the planner. The difference is trench task is a backward-movement task, while the pile removal task is a forward-movement task. Similar to the trench task, suppose the desired pile to remove has a length of l , and width of w . The initial route point of the excavator is located along the pile length

Figure 3. Trench task high level planning.

direction, r_{max} meters back from the pile task zone beginning. After each sub-task finishes, the excavator base moves forward for the next sub-task. The backward distance $d = r_{max} - r_{min} - r_o$. The total number n of material remove sub-task execution is $n = \lceil l/d \rceil$. To meet the pile length requirement, the remote end boundary distance of the last sub-task is $r_{min} + l - (n - 1) \cdot d$.

Pile task zone has a relatively wide width w . We choose sector as the sub-task region shape. If the rectangle task region applied, the top left corner or top right corner may not reachable for the excavator. Fig. 4 shows the high-level planning for pile removal task.

Figure 4. Pile removal task high level planning.

3.4 Large Scale Pile Removal Task

The task zone definition of the large-scale pile removal task is similar to the one of the pile removal task. However, the task zone area is larger than the pile removal task zone that the excavator route path can not be a straight line to finish the task. We denote the maximum width of the pile removal task as q . If the width w of the task zone is larger than q , the task is a large-scale case. Otherwise, the task is considered as pile removal task which described in section

3.3. According to [5], we have:

$$q = 2\sqrt{r_{max}^2 - d^2} \quad (1)$$

Suppose the task zone width w is larger than q , we first separate the task zone into $m = \lceil w/q \rceil$ columns. For each column, we use 180° sector to cover. Consider the limitation of the lidar horizontal field of view in the real application, each 180° sector is further decomposed into a smaller angle range of sectors. The sectors close to each other have an overlap area to secure full coverage. In some applications where the material may be very thick, then multi-layers can be used for sub-task division [5].

Fig. 5 gives an example of large-scale pile remove sub-task regions decomposition. At each route point, the 180° sector is decomposed into 6 parts, and 4 layers are needed to cover whole material. The material-remove sub-tasks sequence of this route point is set to finish the first layer, and sub-region from part 1 to 6. Then move to the next layer until finishing all of it.

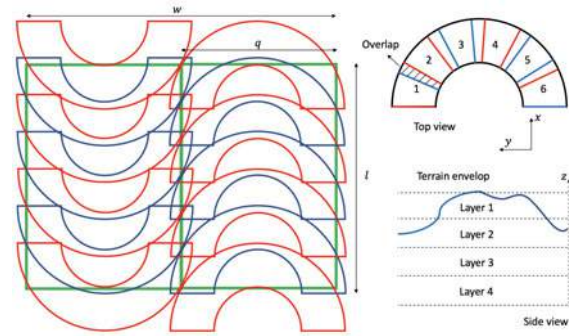

Figure 5. An example of large scale pile remove sub-task regions decomposition.

Between two columns, we design the connection path using a semicircular arc. Since the excavator work area usually has soft ground surfaces, using a small turning radius may cause the excavator to sink into the ground. Fig. 6 shows an example excavator base path planning for the large-scale pile removal task. The initial route point locates at the bottom right corner. The excavator moves straight to the top to finish the first column. Then the excavator moves to the route point marked by red, which represents the route point not associated with a material remove sub task. After that, the excavator follows the semicircular arc as a U-turn to the second column. Finally, the excavator moves straight down to finish the second column.

4 Sub-Task Planners and Motion Primitives

As mentioned in Section 2, we design two sub-tasks planners. Material remove sub-task planner plans dig ma-

Figure 6. An example of large scale pile remove sub-task base move planning.

materials to reach the desired amount and dump them into given positions. While base move sub-task planner is able to navigate the excavator to reach desired position and heading angle. So in following sub-sections, we will bring up the design details of these sub-task planners. After that, we will cover about the motion primitives that these sub-task planners are based on.

4.1 Material Removal Sub-Task Planner

The input of MRSP contains two parts: (1) sub-task configuration from the high-level task planner; (2) states information needed for online planning. Sub-task configuration includes local task zone, target material height, and dump mode. And we use excavator states (such as excavator joint states and base pose) and environment states (LiDAR point cloud) as our states representation. The output of the MRSP is the motion parameters for our motion primitives.

We have shown the procedures of the material-remove sub-task module in Algorithm 1. MRSP first loads the sub-task configurations. Then it plans the dig-and-dump loop until the material height in the local task zone reaches the target height. The dump position is decided depending on the dump mode.

4.1.1 Point of Attack Planning

MRSP finds the Point of Attack (POA) based on the LiDAR point clouds within the local task zone. In this approach, we determine POA based on the highest point with offset ahead. Fig. 7 shows the method to determine POA.

MRSP first finds the highest point and average height of the local task zone. Then, starting from the base link origin, a straight line that connects the highest point is

Algorithm 1 Material remove sub-task algorithm

```

determined. As shown in the top view, a constant distance offset is added to the line and the (x, y) of POA is determined. As shown in the side view, the z of POA is set equal to the average height.

4.1.2 Dig Motion Parameters

Dig motion planner first gets POA for the bucket teeth end to contact. Then the dig motion is divided into three steps. First of all, the bucket penetrates into the material with some depth and distance closer to the base origin. Secondly, the bucket drags backward to the base origin to collect materials into the bucket. At last, the bucket closes until the bucket joint to teeth plane is flat, which prevents material leak in the following motion. Based on the discussion above, a dig motion is defined by 7 parameters. We denote the dig motion parameters as $D = [x_b, y_b, z_b, p_d, p_l, d_l, \delta]$, where x_b, y_b, z_b represent the POA in base frame, p_d represents penetration depth, p_l represents penetration length, d_l represents drag length, and δ represents entire dig motion tilt angle with respect to horizon plane. Fig. 8 shows the dig motion parameters definition.

In our approach, these parameters are determined according to the terrain shape to optimize the material volume collected to match the bucket volume. The final dig motion trajectory is further adjusted based on the excavator base pose to handle the case that the roll and pitch angle of the base is not zero.

Figure 8. Dig motion parameters definition.

4.1.3 Dump Modes

For universality, MRSP provides three different dump modes. The first mode is using a fixed dump point in the base frame of the excavator. The MRSP dumps to the same point every dig-dump cycles. The second mode is using a floating dump point in the base frame. This floating dump point is passed as the output of high-level task planner for the MRSP, which can be used in the dynamic working environment. The third mode is truck-dump mode. In this mode, the MRSP will subscribe the truck pose through perception module, and calculate the appropriate dump point itself. To make the truck loading of material evenly, MRSP will find the dump spot, where material height is low inside the truck bed, to dump.

4.1.4 End Condition

As for end condition, MRSP is designed to have three stopping conditions in favor of different task excavation strictness requirement, namely "rigid", "regular" and "loose".

We denote the goal height as g , the current highest point in the sub-task zone as h , and the current average height of the sub-task zone as a . For "rigid" mode, the finish triggering condition is $h < g$. For "regular" mode, the triggering condition is $a < g$ and $h < g + b$, where b is a positive value, which represents a height margin of the highest point. For "loose" mode, the finish triggering condition is $a < g$.

4.2 Base Move Sub-Task Planner

The base-move sub-task planner navigates the excavator move to the target pose assigned by the high-level task planner. Similar to MRSP, the input of the base-move sub-task planner consists of both the target route point from high-level task planner and the states information required for online planning. The states information includes the excavator base pose and the LiDAR point cloud. While the outputs of the BMSP are waypoints between current route point and next route point as well as relevant walking constraints.

Currently, our BMSP is developed based on the 2-D assumption. So we denote the 2-D target pose as $B = [x_m, y_m, \Theta]$, where (x_m, y_m) is the target position in the map frame, and Θ is the target heading angle in the map frame.

As for global path planning, the Hybrid A* Path Planner algorithm [13] is applied in BMSP. With occupancy map generated by the LiDAR point cloud, current base pose, and target base pose, a smooth collision-free path of the waypoints are generated. In this work, we use the unicycle model [14] as our excavator kinetic model for the MPC controller [15].

4.3 Motion Primitives

Motion primitives are encapsulated from the repeated excavator action, such as digging, dumping and moving base. Therefore, we have designed the dig motion primitive, dump motion primitive and base move motion primitive for our framework.

Joint move primitives, including digging and dumping, require the motion parameters or task configuration as described in section 4.1.2 and 4.1.3. These joint move primitives will calculate the joint trajectories for the PID controllers to follow and finally come up with the joint velocity control commands.

On the other hand, the base move primitive takes the path of waypoints generated by the BMSP as input. And the primitive acts as a MPC controller to generate the base control commands.

For low-level control, both velocity and base control commands will be matched to current inputs of the hydraulic system of excavator using the look-up table.

5 Experiments

We perform trench task, pile removal task in the real excavator, and perform large scale pile removal task in simulation. In the real test, the excavator used is XCMG490DK, where the operating weight is 36.6ton. In the simulation, the excavator used is CAT365CL, where the operating weight is 67.0ton. We used the AGX Dynamics [16] as our simulation environment.

A RTK is used for localization in real test, which provides centimeter positioning accuracy. The position update rate is 10Hz. The joint angle update rate is 100Hz with 0.1 degree of accuracy. And the Lidar we used is Livox mid100. The point cloud update rate is 10Hz. We use same sensor update rates in simulation.

5.1 Trench Experiment

The target trench in experiment has a length of 10.0m, width of 1.5m, and depth of 2.0m. Using the architecture and planner presented, the task finished using 20 minutes.

Based on the trench size, our algorithm automatically set 5 route points and 5 material remove sub-tasks. Fig. 9 shows the on-site trench experiment. The image on the left is before the trench task started. The image on the right is after the trench task finished.

Figure 9. Trench experiment.

5.2 Pile Removal Experiment

The target pile has a length of 8.0m, width of 5.6m, and height of 0.5m. Using our planner, the task finished the task within 16 minutes. Fig. 10 shows the on-site pile removal experiment setup.

Figure 10. Pile removal experiment setup.

Fig. 11 shows 4 moments during the removal experiment setup, where the base located in different route points. Based on the pile size, our algorithm automatically set 4 route points and 4 material remove sub-tasks.

Figure 11. Pile removal experiment process.

5.3 Large Scale Pile Removal Experiment

Large scale pile removal experiment is performed in simulation. The target pile has a length of 36.0m, width of 22.5m, and height of 0.5m. To shorter the simulation time. In the AGX simulator, the pile size is set length equal to 20.0m, width equal to 12.0m, and height remains 0.5m. Fig. 12 shows the simulation results. The figures on the left show the initial simulation configuration, and the figures on the right show the environment when the simulation finished.

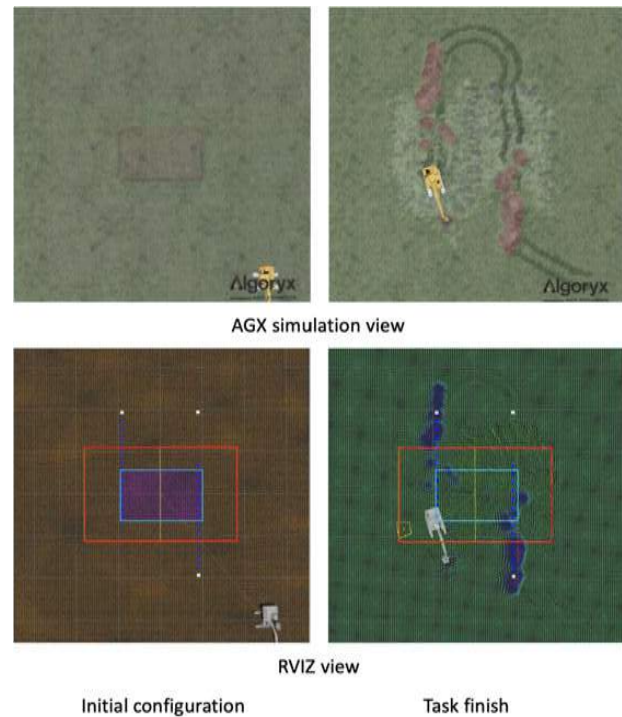

Figure 12. Large scale pile removal experiment using AGX simulator.

Initially, the excavator is located at the bottom right of the environment. It first moves to the first route point planned, and starts manipulation for the first column. Once the first column is finished, it performs a U-turn and then works on the second column. In the RVIZ view, the red box shows the task zone assigned by user, the light blue box shows the actual pile generated in the AGX simulator. The white marker points represent the route point without material-remove sub-task assigned, and blue marker points represent the route point with material remove sub-task assigned. The color shows in RVIZ is base on soil height. In the initial configuration, the color inside the light blue box is very different from the color outside. When the task finishes, the color is uniform which means the task is well done. Since the soil is dumped on the ground directly, there are some small piles locates on the excavator base

move trajectory.

6 Conclusion

This paper presents a novel autonomous excavator planning system design. High-level task planning includes task division and base movement planning. General sub-task planners designed with motion primitives are proposed, which take both arm and base movement into consideration. Based on the experiment results, we conclude that using the proposed material-remove sub-task planner and base-move sub-task planner, our method is a general autonomous excavator planning system architecture that can fit different excavation tasks.

Besides excavation tasks, excavators have also been used for tasks such as surfacing the ground and other tasks. The proposed architecture can be extended to new types of tasks in the future. Currently, our base move planning is limited to 2-D. In some working environments, the excavator may be required to drive on a rugged terrain surface. Thus, another future research direction can be 3-D base move planning with consideration of excavator balancing.

Automated Crane-lift Path Planning Using Modified Particle Swarm Optimization for High-rise Modular Integrated Construction

A.M. Zhu^a and W. Pan^a

^a Department of Civil Engineering, The University of Hong Kong, Hong Kong SAR, China
E-mail: zhuaimin@connect.hku.hk, wpan@hku.hk

Abstract –

Modular integrated construction (MiC) is a most advanced off-site technology. In a MiC project, it is critical but challenging to install prefabricated volumetric modules efficiently and safely, as they are much heavier and larger than conventional construction components and materials. However, the current crane-lift executions are heavily reliant on operators' subjective judgement, which turns out to be time-consuming and error-prone, most notably when jobsites are congested. Automatic crane-lift path planning has been regarded as an important research topic for addressing this problem. Nevertheless, most previous studies did not consider the MiC-specific features of a crane lift such as correlation between module weight and crane trolley movement. Therefore, this paper aims to propose a modified particle swarm optimization (PSO) algorithm to automatically conduct crane-lift path planning for high-rise MiC. A new fitness function and three auxiliary engines are designed for executing the proposed PSO path planner. This novel algorithm is validated using a real-life MiC project. The findings reveal that the optimized algorithm outperforms existing metaheuristics in terms of convergence characteristics and path smoothness. A collision-free crane-lift path can be worked out with a small population size and a few iterations. Practically, this paper should facilitate safe and efficient project delivery of high-rise MiC. Scientifically, the paper contributes to the theoretical development of smart and automated technologies and algorithms in construction.

Keywords –

Tower crane; Path planning; Particle swarm optimization (PSO); Modular integrated construction (MiC)

1 Introduction

Modular integrated construction (MiC) represents the highest level of off-site construction [1]. In a typical high-rise MiC project, multiple heavy and large-sized prefabricated volumetric modules are manufactured first

in factory followed by installation on site. Hoisting those hefty units relies on the stringent deployment of tower cranes, which occupies most of crane-lift tasks [2]. However, it is challenging to get them installed efficiently and safely from confined storage yards to the target position, especially in high-density and congested metropolises such as Hong Kong. Neitzel et al. [3] mentioned that more than 30% of construction and maintenance casualties resulted from cranes. Tam and Fung [4] pointed out that the lack of transferable skills and the fatigue of crane operators are the critical reasons leading to accidents. In high-rise MiC projects, crane practitioners are required to have higher professional skills and should pay closer attention to collision identification. Nevertheless, it is easy to cause time delay and safety hazards when the hoisting executions depend on operators' subjective behaviors.

Computer-aided path planning has become a popular research topic to assist crane drivers in identifying the optimal crane-lift path. However, the literature reveals that existing approaches are highly homogeneous. Genetic algorithms [5-8], for instance, gain the most popularity in metaheuristics. The existing solutions also seldom consider the velocities of the mechanism transmission and the strategies of crane operation, which resulted in impractical lifting trajectory with redundant turns and twists [9]. In addition, other algorithms with high performance such as particle swarm optimization (PSO) have not attracted researchers' attention in the field of path planning. Moreover, few studies conduct path planning for high-rise MiC considering the modular-specific features such as large-sized and heavy modules.

To address the challenges and fill the knowledge gaps, this paper aims to propose a modified PSO algorithm to automatically conduct crane-lift path planning. Based on the existing PSO algorithm, a new fitness function is devised with three significant indicators i.e., overall hoisting time, total movement distance and the collision penalty mechanism. Also, three auxiliary engines, i.e., crane configuration engine, model regeneration engine and collision detection engine are used for PSO execution.

Following this introduction section, Section 2 reviews the crane-lift path planning methods, the published metaheuristics and PSO related research. Section 3 sheds light on the proposed system architecture and its development. Section 4 verifies the proposed

method using a real-life MiC project. The last two sections are presented for discussion and conclusions, respectively.

2 Literature Review

2.1 Overview of Crane-lift Path Planning Algorithms

Finding a collision-free crane-lift path is a scorching research topic among various countries and regions [5-7,10], like India [6], Singapore [7,8], Canada [10], etc. It normally takes two steps to achieve this goal. The first is to transform the work space to the configuration space, in which the information from environmental obstacles and crane's particulars can be well extracted. The other is to screen out or design a proper algorithm to match specific crane-lift scenarios. Researchers have invested tremendous time and energy in exploring adaptable, robust and highly productive algorithms for crane-lift path planning. Those algorithms can be divided into three categories, namely, node-based methods, sampling-based methods, and meta-heuristic methods.

Node-based methods, including Dijkstra's and A*, have a powerful performance in finding a high-quality and collision-avoidance lifting path. Nevertheless, their shortcoming is obvious for the high time complexity, particularly in complicated job sites [11].

With respect to sampling-based methods, rapidly exploring random tree with its variants has been widely adopted. However, the lifting trajectory is prone to more turns and twists, enhancing crane drivers' manipulation complexity [10], although there have been some improvements recently [9].

Meta-heuristic methods contribute a lot to crane-lift research. Genetic algorithms (GAs), ones of the most classical metaheuristics, have attracted huge attention over the past two decades. Researchers from Indian Institute of Technology first started GAs' application to lifting path planning. They initially designed a simple GA model in 2D configuration space for two degrees of freedom (DOFs) crane manipulators [5]. Thereafter, Ali et al. [6] used GA for the dual-crane path planning. Cai et al. [7] improved the fitness function and altered the evolutionary strategies based on Ali's research. To find the erection paths efficiently, their algorithm was implemented via parallel computing on graphic processing units, and then they applied it into four DOFs tower cranes [8]. Although GAs have been widely used among various disciplines, it should not be treated as the only option and it cannot always perform best, compared to other EAs. Wang et al. [12] tried to use ant colony optimization (ACO) algorithm for three DOFs mobile cranes, but their research was at the preliminary stage and the lifting trajectory was hard to manipulate.

2.2 Particle Swarm Optimization (PSO)

Another classical evolutionary algorithm is PSO, which was coined by Kennedy and Eberhart [13] in 1995, inspired by the school of birds and fish. Each particle in the particle swarm represents a possible solution to a problem. Through the simple behavior of individual particles and the information interaction within the swarm, problem-solving intelligence is realized. It has been demonstrated and verified that PSO can perform better in a cheaper, simpler, and faster way than other intelligent algorithms [13,14].

In respect to the construction industry, Zhang and Xing [15] utilized PSO together with a fuzzy-integrated approach to find the best solution for addressing the time-cost-quality tradeoff problem. PSO served as a useful tool for construction layout planning, like unequal-area design [14]. It also presents superb performance for crane optimization issues, for instance, the fault diagnosis of mobile crane [16], and the design optimization of tower crane hoisting system [17]. However, there is a paucity of related research into PSO within the context of tower crane lifting path optimization.

3 System Architecture of Crane-lift Path Planning

3.1 Overview

Given that the conventional construction practice is rather risky, time-consuming, and laborious when conducting crane-lift issues, this paper proposes a modified PSO algorithm to find a collision free crane-lift path automatically, thereby accelerating intelligence and automation in MiC featured projects.

The system architecture builds on two categories of modeling environments and an output illustrated in Figure 1.

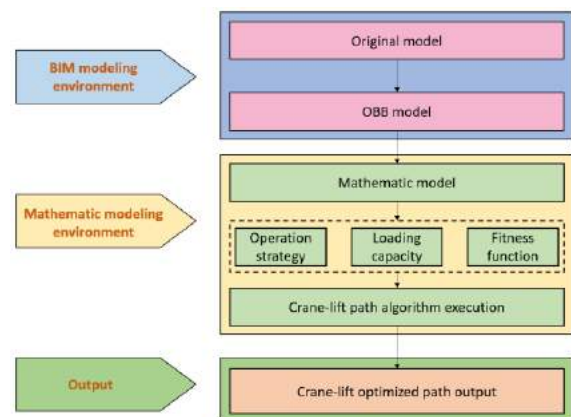

Figure 1. The system architecture of crane-lift path planning

One is the building information modeling (BIM) environment comprising of an original BIM model and an oriented bounding box (OBB) model. Another one is the mathematic modeling environment that gives importance to crane-lift path planning. There are three critical components in mathematical modeling environment: (1) tower crane operation strategy; (2) loading capacity; and (3) fitness function. The output provides the best solution space.

3.2 The Development of BIM Modeling Environment

The BIM modeling environment provides all the necessary information of MiC projects.

First, a delicate BIM model is built using various module families in Revit (Figure 2(a)). Second, to degrade computing complexity of the follow-up path planning issues, the original model is simplified as an OBB model (Figure 2(b)), which can perform more accurately than axis-aligned bounding box or bounding sphere algorithms in collision detection trials.

Figure 2. Project modeling process

Since Revit's dedicated project file with a .RVT extension is not compatible with most software, it needs to be converted to a more general type. In this paper, the .RVT file is transformed to a file with an .OBJ extension containing vertices and polygons of each component. By reading the .OBJ file in MATLAB, the mathematical model can be generated (Figure 2(c)).

3.3 The Development of Mathematic Modeling Environment

The mathematic modeling environment plays a paramount role in finding a collision-free and high-quality solution.

3.3.1 Problem formulation

Assumptions

After conducting a critical literature review, the authors adopted the assumptions of Cai et al. [7], due to the fact that they drew upon the expertise of professionals and scholars.

Degree of Freedom (DOF)

The transmission mechanism of a hammerhead tower crane comprises three DOFs, i.e., jib slewing, trolley

movement, and sling hoisting. In addition to the actuated system, the self-rotation angle of the lifting frame is another non-negligible DOF, altered manually by building workers. Therefore, the tower crane is specified to have four DOFs.

For the convenience of research, the work space is converted to configuration space (C space). In C space, the nodes in the path are called configurations. The set of configurations in the solution space can be written as \mathbf{X} . As a result, the configurations in the i th path is $\mathbf{X}^i = (X_{i1}, X_{i2}, X_{i3}, X_{i4})$, where X_{ij} is a N-by-1 vector, $i \in [1, M]$, $j \in [1, 4]$, M denotes the number of paths and N denotes the number of configurations in each path. The number of columns of \mathbf{X}^i represents the degrees of freedom, corresponding to the self-rotation angle of the lifting frame (equivalent to the rotation angle of the module, denoted as Rotation), the slewing angle of the jib (denoted as Slewing), the range of trolley movement (denoted as Movement), and the height of the hook (denoted as Hoisting).

Those nodes are connected by abstract edges (denoted as \mathbf{E} , where $\mathbf{E}^i \in \mathbf{E}$). In fact, the operation of the tower crane from one configuration to another is the edge.

After giving the above definitions of nodes and edges, any path of the tower crane can be expressed as a sling, marked as $s \in \mathbf{S}$. \mathbf{S} represents the solution space of all paths, whose expression is ruled by

$$\mathbf{S} = \mathbf{X} \cup \mathbf{E} \quad (1)$$

Tower Crane Operation Strategy for MiC projects

As discussed above, $(\mathbf{X}^i)^1$ and $(\mathbf{X}^i)^N$ represent the start configuration and the end configuration in the i th path, calculated in advance. In actual crane-lift tasks, workers often manually rotate the module to a proper pose initially, and then the hook goes up. Therefore, for $(\mathbf{E}^i)^1$, the first edge, randomly alter Rotation and Hoisting of each sling, while other DOFs are aligned with $(\mathbf{X}^i)^1$. When the lifting task is about to end, the hook will slowly descend with the hoisted module. Riggers, in the end, will rotate the module again, placing them to the demand point from a relatively fixed height. Therefore, this paper proposes a pseudo end configuration concept, that is, the end configuration of the planned path is always h higher than the actual one. In the case of this paper, the height of the module is 3150mm, so h is assumed as 4000mm. As a result, only stochastically change Rotation and Movement for $(\mathbf{E}^i)^{N-1}$ and $(\mathbf{E}^i)^{N-2}$ respectively. The purpose of not putting these two variables in one edge is to ensure their strict sequence. The parameters of in-between edges vary randomly.

Loading Capacity and Working Radius

Most of the existing research on tower crane lifting issues has neglected the correlation between modular

weight and working radius of the trolley. In fact, it is challenging to have a unified mathematical expression for multiple of cranes, because the mechanical principles, product materials, etc. of cranes normally differ from each other. To solve the problem, tower crane manufacturers give importance to pre-loading experiments, measuring a series of scattered working radius under corresponding capacities, and providing experimental tables for users to inquire. However, it is not easy to immediately receive the correct working radius once the value of load capacity cannot be found in the table. This paper leverages the cubic spline interpolation method to pre-process those discrete data. Before the algorithm is executed, the maximum working radius will be automatically calculated according to the weight of lifted modules. Figure 3, for example, exhibits the relationship of load capacity and the corresponding working radius of the 50-meter jib of the SANY SYT315 T7530-16 model. When the input value of module weight is 11.85 tonnes, the algorithm will automatically calculate its working radius as 29.29 meters. With a minimum working radius of 3.5 meters, the range of the trolley movement is determined to be 3.5 to 29.29 meters.

Figure 3. Load capacity diagram of 50m jib (SYT315 T7530-16)

3.3.2 The proposed path planning algorithm

Introduction and Definition of PSO

For PSO, each path s can be a representative of the particle in C space with $N \times 4$ dimensions, where N represents the number of configurations in a lifting path. As a result, the position for the i th particle is denoted as $\mathbf{X}^i = (X_{i1}, X_{i2}, X_{i3}, X_{i4})$ identified above, and the velocity for the i th particle is denoted as $\mathbf{V}^i = (V_{i1}, V_{i2}, V_{i3}, V_{i4})$. The best history positions of each particle and the whole particle swarm (i.e., the population) are logged and represented as $\mathbf{P}^i = (P_{i1}, P_{i2}, P_{i3}, P_{i4})$ and $\mathbf{G} = (g_1, g_2, g_3, g_4)$ respectively. Additionally, the range of variables is written as 1) position: $\mathbf{X} \in [-X_{min}, X_{max}]$; 2) velocity: $\mathbf{V} \in [-V_{min}, V_{max}]$, where X_{min} and X_{max} denote the minimum and maximum values among various DOFs of tower crane; V_{min} and V_{max} correspond to the minimum and maximum

velocities of particles.

The evolution of GA relies on its exclusive genetic operators, such as reproduction, crossover and mutation, while the updating process in PSO is quite different. For the i th particle, in the k th iteration, its position and velocity are updated as Equation (2)-(4):

$$\omega_k = \omega_{k-1} \omega_{damp} \quad (2)$$

$$\mathbf{V}_k^i = \omega_k \mathbf{V}_{k-1}^i + c_1 \mathbf{r}_1 (\mathbf{P}_i - \mathbf{X}_{k-1}^i) + c_2 \mathbf{r}_2 (\mathbf{G} - \mathbf{X}_{k-1}^i) \quad (3)$$

$$\mathbf{X}_k^i = \mathbf{X}_{k-1}^i + \mathbf{V}_k^i \quad (4)$$

where ω_k is the inertial weight decreasing with time and balancing the results of global and local optimum, in cooperation with ω_{damp} , the damping ratio of inertial weight denoted as 0.99 over the iterations; c_1 and c_2 correspond to two positive acceleration constants; \mathbf{r}_1 and \mathbf{r}_2 represent two N-by-4 matrices, where the values are uniformly distributed random numbers in the range [0, 1].

The traduction of PSO in a search space mainly encompasses three characteristics: 1) inertial behavior, the first part of Equation (3), in which particles keep existing velocity flying; 2) personal cognition, the second part of Equation (3), in which the velocity of each particle is randomly increased to the history best solution; 3) social perception, the last part of Equation (3), in which the velocity of each particle is randomly reached the history optimum position of the whole population.

Crane-lift Path Generation Mechanism

Figure 4 shows the proposed lifting path generation mechanism, containing four sections, i.e., input, PSO path planner, auxiliary engines and output.

The input information includes confirming the initial population size, the maximum number of iterations, the number of configurations, and various coefficients' values. During the path planner execution, it is necessary to calculate the fitness function value to evaluate the particle's personal and global best outputs and update the particle swarm position and velocity. When PSO reaches the maximum generation, it stops running, performing postprocessing analysis accordingly. Also, the auxiliary engines play a vital role over the iterations. The model regeneration engine assists in creating the mathematical model in MATLAB; then, the crane configuration engine will import the required crane particulars to PSO. In the algorithm iteration process, the collision detection engine will be called all the time to detect constraint points.

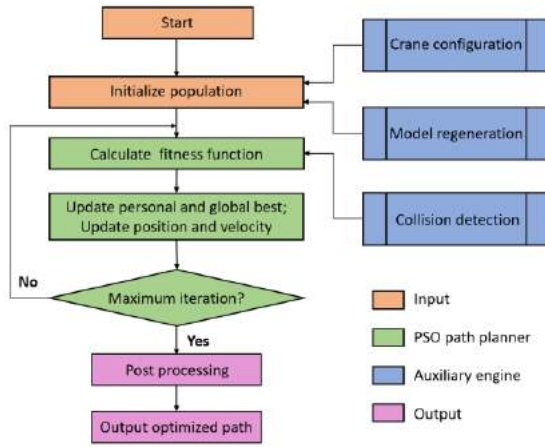

Figure 4. The proposed path generation mechanism

Fitness Function

The modified fitness functions contain three metrics. To receive a more realistic result, the metric r_1 is written as:

$$r_1(\mathbf{m}, \mathbf{n}) = \sum_{i=1}^4 \rho_i |m_i - n_i| \quad (5)$$

where \mathbf{m} and \mathbf{n} are two adjacent configurations in C space; m_i and n_i correspond to each DOF of \mathbf{m} and \mathbf{n} ; a velocity influencing factor ρ_i is devised, $\rho_i = \frac{1}{v_i}$, $\mathbf{v} = (v_1, v_2, v_3, v_4) = (v_{lf}, v_{jb}, v_{ld}, v_{sl})$, representing the velocities of module rotation, jib slewing, module movement and sling hoisting respectively. The last three parameters are the tower crane's transmission mechanism provided by vendors in advance. In contrast, the first parameter is determined by riggers' operational practice, which means that it is hard to give a specific data range. Its research is out of the scope of the current research, temporarily assumed as the same value of Slewing after the interview with crane operators. Taking SANY SYT315 as an example, $v_{jb} = 0.75\text{r/min}$ (i.e. 0.079rad/s), $v_{ld} = 100\text{m/min}$ (i.e. 1666.66mm/s) and $v_{sl} = v_{lf} = 80\text{m/min}$ (i.e. 1333.33mm/s). As a result, the metric r_1 can be utilized to calculate exactly lifting time.

The metric r_2 is used for computing the movement distance, in accordance with crane's operation strategy, which is ruled by

$$r_2(\mathbf{m}, \mathbf{n}) = \begin{cases} |m_2 - n_2| \cdot |m_3| + \sum_{i=3}^4 |m_i - n_i| & \text{if } m_4 < n_4 \\ |m_2 - n_2| \cdot |n_3| + \sum_{i=3}^4 |m_i - n_i| & \text{if } m_4 > n_4 \end{cases} \quad (6)$$

where m_4 and n_4 represent Hoisting. If $m_4 < n_4$,

this means the position of configuration \mathbf{m} is lower than \mathbf{n} ; otherwise, higher.

The metric r_3 is devised for collision detection, which is denoted as

$$r_3((\mathbf{E}^i)^j) = \begin{cases} 1 & \text{condition 1} \\ 0 & \text{condition 2} \end{cases} \quad (7)$$

where the condition 1 means the lifted module collides with obstacles and the condition 2 means the lifting process is collision avoidance. $(\mathbf{E}^i)^j$ represents the j th edge in the i th path. This paper adopted OBB algorithm for crane-lift collision detection.

Based on the above three metrics, a modified fitness function is determined as follows:

$$F(s) = \alpha t(s) + \beta d(s) + \gamma c(s) \quad (8)$$

where,

$$\gamma \gg \alpha, \beta, t(s) = \sum_{j=1}^{N-1} r_1((\mathbf{X}^i)^j, (\mathbf{X}^i)^{j+1}) \\ d(s) = \sum_{j=1}^{N-1} r_2((\mathbf{X}^i)^j, (\mathbf{X}^i)^{j+1}), c(s) = \sum_{j=1}^{N-1} r_3((\mathbf{E}^i)^j).$$

Therefore, the issue of finding a collision-free lifting path in C space is transformed to calculate the minimum value of $F(s)$. α and β are two influencing factors for weighting hoisting time and the movement distance of the tower crane, respectively. To some extent, the first metric is to guarantee that the time is as short as possible. The second metric is to ensure that the movement of the tower crane is reduced as much as possible during the installation process. There are two purposes for this. One is to reduce energy consumption and save costs; the other is to reduce the redundancy of the algorithm and enhance the operational space for tower crane operators.

Furthermore, the influencing factor γ of the third metric is much larger than the first two, which ensures that sufficient punishment is imposed to accelerate the elimination of the collision points in the event of a collision.

4 Case Study

A real-life MiC project was selected to demonstrate the proposed method and to test the performance of the revised PSO algorithm. The case project is a student residence with more than 900 steel-framed modules, and the project is currently under construction.

4.1 Parameter initialization

The initialization data of the tower crane and PSO are shown in Table 1 and Table 2.

Table 1 Tower crane specifications (SANY: SYT315 T7530-16)

Parameter	Input value
X_1	(-1.3089, 2.6275, 27988, 0)
X_{end}	(-3.0618, 0.8924, 17678, 37500)
X_{min}	(-3.1416, -3.1416, 3500, 0)
X_{max}	(3.1416, 3.1416, <u>29294</u> , 50000)
v_{jb}	0.06
v_{lf}	0.06
v_{ld}	1000
v_{sl}	500
W_m	<u>11.85</u>

Note: The underlined fonts indicate that precomputation is required for calculating the maximum working radius.

Table 2 PSO parameters

Parameter	Input value
N	6
M	50
ω	1
ω_{damp}	0.99
c_1	1.5
c_2	2
α	1
β	0.01
γ	10000

4.2 Analysis and Postprocessing

To verify the applicability of the proposed algorithm, this paper sets the population size to 50, and the independent variable is the evolutionary generation, i.e., maximum iteration, ranging from 30 to 350. This study determined ten different scenarios according to the above interval and ran each one independently 30 times. Table 3 recorded the simulation results, where G means the maximum evolutionary generation in each scenario; N_g represents the number of minimum global cost over 30 runs; G_s represents the start generation of the minimum cost (if N_g is larger than one, calculate the average start generation); $N_l = G - G_s$, represents the average number of minimum local cost over the generations; $R_{con} = N_l/G$ represents the convergence rate; $R_{best} = N_g/30$ represents the occurrence rate of the global minimum cost over the runs; C_{min} , C_{max} , C_{ave} represent the minimum, maximum and average cost of all the minima over 30 runs.

The proposed algorithm shows better explore-exploit trade-off according to the experiment results. When the population has only evolved for 30 generations, i.e., Scenario 1, it is relatively close to convergence. Among the 30 optimal costs in this scenario, the minimum, maximum, and average values are only 0.2411%, 7.7952%, and 1.9014% larger than the global optimum whose value is 952.8613 (Table 3), respectively. N_l , R_{con} and R_{best} increase steadily with the increase of evolutionary generation, indicating that the algorithm is accelerating convergence, as shown in Figure 5(a) and (b). Additionally, the convergence solution of the algorithm remains unchanged when the generations are more than 100, indicating that the proposed algorithm is highly stable, as shown in Figure 5(c). When the maximum iteration reaches 300, the convergence solutions of 30 independent runs have up to 26 times, and the trend of change is shown in Figure 5(b).

Figure 6 plots the crane-lift path trajectory of Scenario 9. The crane-lift trajectory is visualized in mathematic modeling environment, whose lifting path is smooth and easy to operate. Plus, Figure 7 depicts the convergence curve of Scenario 9, which manifests PSO reaches its optimal value quickly. Therefore, the modified PSO can obtain a better solution space with only a small population size and evolutionary generation.

5 Discussion

For the sake of a most awesome optimization performance, a well-designed fitness function is treated as a paramount issue. Cai et al. [7] once improved an evaluation function, which was first created and exhibited by Ali et al. [6] in 2005. In Cai's new function, they introduced a metric that indicates the total variations of all configurations. Although they realized the impact of scaling factors on final performance over the iteration loop, those coefficients are determined basically on their own knowledge and experience. Therefore, in the similar metric of this paper, the undetermined factors are equal to the reciprocal of the actual velocity of corresponding DOF, so that an accurate minimum hoisting time can be acquired.

In relation to the convergence characteristics of PSO, it outperforms GA, while the time complexity is unchanged. Cai [7] used GA for crane-lift path planning. The convergence condition of their algorithm is that the population size is 100 and the evolutionary generation is 400, but the corresponding numbers are 50 and 100, respectively in the proposed algorithm.

Furthermore, the path smoothness is a significant benchmark for verifying solution quality. Nevertheless, most of the existing lifting trajectories are redundant. For example, Wang et al. [12] used ACO for mobile crane path planning, but the visualization result illustrated that there were multiple turns and twists in the trajectory. In comparison, the lifting trajectory is extremely smooth in the developed architecture (see Figure 6).

6 Conclusions

This paper has proposed a modified PSO algorithm to automatically conduct crane-lift path planning for high-rise MiC. This research is the first of its kind to introduce PSO for crane-lift path planning, and is an initial and successful attempt of planning crane-lift path in MiC projects. The paper concludes that the proposed algorithm can generate a collision-free crane-lift path with a small population size and a few iterations for

module installation. Also, the lifting trajectory is found to be smooth and easy-to-operate.

Practically, this paper should assist construction planners and crane operators in identifying an optimal crane-lift path, thus facilitating safe and efficient MiC project delivery. Scientifically, the paper contributes to the theoretical development of smart and automated technologies and algorithms in construction. In the future, the research will give importance to multiple-crane path planning in the dynamic environment.

Abstract

To evaluate the safety of construction site workers, deep learning models recognizing workers and safety equipment in construction site images are widely used. However, it is frequently observed that deep learning models based on supervised learning methods do not work well for unseen data in other domains having different visual characteristics. To address this issue, a novel method for generalizing semantic segmentation models was proposed. This method adopts two strategies: a domain adaptation method based on self-supervised learning and a copy-paste data augmentation. Source domain data with annotations (workers and hardhats) and target domain data without annotations are used for model training in a self-supervised learning scheme. The proposed model showed an improved generalization capability in semantic segmentation without annotation data of the target domain.

Keywords –

Semantic segmentation; Domain adaptation; Self-supervised learning; Copy-paste data augmentation

1 Introduction

Computer vision technology has been actively investigated nowadays to analyze jobsite contexts from construction site images for safety management [1], [2]. For example, by identifying workers [3], [4] and their personal protective equipment [5]–[8], it is possible to determine whether the workers comply with safety rules for specific tasks. Convolutional neural network-based architectures, originated from LeNet-5 [9], show superior performance in visual tasks than other traditional recognition models due to the capability of representation learning from training data in the supervised learning manner. However, supervised learning-based models generally perform well on data

similar to a source domain where training images come from and do not work well for unseen data in a different domain. If the training data do not include various visual characteristics of workers and safety equipment, the model is likely to fail in recognizing the same target objects in construction site scenes having different visual characteristics than the training data. Although this problem can be solved by collecting more training data for a new scene, generating a large amount of construction site annotation data consumes a lot of time and money since fine segmentation masks for workers and safety equipment should be annotated carefully. To address this problem, a new domain adaptation method was proposed for semantic segmentation models. The proposed domain adaptation strategy includes two main components: (1) self-supervised learning and (2) copy-paste data augmentation for the model generalization to new data.

2 Related works

For jobsite safety management, previous studies have presented vision-based monitoring methods based on machine learning algorithms. In particular, supervised learning-based models have been utilized to recognize workers and personal protective equipment for ensuring the safety of workers exposed to numerous hazards. Fang et al. [6] trained a Faster R-CNN based Non-hardhat-use worker detection model using 81,000 images collected from various weather, illumination, and visual range situations. Fang et al. [7] trained a worker detection network and harness classification network using 693 positive images having workers with a harness, and about 5,000 negative images having workers without a harness. Similarly, a significant number of training images are required to train a convolutional neural network-based model to have a robust recognition performance with respect to construction site scenes having diverse visual variations.

The preparation of such dataset is time-consuming and labor-intensive especially for semantic segmentation tasks since it entails a manual annotation task requiring high precision on segmentation masks. Training data preparation is often performed again to apply a model to a new target domain. To explore the potential of minimizing data preparation efforts on a new domain, this study proposes a novel domain adaptation method which generalize a pre-trained model on a source domain to a target domain.

3 Methodology

3.1 Domain Adaptive Semantic Segmentation

The proposed method includes two steps: the first step is to train a semantic segmentation model using only a source domain dataset $X_s = \{x_s\}$ with annotations, and the second step is to adapt the model using a target domain dataset $X_t = \{x_t\}$ without annotations. The proposed adaptation method adopted prototypical pseudo label denoising Zhang et al. [10] which is a self-supervised learning technique. In the second step, pseudo labels are generated from the target domain using the model trained with a source domain in the first step, and representative features called prototypes are calculated. There are some noises in the pseudo labels caused by the difference between the source and the target domains. The noises of the pseudo labels are reduced using the distance between the prototype and each feature.

The loss function of the semantic segmentation model here starts from the categorical cross-entropy (CE) loss:

$$l_{ce}^t = -\sum_{i=1}^{H \times W} \sum_{k=1}^K \hat{y}_t^{(i,k)} \log(p_t^{(i,k)}), \quad (1)$$

where $\hat{y}_t^{(i,k)}$ is a pseudo label and $p_t^{(i,k)}$ represents the softmax probability of the i^{th} pixel of the target data x_t classified to the k^{th} class. The pseudo labels are adjusted using representative features called prototypes and the conversion function which outputs the hard labels from the probability, as $\hat{y}_t = \xi(p_t)$. This process is formulated as follows:

$$\hat{y}_t^{(i,k)} = \xi(\omega_t^{(i,k)} p_t^{(i,k)}), \quad (2)$$

The weight $\omega_t^{(i,k)}$ is calculated as the softmax of the feature distance between the prototype and the feature point:

$$\omega_t^{(i,k)} = \frac{\exp(-\|\tilde{f}(x_t)^{(i)} - \eta^{(k)}\|)}{\sum_{k'} \exp(-\|\tilde{f}(x_t)^{(i)} - \eta^{(k')}\|)}, \quad (3)$$

where \tilde{f} and $\eta^{(k)}$ represents the momentum encoder of the feature extractor f and the prototype of the k^{th} class, respectively. The prototype is calculated by the following equation:

$$\eta^{(k)} = \frac{\sum_{x_t \in X_t} \sum_i f(x_t)^{(i)} * \mathbb{I}(\hat{y}_t^{(i,k)} == 1)}{\sum_{x_t \in X_t} \sum_i \mathbb{I}(\hat{y}_t^{(i,k)} == 1)}, \quad (4)$$

where \mathbb{I} is the indicator function. The prototype changes in each iteration as the weights of the feature extractor f are updated.

The total loss function in the domain adaptation network for the second step is as follows:

$$l_{total} = l_{ce}^s + \alpha l_{ce}(p_t, \hat{y}_t) + \beta l_{ce}(\hat{y}_t, p_t) + \gamma_1 l_{kl}^t + \gamma_2 l_{reg}^t, \quad (5)$$

where l_{kl}^t and l_{reg}^t denotes a Kull-back—Leibler divergence loss and a regularization loss, respectively, for making features compact, which enables denoising easier. α, β, γ_1 , and γ_2 are hyper-parameters for each loss term.

3.2 Copy-paste Data Augmentation

Training data with diverse visual features help deep learning models to avoid overfitting and generalize well on unseen data. To increase the visual diversity in the training data which do not have annotations of the source domain, a copy-paste data augmentation method was employed. Figure 1 shows the copy-paste data augmentation framework. First, one of the target domain images is randomly selected. Second, the area containing the foreground is removed. Lastly, instances from the source domain data are pasted into the background of the target domain. In this way, deep learning models can learn the features of the target domain background and the diversified boundaries between the foreground and the background.

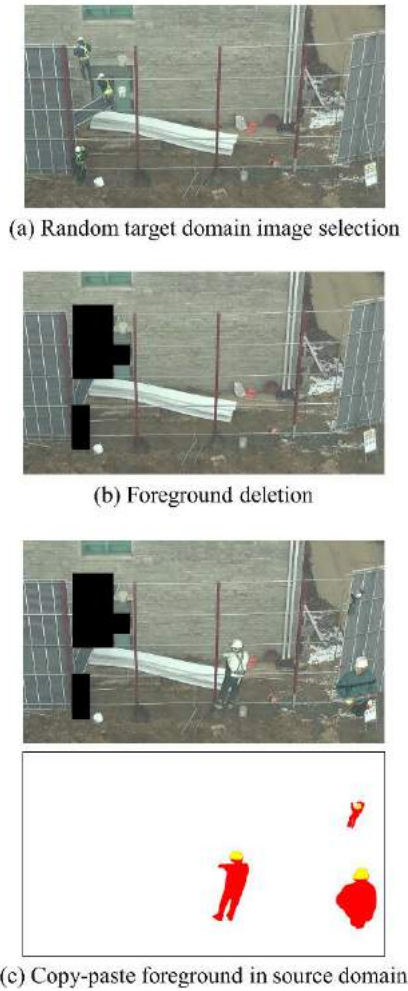

Figure 1. Copy-paste data augmentation process. The upper part of (c) is an augmented image, and the lower part shows its annotations.

3.3 Domain Adaptation Index (DAI)

Domain Adaptation Index (DAI) is developed for evaluating the domain adaptation performance of segmentation models, as shown in Equation (6). This index evaluates how well a model performs on the target domain without target domain annotations. That is, the model will be trained with images from the source and target domains, but annotations are only provided by the source domain. When DAI is 1, the domain adaptive model achieves the same performance as the model trained with the target domain data and its annotations.

$$\text{DAI} = \frac{\text{Performance of a model trained without target domain annotations}}{\text{Performance of a model trained with target domain annotations}} \quad (6)$$

4 Experiments

In this study, one source domain dataset and two target domain datasets were used in experiments. All datasets were collected from three videos of scaffold installation operations at the Sinchon Campus of Yonsei University. Image samples are shown in Figure 2. Target domain 1 differs only in scale from the source domain, and target domain 2 differs in the workers' appearance and the background. DeepLabV2 [11] was used as the semantic segmentation model.

The semantic segmentation performance of target domains 1 and 2 is shown in Table 1 and Table 2, respectively. In Table 1 and Table 2, Source-only is a DeepLabV2 trained with the source domain data only, and Upper bound is a DeepLabV2 trained using the target domain data with their annotations. The performance is shown in four measures: the first and the second measures are the Intersection of Union (IoU) of workers and hardhats, respectively, the third measure, mIoU, is a mean of IoU for all target classes, and the last measure is DAI obtained by dividing the mIoU of the model by the mIoU of the Upper bound.

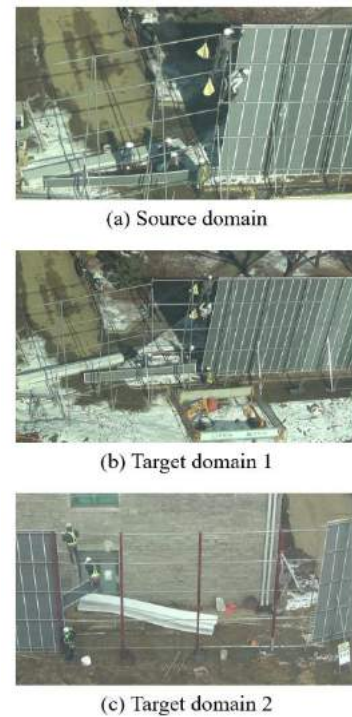

Figure 2. Sample images of each dataset

It was observed that the generality of the segmentation model was improved by the proposed method. When the domain adaptation and copy-paste data augmentation were applied, mIoU increased compared to Source-only in both target domains 1 and 2.

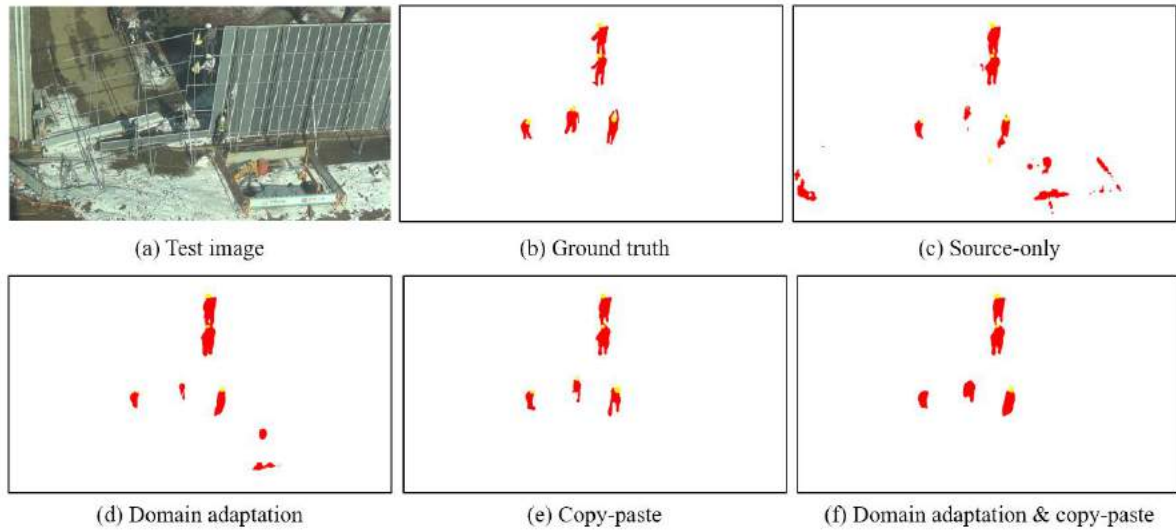

Figure 3. Example test image and the segmentation results of target domain 1

The highest DAI for target domains 1 and 2 were 81.10% and 84.61%, respectively. Especially for target domain 2, which has different visual characteristics from the source domain, mIoU were improved 8.78 and 27.49 percentage points, respectively.

Table 1. Semantic segmentation performance of target domain 1 (D represents the domain adaptation strategy, and C represents the copy-paste strategy).

	D	C	IoU _{worker}	IoU _{hardhat}	mIoU (%)	DAI (%)
Source-only	-	-	42.01	59.93	50.97	68.16
	√	-	54.28	59.63	56.96	76.17
Ours	-	√	62.10	59.20	60.65	81.10
	√	√	63.95	55.21	59.58	79.67
Upper bound	-	-	76.25	73.31	74.78	-

Table 2. Semantic segmentation performance of target domain 2 (D represents the domain adaptation strategy, and C represents the copy-paste strategy).

	D	C	IoU _{worker}	IoU _{hardhat}	mIoU (%)	DAI (%)
Source-only	-	-	45.82	37.71	41.77	50.47
	√	-	49.68	51.42	50.55	61.08
Ours	-	√	65.66	72.86	69.26	83.69
	√	√	70.19	69.85	70.02	84.61
Upper bound	-	-	85.11	80.41	82.76	-

Experimental results for target domain 1 are shown

in Figure 3. The Source-only model incorrectly predicted a large number of pixels in the background as the worker category. Although the noise was partially removed by the domain adaptation model, it missed some parts of hardhats. This result accounts for the increment of the IoU_{worker} and the decrement of the IoU_{hardhat} between the source-only model and the domain adaptation model. The copy-paste model well identified the workers' arms and legs, and all the hardhats. When domain adaptation and copy-paste methods were applied together, a few numbers of hardhats were lost and the shape of the workers, which resulted in 3.99 percent point decrement of IoU_{hardhat}.

Figure 4 shows a test image, its ground truth, and the segmentation results of four different segmentation models. Unlike target domain 1, where the background scene was the same but only different in scale to the background of the source domain, scenes of target domain 2 differs from the source domain scene. The source-only model misclassified many background pixels. The domain adaptation model removed the misclassified noise, and as a result, IoU_{hardhat} was improved by 13.71 percent points. The copy-paste strategy worked effectively for the segmentation of target domain 2. It is conjectured that the copy-paste augmentation contributes to generating boundary information between target objects and the target domain background. The domain adaptation strategy decreased the IoU_{hardhat} while improving the IoU_{worker}, resulting in the increase in mIoU by 0.76 percent points.

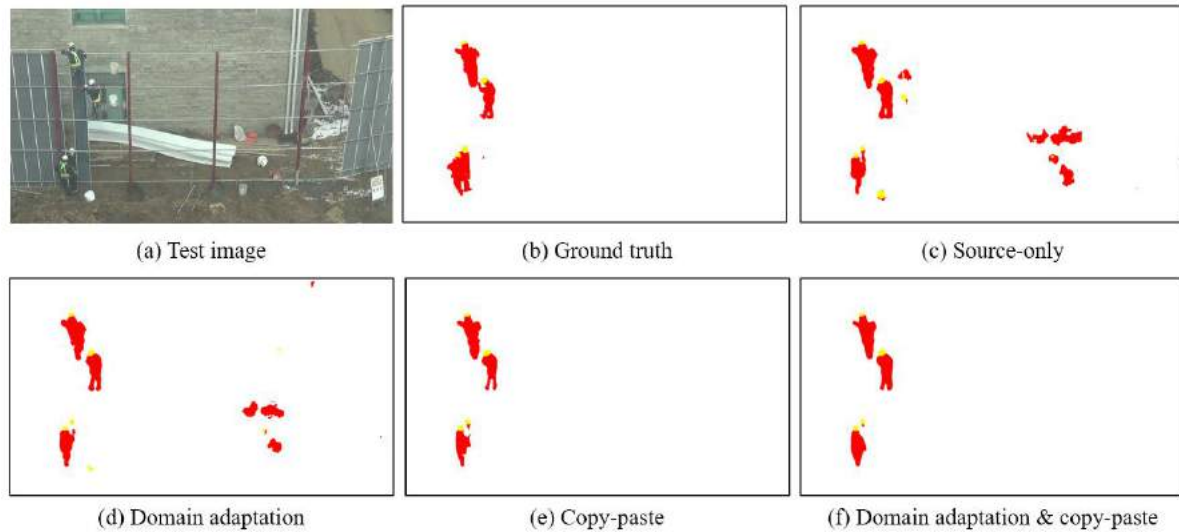

Figure 4. Example test image and the segmentation results of target domain 2

5 Conclusion

This study aims to increase the generalization capability of a semantic segmentation model for workers and hardhats. To address the generalization problem, a self-supervised learning-based domain adaptation and a data augmentation method were experimented for scaffolding installation site images.

The proposed methodology showed the potential of generalizing a semantic segmentation model without additional annotation efforts. The model with the copy-paste strategies achieved a 9.68 percent point increment in mIoU compared to the model trained only with source data for target domain 1. The model incorporating the domain adaptation and the copy-paste strategies achieved a 28.25 percent points increment in mIoU compared to the model trained only with source data for target domain 2. This improvement is remarkable in that the model did not use new annotations from the target domain.

Future study will be conducted to reduce the remaining gap between the highest mIoU of the proposed model and the upper bound model. Additional target domains will also be tested in future study to validate the effectiveness of the proposed method.

Abstract –

Design for Manufacture and Assembly (DfMA) is an emerging concept introduced from the manufacturing sector to transform the construction industry and accelerating “off-site” capabilities. Enhancing the sustainability of DfMA is challenging and requires accounting for various environmental and managerial impacts on the process of manufacture and assembly, especially for the parametric buildings with irregular shapes and unstandardised components. It is essential to compare and make decisions among design alternatives for the best-fit sustainability in the DfMA process. However, there is presently a gap in the DfMA field. This paper proposed a novel BIM-enabled Multi-Criteria Decision Making (MCDM) method for the sustainability assessment of parametric façade design. An under-construction parametric building was used to test and illustrate the method. A parametric façade was selected to demonstrate the application of DfMA to enable mass “off-site” customisation. This is a labour-intensive assembly process, which could significantly benefit from the implementation of such a method. Data collection involves archival data and semi-structured interviews. An integrated fuzzy AHP-TOPSIS was used to analysis the data. This research sheds new lights on DfMA sustainability and its decision support systems. Unlike the usual attention to the construction sustainability of on-site construction, the method involves consideration of both manufacture and assembly stages. It provides practitioners with a decision-making method to select the most sustainable façade alternative available for the parametric design. The findings carry implications for parametric façade design and show the deployment of mass customised unstandardised components. This research opens up new avenues for sustainable DfMA development.

Keywords –

DfMA; Parametric design; BIM; Decision making; Sustainability

1 Introduction

The harsh environmental impact of the building production process makes sustainable design and construction urgently important [1,2]. A key part of the “off-site revolution” must be the consideration of how we can enhance sustainability in design. This requires the integration of sustainability factors and knowledge in different building phases (such as manufacturing, assembly, and operation and maintenance) [3,4]. However, unlike conventional construction methods, off-site construction requires the evaluation of sustainability in the design stage [5,6]. The United Kingdom (UK), Singapore, and Hong Kong governments have identified Design for Manufacture and Assembly (DfMA) as the way to accelerate the efficiency and sustainability of the construction industry [4,7,8]. Although, little is known about how DfMA relates to sustainability research. One of the primary challenges is to compare and make decisions among design alternatives for the best-fit sustainability in the DfMA process.

Decisions are judgments based on information, and poor-quality information inevitably results in poor decision-making [9]. Building Information Modeling (BIM), as an innovative digital technology, is expected to evolve the traditional form of information management [10] and enhance the ability of construction sustainability [11,12]. Horizontal integration between various stakeholders and vertical integration of information at different stages becomes possible with the incentive of BIM [13]. In the early design phase of projects, designers can identify better solutions based on integrated information and various functions from BIM

[14].

Multi-Criteria Decision Making (MCDM) is a basic approach in decision-making procedure which models decision problems by processing various information [15,16]. These decision problems are described by the presence of various decision criteria which could be quantifiable or nonquantifiable [17]. In the Architectural Engineering and Construction (AEC) industry, MCDM has also demonstrated its powerful auxiliary capabilities in decision-making. The potential ability of MCDM in the AEC industry can be better stimulated with the cooperation of BIM [18]. Vice versa, BIM capabilities will also be promoted by MCDM which helps to overcome limitations of BIM related to optimising multi-objectives while still exploiting its benefit [19].

This study aims to establish a BIM-enabled MCDM method that incorporates sustainable assessment. BIM was used in the design optimisation and data collection process. Fuzzy theory, Analytic Hierarchy Process (AHP) and Technique for Order Preference by Similarity to an Ideal Solution (TOPSIS) were combined for the integrated MCDM. An empirical design case with three design alternatives for its parametric façade system was used in this study. A focus on a parametric façade was selected as the case as it provides an example of mass “off-site” customisation and a labour-intensive assembly process. Data collection involved the use of archival data, a series of interviews and questionnaires. In summary, this research contributes a sustainable design evaluation method to the field of DfMA.

2 Literature Review

2.1 Design for Manufacture and Assembly

Boothroyd [20] defines DfMA as a methodology to evaluate and improve product design by considering the downstream manufacturing and assembly processes, which signifies a shift from a traditional, sequential design process to a non-linear methodology. This emerging concept has been widely used in the manufacturing industry and then introduced into the AEC industry by the UK, Singapore, Hong Kong governments in recent years [4,8]. Gao, et al. [21] defines DfMA as 1) design strategy; 2) design evaluation method; and 3) design philosophy. Implementing Design for Manufacture (DfM) and Design for Assembly (DfA) can bring considerable benefits for construction sustainability by simplifying and optimising design and then shortening the construction process. DfMA is thus regarded as a circular economy solution for sustainable development [22]. To move forward the development of DfMA, further research can be conducted to establish related sustainability evaluation methods and strategies.

2.2 Sustainability Assessment

Sustainability assessment focuses on realising positive net sustainability benefits now and in the future. It is the process that leads decision-makers to sustainability [23,24]. The concept of sustainable building usually considers the whole life-cycle performance of sustainability, including social, economic, cultural, and environmental characteristics [25]. Rodríguez López and Fernández Sánchez [26] illustrated the challenges of sustainability assessment in the AEC industry. The spreading of prefabrication and DfMA has been changing the weight importance of different life-cycle building stages. The design process is also changed. Cross-disciplines collaboration and more detailed design would be involved in the early design stage, which raises challenges to traditional construction sustainability assessment. The emerging activities, including off-site manufacturing and on-site assembly, create new opportunities and application scenarios for sustainable design optimisation when compared with conventional on-site construction. Architects and engineers can optimise the design alternative by considering the sustainability performance in the manufacture and assembly stages. Innovation is required, to create a holistic tool for the sustainability assessment. This has been highlighted by both the policy-makers and the scientific community [27]. The authors now consider the development of such a technique.

2.3 BIM-enabled MCDM

Sustainability can be considered as a MCDM problem [28,29]. BIM-enabled MCDM is emerging as a trend in the AEC industry. In addition, there are many sustainability assessment studies at both the building and component level. Yet very little is known about their relationship [30]. Chen and Pan [18] proposed a method for low carbon building measures selection. Mahmoud, et al. [31] developed a global sustainability rating technique for existing buildings. Jalilzadehazhari, et al. [19] used MCDM-enabled BIM to take account of building energy requirements while simultaneously improving indoor environment quality. In the component level, Marzouk and Abdelakder [32] used BIM-enabled MCDM to identify sustainable materials. Jalaee, et al. [33], Khanzadi, et al. [34] and Fazeli, et al. [17] developed tools to select optimal sustainable components. Yu and Woo [35] proposed a model for building-envelope structural modification system for energy efficiency. Juszczak and Zima [36] enhanced the green façade by MCDM. It can be observed that the integration of BIM and MCDM has been profusely applied in sustainability-related issues in the AEC industry [30]. However, there is no research about BIM-enabled MCDM for sustainability assessment in the DfMA

process. A method to allow the consideration of sustainability performance during both the manufacture and assembly stages is however urgently needed.

3 The Proposed Framework

3.1 Criteria System for Sustainability Assessment of DfMA

Various multi-criteria were carefully obtained by considering the literature review and expert opinions. One of the authors dominated the design of three alternatives and worked closely with all other disciplines, manufacturers and contractors. Further data were collected by other authors who conducted a series of informal interviews with the designers, documentations and related articles.

As shown in Table 1, four dimensions can be used to structure DfMA sustainability assessment, including manufacture, assembly, operation and maintenance. Overall 11 criteria are identified. They were derived from the construction-oriented DfMA guidelines [4].

Table 1 Criteria System for Sustainability Assessment of DfMA

L2 Dimension	L3 Multi-Criteria
Manufacture	A1 Reduced number of molds
	A2 Reduced number of part counts
Assembly	A3 Reduced and standardised number and type of connectors
	A4 Assembly error tolerance
	A5 lightened material and components
Operation	A6 Environmentally friendly materials
	A7 Low operation energy consumption
	A8 Environmentally friendly building forms
	A9 Environmentally friendly indoor space
Maintenance	A10 Reduced fragile parts
	A11 Easy replacement of building components and materials

3.2 Fuzzy AHP Method

The aim of this analysis is to compare different criteria to optimise and determine the most appropriate sustainable design based on BIM platform. Combining MCDM methods with BIM has been systematically analysed in previous study [30]. AHP is a widely used method with MCDM to facilitate the selection among various alternatives. The AHP method has been used to weight each criterion by decision makers or experts, and then to generate priorities by constructing a hierarchy. The FAHP methodology has further developed the conventional AHP method by integrating fuzzy set theory to analyse uncertain judgment of experts, such as using natural language.

The concise steps of the Fuzzy AHP Method are as follows:

Step 1. Define linguistic scale of relative importance used in the pairwise comparison matrix

In practice, the Triangular Fuzzy Number (TFN) scale from 1 to 9, is commonly used to structure a comparison matrix. And the TFNs are defined with the membership function referred to the research Metin Celik (Table 2):

Table 2 Scale of Relative Importance

Intensity of Fuzzy importance	Fuzzy number	Linguistic variables	Membership function
1	1	Equally important/ preferred	(1, 1, 3)
3	3	Weakly important/ preferred	(1, 3, 5)
5	5	Strongly more important/ preferred	(3, 5, 7)
7	7	Very strongly important/ preferred	(5, 7, 9)
9	9	Extremely more important/ preferred	(7, 9, 11)

Step 2. Construct a fuzzy comparison matrix

The experts are given a questionnaire to make a pairwise comparison weight for criteria. The fuzzy comparison matrix is calculated by the Equation (1):

$$A = \begin{bmatrix} 1 & \tilde{a}_{12} & \dots & \tilde{a}_{1n} \\ \tilde{a}_{21} & 1 & \dots & \tilde{a}_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ \tilde{a}_{n1} & \tilde{a}_{n2} & \dots & 1 \end{bmatrix} \quad (1)$$

Step 3. Check consistency of the matrix

In order to balance the results of the method, it is necessary to calculate the consistency ratio (CR) for each of the matrix and overall hierarchy. The consistency check process is as follows.

i) Calculate the largest Eigen value of the comparison matrix.

$$Aw = \lambda_{\max} w \quad (2)$$

ii) w is principal Eigen vector of the matrix. Calculate the consistency ratio.

$$CR = \frac{CI}{RI} \quad (3)$$

$$CI = \frac{\lambda_{\max} - n}{n - 1} \quad (4)$$

RI is random index (Table 2). CI is consistency index and n is matrix size.

Table 3 The Random Index RI

Size (n)	1	2	3	4	5	6	7	8
RI	0	0	2	9	1	5	5	0

The consistency ratio should followed the rule that only if the $CR \leq 0.10$ is acceptable.

Step 4. Compute the weight of each criterion

3.3 TOPSIS Method

TOPSIS is one of the useful MCDM methods and can be combined with AHP. According to this technique, the best alternative would be the one that is nearest to the positive ideal solution and farthest from the negative ideal solution. The positive ideal solution is a solution that maximises the benefit criteria and minimises the cost criteria, whereas the negative ideal solution maximises the cost criteria and minimises the benefit criteria. In this study, TOPSIS method is used for determining the final ranking of the façade design. The method is calculated as follows:

Step 1. Decision matrix is normalised:

$$r_{ij} = \frac{w_{ij}}{\sqrt{\sum_{j=1}^J w_{ij}^2}} \quad j = 1, 2, 3, \dots, J \quad i = 1, 2, 3, \dots, n \quad (5)$$

Step 2. Weighted normalised decision matrix is formed:

$$v_{ij} = w_{ij} * r_{ij}, j = 1, 2, 3, \dots, J, i = 1, 2, 3, \dots, n \quad (6)$$

Step 3. Positive ideal solution (PIS) and negative ideal solution (NIS) are determined:

$$A^* = \{v_1^*, v_2^*, \dots, v_n^*\} \text{ Maximum values} \quad (7)$$

$$A^- = \{v_1^-, v_2^-, \dots, v_n^-\} \text{ Minimum values} \quad (8)$$

Step 4. The distance of each alternative from PIS and NIS are calculated:

$$d_i^* = \sqrt{\sum_{j=1}^n (v_{ij} - v_j^*)^2}, j = 1, 2, \dots, J \quad (9)$$

$$d_i^- = \sqrt{\sum_{j=1}^n (v_{ij} - v_j^-)^2}, i = 1, 2, \dots, J \quad (10)$$

Step 5. The closeness coefficient of each alternative is calculated:

$$CC_i = \frac{d_i^-}{d_i^* + d_i^-}, i = 1, 2, \dots, J \quad (11)$$

Step 6. By comparing CC_i values, the ranking of alternatives is determined.

4 Case Study

4.1 Context and Background

The case is a façade renovation project located in Wuhan, China. One of the authors took the lead for the architectural design. Three alternatives were selected for the sustainability assessment, as shown in Figure 1, 2, and 3. BIM models were used for data collection and analysis. The façade system was manufactured off-site and assembled on site. The parameterised special-shaped façade in some design schemes has brought great challenges to manufacturing and assembly, especially in terms of sustainability assessment.

Figure 1 Alternative façade design A

Figure 2 Alternative façade design B

Figure 3 Alternative façade design C

4.2 Case Study results

By applying the proposed computational framework to the case study, the several steps below were generated to explore the best solution among design alternatives.

Step 1. Fuzzy AHP to calculate the weight

The experts made pairwise comparisons of 4 dimensions and 11 criteria to construct a fuzzy comparison matrix by using linguistic scale Table 2. FAHP then calculated the matrix weight. The results of the weight calculation are given in Table 4 and Table 5. The Consistency Ratio (CR) value of all matrixes was tested at less than 0.1. Thus, these results are acceptable. And Table 5 reveals the ranking of the 11 criteria.

Table 4 Weight of the 4 dimensions and the CR value

Dimension	Weight	CR
Manufacture	0.2833	
Assembly	0.2	
Operation	0.35	0.0313
Maintenance	0.1667	

Table 5 Weight of the multi-criteria and the ranking

Dimension	Criteria	Criterion weight	Ratio	Rank	CR
Manufacture	Reduced number of molds	0.2267	0.8	1	
	Reduced number of part counts	0.0567	0.2	9	0
Assembly	Reduced and standardized number and type of connectors	0.0667	0.333	8	
	Assembly error tolerance	0.0333	0.166	11	0.022
	Lightened material and components	0.1	0.5	4	
Operation	Environmentally friendly materials	0.09	0.257	5	
	Low operation energy consumption	0.1198	0.342	2	
	Environmentally friendly building forms	0.0731	0.208	6	0.097
	Environmentally friendly indoor space	0.0672	0.191	7	
Maintenance	Reduced fragile parts	0.1167	0.7	3	
	Easy replacement of building components and materials	0.05	0.3	10	
					0

Step 3. TOPSIS to evaluate the priority of alternatives

In this stage, the TOPSIS procedure commenced from calculating the weight of each criterion of the decision matrix according to the FAHP analysis result and experts survey which showed in Table 6. Then, the method determined the positive ideal and negative ideal solutions presented in Table 7. After that, the relative closeness of each design alternative to the ideal solution was calculated separately. The final result of TOPSIS is shown in Table 8 which reveals the facade Design 3 is the highest rank solution.

Table 6 The weight of each criterion

Criterion	A1	A2	A3	A4	A5	A6	A7	A8	A9	A10	A11
P1	0.6801	0.1701	0.4002	0.0999	0.0277	0.2092	0.4755	0.3636	0.336	0.9336	0.4
P2	1.1335	0.2268	0.4669	0.2664	0.0287	0.2086	0.5117	0.336	0.369	0.813	0.3

5 Discussions and Conclusions

Conventional 2D drawings cannot accurately deliver the information of complex buildings, which brings great difficulties to sustainable assessment and design optimisation. The optimisation result may be inconsistent with the architectural design and lead to high manufacture or assembly cost. At the same time, it may have a serious impact on construction sustainability. BIM has the opportunity to overcome this difficulty and facilitate decision-making in the DfMA process.

The facade design optimisation is critical to the fabrication of complex building shapes. The division of the façade system is not only limited by the technical requirements of the façade system itself, but also has an impact on structural design, and even affects the later mechanical and electrical installation. This requires that in the early stage of design optimisation, the construction team not only needs to coordinate various disciplines and understand the constraints of facade optimisation. There is also a need to determine the expected results of facade optimisation from the perspective of sustainability.

This study proposed a decision-making method to incorporate sustainability assessment into the DfMA process by comparing among design alternatives. The multi-criteria for sustainability assessment consists of four dimensions, including manufacture, assembly, operation and maintenance. Totally, eleven criteria were used to establish the FAHP-TOPSIS method, including reduced number of molds, reduced number of part counts, reduced and standardised number and type of connectors, assembly error tolerance, lightened material and components, environmentally friendly materials, low operation energy consumption, environmentally friendly building forms, environmentally friendly indoor space, reduced fragile parts, easy replacement of building components and materials. The computational method adopted an under-construction case with three façade alternatives.

This research contributes to the field of DfMA by providing a new approach to BIM-enabled MCDM, and sustainability assessment. It supports the design evaluation of DfMA by establishing a BIM-enabled MCDM method. Practitioners can use this method to evaluate the sustainability of the design of prefabricated buildings, thereby optimising the concept design and split design. The findings carry implications for parametric façade design and support the deployment of the mass customisation of unstandardised components. However, the case has a relatively low level application of BIM,

and BIM models were only used for data collection and evaluation. Future research is needed to collect data on case types and multi-criteria decision making to validate the application and expanded use of such methods.

Abstract

Delays and cost overruns are frequent in infrastructure construction projects. Traditionally, deviations are often identified late, and it is very difficult to trace back the causes. Decisions are often taken by experience and not with the support of data directly coming from site. Moreover, schedules are often static and thus not able to reflect the real conditions on-site. Emerging technologies like Building Information Modeling (BIM), mobile cloud computing, and advanced sensors can help to overcome the previously mentioned issues. The collection of production data by sensors with the aim to compare production metrics with the schedule in order to introduce a Continuous Improvement Process (CIP).

In the paper, we propose a framework for a digital platform to gather production data in real-time and to identify early on bottlenecks that could potentially lead to delays and deviations. The proposed platform should support in collecting, analyzing, and structuring production data. Furthermore, the platform should give insights and support organizational decision making of a CIP. With a demonstration case we show the three main functionalities of the platform: 1) retrospective analysis, 2) live analysis and 3) predictive analysis. In future research, the platform will be implemented and validated within railway construction projects of the company Rhomberg Sersa Rail Group AG.

Keywords –

Real-time; Lean Construction; Continuous Improvement Process; Infrastructure; Digitalization

1 Introduction

Delays and cost overruns are frequent in infrastructure construction projects. Only around 25% of construction projects worldwide have come within the range of 10% of their original deadlines from 2012 to

2014 (KPMG 2015). Globally, rail construction projects are frequently affected by budget and schedule overruns by an average of 44.7% (McKinsey Global Institute 2015). Whereas other industries almost doubled their productivity over the past decades, the construction industry remained the same (McKinsey Productivity Science Center, 2015). Considering railway construction projects, short durations for maintenance as well as new installments are crucial to avoid a breakdown of the railway network. Otherwise, time overruns are often fined with high penalties.

Traditionally, one of the biggest issues is the usage of static schedules that do not reflect real conditions on-site (Dallasega et al. 2018). As a result, schedules become useless and coordination is based on improvisations. Furthermore, progress tracking is often based on rough estimations and thus schedule deviations are not known in detail. Scheduling is usually done according to the experience of the project or site manager and not based on the monitoring of the construction progress. Thus, it is very difficult to identify bottlenecks, as for example a machine that reduces speed and thus leads to a potential decrease of productivity of the following construction processes.

As a result of the previous mentioned issues, problems are often identified in a late stage making it difficult to implement appropriate improvement actions in time. Furthermore, construction projects are loosely connected and improvements are not systematically stored or transferred to future projects (Tetik et al. 2019). Early identification of bottlenecks and a dynamic definition of improvement actions as well as their impact would decrease variability and thus reduce budget overruns.

In order to minimize delays and defects, other industries such as manufacturing implemented Lean Management Principles that are based on the Toyota Production System. Lean Management focuses on the improvement of the processes by defining and evaluating the Value Stream with a focus on Value-Adding activities and the elimination of waste which is defined as ‘any

activity that does not add up to the products value' (Womack and Jones 2003). A central element of the Lean Management is Visual Control of process execution and deviations. Appropriate Improvement actions are also visualized and responsibilities are defined that leads to process improvement accountability (Mann 2014).

The Plan-Do-Check-Act (PDCA) approach is a framework to improve processes and track the progress of improvement in manufacturing companies. The approach consists of 4 phases (Chong and Perumal, 2020). The first is defined as the pre-implementation (Plan) where the improvement actions get planned. The second stage is the implementation of the planned actions (Do) in which the Lean tools of improvements get carried out. The third phase is the evaluation (Check) in which the performance of the improvement actions is analyzed. The last phase is the standardization and documentation of the successfully implemented actions (Act) (Chong and Perumal, 2020).

The implementation of Lean Construction is well researched and methodologies such as the Last Planner System (LPS) (Ballard 2000), Takt Planning (Haghsheno et al. 2016), or Location-Based Management System (Kenley and Seppänen 2009) have been applied in practice. However, the identification of waste in construction is usually reactive. Commonly used Key Performance Indicators (KPI), like the Cost Performance Index (CPI) or the Schedule Performance Index (SPI), are unable to provide in-depth analyses about causes of problems and thus they give limited support in suggesting appropriate improvement actions (Dallasega et al. 2020).

Commonly used software tools, like Vico Office Software (<https://vicooffice.dk/en/>), visualize construction schedules with a flowline based on quantities and production rates derived from BIM models. However, these types of software give a limited support in proposing appropriate improvement actions in case of schedule deviations. A platform that collects production data in real-time and compares it with the planned ones, incorporating a continuous improvement process (CIP) would enable higher productivity rates. So far most of the works in this area are very conceptual and lack empirical validation (Tetik et al. 2019).

Considering the manufacturing industry, the usage of real-time data to optimize production processes is one of the main pillars of Industry 4.0 (Schuh et al. 2012). Although, the utilization of real-time data coming directly from site to support scheduling and monitoring processes is currently not widely researched and practiced in construction. Therefore, we propose a framework for a digital platform that allows the comparison of planned and as-built data enabling a CIP to support early identification of problems in construction. The proposed framework for the digital platform is structured in three main functionalities:

1) retrospective analysis, 2) live analysis, and 3) predictive analysis.

The previously listed functionalities are motivated by using three demonstration cases that were derived from a project of the company Rhomberg Sersa Rail Group in Switzerland.

2 Literature Review

Traditionally, live data is barely collected in the construction industry and, therefore, platforms to document progress or production data in real-time are not widely distributed. According to Zhao et al. (2019), the traditional process of data collection has remained manual in the construction industry. In their research they propose a platform model that combines Bluetooth Low Energy technology and 3G/4G network as connection methods that explore the movements and time information of workers on site which is used to manage resource flows using lean principles (Zhao et al. 2019).

Similarly, Tetik et al. (2019) proposed a framework to improve construction performance through closing the loop from construction to design. They propose to centralize the As-Built BIM model and gather production data for reuse in future projects. The aim is to use the platform as a knowledge database. However, live data analysis is not part of the research.

Another digital platform is proposed by Rossi et al. (2019) that focuses on the productivity measurement of machines to identify their value-adding activities. Although, they do not consider interdependencies of different machines which is an important aspect to consider in infrastructure projects. In this way, bottlenecks can be identified but appropriate improvement actions cannot be derived.

According to Akhavian and Behzadan (2015) direct observations such as surveys in the field to obtain large volumes of high-quality data is inefficient since manual gathering is time consuming and inaccurate. Automated data collection using sensors, vision-based systems and laser scanners gained importance in quantitative analysis of construction activities. The authors propose a framework to analyze the production data on different granularities to gain accuracy in the data collection and establish a Level of Detail (LoD) for processing production data. (Akhavian and Behzadan 2015).

Song and Eldin (2012) propose a framework for real-time tracking that contains process knowledgebase, adaptive modeling and simulation services. The system constantly tracks operation activities and data is used for accurate lookahead scheduling. However, a structured way to identify root causes is not considered in the approach.

Another framework for data gathering and processing was proposed by Vasnev et al. (2014), which should

support decision making based on production data in three different levels: operational, tactical and strategic. The aim of the framework is to run post-construction analyses of the production process (Vasnev et al. 2014).

The literature review shows that a platform that processes production data is researched in the field. Several functionalities of a platform are proposed with a different focus. The reviewed research mostly focuses on the data gathering and the evaluation of productivity rates respectively value adding activities. Nevertheless, to the best of our knowledge, a platform that focuses on Continuous Improvement actions based on production data can be considered as novel in the field.

3 Concept

This paper proposes the framework for a CIP platform to collect, analyze and adapt the production planning of railway construction projects. The platform will collect as-built production data. It will analyze how causes of problems (losses) can be identified retrospectively (Demonstration case - Scenario 1) to provide better planning data for future infrastructure projects. Next, it will identify problems in real-time to implement appropriate improvement actions (Demonstration case - Scenario 2). Moreover, it will identify potential future problems before their occurrence to proactively avoid budget and schedule overruns (Demonstration case - Scenario 3). The developed framework will be implemented and validated in selected project scenarios of the company Rhomberg Sersa Rail Group.

The proposed framework of the platform should support the collection, analysis and structuring of production data in real-time. A centralized platform will enable on site as well as remote access to the data. Gathering the data in an overall database promotes a holistic view on construction performance. It will run a live comparison with the planned schedule data in order to identify bottlenecks that led to potential deviations. The system that performs the analysis will be defined within the future implementation. As shown in Figure 1, the platform is the link between Planning and Production that processes both sides and can enhance data driven decision making.

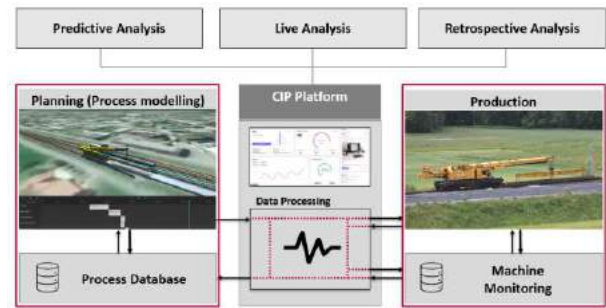

Figure 1: Concept diagram

In order to run a comparison of the planning- and production data, the dataset has to be aligned and defined by the same measurement unit e.g production speed. The data analysis comparison is performed by overlaying the data in a backend system respectively database that runs a permanent data evaluation. The analysis can be performed in various ways respectively with different scopes. Our concept proposes three main functionalities for the evaluation of the production data: retrospective analysis, live analysis, and predictive analysis.

1 Retrospective Analysis

The retrospective analysis identifies production bottlenecks after the construction process was carried out. If the analysis is executed in short cycles, appropriate improvements can be made for following processes within the actual or future projects. For example, if the daily target of a construction site is not reached, the proposed platform will support the identification of the root cause by pointing out the bottleneck. Improvement actions in order to adhere to the schedule in the following days or to avoid the problem to cause deviations again are suggested.

2 Live Analysis

The live analysis compares the production data in real time and indicates deviations from the planned schedule. Then, adjustments can be evaluated and implemented in real time. For example, the productivity rate that is necessary in order to adhere to the schedule can be displayed in the cockpit of the machine. The data provides live performance measures and the status of the production. It requires a setup with high bandwidth on site in order to process the data between the machines and the platform. The live comparison of the production data to the planned production schedule leads to the possibility to take live improvement actions such as increasing productivity rates. Even if an unpredictable deviation occurs, the data processing conducted live in the background can propose the right production speed to recover delays and assure schedule adherence.

3 Predictive Analysis

Based on data of previous projects, problems can be identified before they occur. The provision of production data respectively the production problems in the design

and work preparation leads to a more stable schedule and a decrease of variation. The more high-quality data is provided the more stable the prediction will get. Technologies such as Artificial Intelligence (AI) can support the analysis of large data sets. Machine Learning can support a predictive analysis of a likelihood of a certain problem if the input data is structured accurate. (Taofeek et. al, 2020)

For each process or machine a threshold productivity value has to be defined that can be supported by Machine Learning. If the value is out of the defined threshold, then the platform will give a notification for that point in the schedule. The notifications can then be set in focus and the reason for deviation identified and categorized. The proposed classification functionality will get integrated and the reasons that commonly lead to deviations predefined. If a certain deviation occurs the platform supports in the identification of causes and improvement actions. As a structure to support the root cause analysis the Lean tool 'five whys' will be used. According to David Mann the 5 whys is a basic method of root cause analysis. Every Why is intended to go deeper into the cause of a situation (Mann, 2014). The predefined tree diagram extends over the time and the user has the ability to complement the categories in order to cover every reason for deviation and preparation for further deviations. The classification according to the tree diagram respectively 5 Why can enhance project specific as well as organizational decisions.

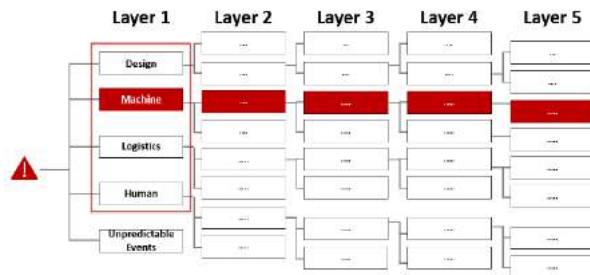

Figure 2: Problem Classification - Tree diagram

The tree-diagram (Figure 2) captures the layers of the 5 Whys' and supports in defining the root cause by proposing previous documented reasons for deviation. If e.g., the overall evaluation points out that a high percentage of problems lead back to production machines, improvement actions can be focused to maintenance tasks. We propose each level of the tree diagram has a named definition and will be accessible by the people who can use the information for their decision making. However, the adoption of the tool is an important aspect of success. In order to analyze the root causes the categorization is essential. The layers will be defined by

analyzing reasons for deviations of past projects by evaluating existing data and experience from people working on site. The definition of the layers will be defined according to the results of the analysis.

4 Demonstration Case

The scenario of the demonstration case was derived from a previous project of Rhomberg Sersa Rail Group. The planned data was gathered according to a project schedule. Nevertheless, the As-Is production data was derived from feedback of the site manager based on his knowledge. The production data wasn't gathered while operations because such a system isn't in place on the construction sites of the Rhomberg Sersa Railgroup. To describe the functionalities of the platform, two processes are focused. The goal of the chosen schedule cutout is to build the ballast track bed and the laying of rails. Both processes are conducted by machines (M1: Ballast Track machine, M2: Track crane).

Productivity rates of both machines are the same that leads to a harmonized production speed. The construction of 200 m starts at 06:00 am and the completion is planned at 12:30 pm (Figure 3). The As-Is completion occurred at 13:30 pm. Thus, the schedule was exceeded by one hour. A reflection of the delay was conducted but a valid identification of the root cause was not possible due to missing data. The usage of the proposed platform will enable different ways of analyzing the data and furthermore conduct appropriate improvement actions. The Rhomberg Sersa Railgroup is currently developing a software used to model the construction processes within a BIM environment. A novelty of that software is that the machines are integrated into the 4D planning environment and their motion respectively process execution is simulated. The aim of that software is to run process simulations in order to check the feasibility based on 4D clash detection and decrease variability. Standardized construction process modules can be used in order to improve the planning process. However, the integration of feedback from site in real-time is not yet considered in the software. Furthermore, the Rhomberg Sersa Railgroup recently launched a machine monitoring tool that structures complex machine data and makes it accessible. In the following chapters we describe the functionalities of the platform according to a demonstration case.

Figure 3: Demonstration Case: Schedule (Planned)

4.1 Scenario 1: Retrospective Analysis

The retrospective analysis of the production data leads to a bottleneck identification after the construction process was carried out. If the analysis is executed in short cycles appropriate improvements can be made for following processes within the actual or future projects. The analysis of the As-Is data in this scenario points out that M1 had a loss of productivity in the area between 75m and 100m. The loss occurred between 08:15 and 10:00 am. M2 had to adjust the speed due to the loss of M1 (Figure 4). According to the data M1 is the bottleneck and the reason for the delay. The red marked area highlights the area the deviation occurred. The As-Is graph of both machines points out that the adjustment of M2 was reactive and a collision was prevented on short notice on site. The analysis gives an indication about the time and the area. The identification of the root cause of the problem can be narrowed down with this information and further investigations can be done. The identified problem point will then be classified supported by the proposed root cause analysis tool respectively with the tree diagram.

Figure 4: Way-time diagram - Retrospective Analysis

4.2 Scenario 2: Live Analysis

As described in the concept the machines are connected through the platform and the productivity can be compared to the planned in a continuous way during production. At 08:00AM when M1 slows down the information goes directly to M2, which can adjust its speed (Figure 5). At the moment when the productivity reaches the average, the platform can propose the right speed in order to adhere to the schedule. The information can be integrated into the system and the machine can be operated according to the information calculated in the platform. The live analysis enables not just live evaluation but also a live conduction of improvement actions such as the adjustment of the productivity rate in order to reach the planned schedule.

Figure 5: Way-time diagram - Live Analysis

4.3 Scenario 3: Predictive Analysis

In this scenario a potential problem will be highlighted in advance (Figure 6). The construction team is able to perform measures in order to prevent the occurrence of the problem. The platform detects a potential risk based on the data of previous projects. The graphs show that the As-Is production was as planned. The machines were able to perform the planned productivity starting 06:00AM to 12:30PM. Furthermore, proposals for the mitigation of the risk are linked based on the previous improvement actions. As shown in Figure 6 the productivity remains as planned. Both machines can work as planned and the risk for delay can be eliminated. The outcome assures schedule adherence.

Figure 6: Way-time diagram - Predictive Analysis

5 Discussion

The proposed framework has its focus on railway construction projects. Nevertheless, the functionalities can be transferred to other machine-driven infrastructure projects such as road construction. Due to the lack of possibilities of data collection supported with sensors the use in building construction projects it is not in scope but can be further evaluated in the future research.

6 Conclusion & Outlook

A platform for the analysis of production data in real-time by comparing it with the planned schedule and providing a structure to categorize reasons for deviations would decrease variability in the construction industry. As described in the literature review several concepts for live data collection and analysis were proposed. However, to the best of our knowledge, a platform that focuses on Continuous Improvement actions based on production data could be considered as novel in the field. The proposed functionalities of retrospective, live, predictive analyses offer different ways to analyze and improve the production. The retrospective analysis enables a data driven review and supports identifying bottlenecks retrospectively. The live analysis enables live improvement actions such as increasing or decreasing productivity rates. The live processing of the data enables a data driven proposal of adaptations. When combined with machine learning, the collection of this high-quality production data can enable predictive analyses. The knowledge of previous construction projects can so be used to improve the planning process by considering potential risks that usually appear during construction.

The detection of problem points with the classification functionality enables a focused CIP. The overall evaluation of the problems from production will enable a data-based decision making on different organizational levels. However, the implementation has

to be accompanied with a comprehensive roll-out plan in order to increase acceptance. The unveiling and visualization of problems can lead to resistance from the workforce.

The framework will be developed and practically evaluated in future projects of the company Rhomberg Sersa Rail. Further research activities should be the creation of a database for the comparison of the planned and the production datasets. The gathering of production data of manual tasks is very difficult and therefore it should be analyzed how this could be supported with emerging technologies (e.g., reality capture, motion capture and others).

The functionality of the deviation recognition should be implemented based on the dataset to allow a Continuous Improvement Process or Root Cause Analysis of identified problems. The tree diagram as shown in Figure 2 should be systematically developed and extended with specific construction site experience.

The authors would like to thank the company Rhomberg Sersa Rail for providing an insight into their practical processes and supporting the research.

Abstract –

The construction industry is increasingly using information technologies (IT) and operational technologies (OT) to enhance processes and operations through digitalization. Creating, editing, storing, and sharing information in digital environments is only one side of the coin; the other involves monitoring and controlling physical processes on construction sites. Given the nature of construction sites, where humans and machines/equipment work collaboratively, safety concerns arise. Utilizing interconnected and cyber-physical systems such as (semi)autonomous and remote-controlled machines on-site magnifies the importance of robust cybersecurity. Therefore, it becomes necessary to understand the threats against each networked equipment, analyze the vulnerabilities, assess the risks, and provide mitigation methods. Cybersecurity frameworks are effective solutions for this purpose; however, they are usually generic and thus require customization to be employed in the construction site environment.

Against this background, this paper reviews existing cybersecurity frameworks/standards and selects the most suitable one to implement in the construction environment. The implementation was performed by customizing the selected generic framework considering the needs of a hypothetical construction site that utilizes autonomous earthmoving equipment. For the evaluation, a scoring system that was not included in the original framework was proposed. Given the paucity of studies in this field and lack of cybersecurity awareness in the construction industry, this study aims (1) to raise awareness about the potential cyber threats against construction sites that are increasingly interconnected, (2) to point out the need for a customized cyber assessment method on-site, and (3) help building a security-minded approach within the construction industry.

Keywords –

Construction 4.0; Cybersecurity; Cyber-Physical Systems; Cybersecurity Frameworks; Vulnerability Assessment; Autonomous Earthmoving Equipment

1 Introduction

Construction is one of the industries that has been increasingly globalized over the years with the advances in transportation and communication, and with trade agreements, leading to an increasing interconnectedness across countries [1]. The increasing globalization forces construction companies to re-engineer their processes and utilize novel technologies to stay competitive [2]. These technologies transform the way data is created, stored, and exchanged and how construction activities are performed, controlled, and monitored. The efforts to employ increasingly digitized processes in the construction industry are often called Construction 4.0, and the use of cyber-physical systems (CPSs) is an essential component of it [3].

Some potential benefits of digitalization in construction projects are cost efficiency, reduced durations, improved quality, and enhanced site activity tracking. On the other hand, cyber threat surface increases with the use of common data environments (CDEs) to exchange information in cyberspace and networked CPSs to perform different tasks during the construction and operation & maintenance (O&M) phases.

Information technologies (IT) and operational technologies (OT) domains have been isolated from each other for many years [4]. However, the need for enhanced performance, reduced costs, and improved control over the operations necessitated IT-OT convergence [4]. It is possible to see the examples of this convergence on construction sites, such as retrofitting legacy equipment with control systems (e.g., conventional excavators retrofitted with sensors and control units for autonomous operation) and employing new equipment designed with both IT and OT components (e.g., 3D concrete printers,

autonomous earthmovers, automated site-measuring robots, reinforcement positioning robots [5]). The report published by Trend Micro Research [6], analyzing the security levels of remote controllers used in industrial applications, indicates that millions of vulnerable radio frequency (RF) remote controllers are installed on heavy machinery in various industries, including construction. Long life spans of industrial equipment and high replacement costs lead companies to retrofit their legacy machinery with these remote controllers [6], which results in significant cybersecurity vulnerabilities. State-of-the-art equipment designed to operate connected to a network comes with enhanced cybersecurity and protection against known threats; however, evolving cyber threat-environment requires companies to stay cautious and proactive [7].

So far, several studies have been conducted to research cybersecurity aspects of OT utilized in environments such as manufacturing, water treatment plants, and smart buildings. The common point of all these environments is that they are more structured and stable than construction sites. The changing environment and lack of stability on-site [8] increase the challenge of providing robust cybersecurity during the construction phase. In addition, the collaboration between humans and machines raises safety concerns [8] considering potential cyber-physical attacks. Therefore, understanding the potential threats against OT on construction sites, detecting security vulnerabilities, and providing mitigation methods are paramount. A few studies have focused on the OT cybersecurity aspects of construction sites, such as [9] that proposed a preliminary threat modeling method for construction projects based on the Quantitative Threat Modeling Method (QuantitativeTMM) and demonstrated it with a 3D concrete printer, [10][11] that implemented the Common Vulnerability Scoring System (CVSS) to evaluate and quantify the vulnerabilities of construction networks, [12] that investigated the gaps in the cybersecurity of OT utilized in construction and suggested future directions for the industry and academia, and [13] that pointed out the potential physical damages that might occur as a result of hijacked autonomous construction equipment. To the authors' knowledge, there is no previous study investigating the use of cybersecurity frameworks during the construction phase.

This study proposes implementing a generic cybersecurity framework considering the characteristics of construction sites utilizing autonomous earthmoving equipment (AEE). The implementation was performed only considering AEE to keep it more specific. A hypothetical site with AEE was designed to demonstrate the practical aspects of the proposed implementation. The rest of this paper is structured as follows. Section 2 provides summaries of the prominent cybersecurity

standards/frameworks, presents the selection process of a suitable generic cybersecurity framework to employ in this study, and gives a brief overview of the selected framework and its structure. Section 3 explains the implementation of the selected framework on the designed hypothetical construction site and demonstrates it step by step. In Section 4, the provided implementation is discussed considering its benefits for the construction sector and its limitations to be further studied. Finally, Section 5 presents the conclusions and planned future work.

2 Cybersecurity Frameworks/Standards

The increasing need for identifying cyber vulnerabilities and threats, assessing the level of cybersecurity, protecting the assets from potential attacks, and managing risks requires a well-organized and systematic approach. For this reason, many organizations and government bodies developed cybersecurity frameworks and standards. In addition, some governments enforce compliance with a cybersecurity standard. For example, in 2018, the United Kingdom (UK) government published the Minimum Cyber Security Standard (MCSS) [14] to set the minimum requirements expected to be accomplished by government departments. However, cybersecurity frameworks/standards are invaluable for companies to assess where they stand compared to the best practices even without legal obligations. Some local and international institutions developing such guidelines are the National Institute of Standards and Technology (NIST), National Cybersecurity Centre (NCSC), Institution of Engineering and Technology (IET), International Electrotechnical Commission (IEC), and International Organization for Standardization (ISO). Relevant documents from these institutions are summarized next.

2.1 Review of Cybersecurity Frameworks and Standards

This section presents the most prominent cybersecurity frameworks/standards developed by government bodies and internationally recognized non-governmental organizations. These documents were reviewed considering their suitability to the construction site environment. Additionally, their usefulness for assessing OT cybersecurity was considered since this research particularly focuses on the potential threats against OT utilized on-site.

ISO/IEC 27001:2013: This standard [15] provides a set of requirements for companies to establish and maintain an information security management system (ISMS). It is a generic standard and targets organizations of all sizes

from all sectors regardless of their work environment. The standard employs the “Plan-Do-Check-Act” model to structure the processes of ISMS. The organizations that claim conformity to this standard are expected to meet all given requirements or provide justification and evidence if they exclude any of them.

ISO 19650-5:2020: This international standard [16] provides a guideline for a security-minded approach in construction projects and built environments that utilize building information modeling (BIM) processes. One of the focuses of this document is the cybersecurity of the sensitive information exchanged during the lifecycle of built environments from the design to O&M phases. While ISO/IEC 27001 sets out generic information security requirements that can be applied across various sectors, ISO 19650-5 differentiates itself by targeting collaborative data sharing processes of the built environment industry.

Cyber Assessment Framework v3.0 by NCSC: This is an extensive framework [17] published by NCSC (UK) in 2019 and designed to be utilized for the cybersecurity assessment of organizations by their internal teams or by third-party companies. The assessment structure includes four main objectives: protecting against cyber-attack, managing security risk, detecting cybersecurity events, and minimizing the impact of cybersecurity incidents. Overall, there are fourteen principles under these main objectives that are broken down into thirty-nine contributing outcomes for a detailed assessment. The organizations using this framework are expected to evaluate whether each contributing outcome is achieved, partially achieved, or not achieved.

Network and Information Systems (NIS) Directive by the European Union (EU): This is a legislative document [18] that aims to enhance the overall cybersecurity within the EU. More specifically, it requires each member state to improve its national cybersecurity by adopting a national information system and network security strategy. Moreover, it promotes EU-level cooperation among the member states for improved cybersecurity. It also sets out requirements for reporting incidents and risk management for essential and digital service providers.

Code of Practice for Cyber Security in the Built Environment by IET: This code of practice [19], published in 2014, provides cybersecurity guidance to the stakeholders involved throughout the lifecycle of built environments. It analyzes the specific cybersecurity needs, potential threats, hostile agents to be considered for each building lifecycle phase. Additionally, different aspects such as the procedures, the involvement of humans in the processes, cybersecurity policies for buildings, and the trustworthiness of utilized software are discussed in the built environment context.

Framework for Improving Critical Infrastructure

Cybersecurity v1.1 by NIST: This document by NIST [20] addresses the cybersecurity risks associated with critical infrastructures (CIs) and aims to provide a flexible, repeatable, and voluntarily applied framework to CI owners and operators. It has three main parts: the Framework Profiles, the Implementation Tiers, and the Framework Core. The Framework Core uses various references such as industry standards and guidelines to help companies identify their current profiles and prioritize cybersecurity activities to achieve their targets.

2.2 Selection of the Suitable Cybersecurity Framework

Given each document’s scopes and brief overviews presented above, a comparison has been conducted to choose the most suitable option for this study. The review of ISO/IEC 27001:2013 shows that it mainly focuses on the information security aspects, as its name suggests. Therefore, it does not adequately address the OT-specific cybersecurity issues on-site. The NIS Directive by the EU provides an extensive set of requirements; however, its structure is not as modifiable as the other reviewed documents. Finally, the Code of Practice for Cyber Security in the Built Environment by IET thoroughly addresses both IT and OT security aspects in all phases of built environments. However, it does not provide a structured framework format that can be utilized to create a checklist for cyber assessment. As a result, although these three documents are comprehensive enough, they do not meet the requirements of this study.

The remaining documents—ISO 19650-5, the Cyber Assessment Framework by NCSC, and the Framework for Improving Critical Infrastructure Cybersecurity (FICIC) by NIST—address both IT and OT cybersecurity aspects, which increases their suitability for this research. In addition, they all can be used for creating bespoke cyber assessment checklists for organizations due to their well-organized and flexible structures. However, the FICIC differs from the other two in a significant way: its ability to use the related frameworks and standards. The informative references in the Framework Core (e.g., ISO/IEC 27001:2013, NIST SP 800-53 Rev. 4) allow users to go through the sections of different sources relevant to each category (e.g., Risk Assessment (ID.RA), Response Planning (RS.RP)), and subcategory (e.g., ID.RA-3: Threats, both internal and external, are identified and documented). Furthermore, the FICIC is “[...] *applicable to organizations relying on technology, whether their cybersecurity focus is primarily on information technology (IT), industrial control systems (ICS), cyber-physical systems (CPS), or connected devices more generally, including the Internet of Things (IoT)*” [24, p. vi], which adequately addresses the cybersecurity issues escalating with the utilization of automated equipment on construction sites. For these

reasons, this study employs the FICIC v1.1 by NIST for the implementation and demonstration steps presented in Section 3.

2.3 Overview of the Selected Cybersecurity Framework

The FICIC encompasses three main components with different purposes. These components are briefly explained as follows:

Framework Core: This framework component provides a group of outcomes to achieve better cybersecurity management and introduces reference documents as guidelines. The Framework Core has four main parts, namely Functions, Categories, Subcategories, and Informative References. The structure of the Framework Core and five different functions can be seen in Figure 1.

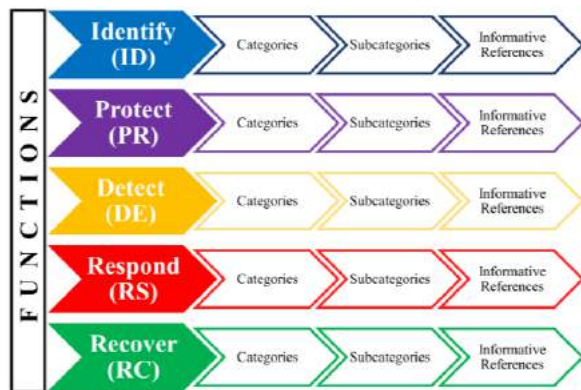

Figure 1. Structure of the Framework Core of the FICIC (adapted from [20])

In total, there are 23 categories and 108 subcategories, and several informative references are presented under each subcategory. The Framework Core does not provide a checklist with questions to assess the current cybersecurity level. Instead, it guides organizations to create their assessment schema by providing different cybersecurity aspects in each subcategory and related reference documents. Moreover, it allows for flexibility by letting organizations customize the framework by selecting the necessary subcategories and references for their particular needs. As an example, Table 1 presents a section from the Framework Core that includes two subcategories under the Risk Assessment category in the Identify function.

Implementation Tiers: The implementation tiers indicate to which extent the organization implements cybersecurity risk management practices in its processes. There are four tiers: Tier 1-Partial, Tier 2-Risk Informed, Tier 3-Repeatable, and Tier 4-Adaptive. Organizations are suggested to take necessary actions to progress towards higher tiers if their cost-benefit analysis also

supports it. Therefore, organizations can decide on their target tier by determining the most cost-effective solution.

Table 1. Section from the Framework Core of the FICIC for a specific function, category, subcategory, and related informative references

Function	Category	Subcategory	Informative References
IDENTIFY (ID)	Risk Assessment (ID.RA)	ID.RA-1: Asset vulnerabilities are identified and documented	CIS CSC 4 COBIT 5 APO12.01, APO12.02, APO12.03, APO12.04, DSS05.01, DSS05.02 ISA 62443-2-1:2009 4.2.3, 4.2.3.7, 4.2.3.9, 4.2.3.12 ISO/IEC 27001:2013 A.12.6.1, A.18.2.3 NIST SP 800-53 Rev. 4 CA-2, CA-7, CA-8, RA-3, RA-5, SA-5, SA-11, SI-2, SI-4, SI-5
		ID.RA-2: Cyber threat intelligence is received from information sharing forums and sources	CIS CSC 4 COBIT 5 BAI08.01 ISA 62443-2-1:2009 4.2.3, 4.2.3.9, 4.2.3.12 ISO/IEC 27001:2013 A.6.1.4 NIST SP 800-53 Rev. 4 SI-5, PM-15, PM-16

Framework Profiles: The profiles show the alignment of an organization's risk tolerance and commercial requirements with the outcomes in the Framework Core. Organizations can identify their Current Profile by assessing which outcomes from the Framework Core are currently achieved. Next, the Target Profile for reducing cybersecurity risks can be established considering the company's business-specific needs and cyber-risk tolerance. After the Current and Target Profiles are identified, an action plan can be prepared to bridge the gaps starting from the business priorities.

3 Implementation of the Selected Cybersecurity Framework

As the FICIC by NIST has been developed to suit the needs of various industries and work environments, it includes different generic categories and subcategories that must be customized for specific applications. For this study, a hypothetical scenario was created considering the ongoing adoption of new technologies in construction sites, and the customization of the framework was performed based on this scenario. The scenario assumes a construction site that utilizes AEE to support earthworks activities. AEE is chosen for the hypothetical scenario since automating repetitive earthworks tasks has been a trending construction automation topic in the last decades. The mining industry was one of the first to employ the use of self-driving tech. For instance, Caterpillar started with its automation program more than 30 years ago. More recent examples include the works by [21] that proposed using a time-delayed neural network architecture for automatic bucket-filling and demonstrated it with a wheel-loader and [22] that introduced an autonomous excavator system that can perform earthmoving tasks for long durations without any human intervention. In addition, heavy equipment manufacturers, such as Komatsu and Caterpillar, and

start-ups such as Built Robotics, are working on making self-driving bulldozers and excavators common on construction sites.

3.1 Hypothetical Construction Site with an Autonomous Earthmover

The hypothetical construction site considered in this study is presented in a diagram shown in Figure 2. Different elements of the diagram and their roles in the hypothetical scenario are explained as follows:

A. Control Room: The control room serves as a bridge between the autonomous equipment and the technical office. There is an operator in the control room who manages the human-machine interface. As the monitored equipment is assumed to be autonomous—not semi-autonomous or teleoperated—the human-machine interface (HMI) aims to provide interactive oversight over the equipment’s actions and allows the operator to intervene only when necessary [23]. Therefore, the operator can simultaneously manage multiple machines by following the notification system without actively monitoring all of them [23].

B. CDE: The CDE of the construction project provides a centralized platform for simultaneous data exchange between different stakeholders. The HMI is connected to the CDE and the AEE via a wireless communication network. The type of wireless network is assumed to be 5G due to the low latency and high mobility requirement [24].

C. Technical Office: The technical office exchanges data with the HMI over the CDE. For example, the HMI can receive the BIM model from the CDE and send the required directions to the AEE related to the excavation and fill operations to be executed based on the information and requirements from the BIM model and planned schedule. Similarly, the technical office can access the excavation/fill amount performed by the AEE to date (and in real-time).

D. AEE: As suggested by [8], it is assumed that the control system of the AEE has three main units, namely the vision unit, control unit, and execution unit. The vision unit receives data from the Light Detection and Ranging (LiDAR) system and cameras placed on the AEE for object detection and collision avoidance and passes the collected data to the control unit for further processing. The execution unit receives data from the real-time location systems (e.g., Global Positioning System (GPS), Ultra-Wideband) for accurate positioning [25] and from the pressure sensors to measure the reaction forces on the bucket [21]. The control unit conveys the vision unit data and the execution commands received from the HMI to the execution unit. Finally, the execution unit sends the required commands to the actuators (e.g., boom actuator, arm actuator, bucket actuator), steering, brakes, and accelerator.

E. Other equipment and workers on-site: The AEE interacts with other equipment and workers on-site, which increases the significance of providing robust cybersecurity for the communication network.

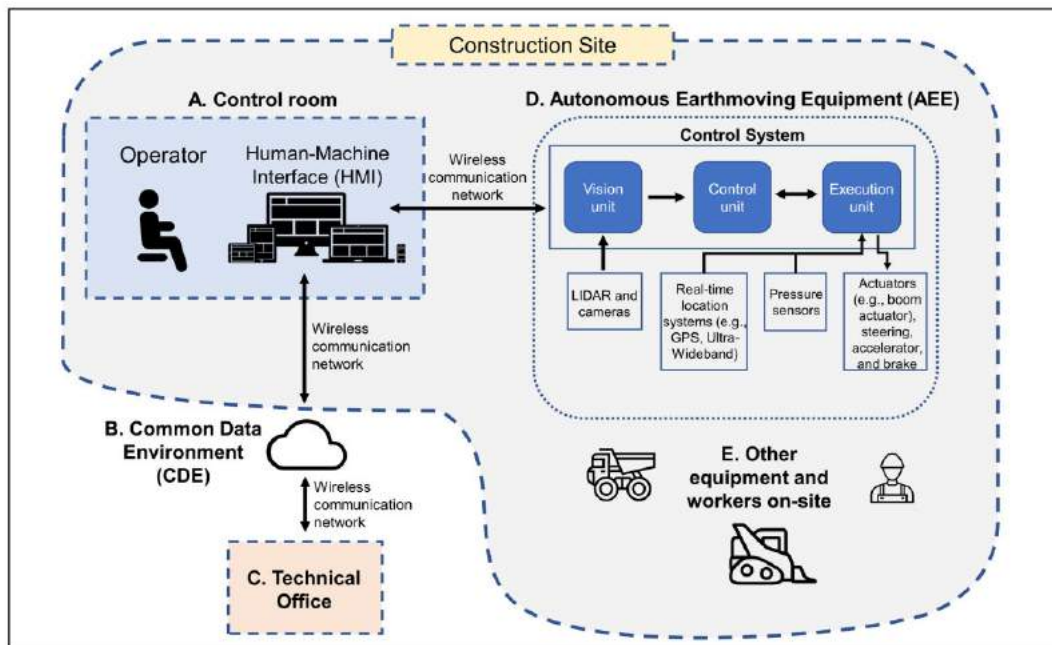

Figure 2. Diagram of the different components for the hypothetical construction site used in this study

3.2 Customization of the Framework

To customize the Framework Core, initially, the most relevant categories from each function and the most suitable subcategories from the selected categories were selected considering the characteristics of the hypothetical construction site. The selected categories and subcategories are shown in Table 2. This study does not intend to go over all functions, categories, and subcategories but to show a couple of applications as examples. In particular, the number of selected subcategories chosen was nine (Table 2). Of course, in real-life applications, these categories and subcategories can be extended to cover a broader range of cybersecurity aspects and increase the assessment's accuracy depending on the project needs.

Table 2. Selected Subcategories for Customization

Function	Category	Subcategory
IDENTIFY (ID)	Asset Management (ID.AM)	ID.AM-5: Resources (e.g., hardware, devices, data, time, personnel, and software) are prioritized based on their classification, criticality, and business value
	Risk Assessment (ID.RA)	ID.RA-1: Asset vulnerabilities are identified and documented ID.RA-3: Threats, both internal and external, are identified and documented
PROTECT (PR)	Identity Management, Authentication and Access Control (PR.AC)	PR.AC-1: Identities and credentials are issued, managed, verified, revoked, and audited for authorized devices, users and processes
	Maintenance (PR.MA)	PR.MA-1: Maintenance and repair of organizational assets are performed and logged, with approved and controlled tools
DETECT (DE)	Anomalies and Events (DE.AE)	DE.AE-2: Detected events are analyzed to understand attack targets and methods
	Security Continuous Monitoring (DE.CM)	DE.CM-1: The network is monitored to detect potential cybersecurity events
RESPOND (RS)	Response Planning (RS.RP)	RS.RP-1: Response plan is executed during or after an incident
RECOVER (RC)	Recovery Planning (RC.RP)	RC.RP-1: Recovery plan is executed during or after a cybersecurity incident

Following the selection of the categories and subcategories, an additional column was added to the Framework Core to include questions, which is not included in the original FICIC. These questions aim to assess the implementation level of the outcomes in each subcategory and transform the Framework Core into a

checklist format. Thus, the utilization of the framework becomes more practical, and the evaluation of the different cybersecurity practices being implemented is facilitated.

Several questions were created by going through the provided informative references. For example, two questions were created for the subcategory "ID.RA-1: Asset vulnerabilities are identified and documented" under the Risk Assessment category in Identify function (Table 3). Initially, each informative reference provided in the Framework Core for the subcategory "ID.RA-1" was scrutinized to find the appropriate options for the demonstrated construction site scenario in Figure 2. The Framework Core provides five different documents and their relevant sections for this subcategory. Two sections from two different documents were selected for creating Q3 and Q4 presented in Table 3: Section 4 (i.e., Continuous Vulnerability Assessment and Remediation) of the Center for Internet Security (CIS) Critical Security Controls (CSC) and Section CA-8 (i.e., Penetration Testing) of NIST SP 800-53 Rev. 4. The former suggests scanning the network for vulnerabilities with an automated tool on a weekly basis or more often. The latter recommends conducting penetration testing on the required systems with an organization-defined frequency. The mentioned suggestions were converted into questions to evaluate the security of the network that connects the HMI and AEE (Figure 2) on the hypothetical site, considering this connection's safety-critical role. Table 3 shows Q3, Q4, and four other questions created with the explained logic.

The questions created during the customization of the framework have a crucial role in developing a cybersecurity assessment checklist. However, the assessment also needs to provide a structured way to answer these questions to interpret the results better. Therefore, the following subsection proposes an evaluation method to address this need.

Table 3. Section of the customized Framework Core with questions

Function	Category	Subcategory	Informative References	Questions
IDENTIFY (ID)	Asset Management (ID.AM)	ID.AM-5: Resources (e.g., hardware, devices, data, time, personnel, and software) are prioritized based on their classification, criticality, and	NIST SP 800-53 Rev. 4 SA-14	Q1. Is there a functional criticality analysis in place to assess the most critical components of the network that connects the AEE and HMI?
			CIS CSC 14	Q2. Do all network switches allow Private Virtual Local Area Networks (VLANs) to limit the communication between the components of the AEE and the private devices connected to the same network?
	Risk Assessment (ID.RA)	ID.RA-1: Asset vulnerabilities are identified and documented	CIS CSC 4	Q3. Is there an automated vulnerability scanning tool employed to scan the network that connects the AEE and HMI on a weekly-basis?
			NIST SP 800-53 Rev. 4 CA-8	Q4. Does the organization conduct penetration testing on the network connecting the AEE and HMI in a monthly basis to detect potential vulnerabilities?
		ID.RA-3: Threats, both internal and external, are identified and documented	NIST SP 800-53 Rev. 4 PM-16	Q5. Is there a threat awareness program in place to inform the employees about the constantly changing threat environment targeting the CPSs utilized on construction sites?
			NIST SP 800-53 Rev. 4 PM-12	Q6. Is there an insider threat program in place to continuously monitor critical systems (including the systems linked to the AEE) and detect potential malicious insider activity?

3.3 Evaluation Method

For assessing the cybersecurity implementation level

of the construction site, a score-based evaluation method is proposed in this study. According to the proposed method, there are five different implementation levels to

be selected in response to each question under each subcategory. The Implementation Tiers of the FICIC were partially considered while deciding on the implementation levels in the score-based evaluation method. These implementation levels and the corresponding scores can be seen in Figure 3.

SCORECARD	
0	No awareness
1	Awareness without implementation
2	Partial implementation
3	Full and repeatable implementation
4	Adaptive Implementation

Figure 3. The scorecard to be used for evaluation

Different scores presented in Figure 3 are explained as follows:

- 0** – There is no awareness about the mentioned cybersecurity practice.
- 1** – There is awareness about the mentioned cybersecurity practice; however, there is no current implementation.
- 2** – The mentioned cybersecurity practice is not formalized but partially implemented and utilized on an ad-hoc basis.
- 3** – The mentioned cybersecurity practice is formally approved and updated regularly.
- 4** – There is a continuous adaptation of the mentioned cybersecurity practice into the changing threat landscape. Lessons learned and predictive tools are utilized to improve the implemented practices.

The average scores for each category and subcategory are calculated and used to identify gaps between the current practices and targets. The score-based evaluation also allows obtaining a qualitative overview of different cybersecurity practices' current implementation levels (i.e., low score = low implementation level, and vice versa), thus channeling resources into the required areas and prioritizing cybersecurity actions.

3.4 Demonstration of the Evaluation Method

A demonstration of the evaluation method described in the previous subsection is presented in Figure 4, considering the hypothetical construction site. The responsible person for the cybersecurity assessment on-site is assumed to conduct this evaluation, and his/her hypothetical scores are shown in Figure 4.

The scores shown in Figure 4 indicate the implementation levels of the cybersecurity practices covered in each category and subcategory. For example, according to the scores in Figure 4, the Asset Management-related cybersecurity practices are implemented at a lower level—1.5 on average—than the ones related to the Risk Assessment—2.25 on average. Based on the scores and the organization's priorities, a

roadmap can be developed to improve the low-scored cybersecurity practices and achieve the target levels.

Function	Category	Average Category Scores	Subcategory	Average Subcategory Scores	Questions	Scores
IDENTIFY (ID)	Asset Management (ID.AM)	1.5	ID.AM-5	1.5	Q1	1
					Q2	2
	Risk Assessment (ID.RA)	2.25	ID.RA-1	3	Q3	3
					Q4	3
			ID.RA-3	1.5	Q5	2
					Q6	1

Figure 4. Demonstration of the evaluation method

4 Discussion and Limitations

The customization of the framework—including the questions created for each subcategory—and the proposed evaluation method—that was not included in the original framework—provides an efficient way to assess the implementation levels of different cybersecurity practices on construction sites that utilize OT. As demonstrated in Section 3.4, the assessment results aim to guide the organization to set a roadmap towards a more secure construction site. Scores for each question lead to the average scores of subcategories and categories, as shown in Figure 4.

The average scores show where the construction site stands in terms of the evaluated cybersecurity practices. However, the scores by themselves are not sufficient for a thorough evaluation. Deciding on the actions to improve the current cybersecurity level also requires setting target levels for each practice. These targets can be set by the cybersecurity experts and the project management team based on the priorities and risk appetite of the organization. In this study, a methodology for setting targets is not provided, which is a limitation. Another limitation is using equal weights for each question, subcategory, and category. Assigning different weights for each aspect would lead to a more comprehensive evaluation. Finally, having one person conducting the assessment instead of a group of evaluators with mixed backgrounds reduces the accuracy of the results.

5 Conclusions and Future Work

There has been a lack of attention from the industry and academia towards the cybersecurity aspects of the construction industry. Moreover, to the best of the authors' knowledge, the implementation of cybersecurity frameworks on construction sites has never been discussed in the previous studies. Therefore, this study targets to raise awareness about the potential cybersecurity vulnerabilities of construction sites—that

are increasingly interconnected and automated—and points out the need for customized cyber assessment frameworks to evaluate these vulnerabilities and mitigate them. With this purpose, an implementation of a generic cybersecurity framework (i.e., the FICIC by NIST) that assesses the employed countermeasures against the construction-specific cyber threats was presented in this paper. The implementation included customizing the existing framework (i.e., selecting the necessary categories and subcategories and adding questions to each subcategory), proposing a score-based evaluation method—which was not included in the original document—and demonstrating the assessment on a hypothetical construction site that utilizes AEE.

Future work will extend this study to include a complete evaluation, covering more subcategories, categories, and functions. Also, a more comprehensive scoring system—where each cybersecurity aspect has an individual weight, and a mixed group of evaluators conducts the assessment—will be proposed for more accurate results. This paper did not include an implementation on a real construction site since the primary purpose was to direct the attention of the industry and academia towards the potential cybersecurity issues on smart construction sites and introduce the authors' approach to address these problems. However, a case study that implements the complete evaluation on a real site will be conducted in future work to present more concrete findings.

Abstract

Construction management can be grouped into two different levels: strategic early planning, that provides the baseline for project monitoring, and short time initiatives, based on objectives and self-organization from actors who are involved in on-site processes.

This is currently managed through the representation of many separate processes and this does not eliminate the inefficiencies that arise at the level of synchronization of the individual tasks performed by different organizations. Efficiency in construction management implies to take into consideration choreographies because they better reflect synchronization of different organizations management processes.

On the other hand, smart contracts linked to single task execution assure both promptness and irreversible tracking at single task level. The actual execution of processes depends both on what happens and on the information that flows between the subjects who actually carry out processes asynchronous to each other, so the only possibility to synchronize them is information.

This research describes a framework for applying BPMN choreographies to construction site processes in order to better model processes and integrate them with smart contracts. Every single activity in the baseline can be modelled as a choreography at a lower level. On the other hand, process performance monitoring can be performed thanks to blockchain tasks notarization.

Concrete casting quality assessment process has been chosen as use case. A BPMN choreography has been defined for this purpose and blockchain application for accomplished tasks and information notarization has been developed and tested on a construction site.

Keywords –

Smart contracts, Process modeling, Process management, BPMN Choreographies.

1 Introduction

Construction site is notably a distributed environment, where each participant is responsible for running its own activities as well as business processes with tools of its choice. The passage from project scheduling to on site operations management requires a change of perspective. The latter can be considered as a complex system management issue since it presents emergent behaviors thus it can not be handled in a traditional way.

Full adoption of digitalization on the other hand asks for a better management of data, where issues like provenance tracking, traceability and record keeping are resolved [1]. Blockchains are candidates to be tools able to guarantee these requirements and smart contracts are successfully used to enforce compliance with the agreed process steps. Reasons for this success lie mainly in the fact that blockchains and smart contracts are technologies enabling decentralization of operations, better transparency, and immutability of stored information. This is implied by the fact that smart contracts must be verified by a community of independent verifiers in order to be executed[2].

This work proposes an approach to process management in the construction domain where all relevant data and events produced by different participants are stored immutably. Therefore, the solution proposed in this work is characterized by the following aspects:

1. the use of blockchain, which overcomes the need for manual data recording and ensures reliability in notarizing events;
2. the need for a domain expert formalizing choreographies of processes, checking the

- compliance of the lookahead plan, and deploying the automatically generated smart contracts on the blockchain;
3. the feasibility study of the proposed process starting from the formalization of the choreography to the application to a real case in the production and verification processes of concrete specimens.

2 Literature review

2.1 Blockchain based construction management on-site

Construction management includes the optimization of on-site operations by planning, scheduling and controlling building processes. Many scheduling methods and approaches have been proposed to manage efficiently construction, and lean production philosophy seems to be the roadmap to follow. Koskela [3] claimed the need of new conceptualization of construction that views production as a flow of materials and information to the end product. Following this philosophy, Ballard and Howell [4] proposed a new approach to construction production, and later Ballard [5] developed the Last Planner System (LPS) that performs work structuring in the control stage i.e. the process of activity identification, sequencing and scheduling. Ballard [5] proposes a scheduling process articulated into four levels of detail (Master Schedule, Phase Schedule, Look-ahead Schedule and Weekly Plan). The lookahead schedule is the most important element of the workflow control system and covers the next 3 to 12 weeks, entailing the current Weekly Work Plan.

Distributed ledger technology (DLT), or Blockchain is frequently presented as a driver of innovation in the construction sector [6]. Blockchain is a distributed ledger based on the internet. When a transaction is broadcast to the network it is received by all nodes who validate and verify its existence through a sequence of pre – defined checks [7]. Smart contracts is one major application of Blockchain in construction. It is a computerized transaction protocol that executes the terms of a contract [8]. Smart contract has the goal of satisfying common contractual conditions while minimizing exceptions and the needs of trusted intermediaries, lowering transaction costs. This tool with blockchains could be part of the solution for interlinking work processes, stakeholders and assets' life cycle phases [9]. Blockchain is also often seen as a perfect tool for improving trust among actors involved in the construction process [10]. A thorough review of blockchain potentials in literature has been provided by the Construction Blockchain Consortium [11], which

mentions transparency of transactions and reliability of data flow across the distributed supply chain among the most desired benefits induced by the integration of blockchains with the existing ecosystem of IT infrastructures and services in the AEC industry.

2.2 Choreographies notation for managing construction

Process-based simulation and planning are innovative techniques in the field of construction projects management. After several years of research, tools and methodologies have been developed and applied to concrete case studies, proving their effectiveness [12,13,14,15]. Compared to traditional techniques, based on PERT diagrams and Gantt charts, process-based techniques allow the generation of plans that take into consideration constraints imposed by using available resources (e.g. limited availability, non-overlapping tasks using the same resource, etc). So far, researchers focused on project management using Collaboration diagrams, using the BPMN Process notation.

Such diagrammatic representation is more suitable in case the project manager knows the internal details of the processes involved in the overall project. Construction projects, on the contrary, are examples of complex systems, where most of the internal details of involved processes are hard to elicit. For this reason, BPMN Choreography diagrams have been introduced as part of the BPMN 2.0 formalism by the Object Management Group [16]. Such diagrams more conceived about information exchange gives necessary freedom for organizations to better organize their internal processes.

Thus, BPMN Choreography Diagrams represent how the participants should interact, without introducing details on the specific process implemented by each participant. In case several suppliers or collaborators, that are external to the organization, participate in the construction process, the project manager can agree with them the expected information to be provided, the logical order in which they should be provided, and the time constraints when they should be provided; on the other side it is not necessary to know the internal steps taken by the supplier or collaborator, in order to provide such information. To the best of our knowledge, BPMN Choreography diagrams have not been used to coordinate the participants of a construction process, but several researchers have developed techniques and tools combining BPMN Choreography diagrams with the smart contracts executed on the Ethereum blockchain in order to notarize the execution steps of the processes

implementing the choreography, as well as ensuring that the choreography will be executed by the participants as expected [17, 18, 19].

2.3 Research questions

The fragmented world of construction involves the interaction of multiple parts from the design phase through construction till operations. During construction, in fact, multiple players participate simultaneously, which raises the question of trust between the parties and traceability of performed tasks.

In addition, on-site planning can differ from programmed planning because of instances arising from the interaction of different actors.

In the light of the just defined scenario, this research aims to respond to the need of formally represent site processes and of the notarization of the key processes steps. This is done by using the lookahead plan, well-known in construction, and translating it into a BPMN of processes. These BPMNs then act as a railway for the blockchain service as a means of traceability and reliability of information exchange among construction participants.

3 Methodology

Figure 1 depicts the steps of the adopted methodology. The *Choreography Definition* step analyses laws and regulations as well as international standards in order to specify how participants should interact in order to reach the overall task. In particular, it sets the documents or artifacts that are supposed to be exchanged and their expected appearance along the execution. This step is conducted by a domain expert, who collects the knowledge and represents it as a BPMN Choreography diagram. From the choreography, a smart contract written in Solidity is automatically generated and deployed on the Quorum blockchain. The *Lookahead Planning* is a responsibility of the project supervisor that, for the specific project, coordinates and schedules the on-site and off-site activities using, indeed, a lookahead plan. The lookahead plan contains detailed information about the actions to be taken by each participant, and the days when such activities are going to happen. In our methodology, the lookahead plan is extended in order to convey additional information about what documents or artifacts each participant is

expected to *produce* or *consume*, at any given activity. An example of the extended format of the lookahead plan will be given in Fig. 2. The next step is *Conformance Checking*, where the lookahead plan is compared against the choreography. This comparison yields a *positive* answer in case the participants and activities in the lookahead plan produces and consumes documents and artifacts in some order that is compliant with the given BPMN choreography. The conformance checking can be either done manually or automatically: the key idea is that the lookahead plan describing the scheduled activities can be translated onto a BPMN collaboration diagram, and the latter can be checked for compliance against a BPMN choreography using model checking algorithms [17]. In case of a negative answer, it means that the designed lookahead plan breaks laws or regulations described in the BPMN choreography, thus activities must be re-scheduled.

Finally, the *Monitoring and Notarization* step monitors the activities executed by the participant in their processes and stores the relevant information about their execution on the blockchain through the smart contract deployed in the first step.

Let us underline that the proposed methodology has two steps marked as initial, viz. *Choreography Definition* and *Lookahead Planning*. The former is taken the first time that the knowledge about laws and regulations is encoded as a BPMN choreography, and every time it changes. The latter is taken at the beginning of each construction project, and every time the project activities require a re-scheduling.

The methodology has been tested on a real case study using a prototype architecture implementing the aforementioned steps and interacting with the users using a web interface.

3.1 Choreography definition

A model of the inspection procedures of ready – mix concrete testing have been proposed with Business Process Modelling and Notation (BPMN) 2.0 language.

The latter is a process description language that use a flow – chart machine-readable notation. Basically, it allows to map the visual description of a process in the appropriate execution language. The advantages offered by BPMN are the following:

- flow charts to represent business and production processes;

Figure 1 - Methodology steps definition

Figure 2. The lookahead plan improved with the communication features

- standardization of flow charts components, that facilitates communication;
- a human comprehensible representation of constructs defined in software-execution language.

BPMN can be used to present three main categories of processes: orchestration, collaboration and choreography.

Orchestrations are a standard process descriptions involving a single entity executing its own tasks. Collaborations describe the interaction of several actors, attaching to each of them an orchestration. Choreographies, instead, shows only the interaction points between participants and focuses on message flows (Fig. 3).

The most important players involved in the choreography of the ready-mix concrete inspection are: Project supervisor, Site supervisor, Construction Company, Concrete supplier. Other players involved are the owner, the official tester and the local building office. The inspection procedure involves a complex set of activities, sequences and feedback processes, communication and issue of documents, as depicted in Figure 3. Starting from the mandatory steps and responsibilities identified by the NTC2018 the process has been modelled focusing on the information exchange.

3.2 Lookahead planning

The lookahead plan [5] is a construction stage bar chart developed by the contractor that has a time range of 4 to 6 weeks. In the Lookahead plan construction activities and single tasks are scheduled considering the needed resources.

The following set of information can be found in the lookahead plan: activities and tasks, activity timing, participants and operational resources, activity needs (predecessors, materials, tests).

The choreography definition of the inspection procedure for the selected case study needs the addition of a set of information concerning each activity. Therefore, for each activity IN and OUT information have been added, with the objective of highlighting communication needs of the inspection procedure. The lookahead plan improved with the communication features of each activity can be found in Figure 2. Activities are grouped by construction resources, i.e. crews.

3.3 Conformance checking

The lookahead plan contains enough information for describing the actual construction processes happening on the field. It is immediate to encode the information of the lookahead plan as a BPMN Collaboration diagram: for each crew appearing in the lookahead plan, a separate BPMN Process lane is drawn, combining the sequence of activities mentioned in the lookahead plan itself. Activities are mapped onto tasks, in the BPMN diagram, and whenever two or more activities can happen on the same day, they are translated onto tasks that are executed in parallel, using the BPMN parallel gateway. Whenever an activity A must be finished before another activity B can start, then task A is followed by task B. If two or more activities (e.g. A1, A2) must finish before the task B can begin, then tasks A1, A2 are joined together using a parallel gateway with several incoming connectors and one outgoing connector towards task B.

The input and output messages mentioned in the *Information* column are used to discriminate whenever a task is expected to throw a new message (OUTPUT) or to catch a message generated by another participant (INPUT).

A successive step is checking whether the BPMN Collaboration diagram fulfils the given BPMN Choreography diagram. In fact, the former contains the precise sequence of tasks and events that throw and catch the messages mentioned in the Choreography diagram. During the conformance checking phase, the project supervisor verifies (1) whether the sequences of messages thrown and caught as specified in the BPMN Collaboration diagram satisfy the order of messages given in the BPMN Choreography diagram, and (2) whether each message is thrown following the associated task, and is caught just before the begin of the expected task. This task can be automatized by using model checking algorithms [5].

3.4 System architecture

The proposed methodology has been tested using a prototype system that uses smart contracts on a Quorum blockchain to monitor the activities of processes happening on the site. The main architectural components of the system are as follows:

Ethereum Virtual Machine. It allows a local node to deploy new Smart Contracts on the Blockchain, and interact with them.

Smart Contract Generator. It translates a BPMN choreography diagram onto a smart contract written in Solidity ready to be compiled and deployed onto a Quorum blockchain.

Smart Contract Compiler. It allows to compile a smart contract written in Solidity onto the bytecode language interpreted by the Ethereum Virtual Machine.

Business Process Execution Engines. Each organization involved in the activities happening on the construction site, execute their own BPMN processes using their favourite BPMN execution engine.

Smart Contract Connector. It is a driver connecting the Business Process Execution Engine chosen by the organization and the Smart Contracts deployed on the Quorum Blockchain, through the Ethereum Virtual Machine. Whenever a choreography action is required the Smart Contract Connector invokes the smart contract to check whether the required exchange is compliant with the choreography encoded in the smart contract itself. In case of positive answer, the Smart Contract Connector enables the Business Process Execution Engine to do so, otherwise the connector raises an exception that will be handled by the Business Process Execution Engine.

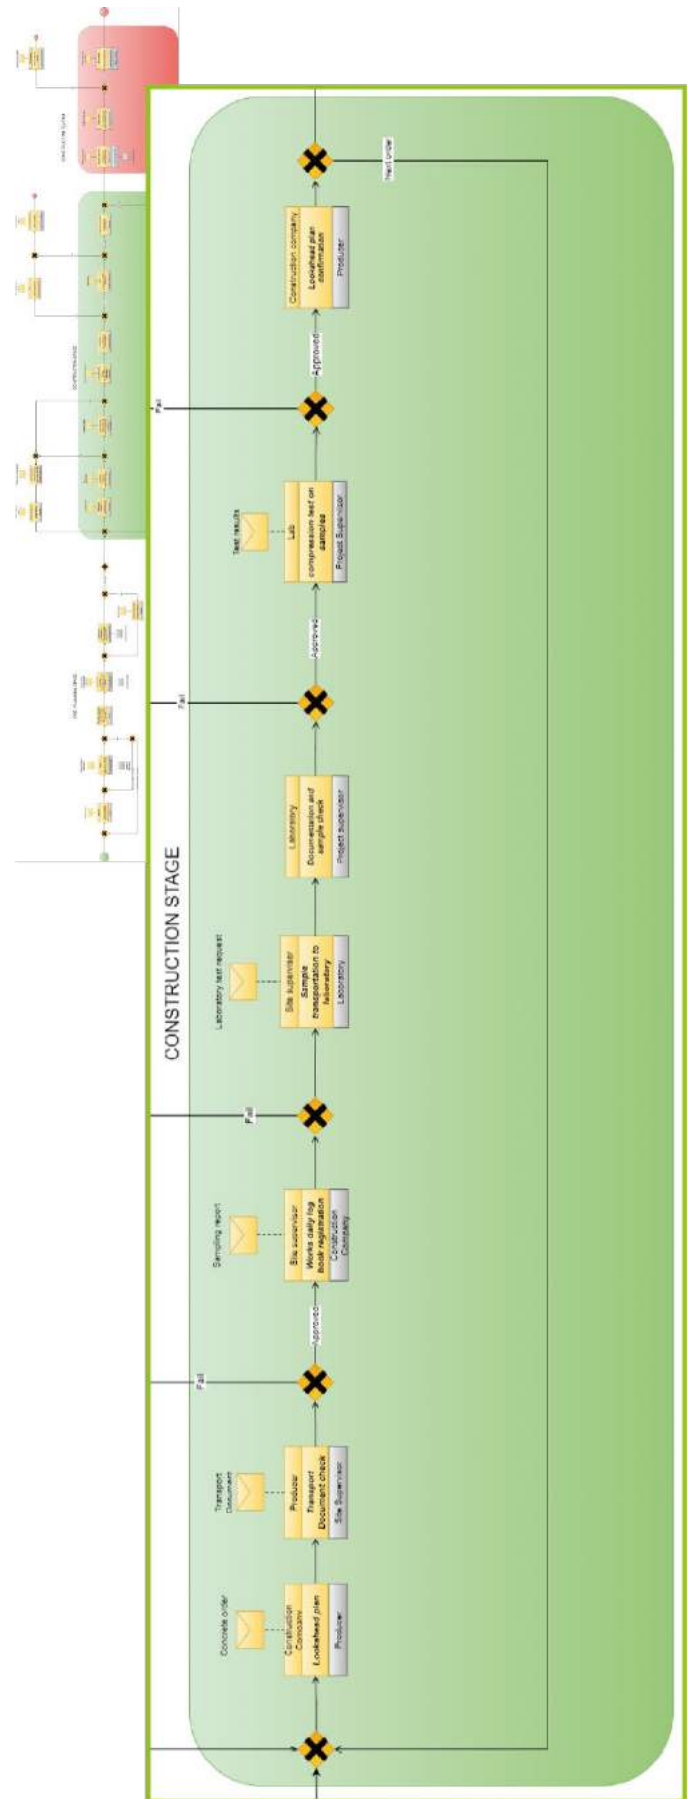

Figure 3 - Concrete test on site choreography BPMN process.

The overall system implements a so-called DApp (Distributed Application), where each organization runs its own instance of the Business Process Execution Engine, and all such instances synchronize among themselves using a single instance of smart contract deployed and running on the nodes of the Quorum blockchain. The smart contract is signed and deployed on the blockchain, thus its state is accessible to all the participants of the construction contract and not accessible to any other participant in the Quorum blockchain.

By the very definition of Quorum smart contract, each allowed participant can inspect the state of the smart contract itself at the same level of detail. This ensures that no participant is in the position of hiding information to the others, thus no participant can become a bottleneck of the information flow during the construction activity.

3.5 Case study

The inspection of ready-mix concrete cast-in-place process is analysed as sample case study. The cast-in-place of concrete in formworks is a very common construction sub-process, and the project supervisor must perform contract-based and regulation-based quality tests. The inspection procedure is characterized by many correlated sub-processes and implies a remarkable modelling complexity. Furthermore, the

inspection of ready-mix concrete cast-in-place is a critical task for detecting a building structure quality and therefore needs to be assessed by several documents, following national standards, regulations and guidelines. The case study of the construction of a large warehouse building in northern Italy has been used to test the proposed method. The warehouse building structure is made of prefabricated components of reinforced concrete and has a one / two storey hall-like shape. The load bearing structure is made of a prefabricated reinforced concrete frame system (columns and beams), the envelope is made of reinforced concrete prefabricated wall panels and corrugated roof metal slabs. The foundations are individual spread footings for each column, joined together by ground beams, made of reinforced concrete. The project quality test of the conversion process of ready mix cast-in-place reinforced concrete construction of the foundations has been used to test the proposed system. The inspection procedures are defined by the Italian technical regulation of construction [20]. The ready mix quality test consists in taking a sample of concrete during pouring operations. A cube – shape formwork, of 150 mm of side is filled with concrete, delivered to an accredited structural mechanics laboratory. According to the regulation then the laboratory will perform a compression resistance test on the sample after 28 days from the preparation and not

The screenshot shows a web application interface for a workflow task. The interface is divided into three main sections: a sidebar, a main content area, and a right-hand panel.

- Sidebar:** Contains a navigation menu with items like 'Workflow', 'Inbox', 'Unassigned', 'Participated', and 'Processes'. The 'Workflow' item is currently selected.
- Main Content Area:** Displays a task titled 'Concrete samples'. It includes a 'FILE' button, a 'skip' checkbox, and a 'NOTES' section. The task details show 'Latitude: 43.5942' and 'Longitude: 13.5034'.
- Right-hand Panel:** Contains two sections:
 - Concrete Sample Process #11:** Shows details for the current task, including 'Flow: Concrete samples', 'Status: NEW', 'Created: July 19, 2021, 9:31 a.m.', and 'Name: CANTIERE TEST'.
 - Supplier #11:** Shows details for the supplier, including 'Created: July 19, 2021, 9:31 a.m.', 'Modified: July 19, 2021, 9:31 a.m.', 'Name: Gregoriotti Edilizia', 'Vat / Fiscal Code: 256630104', 'Address: via Circonvallazione 6', 'City: Ancona', 'Zip: 60124', and 'Country: Italy'.

Figure 4. Web app screen of transport document request

later than the following 45 days. The aim of this first application is to test the notarizing process system with the delicate process of concrete mixing test that involves different figures and presuppose trust.

The choreography designed for the case study (see Fig. 2) involved 8 actors: Designer, Owner, Project Supervisor, Municipality, Construction Company, Concrete Supplier, Site Supervisor, and Laboratory. It includes 21 user tasks, one start event, two terminating events, 15 parallel gateways, 41 flow arrows connecting tasks and gateways among themselves, 17 produced documents and 4 returned receipts.

4 On-site feasibility test

The experiment conducted at the site involved notarizing all steps of the concrete testing choreography. A web application was developed to allow notarization of the various steps on site directly via smartphone or tablet. The part of the entire modeled choreography that was possible to test live on site begins at the arrival of the concrete mixer truck and is highlighted in green in Fig. 2.

The web app requires a log-in procedure so it presents different screens depending on whether the person logging in is the project supervisor or the lab performing the testing for example. Once the new process has been created, the first information to be noted is that concerning the concrete supplier company. In Figure 4 it is possible to notice that in this phase also the transport document can be uploaded as an image and then sent to the blockchain service to be stored immutably.

At this point we proceeded with the actual formation of the concrete specimens whose images can be seen in Figure 5. It was possible to upload and notarize a picture of the tested concrete specimens in the application.

In the case study a sample concrete cube from the truck mixer has been prepared during the pouring of a spread footing of the foundations of the building.

To the aim of digitalizing the testing process a RFID digital tag has been used to identify the cube sample. The RFID tag has the size of a coin and has to be placed on the surface of the concrete cube.

In this case the photo, Figure 5, was particularly useful because the concrete specimens were provided with an RFID tag in order to verify their identity once transported to the laboratory. The photo is therefore useful to verify the correct positioning of the tag.

Finally, the reading of the RFID tag together with the geographic coordinates of where it happened have been notarized by reporting the identification code of the passive instrument inserted in the specimen.

The last document of this part of the process to be noted is the report of the results of the compression test of the concrete mix. The test aimed at demonstrating the feasibility of the presented methodology. It should be specified that prior to the on-site test, training was given to the figures involved, with particular reference to the project supervisor, who was in charge for carrying out most of the operations.

5 Conclusions

The introduction of a rigorous translation of construction industry processes through standards is still slow in coming while it could be a valuable tool within a sector characterized by high fragmentation. The aim of this work has been to propose a methodology to integrate process modeling through BPMN with smart contracts. This has the advantage of being able to attest reliability and accountability in the completion of tasks. Starting from the case study that in this case has focused on the construction phase and in particular on a delicate process rich in infiltration as concrete quality control, a blockchain has been proposed for the notarization of the information flow.

For modeling of construction management processes, we started from the application of traditional tools such as the lookahead plan and then proceeded to the translation into BPMN. The first process modeling made use of BPMN Collaboration then translated to BPMN Choreography since the latter representation better mimics the structure of construction industry. In our case study, compliance between the BPMN Collaboration diagram and the BPMN Choreography

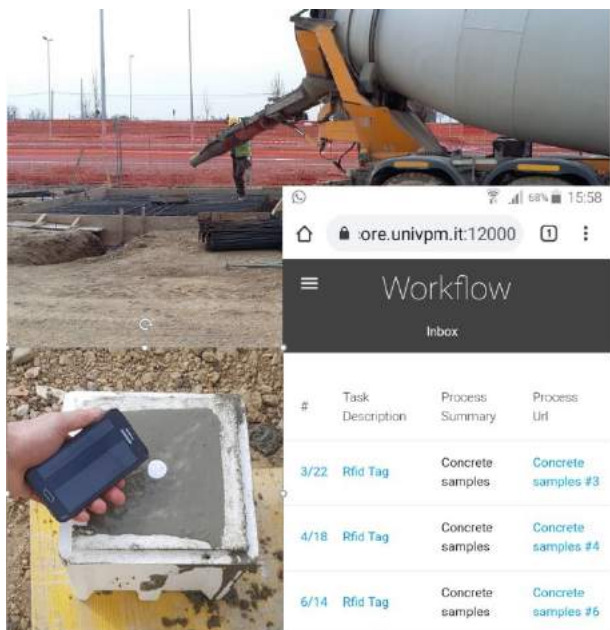

Figure 5. Clockwise from top to bottom: concrete mixer for casting concrete foundations; webapp for blockchain; on site concrete specimen with rfid read with smartphone.

diagram was conducted manually. We leave as future research the implementation of automated procedures to conduct this comparison.

A web application was then developed to map the modeled process to annotate the flow of information between the different actors in the process, which in this case were the project supervisor and the testing laboratory.

The whole proposed system was tested in a construction site in northern Italy in order to evaluate the feasibility on site and to investigate possible fraud attempts. While this test focused on a specific choreography of processes, the presented methodology can easily be applied to other construction processes, in order to test its extendibility and effectiveness.

Abstract –

Construction automation helps to improve productivity and project performance. This study demonstrates a methodology for evaluating project performance improvement through appropriate automation of construction processes. This quantitative evaluation approach involves a compositional modeling driven case-based reasoning methodology. Potential processes for executing the activities in a project can be explored by generating combinations of process fragments compiled from cases. This approach is demonstrated through an example of RCC column construction. It is shown that a large number of processes are possible even for simple tasks and a systematic procedure for evaluation is necessary for identifying the appropriate level of automation.

Keywords-

Case Based-Reasoning; Compositional Modeling; Discrete Event Simulation; Automated Construction; Level of Automation; Therbligs; Project Performance Improvement

1 Introduction

Automated construction has been gaining attention in the recent past because of the success of robots in other fields such as manufacturing. With growing urbanization and housing deficit in many countries, automation in construction is a promising approach. In spite of the general consensus that automated construction reduces time and cost, there is not enough research in quantitative methodologies for evaluating productivity improvement through implementing appropriate automation in construction. The broad aim of this research work is to develop a systematic methodology for productivity analysis of automated construction processes. The study specifically explores the use of simulation tools to predict productivity improvement through creating multiple processes by combining process fragments from a case

base.

2 Literature Review

Simulation based performance analysis of construction projects has gained renewed interest in the recent past. Literature shows the usage of simulations in a variety of projects [1-6]. Discrete event simulation tools involving time-cost studies have been utilized for construction project performance improvement [7-10]. However, there has been limited focus on quantitative evaluation of automated construction processes [11].

An important research question is: How do you identify the optimal level of automation in construction such that there is maximum improvement in project performance?

The present DES approaches are unable to perform simultaneous analysis of multiple construction process fragments which makes the task of identifying appropriate automation challenging. The representation of non-static construction processes in DES for simulating and identifying appropriate level of automation is a significant knowledge gap in literature.

This paper introduces a methodology for addressing this knowledge gap. The novelty of the present work is in resolving the challenge of representing, modeling, and simulating non-static construction processes. This addresses “the search and explore based approach” of simulating construction operations for identifying appropriate levels of automation which would lead to overall project performance improvement through time-cost optimization.

3 A Methodology for Productivity Assessment in Automated Construction

A compositional-modelling driven case-based reasoning methodology is developed for accomplishing the objectives of this study (Figure 4). It involves discrete event simulations for the calculation of the duration taken

for activities to complete the construction process. The entire construction process is decomposed into a work breakdown structure with fine levels of details. The activities are refined down to the level of basic elementary tasks called therbligs [12], which are used in the study of motion economy in workplaces for the optimization of manual labor. See Table 1 for the list of therbligs.

A case library containing multiple cases of construction activities is developed through case-study observations and by analysing videos of construction activities from the world wide web. The construction activities in each case are decomposed into a hierarchical structure as shown in Figure 1. Depending upon the processes that are adopted in a case for the sub-activities, cases performing the same top-level activity might have different decompositions. An object-oriented representation is used to represent activities in which the activities are grouped into activity classes. Any two activities that belong to the same parent class can potentially be interchanged during case adaptation, provided all the constraints are met. Thus, case adaptation helps to create multiple processes for the same top-level task.

9	Assemble	18	Rest

Figure 1. A schematic representation of multiple activity cases

3.1 Description of RCC Column

An example of RCC column (Figure 2) construction is taken here to illustrate the concept of model composition and performance evaluation. Many methods of column construction are automatically generated and simulated for identifying the best process meeting the requirements of time and cost. The properties are listed as follows: Dimension: 300 x 200 x 3200; Reinforcement details: 6 numbers of 14mm rods as main reinforcement; 8mm diameter shear stirrups @ 100mm c/c with 25mm cover.

The following assumptions are made: the column is at the ground level and the foundation work is completed already. The main reinforcements of the column are lapped to the foundation reinforcement. The resources are already available at site for preparation and execution.

Remark: The illustration is a part of a larger RCC-frame structure involving a combination of columns and beams, which is significantly complex, voluminous, and sophisticated. However, the authors have chosen to present a single column based demonstration in this paper for introducing the research framework with emphasis on the fundamental concepts in it.

Figure 2. Cross-section of RCC column

3.2 Work breakdown structure of RCC Column

A detailed work breakdown structure of the RCC column construction is presented here for illustration. This hierarchy contains the construction of the Column unit as the top-level task (Table 2). Steel work and concreting are the main sub-activities. The steel work is further decomposed into main reinforcement and stirrup work. The main reinforcement activity is decomposed into transporting from stock to cutting yard, cutting, transporting to site location, assembling. Similarly, the stirrup activity is decomposed into transporting from stock to cutting yard, cutting, bending transporting to site location, assembling. The concreting involves shuttering, concreting, de-shuttering, and curing.

Table 2. A portion of work breakdown structure for

RCC column construction

Activity	Description
1	RCC column construction
1.1	Steel reinforcement assembly
1.1.1	(A) Fabrication
1.1.1.1	(A.1) Main reinforcement
1.1.1.1.1	(A.1.1) Transporting from Stockyard to Cutting yard
1.1.1.1.2	(A.1.2) Cutting to Measured Size
1.1.1.2	(A.2) Stirrup
1.1.1.2.1	(A.2.1) Transporting from Stockyard to Cutting yard
1.1.1.2.2	(A.2.2) Cutting to Measured Size
1.1.1.2.3	(A.2.3) Bending to Shape

3.3 Case-library of construction processes

A case-library of construction processes has been compiled from on-site observations and videos of construction activities. The cases contain multiple possibilities of activity execution modes based on the work breakdown structure of the activities used for the construction. For every activity, cases of either manual, mechanical, or electromechanical options are considered. The therbligs based data for the case library is acquired by analysing world-wide-web based video resources.

4 Performance evaluation of processes

For a new project, multiple processes are generated by adapting similar cases. The primary method of adaptation is substitution of similar activities based on their inheritance relationship. The generated processes are simulated using a discrete event simulation software. Implementation details of modeling and simulation are provided below.

4.1 Model generation

Cases are represented in XML format. Cases contain the decomposition of the process as well as the resources utilized for the activities. The activities are decomposed in to therbligs with corresponding durations (Figure 3). Data required for executing simulations are also included in the case files.

All activities are classified using inheritance relationships. The activities can be run in sequence or parallel based on the case considered. The number of cycles of therbligs are also specified. A sample XML file is shown in Figure 5.

4.2 Generating solutions for a new problem

The data related to the new project is provided as input to the CBR module. Multiple processes are generated by case adaptation. Each adapted case combines parts of activities of the previous cases and generates a new process solution. This approach of combinatorial model generation leads to development of new processes that includes combinations of activities from across the case library.

An in-house developed simulation tool, AutoDES, is utilized for performing discrete event simulations of generated processes. The simulations provide the time durations for each activity of the process (Figure 6). The cost of resources and capital costs are computed separately for each process solution.

5 Results

Simulations using compositional modeling driven case-based reasoning methodology were able to identify best processes for RCC column construction considering time and budget. The procedure involved search and exploration of activities and resources from the case library. The simulation approach offers the possibility of generating millions of combinations of activities to identify the optimal process.

For example, transporting main reinforcement from stockyard to cutting yard was most efficient with *Case 1: using a Bar Spider lifting equipment with automatic release system* (29 sec), whereas *Case-1: using a Mobile-Crane and 4 labors* was least efficient (89 sec). The cutting of main reinforcement to measured size with *Case 5: Cutting rebar with a Circular Saw* took 16sec, while *Case 4: Cutting rebar with a handheld hydraulic rebar cutter* took 30sec. Rebar bending with *Case 2: Mechanical bending of rebar to shape with a bar-bender* took 84sec, whereas Cases 4 and 5: *Automated bending of rebar to shape with a bar-bender: Type-1* and 2 took only 44sec.

Considering the combinatorial possibilities, least time consuming RCC column construction process took 1342 sec, the most time consuming process took 4125 sec, and the optimal time consuming process took 2116 sec. (It should be noted that activities related to formwork, curing, etc. have not been included in this model, to keep the example simple enough). All the three solutions are a combination of manual, mechanical, electromechanical device based activities. It was possible to identify the level of automation for each of the solution cases through this methodology.

6 Summary and Conclusion

This paper introduced a compositional modeling driven case-based reasoning methodology for improving project performance through optimal level of automation in construction process. For illustration, a typical RCC construction task was considered. In order to explore various methods of construction with different levels of automation, a case library was used. Each case consists of a method of construction using different tools and techniques. Representing a case involves breaking the construction process in to activity fragments up to the basic level of elementary tasks called therbligs. These activities can be performed through multiple approaches involving manual, mechanical, electro-mechanical or any other means.

The study demonstrates that a large number of processes are possible even for simple tasks in construction and a systematic methodology is needed for identifying the best process involving appropriate level of automation. Results indicate possibility of significant savings in construction time through automation implementation. Moreover, present study showcases a process simulation tool that can be utilized for the evaluation of the overall construction process of a project.

Further work is in progress involving refining and testing of the methodology through much more complex combination of activity cases. Future research would lead to a greater and deeper understanding on implementation of optimal level of automation in construction process. This would possibly prove positive impact of automation on the overall project performance.

7 Acknowledgements

The authors wish to thank Mr. Saqib Bhat and Mr. Utkarsh Kumar who helped in this study during data segregation and pre-processing while generating the construction process case library.

Quality Management Processes and Automated Tools for FM-BIM Delivery

Romain Leygonie and Ali Motamedi

Department of Construction Engineering, École de Technologie Supérieure, Canada
E-mail: romain.leygonie.1@ens.etsmtl.ca, ali.motamedi@etsmtl.ca

Abstract –

Despite the significant benefits of Building Information Modeling (BIM) that can be potentially achieved during the operation and maintenance (O&M) phase, industry has so far mainly focused on its implementation in the design and construction phases. As-built BIM models cannot be efficiently used mainly due to a lack of expertise on the owners' and operators' side to update and use them. Moreover, industry standards do not contain precise guidelines to ensure the ease of use, interoperability, and maintainability, for an efficient and effective utilization of models. Additionally, as these models are mainly developed for the design and construction phases, they usually lack information required for the building's operations and contain many superfluous details. These issues constitute some of the main barriers to the adoption of BIM for O&M. In this light, this research investigates delivering correspondence between as-built models and O&M requirements, using procedures and automated tools to facilitate quality management activities for FM-BIM.

BIM; Quality Management; BEP; IFC

1 Introduction

Building Information Modeling (BIM) consists of the creation of a digital representation of the physical and functional characteristics of a facility as an integrated database of coordinated, consistent, and computable information (Ramesh, 2016). It serves as a shared knowledge resource for information about a facility and provides a reliable reference for decisions throughout its lifecycle, to maximize efficiency, improve information exchanges, and reduce costs (Vega Völk, 2017). The use of BIM has thus far mainly been focused on design and construction phases. However, its main benefits can be achieved during the Operation and Maintenance (O&M) phase.

Aside from aspects such as generating savings

during the design and construction phases, BIM provides a repository of detailed information of the built asset that can be used during operations. Consequently, receiving a complete BIM model at the end of the construction project is becoming increasingly important for the owners. However, even though the commissioning and handover process of delivering physical assets is very well defined, the lack of standards or procedures for digital project delivery creates confusion for owners in terms of deliverables. As a result, the delivered models are not ready to be used by operators as they lack the relevant information and contain superfluous data.

Hence, it is crucial that the owner can constantly check the quality of the models before the delivery and during the handover, to monitor the progress of model development and to solve issues as early as possible. On the other hand, having standard procedures and tools will help the designers and engineers create useful models for operation, as it makes it possible for them to perform quality control before delivery. The main objective of this research is to investigate quality management aspects of FM-BIM models and to develop automatic quality improvement and control tools.

2 Literature Review

2.1 BIM for Operations and Maintenance

To efficiently perform its tasks, Facilities Management (FM) must centralize information from various fields under one roof. Information should be managed and analyzed in a structured and systematic way to facilitate decision-making. FM activities depend on the accuracy and accessibility of data created in the design and construction phases and maintained throughout the O&M phase (GSA, 2011). The BIM model can supply 3D geometry as well as the data of assets and spaces to FM databases to be used for activities such as planning for maintenance and renovation.

Although BIM models are successfully used in the design and construction phase, most models created for

these phases contain significant quality issues including inaccurate, incomplete, or unnecessary information for facility managers (Zadeh et al., 2015). As a result, the use of BIM during the O&M phase remains limited as the models are not readily usable and require extensive modifications and quality improvement, which is costly and time-consuming.

In addition, industry standards do not contain guidelines to ensure the ease of use, efficiency, interoperability, and maintainability of FM models. Motamedi et al. (2018) stated that the FM models should evolve from as-built and as-designed models: they must include geometry and be lightweight. They further noted that models must include all relevant attributes for inspection, maintenance and simulation, as well as the relationship between elements. The quality of data and its availability is crucial as it enables the FM database to provide the information with the required level of detail.

2.2 BIM Quality Assurance and Control

The National BIM Guide identifies procedures to be defined and documented within the BIM Execution Plan (BEP), such as a QA approach for monitoring the modeling process and a QC approach to test the compliance of the final deliverables with quality standards (Motamedi et al., 2018). However, current BEPs do not feature comprehensive QC/QA processes. A continuous QA mechanism set up by the owner guarantees the quality of the model throughout the project lifecycle.

Zadeh et al. (2015) identified different types of BIM data quality issues (e.g. incompleteness, inaccuracy, incompatibility, incoordination, incomprehensibility) and categorized them according to different perspectives (e.g. entity-, model-, or user-level) and relevant facility management perspectives (e.g. assets, MEP systems, spaces). Furthermore, Ramesh (2016) proposed comprehensive quality attributes (i.e., availability, consistency, accessibility, timeliness, relevancy, completeness, accuracy) and a QA and QC planning procedure. The procedure allows owner organizations, along with project teams, to systematically identify areas of concern when documenting and delivering facilities information, and to eventually define ways to manage them. This procedure consists of 1) identify facility information users; 2) understand user needs; 3) translate needs to quality attributes; 4) establish process controls; 5) define product controls. The procedure identifies the goals of owner organizations, lists their concerns and enables the development of a strategy for quality management, enabling the exchange of usable information. However, Ramesh's procedure does not include the model's assessment method.

Regarding QC, the designers' work is reported at

project meetings and a report is prepared for project-specific official checkpoints, describing the priority issues that require attention. At these checkpoints, QC include several steps, such as a self-check, carried-out by the designer, internal check, by the project manager, and client assessment (Kulusjärvi, 2012).

However, the goal of the model preparation process is to have a lightweight federated model that complies with a standard format and is enriched with FM data. To achieve this goal, Motamedi et al. (2018) proposed a QC checklist, yet, it needs to be further expanded. To automatically assess the model, automatic model-assessment tools are available on the market (e.g. Solibri, Revit Model Checker), but the applicability of these tools for FM purposes regarding the owners' requirements must be evaluated, especially for COBie deliverables (Patacas et al., 2014).

2.3 COBie

Construction Operations Building information exchange (COBie) is a non-proprietary data structure that enables the creation and transfer of asset information. It is used as a data handover tool for transferring the data taken from the BIM models. However, COBie is only a platform for data capture and transfer and does not include specific data requirements for each asset type. Additionally, BEPs are generally imprecise regarding data requirements, delivery schedule, and data quality of COBie deliverables.

2.4 Research Gaps and Research Steps

The literature highlights a lack of comprehensive checklists and procedures to assess the quality of the BIM model for FM. There is also a need for an automated method for identification and correction of quality issues. The research proposes a comprehensive list of required items and information that must be present in the model for the operations of the facility, alongside a list of unnecessary items that must be purged from the design and construction models. The research proposes automated checking and purging methods. Model-checking tools and visual programming are used to develop an auditing tool useful for the construction firms and the Facility Managers. Moreover, a QA process flow to be used by owners and constructors regarding the requirements for FM is proposed. The developed tools and procedures were used in a real project to assess their applicability and to gather feedback for future improvement.

3 Proposed Solution

3.1 Checklist for BIM Model Quality Control and Purge

Alongside the specific data required by the owner, which vary from one project to another, the overall quality of an FM-BIM (e.g. data format, assets relationships, room definition) must be evaluated. Since this model derives from either an as-build model or a design-intent model, a preliminary preparation step is needed to ensure that all the required data are included in the model following a comprehensive checklist.

Tables 1 and 2 show the extended version of the tables developed by Motamedi et al. (2018). They include items that are generic for all BIM models, regardless of the authoring software. Additionally, they include highlighted items related to a specific authoring tool (i.e., Autodesk Revit). Although the terminology used to describe the highlighted items is tool-specific, it can be transposed for other tools. Finally, the items were categorized.

Since the as-built model contains unnecessary information for the purpose of O&M (e.g. structural elements, assembly, parts), the model should be purged. As a result, the model is more lightweight and, if possible, federated. Table 2 shows the proposed items to be purged from the model. Finally, once the model containing all the necessary information (owner's requirements) attains a sufficient level of quality and all superfluous information has been removed, it can be exported in an interoperable format, such as IFC. The model's data is then transferred to CMMS or CAFM platforms.

Table 1. FM-BIM quality control checklist

Cat.	Item	Description
Delivery	Standalone models	FM-BIM models should be delivered standalone with multiple models combined.
	Completeness	Delivered models should be complete, including: Floor plans, Reflected ceiling, Mechanical ductwork and piping, Lighting, Electrical power, Electrical panel diagrams, Fire protection, Data system.
File Management	Compatibility information	Details about the compatible version of the viewing and editing applications should be provided per model.
	Geolocation	The model should be geolocated.
	Model alignments	The architecture, structural and MEPF models should match and align.
	Folder structure	Models are organized in a standard and consistent directory structure.
	Pinned links Nested links	Links should be pinned in place. Reference nesting should be avoided.

General	Link path	Links should have relative paths.
	URL	URLs must only be used when it is impossible to provide the content locally.
	Asset modeling	Assets should be placed only in their associate models.
	Elements visibility	There should not be hidden elements.
	Phase elements	Each object should be modeled in the proper phase.
Spatial element creation	Units	Consistent units should be used for the properties of assets.
	Space completion	There should not be any missing spaces.
	Room location	Rooms should not be located on the roof or outside.
	Room tags	Room tags should be displayed in the center of each room in a floor plan view.
	Room level hosting	All rooms/spaces should be hosted at the level in which they contribute to the net and/or gross building square footage.
	Room and space definition	Rooms and spaces should be in a properly enclosed region.
	Room duplication	There should not be multiple Rooms in the same enclosed region.
	Room height	Room volume should go from its current level to its above ceiling.
	Space height	Space volume should go from current level up to above slab.
	Room identification	Unique name and numbering should be used for rooms in the building.
Spatial element properties	Room finishes	Surfaces of rooms should have finishes.
	Related space naming	Space names should correspond to room.
	Definition of areas	Areas are defined for grouping by function purpose.
	Gross area definition	The calculation method should comply with a guideline.
	Zone definition	Zones should be created.
	Zone assignment	Every space should be assigned to at least one zone.
Relationships/Assignments	MEP equipment location definition	Location relationship should be based on the space from which the equipment is accessed.
	Object duplication	There should not be duplicate objects.
	Architectural components location definition	Architectural components should be associated to the room where they are located/from where they will be maintained.
Systems	System modeling	There should not be any components with no system definition (Unassigned System).
	Floors definition	Floors should be properly defined and should not exist as ceilings.
Levels and ceilings	Ceilings definition	Ceilings should not be cut by a room.
	Room bounding	Ceilings should not be room-bounded to enable correct space height.
	Duplicate levels	There should not be multiple levels at the same elevation.
	Helper levels and floors	Helper levels and floors should be removed.
	File naming	Model file names should conform to a standard.

View/Sheet naming	Model view and sheet names should be consistent and conform to a standard.
Level naming	Level names should be consistent and conform to a standard.
System naming	System names should be consistent and conform to a standard.
Family naming	Family names should conform to a standard.
Type naming	Type names should conform to a standard.
Room/Space naming	The names of rooms and spaces should be consistent and conform to a standard.
Room/Space classification	Rooms and spaces should be classified following a standard classification scheme.
Equipment naming/identifiers	Equipment names should be consistent and conform to a standard.
Equipment classification	Assets should be classified following a standard classification scheme.
Annotations	All annotations and title blocks should be consistent and conform to a standard.

Table 2. Purge checklist of items to be removed from the FM-BIM

Cat.	Name	Description
Annotative elements	Annotations	All unnecessary annotation should be deleted, specifically related to structure, installation, assembly or construction.
	Revisions	Revisions information should be purged from the model. Revisions cannot be deleted, but they must be "un-issued".
	Line styles	All unnecessary line styles should be removed, specifically related to structure, installation, assembly or construction.
Views	Legends	All unnecessary legends should be removed, specifically related to structure, installation, assembly or construction.
	Schedules	All unnecessary schedules should be removed, specifically related to structure, installation, assembly or construction.
	Sheets	All unnecessary sheets should be removed.
	View templates	All unnecessary view templates should be removed, specifically related to structure, installation, assembly or construction.
	Scope boxes	All unnecessary scope boxes should be removed.
	Views not on sheet	All views not on any sheet should be removed (e.g. plan, section, elevation, detail, test, work in progress and drafting views).
	Design options	All unnecessary design options should be removed.
Customization	Area space schemes	All unnecessary area space schemes should be removed, specifically related to structure, installation, assembly or construction.
	Worksets	Worksets should be discarded.
	Browser organization	Keep only one browser organization for views, sheets and schedules ("all")
	Visibility	Turn on all model objects, all annotation objects, remove all filters, and turn on the visibility of all worksets and links.
el integ	Generic models	All unnecessary generic models should be removed. They should be avoided in general.

File	In-place families	All unnecessary in-place families should be removed. They should be avoided in general.
	Unused elements	All unused objects should be purged and removed.
	Mass elements	All unnecessary mass elements should be removed. They should be avoided in general.
	Detailed components	All unnecessary detailed components should be removed.
	Groups	All groups used to model the building must be ungrouped.
	Purge	The models must be purged multiple times before being shared.
	Linked files	All non-transmittal linked-in files (CAD/Revit) should be removed from the model.
	Images	All unnecessary images should be removed.
	Warning count	Warning count should be reduced to zero.
	Merging files	If possible, architectural, mechanical, electrical, fire protection and specialized equipment should be merged into one file.

3.2 Solution for implementing the checklist

In this research, several commercial quality control tools were assessed, such as schedules in Revit, Revit Model Review, Revit Model Checker, Solibri, and Dynamo. Aside from Solibri, these tools are embedded in Revit. However, it is possible to import an IFC file generated in other tools to Revit and then perform the quality control. As no single tool adequately supports all the required checks, a combination of them is required to achieve a sufficient level of quality control implementation.

Revit Model Checker is identified as the tool in which a large portion of the quality control checklist items can be programed. Table 3 shows a sample model-checker script that reports the spaces where their names and numbers do not match the names and numbers of their corresponding room. Revit Model Review is then used to complement Model Checker for specific checklist items (e.g. it checks that each enclosed region in the model has a defined space or room).

Table 3. Example of check code using Model Checker

Check Name	Check Code
Space matches room	(Category OST_MEPSpaces Included Code:True AND Type or Instance Is Element Type = Code:False AND Parameter SPACE_ASSOC_ROOM_NAME Does Not Match Parameter Code: ROOM_NAME)
	OR (CATEGORY OST_MEPSpaces Included Code:True AND Type or Instance Is Element Type = Code:False AND Parameter SPACE_ASSOC_ROOM_NUMBER Does Not Match Parameter Code: ROOM_NUMBER)

For purging, Dynamo scripts are used to implement most of the cleanup checks in a semi-automated way. Most codes list all the elements corresponding to an

item of the checklist and allow the user to remove the unnecessary elements by filtering through a keyword or chain of characters (e.g. all view templates that contain “struct”). The process requires a human input to identify the keywords or take the final decision on the deletion of the data. This method is efficient for viewing a list of potential unnecessary similar items and removing them once.

Finally, an Excel dashboard was created to keep track of the improvement of the model’s quality. This dashboard is populated by the results of the assessments of Model Checker, displaying figures both related to quality control and purgeable items. It makes it possible to quickly visualize the model’s quality status.

3.3 Procedure for the Use of Developed Tools

Figure 1 shows the proposed procedure for FM-BIM model preparation. The assessment of the models occurs at two levels: 1) the modeler carries out self-checks using the above-mentioned auto-evaluation tools (self-check boxes in Figure 1); 2) at specified milestones—to be determined in the BEP—the project manager executes a control of the models using a combination of the developed tools. The generated report populates the dashboard to monitor the quality status and to determine any necessary improvements. After a number of iterations, the FM model is exported in an interoperable format, such as IFC, and delivered to the client. It is important to convert the model to the IFC format when it is of a sufficient quality, as the checks are carried out in the authoring software using the native format.

4 Case Study

he developed tools and procedures were assessed in

a project of a general contractor based in Quebec. A building of a care center mandated by a major provincial owner organization was selected for the case study. The purpose was to assess the usability of the tools and the process and to gather feedback from stakeholders for future improvements. The project delivery mode was design-build and the company was in charge of managing the production of as-built BIM content and a customized COBie file.

In the complete COBie standard worksheets, the client requested only the design-related sheets (i.e. Contacts, Facility, Floor, Space, Type, Component, System). The required rules defined in the COBie standard and some optional properties to be transferred to the operations database were listed in the initial contract. A further analysis of the standard, contractual documentation, and interviews were performed to complete the data requirements of the client.

4.1 Utilization of developed tools

For the purpose of assessing COBie deliverables, two available tools were assessed. COBie QC Reporter, a java-based program, is used to assess the content of COBie files, however, the tool is complicated to work with and is not capable of verifying all the fields required for the project. Revit Model Checker is an alternative tool in the BIM Interoperability Toolset. A functionality comparison of these tools was performed and is presented in Table 4. The numbers in each column indicate the number of assessed rules for each COBie sheet. The results show that none of these tools is capable of assessing all the rules and they need to be used in parallel.

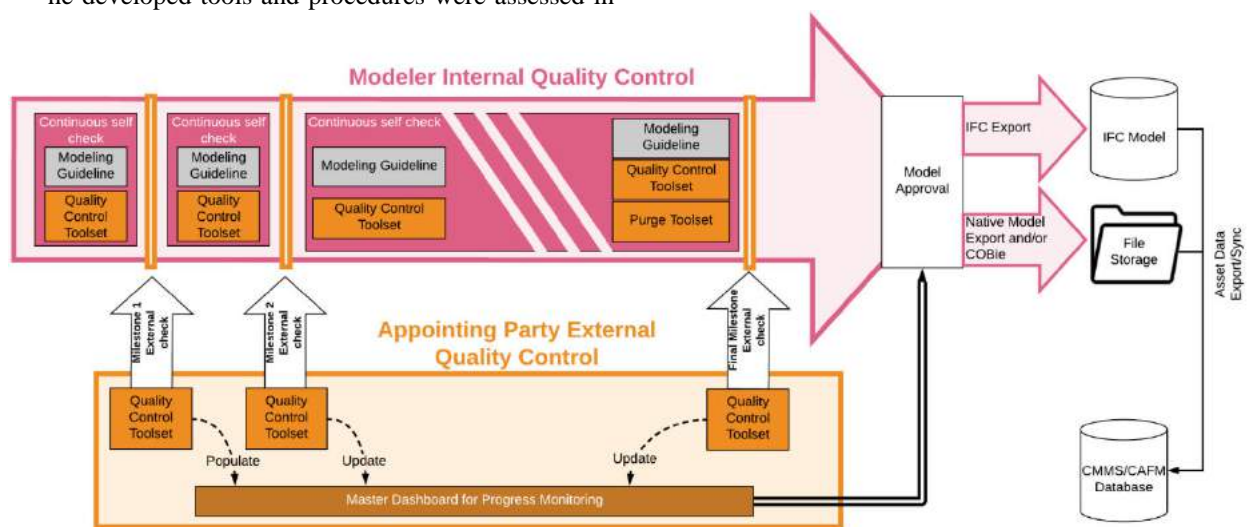

Figure 1. Overall workflow view of FM-BIM preparation showing checks performed at milestones

Table 4. Comparison of number of rules assessed by each COBie control tool

COBie Sheet Name	Only Model Checker	Only QC Reporter	Shared between tools
Contact	0	20	0
Facility	6	2	14
Floor	1	1	10
Space	2	1	15
Zone	1	3	7
Type	6	7	32
Component	0	6	14
System	3	3	8

The Model Checker template for COBie assessment does not include all the required rules and fails to detect many existing errors. Additionally, the format of the values (e.g. classification parameter or picklist) cannot be assessed by the template. Thus, a new set of checks was implemented and both tools were successively run. Finally, the data is exported in an Excel format and the QC Reporter is used to assess the remaining rules (e.g. contact rules, or sheet cross-referencing). Additionally, some non-COBie related checks proposed in this research were run to improve the quality of the model. For example, the developed Dynamo code to assess the height compliance of rooms and spaces was used to ensure that each COBie component is correctly included in a space or room volume.

4.2 Process design for the use of tools

A detailed process map was proposed regarding the use of tools. Figure 2 shows the process flow for the generation of COBie data and the utilization of the developed QC tools. The process includes a detailed identification of COBie requirements (i.e. sheets, fields,

assets, classification standard and naming conventions). At the beginning of this project, the process and the required data items and formats were not adequately defined, which made the process of updating the model very tedious.

Once the COBie requirements definition is completed by the client/owner, the project manager, together with the designers, can set up the models of various disciplines accordingly by creating the parameters and choosing the appropriate classification system. The task of populating the model with the COBie data is to be carried out by the corresponding designer. Quality control is then performed by the project-manager, using COBie schedules embedded in Revit and the Model Checker. Once the model is complete, the COBie file can be generated and assessed using QC Reporter. Finally, the COBie file and the report are shared with to the client for evaluation.

Since multiple iterations are likely to occur in the COBie generation process, a dashboard, is developed to monitor the progress of the quality assessment. The dashboard is intended to provide a better visualization of the result of the checks implemented in Model Checker, as they can be directly exported in Excel. The tool was validated in the project and will be used (together with the workflow) for upcoming projects of the company to improve the delivery of COBie.

5 Conclusions and Futurework

This research project addressed the lack of methods to control and improve the quality of BIM models for O&M by proposing checklists of necessary items to be included in the FM-BIM, as well as superfluous items to be purged from the model. Additionally, a new method

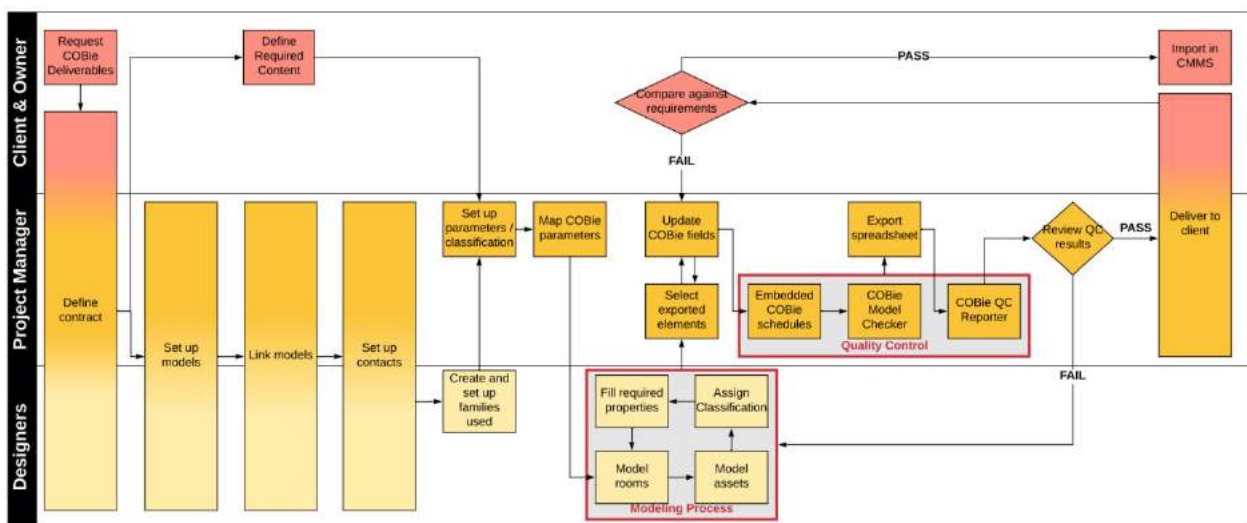

Figure 2. Proposed workflow to deliver a high-quality COBie

and tools to evaluate the quality of BIM models for the O&M phase were proposed. They facilitate the delivery of complete and usable FM BIM models. The applicability of the tools and methods were assessed in a real project by applying the rules related to the quality of COBie data in a BIM model.

The results of this research contribute to creating more useful BIM models for FM, which will eventually increase the quality of operation. High-quality BIM models help to increase the efficiency of building operations and to achieve major cost reductions. Ultimately, the effective management of buildings will also help to increase the comfort and quality of life of their inhabitants.

Although the developed tools addressed multiple items of the checklist, there is still quality control items that their assessment can be automated. Additionally, the checklist can be further extended by considering new requirements in the industry. The developed tools can be further improved to automatically fix the problems in the model (e.g. space and room height auto adjustments). Moreover, changes to contract templates or BEPs should be proposed to precisely define quality assurance procedures.

Abstract -

This work examines the potential of process mining in the Architecture, Engineering, Construction, and Operation (AECO) industry, where process mining is rarely applied. The main reason is that standardised processes are hardly ever performed due to the complexity of projects. To address this application gap, the software-supported cost estimation process for a tender in a German construction company is examined. For this purpose, data sets from three different projects are exported from the software *RIB iTWO™* and analysed with regard to process discovery. Investigations are carried out from the control flow, case and organisational perspectives. A particular problem in the analysing part is the currently inadequate quality of the data sets to be examined. Due to data quality issues the consideration of temporal aspects is rather not possible. Therefore, consistent and appropriate forms of logging must be implemented in software systems that are used to support the AECO industry. For the present use case an automated working script was created to process the log data to fix further quality issues and meet process mining requirements.

The results show that it is essential to establish standardised language rules that are generally valid throughout the industry and that are subsequently referenced by all utilised software systems. This enables comparative analyses across projects and companies to make process mining methods become routinely and profitably applicable in the AECO industry.

Keywords -

Process Mining; Process Discovery; AECO Industry; Civil Engineering; Building Construction; Cost Estimation

1 Introduction

Process mining is to be seen as a link between data science and process science since it brings together traditional model-based process analysis and data-centric analysis techniques [1]. While several process mining applications can be mostly found in the areas of financials, healthcare or manufacturing, the method is rarely applied in the Architecture, Engineering, Construction, and Operation (AECO) industry [2]. In the planning phase within the AECO industry, there are usually complex and individual projects handled [3]. Standardised processes are rarely found. Tasks that require creativity and problem-solving skills may lead to unstructured process flows and usually challenge the applicability of process mining methods [1].

Nevertheless, process-supporting software is also increasingly being used in the AECO industry. Countless

data is already collected in everyday business, but is hardly ever analysed. It is necessary to verify that meaningful interpretations of the collected data can be implemented with the help of process mining. Currently, only a few research is conducted on the use of process mining methods in the AECO industry. This emphasises the importance of the scientific work highlighted in this paper, that addresses the cost estimation process of a construction company.

In this paper, Section 2 reviews available scientific studies on process mining applications in the AECO industry and underlines the sector specific application gap. Section 3 describes the fundamentals of process mining and the case study from this paper. In Section 4 the investigated use case is presented. Section 5 shows the critical conclusions and recommends topics to be addressed in future work.

2 Related Work

Overall, only a few research studies are done on the use of process mining methods in connection with the AECO industry.

In [4] two disciplines of process mining, process discovery and conformance checking, are used to analyse process steps in modular construction through RFID tracking data. The case study is conducted as a laboratory experiment and can generally be assigned to a rather structured manufacturing process than to the classical AECO industry.

In the context of [5] three case studies in the field of civil engineering are investigated to cover different phases of civil engineering projects. The first case study is about the planning phase of a civil road construction project with data from a project management tool to find loops and bottlenecks in the execution. In the second case study data from drone images documenting construction progress in the form of point cloud models (as-built models) are compared with planned (as-planned) Building Information Modeling (BIM) models. The third case study was in the context of facility management using maintenance (error) data.

Some more scientific work can be found in the context of BIM with [6, 7, 8, 9, 10]. All of them treat real project or laboratory data from the design authoring tool *Autodesk*

*Revit*TM [11]. The in the present work investigated software system, *RIB iTWO*TM, can also be used in the context of BIM, for example to take over design authoring tool data to perform automatically mass determination of building elements.

Zhang et al. [6] aim to provide a productivity measurement in the workflow of different BIM design authors. Therefore, it concentrates on the most frequent patterns (sequence of commands) within all the log data from real life projects to assess the process duration of those patterns. The work of Yarmohammadi et al. [7] addresses the same topic but just examines patterns within real project data with the most frequent activities without considering time aspects. Other scientific work in the context of BIM like [5, 9, 10] focus rather on a complete (from starting point to ending point) process view over process instances with respect to time aspects. The latter is more common as an holistic process mining approach.

Two of the authors from [6] conducted another case study in [8] on real data to discover social networks in BIM-based collaborative design and furthermore confirm findings through interviews with several design project managers of the related company.

Kouhestani and Nik-Bakht [9] aim to use log data which have arisen from staged processes to measure the performance of the project teams with focusing on the design authors as cases to track their individual workflow. It is already outlined that the AECO industry has in general a lack of log data collections due to the fact that digital planning methods are just recently about to be applied with BIM methods [9]. The same authors in a later work [10] present firstly the same case study as [9] but utilise building elements as cases instead of the design authors to discover and analyse the element centered processes completed by the design team during design authoring. A second case study considers a bigger data set from again staged processes, and process conformance analysis is furthermore carried out in addition to process discovery.

In [12] a case study on Engineering Change Request (ECR) is examined to explain the importance of pre-processing the event logs before importing them into process mining software. The investigated data set covered only 58 cases and thus represents a small data base. Nevertheless, it is already shown too, that there can be quality problems in the context of log data in the AECO industry, which require extensive processing of the data.

In summary, there is only a small number of case studies that deal with process mining in the AECO industry, most of which focus on design authoring in the context of BIM. To address the often criticised data quality issues and make the application of process mining methods in the AECO industry more feasible, the present work examines the software-supported cost estimation process

in a German construction company. This paper follows the similar objectives as [12], as it mainly addresses data pre-processing obstacles, but furthermore conducts initial analysis and interpretation steps.

3 Fundamentals of Process Mining and Adopted Approach

In the Process Mining Manifesto [13], written by members and supporters of the IEEE Task Force on Process Mining, process mining is described as follows: “The idea of process mining is to discover, monitor and improve real processes (i.e., not assumed processes) by extracting knowledge from event logs readily available in today’s (information) systems.”

Process Mining faces event data (i.e., observed behavior) and process models (handmade or discovered automatically) [1]. Mainstream data science approaches like data mining, statistics and machine learning techniques do not consider end-to-end process models [1]. Process mining takes them into account. Compared to process science approaches like mainstream Business Process Management (BPM) ones, that deal with design, execution, control, measurement and optimization of business processes with an emphasise on explicit process models, the focus of process mining is not on process modelling, but on the use of event data [1]. In general, process mining is divided into three different types [1, 13]:

1. Process Discovery:
As-is process models are generated from event logs.
2. Process Conformance:
An existing as-planned process model is compared with the as-is model of the same process generated from the event log.
3. Process Enhancement:
An existing as-planned process model is extended through continuous comparison with actual data from event logs to improve the existing model.

Figure 1 shows how the three process mining types mentioned above and their relations to each other. The process mining types communicate with the real world through process models and interact with the software environment through event log data, which takes on supporting as well as controlling functions towards the real-world processes. Process models and software systems are also connected through further development aspects [1]. Figure 1 also shows the tasks handled in the present case study. The construction company provided data from the supporting software system and knowledge about as-planned processes. The received data was processed and analysed by the authors to gain explicit knowledge about the as-is processes.

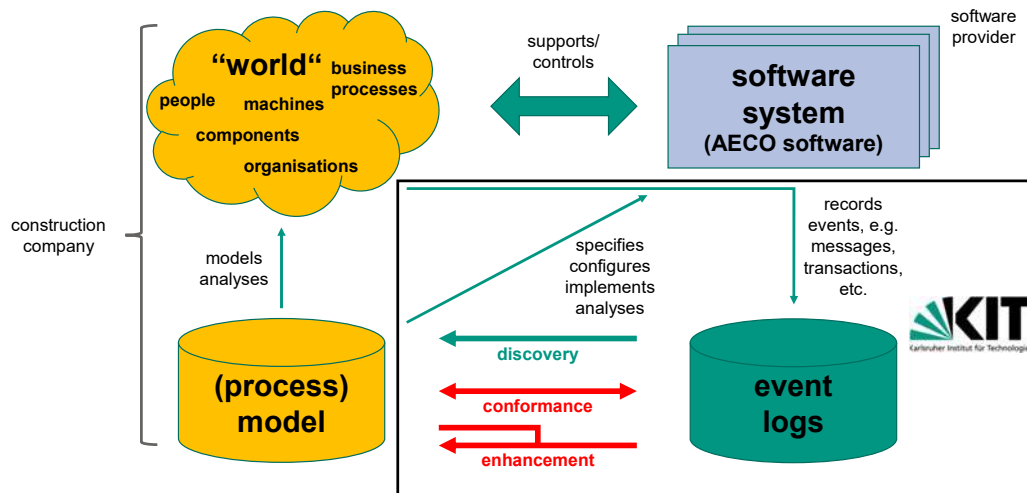

Figure 1. Positioning of the three main types of process mining: discovery, conformance, and enhancement. Allocation of project affiliations. (adapted from [1])

4 Application of Process Mining Methods - Use Case

4.1 Data Collection and Raw Data Export

The German construction company *Wolff & Müller Holding GmbH & Co. KG* uses *RIB iTWOTM 2019 Enterprise* [14] to support processes concerning call for tenders, awarding of contracts as well as accounting and billing. For the process mining analyses in this work, the *RIB iTWOTM* data from the bidding phase of a tender of three building construction projects is exported. More precisely, the log data deals with the cost estimation process. Projects 1 and 2 are new construction projects and Project 3 is a renovation project. Because tendering processes for the three projects were in full progress, no further general information on the projects was processed to ensure data protection. However, for processing and analysing the log data, the elaboration of further general project information was not necessary.

For Project 1 there were three data sets available, each for one individual calculation variant that was conducted by the construction company. Table 1 shows main information regarding the five data sets of the three different projects (Project 1 - Variant 1,2,3; Project 2; Project 3). The exported raw data across projects cover the time span from 14-11-2019 to 04-02-2020. This means that, at the maximum, data is available for a period of slightly more than 11 weeks (Project 1 – Variant 1). In the other data sets, this period is somewhat shorter. This has mainly two reasons. Firstly, a final export of the log data of all projects took place on 04-02-2020. The fact that the date of the last event in four of the five data sets is before 04-02-2020 is because no activities were carried out in the meantime in

these projects or project variants. Secondly, for Project 2 and 3 the recording of changes and the log data extraction began one week later than for Project 1 because the realisation of the change logging in the construction company has been slightly delayed for those projects. Since the case study only evaluates a short time frame the exported data of all projects does not cover the entire process for all cases and accordingly all calculated elements. In total, around 100.000 log entries were recorded in all projects. The largest data set for a particular project, namely Project 2, contained about 33.500 entries and thus 33.500 events.

Table 1. Scope of the exported project data sets

Project	First Event	Last Event	Events
1 - Variant 1	14-11-2019 10:48:34	22-01-2020 08:17:54	14.496
1 - Variant 2	14-11-2019 10:48:34	13-01-2020 17:23:01	2.355
1 - Variant 3	14-11-2019 10:48:34	04-02-2020 09:48:26	28.628
2	21-11-2019 09:53:47	27-01-2020 17:45:10	33.495
3	21-11-2019 07:22:40	28-01-2020 17:25:06	20.962

The log entries generally contain information about the executed activity, the user involved, a timestamp and the ordinal number of the processed element, which at the same time represents the case id. An extract of a CSV file exported from *RIB iTWOTM* is shown in Table 2. One row corresponds to one event. In addition there is a fifth column containing details of the activity carried out. However, since there were already 58 different activities across the projects, this paper only deals with the activities and not with their detailed specifications.

Timestamp	Ressource (user) - anonymous	Case id	Activity	Activity Detail

Table 3. Data quality issues and R script data pre-processing solution

No.	Issue	Solution
1	Case ids change in event logs due to different types of movement of elements within the bill of quantities	Tracking of changes and assignment of the last ordinal number as unique case id to the related events.
2	Events sometimes do not receive a correct timestamp, as they are partly not automatically logged.	No solution for this quality issue. Further ideas for sorting are to be developed in the future.
3	Some events that belonged to a case were assigned to a parent group of the case within the event log.	The script assigns the entries back to the corresponding case again.
4	A manual activity induces several entries in the change logging, even for other cases.	No solution for this quality issue. The number of events is not to be used as the sole criterion for evaluating the cases.
5	The software logs auxiliary events automatically while executing a virtual intermediate step.	The script eliminates these entries from the event log.
6	After elements are deleted from the bill of quantities, their events remain in the event log.	All events of the associated cases are eliminated by the script.
7	Two different manual activities led to events with the same activity name. It was not possible to determine by the data which activity had taken place.	All events of the associated cases are eliminated by the script.
8	After all the other solution steps there have been still some events in the log data for cases that do not appear in the bill of quantities.	All events of the associated cases are eliminated by the script. However, this observation shows that there are uncertainties in the event log that have not been fully clarified until now.

4.2 Pre-processing the Data

All the five data sets had quality issues which made immediate analysis impossible. The biggest quality issue was the fact that there was no unique case id in the log data. However, the case id and accordingly the ordinal number of an element can change when elements are moved within the bill of quantities in *RIB iTWOTM*. In the data records, like this entries are assigned to different case ids that actually belong together. This issue and others that were detected are listed in Table 3. To address the quality issues the exported raw data is to be processed by a specially created script in the programming language R [15]. It was developed with the help of the open source integrated development environment R Studio [16]. The automated script properly merges all entries that belong to an element by unifying different case ids in related entries. Where applicable, the script also covers the other quality issues. The solutions offered by the script as well as further conclusions from unsolved problems are presented in Table 3. Only through necessary work steps of the script are evaluations with process mining methods possible.

However, it must also be said that the data pre-processing discards over 50.000 events of the original 100.000 events from the raw data. Since process mining analyses depend on the availability of large data sets, discarding such large data parts significantly worsens the general initial situation.

4.3 Discovering the Process Models and further Filtering

The commercial process mining software *MinitTM* [17] was used to execute the process discovery based on the data. However, it is possible to carry out simultaneous analyses with other commercial tools or with open source alternatives such as *ProM* [18]. During this work, different tools were tested equally, but the visual representations of *MinitTM* were subjectively chosen for this paper. *MinitTM* was used with an academic licence.

After pre-processing all five datasets the largest data set is still the one from Project 2. A total of 16.216 events are assigned to 2.918 cases in this data set. Subsequent analyses are presented in this paper representatively based

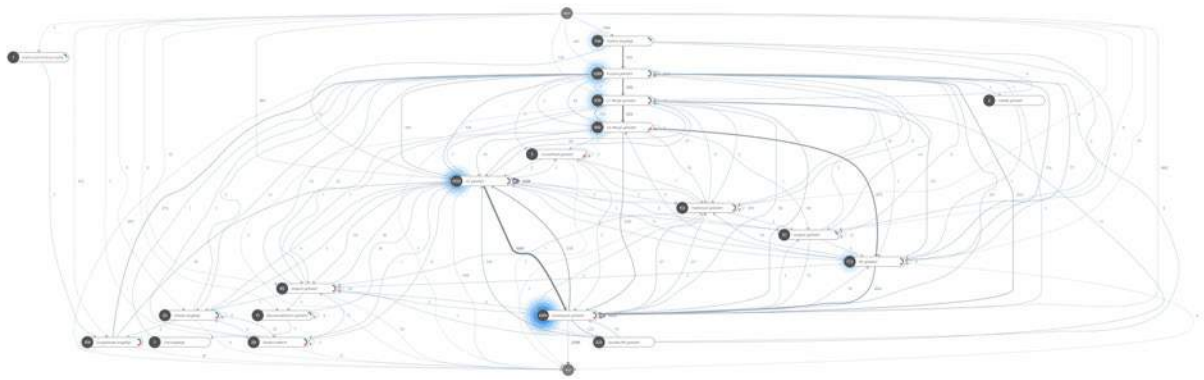

Figure 2. Process model of project no. 2 with 100% of the activities and 100% of the available paths. (adopted from *MiniitTM*)

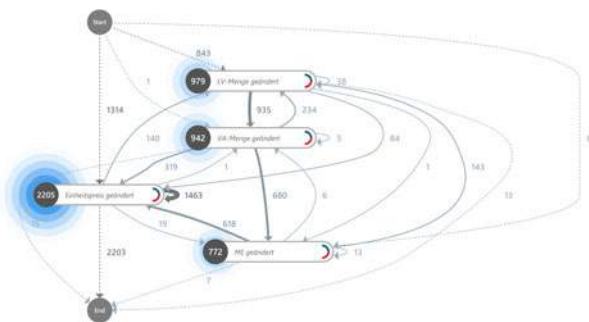

Figure 3. Process model for a data set with four selected activities of project no. 2 with 100% of the activities and 100% of the available paths. (adopted from *MiniitTM*)

on this data set but could be done analogously to the others as well. Firstly, the control flow perspective is considered. The sequence of the executed activities is shown in Figure 2. It is immediately apparent that the as-is process under study is an unstructured process. One can hardly extract any information from this process model. It is worth noting that Figure 2 accurately reflects the behavior that occurs in the dataset.

In order to obtain a comprehensible control flow model the analysis can be limited to selected activities. In consultation with the lead of process management at the construction company, four activities subjectively considered important were selected for further analysis. Cost estimators were asked for their consent to provide data but they were not further involved in the analysis. For future work it would be beneficial to take the calculators opinion into account too, since they work directly within the software system and have more in-depth operational process knowledge.

Figure 3 shows a process model that only contains

the activities "LV-Menge geändert" (engl. "LV quantity changed", as-planned quantity of element), "VA-Menge geändert" (engl. "VA quantity changed", as-is quantity of an element that can change during later stages when project is carried out), "Einheitspreis geändert" (engl. "Unit price changed", unit price change of an element) and "ME geändert" (engl. "ME changed", change of the unit of measure for an element). After filtering the data set of Project 2 with just the four selected activities the filtered data set consists of 8.855 events and 2.238 cases. The following visualisations and interpretations continue with this filtered data set.

Figure 4. Process model for a data set with four selected activities of project no. 2 with 80% of the activities and 80% of the available paths. (adopted from *MiniitTM*)

Considering only the most frequent behaviour (e.g. 80% of the behaviour) in the dataset results in the process model in Figure 4. In Figures 2, 3 and 4, the number of cases in which this behaviour was observed is indicated on the activities and the path connection. For example, the activity „LV-Menge geändert“ (change of as-planned quantity of

an element) was carried out for 979 cases and 843 times it was the first activity executed within the process flow.

Even in a simplified process model, as in Figure 4, there are two-way path connections. This means that one cannot derive a directed process flow from this model. In addition, the process model is so simplified that it only reflects the real data set behaviour (see Figure 2) and thus the real process of cost estimation to a limited extent. The timestamps of the entries from the log data are not always in conformity with reality due to the software specific change logging and therefore a consideration of the time perspective is omitted at this point. Hereafter, there will be a view on the data records from the case perspective and the organisational perspective presented.

Table 4 shows an exemplary data set view from the case perspective. It is possible to sort the individual elements according to the number of activities carried out in connection with them or one can read out the respective processing start and end times. Based on this, it is possible to draw conclusions about the effort required to calculate an element. To this aim, however, it is absolutely necessary to look at the individual activities carried out regarding the single elements as well. This is because there are some activities that took place at the same time due to the specific change logging of *RIB iTWOTM*. The absolute number of activities does not correspond to the number of activities carried out in reality. In addition, there are some activities that do not correspond to any real activity. These are activities that reflect a virtual intermediate step that is automatically carried out by *RIB iTWOTM*.

Figure 5 shows an exemplary data set view from the organisational perspective. It is a so-called "social network" [1]. Staff roles can possibly be derived from the connections shown. In Figure 5, "nrti" has the most case involvements. With the exception of "namn", to which there are reciprocal connections, other paths lead unilaterally to "nrti". Presumably, "nrti" takes over controlling tasks in Project 2 and coordinates them with "namn". According to Figure 6, the employee "dabu" carries out activities mostly in a self-loop and there are only outgoing connections to

other employees. This can be an indication of the processing of specific crafts or elements, which are then released for further controlling. Such interpretive approaches can be used to highlight valuable information about collaboration within a project. The process manager can see if there are unexpected handovers of tasks, unwanted loops in handovers or missing links between staff. However, it must be checked on the basis of actual role distributions whether such observations correspond to reality. To this aim, data protection-relevant preliminary considerations must be taken into account and the consent of the participating stakeholders for personal data-related investigations must be obtained.

Furthermore, it is possible to combine the case perspective and the organisational perspective in order to gain interesting insights. For this purpose, individual elements can be selected in the case perspective and their respective social networks can be examined. From the combination of case and organisational perspective, correlations can be determined, for example, between cases involving higher efforts and the number or the combination of employees involved in the case.

5 Conclusions and Future Work

Summarising it is necessary to examine the entire cost estimation period in order to be able to map the complete process flow. The recording of the project data must be continuous and linked to the project start and end dates to document the entire project. With such a shortened observation period, like with approximately 11 weeks in the present case study, it is highly probable that a large number of the cases and accordingly the elements from the bill of quantities did not run through the entire cost estimation process to be examined.

Within the scope of the present work, an interface was created between the software *RIB iTWOTM*, that supports the cost estimation processes in a construction company, and common process mining software. A specially developed R script prepared non-continuous case ids which exist in this unsuitable form from the data structure of *RIB*

Figure 5. Social network with absolute number of cases and accordingly elements of the bill of quantities worked on. Data set with four selected activities of project no. 2 with 80% of the personnel resources and 80% of the path connections between the personnel resources. (adopted from *MinitTM*)

iTWOTM. Only by implementing a unique identification number it can be ensured subsequently that elements of the bill of quantities can be traced over the entire cycle of their existence. The case id is the key element in process mining and is absolutely dependent on consistency. By filtering, data with uncertainties can be removed from the event log to enable process mining analysis. However, this eliminates large parts of the event logs which is problematic for well-founded analyses. To prevent the discarding of data in the future, consistent case ids must already be created for elements from the bill of quantities within the utilised software systems.

It has to be mentioned that the generated as-is control flow models from the present case study are on a different and more detailed level of abstraction than the manually created as-planned process models of the construction company which define general process flows in a comprehensible way. This makes process conformance checks or enhancement approaches impossible without further adjustments. To enable further investigations that go beyond process discovery, the level of abstraction from as-is and as-planned models have to be aligned in future work.

At this point, it is advised to look at the event logs from the case perspective, the organisational perspective or a combination of both in order to find starting points for further analysis. If starting points for process optimisations are found by looking at the data from different perspectives, these must be communicated to the employees, that execute the real processes. An examination from the time perspective was not possible with the *RIB iTWOTM* data sets because the timestamps were not always in conformity with reality.

As shown, process mining methods can be used in the context of construction planning projects, when process relevant log data from supporting software systems, like *RIB iTWOTM*, is accessible. The investigations may provide valuable insights into complex AECO disciplines that required particular attention during the process execution. However, the quality of the exported data sets is decisive for the success of the analyses to be carried out. There is great potential for improvement here. The software systems that are used in the AECO industry should be equipped with appropriate documentation mechanisms to routinely meet the process mining requirements. In order

to enable reliable analyses, it is sufficient if the documented events of the event logs each contain a case id (for case classification), a timestamp (for time classification) and the executed activity or task. Seamless event logging and taking data protection aspects into account, is a basic requirement for the change logging in software systems and the export and analysis of data sets.

In order to be able to carry out comparative analysis across projects and also across companies, it is urgent to introduce uniform semantics (e.g. for crafts, elements, tasks, processes). For this purpose, generally applicable language rules must be developed for the entire sector, which are then referenced by all utilised software systems. Building on this, it may be possible in future to use process mining routinely and profitably in the AECO industry.

Abstract –

To ensure public safety, major cities in the U.S. have façade ordinances that require periodic façade inspections and reporting of façade conditions. Our shadowing works show that the current inspection processes are based on inspectors' experience rather than systematic inspection guidance. Besides, façade inspectors have different preferences to group their inspection findings (e.g., grouping inspection results based on a defect type or façade component), resulting in a need to provide flexibility to inspectors to organize façade inspection results based on their preferences. Building Information Modelling (BIM), with the ability to support storage, extraction, and exchange of facility information, can help with a systematic and comprehensive inspection of façades and store and exchange the façade inspection results with the third parties. To enable model-based guidance for a comprehensive inspection of any given building and to bring flexibility to restructuring the model and inspection data based on inspector preferences, an essential step is to define information requirements and develop a generic data representation for façade inspection. We have identified a generic taxonomy of façade components, defect types, defect attributes, and the relationships among the identified elements to enable comprehensive façade inspection guidance and flexible restructuring of the inspection findings. This paper provides the details of data exchange requirements and the initial ontology for a model-based façade inspection process. The ontology builds on the Industry Foundation Classes (IFC) specification and extends it to include entities, attributes, and property sets required for model-based façade inspection. This work provides the underlying data representation requirements for supporting the reasoning mechanisms that take a model as an input, generate a comprehensive checklist for inspection, and enable grouping façade elements flexibly based on inspector preferences for inspection data storage and visualization

Keywords –

Façade Inspection, Building Information Modelling (BIM), Industry Foundation Classes (IFC), Ontology

1 Introduction

Mandatory façade inspection programs have been adopted in major cities in the U.S. to ensure public safety. However, even with the ongoing façade inspection programs, accidents caused by debris falling from façade surfaces still occur in cities [1, 2]. Aside from the reported accidents, complaints are filed by citizens on dangerous situations to city agencies. For example, more than 1,000 complaints were filed each year to the New York City agency about façade safety during the past decade [3]. These point to a necessity to improve the current façade inspection processes. With this objective in mind, we identified several challenges observed in the current façade inspection practice in earlier work [4]. These challenges included (a) a lack of systematic guidance for inspectors to check façades comprehensively, (b) a lack of mechanisms to flexibly regroup and restructure building façade data and inspection findings based on inspector preferences.

To address the identified challenges, we have been working on a model-based approach to streamline the current façade inspection practice, where customized checklists are generated for each given façade based on a generic set of information requirements, and inspection data could be stored and visualized based on flexible regrouping of the model data. Available resources (e.g., practice standards, city ordinances, façade condition glossaries, previous researchers' findings, and historical façade inspection reports) have been analyzed to identify generic categories of information requirements for a comprehensive façade inspection. Historical façade inspection reports that have been analyzed using Natural Language Processing (NLP)-based approaches have resulted in generic vocabularies for each identified information requirement category and relationships

between major concepts [5]. This paper provides the details of the formal representation of the accumulated outcomes of this broader research agenda as an ontology to support model-based inspection. First, the major concepts and their relationships to a building façade will be described. Next, additional concepts and relationships that are needed to support the two reasoning mechanisms (i.e., checklist generation and flexible regrouping) will be presented in this paper.

2 Motivating Case Study

We conducted a shadowing work with an experienced façade inspector for three inspection projects on buildings with different façade types. General findings of this work, along with analysis of historical inspection reports, have resulted in two major challenges:

Challenge 1: Lack of systematic guidance for inspectors to conduct a comprehensive inspection. During the shadowing work, we noted all the façade condition information that the inspectors collected in the inspection process and identified three major groups of information: the façade components, the defect types, and the associated defect attributes (e.g., location of the defect, associated deteriorations, affected area, etc.). Based on our follow-up interviews with the inspectors, it was clear that the inspection information they collect (e.g., defect/attributes they check) varies based on the inspectors' experiences and may lead to different inspection results for the same building. Table 1 shows an example of varying inspection results in two inspection reports done with different inspectors for the same brick masonry building. Such differences show a need for a checklist that the inspectors can follow to conduct an in-depth and comprehensive inspection regardless of their personal experience.

Table 1. Example of different façade condition information collected during inspections

Building components in building A	Inspector 1	Inspector 2
Parapets	Presence of the parapet; Material of the parapet; Location of the parapet.	Presence of the parapet; Material of the parapet; Location of the parapet; Estimation of height.
Balconies	Railings height; Structural stability.	Material of railings; Railings height; Gaps between

Cracked brickwork; Spalled brickwork; Defective caulked coping; Cracked and spalled brickwork mortar joints; Rusted/deteriorated lintel Out of alignment parapet wall
----------------------------	--	---

Bold and Italics: Differences identified in the inspection of the same building components.

Challenge 2: Lack of mechanisms for capturing and storing inspection findings with respect to façade components. Besides the differences in what is being checked and what data is collected by the inspectors, we also identified different styles the inspectors used to record the façade conditions in historical façade inspection reports. We reviewed 40 blindly selected reports out of 2400 reports and examined how inspectors grouped the inspection findings. Initial review of the reports revealed at least three inspection data grouping styles : 1) grouping all related components and locations under the same defect type (Figure 1a.); 2) grouping all related defects under the façade component (Figure 1b); and 3) mixed grouping given grouping types 1 and 2 (Figure 1c). A flexible data representation that can regroup the building façade information and inspection findings based on the inspectors' preferences is needed.

Crazed/cracked/spalling/spalled architectural CMU along all facades and bulkheads. (c.)
 Cracked/spalling brickwork/architectural CMU mortar joints affecting approximately 20 percent of south and north façade masonry.
 Cracked/spalled brickwork/architectural CMU mortar joints and horizontal mortar joints between steel window lintels and the first course of brick/CMU above, affecting approximately 5 percent of masonry along all facades.
 Non-height-compliant parapets at the 4th floor roof.

Figure 1. Different styles of façade conditions description: (a.) grouping information based on façade defects where condition observed is the defect type (i.e., cracked brickwork in this case) and all locations/components where this defect is observed is bundled up under this defect category in the report; (b.) grouping information based on façade components, where window frames and window sills are the components that are checked where all problems/defects for the same component type are listed; (c.) general description without grouping.

Domain-specific ontology developed by the authors is able to provide a standard way to capture and exchange the façade data and its inspection data.

3 Literature Review

Ontology is defined as a conceptual model that supports knowledge reuse and sharing in a domain among different stakeholders by providing formal representation for "classes, relations, functions, and other objects" [6, 7, 8]. Ontology systems can be classified into terminological ontologies (e.g., glossary, taxonomy, and thesaurus, etc.), implementation-driven ontologies (e.g., conceptual schema, knowledge base), and formal ontologies based on the level of semantics they capture [9]. Research studies resulting in formal ontologies in civil engineering have mainly focused on domain knowledge representation for specific tasks; such as capturing and representing construction project histories [10], virtual collaboration in project design and construction modeling [11], construction and project management [12, 13], infrastructure management [14, 15], risk management [16, 17], etc. The presentation of domain knowledge for façade inspection is missing in the literature. This ontology builds on the findings of the taxonomy, mapping relationships among the essential information (i.e., façade component, defect types, and defect attributes) to support checklist generation and model restructuring for storing and exchanging inspection findings.

BIM supports information visualization, sharing, and management in different stages, from design to facility management. Several BIM-based approaches have been proposed, including bridge inspection [18], highway construction inspection [19], buildings defect and maintenance history data management [20-22], and infrastructure facilities inspection [23]. This study differentiates from earlier work by focusing on building façades and their inspection. To streamline the façade inspection practice with model-based guidance, we

developed a façade inspection ontology here to capture the façade inspection entities and relationships. This paper provides the major concepts and relationships to support model-based façade inspection.

4 Methodology and Findings

The authors develop the ontology by first performing shadowing work, investigating relevant documents to extract the main concepts and terms for façade inspection, and analyze historical façade inspection reports. The documents include 1) façade inspection regulations (e.g., [24, 25], etc.); 2) international standard practice for periodic façade inspection (e.g., [26]); 3) façade condition glossaries [27-29]; 4) Autodesk BIM library; and 5) the available façade inspection reports. Next, the authors identified the taxonomies and vocabularies for the necessary concepts to be represented. The authors also investigated the classes, attributes, and relationships that would be needed to enable automated checklist generation and flexible data regrouping. The IFC schema has been evaluated for its capability to represent the identified concepts and relationships. Findings are presented as follows:

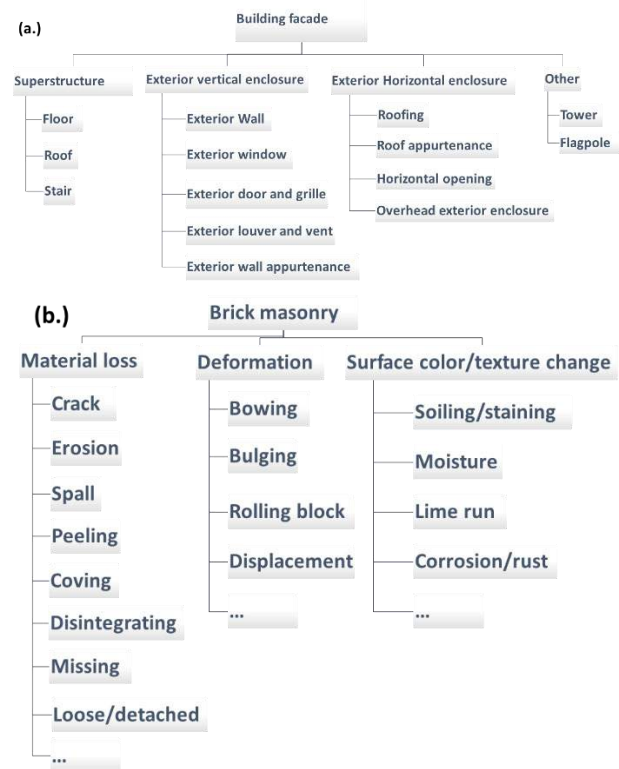

Figure 2. An overview of (a.) the identified major façade components at Level 2 and (b.) categorized defect types.

(1) **Major entities: Façade components, defect categories, and attributes.** In the shadowing work, we

identified three major information groups that were noted by inspectors: façade components on which the identified defects occur, defect types and defect attributes such as the location of defects, size of defects, patterns, and related conditions, etc. After investigating the related documents and analyzing the historical façade inspection reports [5], we combined a hierarchically organized vocabulary of façade components and decompositions, and defect types. The façade components and their hierarchy have been represented using Uniformat classification, including Level 4 elements (e.g., Level 2: Exterior Wall; Level 3: Parapet; Level 4: Unit Masonry). An overview of the major categories of façade components is presented in Figure 2a. Each category identified can be extended into a detailed level to guide inspectors through façade condition information collection.

The possible defects for different façade types are identified and grouped into three major categories based on the visual inspection evidence, namely material loss, deformation, and surface color/texture change (Figure 2b shows the subcategories for brick masonry façades). Material loss defect refers to the presence of defects where the façade material (e.g., brick unit and mortar joint on brick masonry façade) was lost. The most common defects in this category are crack, spall, surface abrasion, and missing components. Deformation refers to defects that lead to a shape change in façade components. The most common deformation defects identified are bowing, bulging, and displacement. The third category covers defects, such as water leakage, efflorescence, and corrosion, which can be identified by surface color or texture changes.

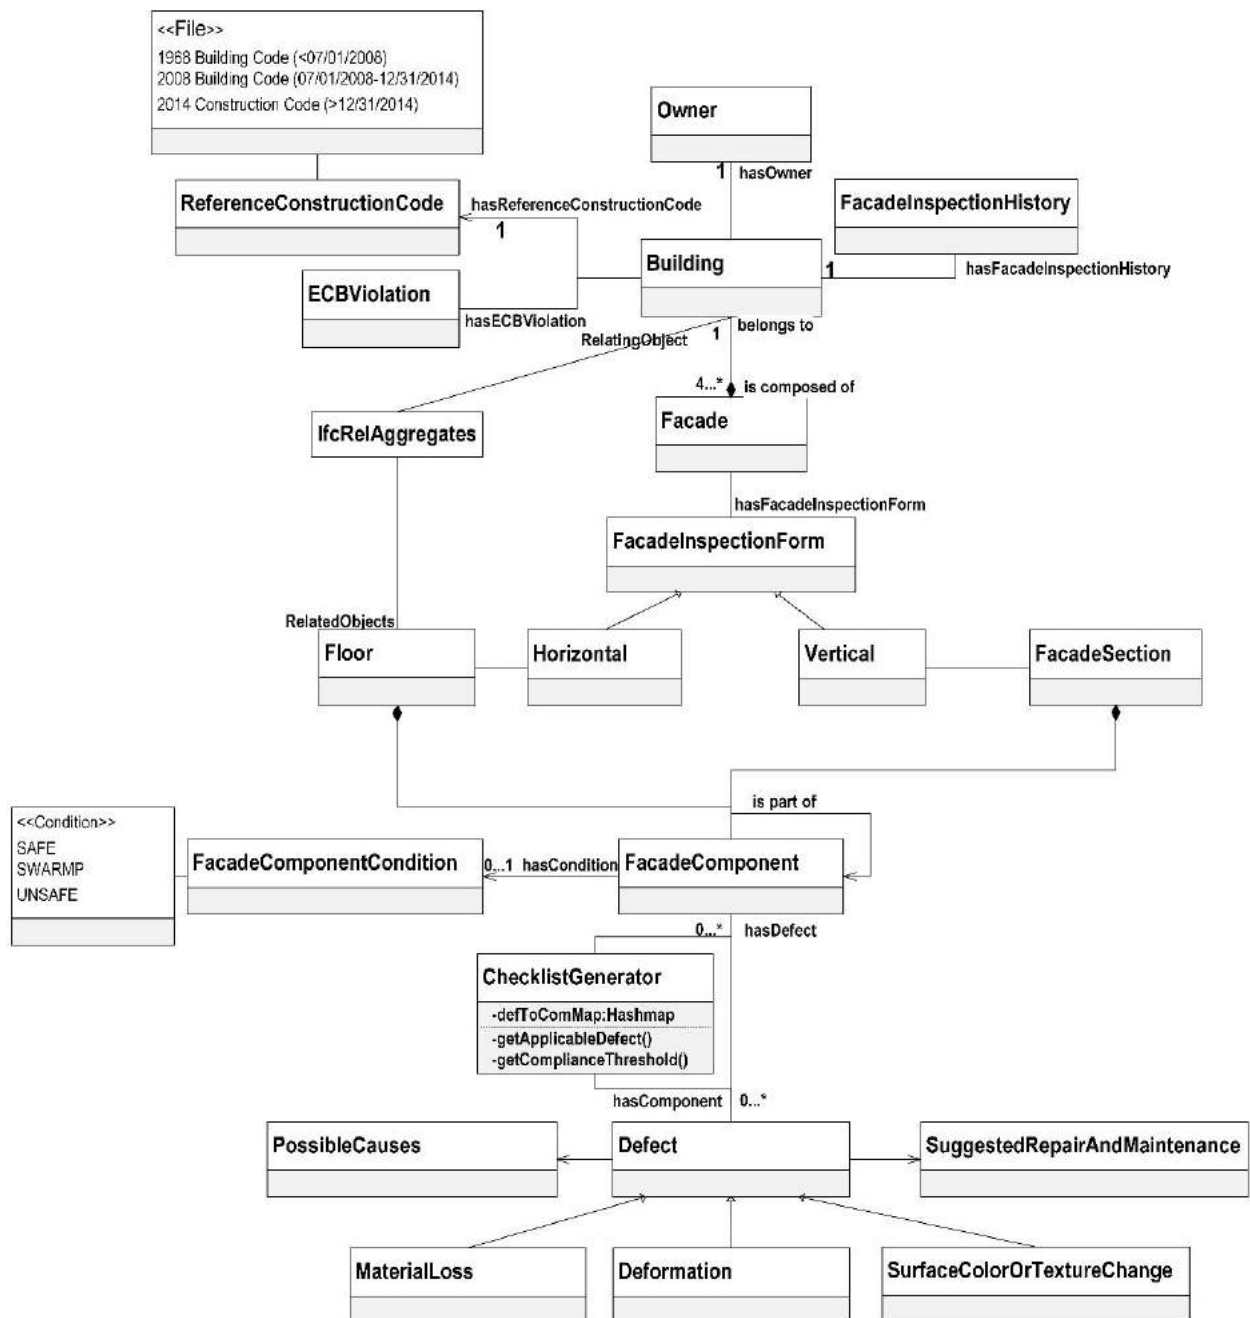

Figure 3. Part of the UML from the ontology showing the representation of façades, façade components, and defects.

Defect attributes are essential for inspectors to assess the severity of identified defects and serve as a reference value for inspectors to propose follow-up repair plans after the inspection. The authors identified several generic defect attributes together with their corresponding data types. "Location," "size," "direction," "associated façade component," "% of the affected surface on the associated component" are typically captured data in relation to defects. Another essential attribute is the presence of subsequent defects, which is

mainly applicable to deformations

The general composition and aggregation relationships between façade components have been augmented from Uniformat Classification for B. Superstructure hell. IFC schema has been utilized to represent buildings, floors, building elements, and geometrical and spatial relationships that are needed for façade inspection purposes (see Figure 3 for major concepts). Defects and associated data have been represented in relation to façade components in Figure 3.

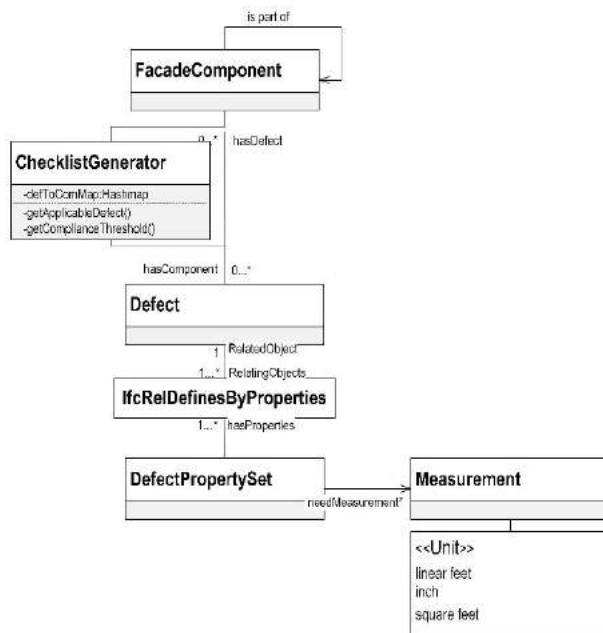

Figure 4. Part of the UML from the ontology showing major entities for checklist generation.

(2) **Necessary classes and attributes to support checklist generation and automated regrouping.** To enable the model-based customized checklist generation, we proposed a ChecklistGenerator class (Figure 4). This class is needed to identify applicable defects to a given façade component in a list of components that belong to a section or a floor of a façade and is represented as a HaspMap of component type as an index and corresponding list of defects as an ArrayList. The type of a façade component defines the applicable defects to be checked by inspectors and the defect attributes to be collected in the inspection process. For this purpose, a mapping matrix has been defined and used by the checklist generator.

Figure 5. Mapping of façade components and defect types for stone/limestone façades.

The mapping between façade components and applicable defects (and applicable attributes) has been identified by analyzing façade inspection relevant documents and historical inspection reports (see Figure 5). This matrix contains information about the defects that are applicable to Level 4 façade components and constraints on the applicability of defects when the materials of these components are different.

Figure 6. Examples of inspection forms for façades: (a.) vertical inspection of the façade, and (b.) horizontal inspection of the façade.

Each inspection starts with a façade direction (e.g., North, South, East, and West). Depending on whether a given direction faces a street or not, inspectors decide on the form of inspection (e.g., vertical drop-down, horizontal binoculars, and horizontal boom lift). BIM has to be divided into sections in each direction depending on the form of inspection (see Figure 6 for examples). So, sections need to be represented to understand which components fall into a section during an inspection and will be essential for regrouping information when needed.

With a BIM decomposed to a list of façade components per section, the component's material serves as a constraint, getApplicableDefect will loop through the matrix and extract the defects that need to be checked with that component and material type. getComplianceThreshold will check the related library for compliance checking, such as the height of parapets and railings. Each defect has the same generic set of attributes (i.e., description, possibleCause, referenceData, floorNumber, etc.) at the class level, and relevant defect types have a related DefectPropertySet that provides a list of defect attributes needed for façade condition assessment for that particular defect. Defect property sets have been represented using the IFC representation and relationships for attaching properties to building elements.

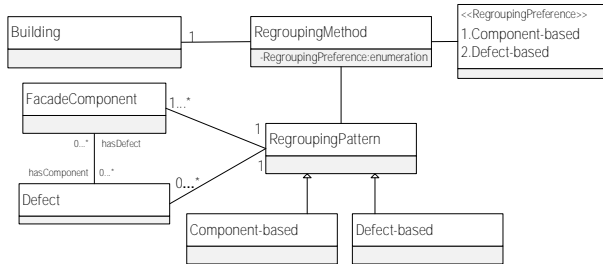

Figure 7. Part of the UML from the ontology showing high-level entities for flexible regrouping of inspection results.

Regarding the flexible regrouping of façade components to store and then retrieve using any predefined preference, the ontology includes a class called *RegroupingMethod* (see Figure 7), which has an enumeration of preferences to restructure the building elements either based on façade component hierarchies or based on the defect classification, or a mixed version of the two depending on an inspector defined tree structure. This class has a relationship with the *Building* class, as this is defined at once for all the façades of a building to be inspected. *RegroupingPattern* is a class defined in the ontology to store a preset hierarchy of façade elements based on the regrouping preferences (i.e., three types) that will speed up the regrouping for data retrieval. *RegroupingMethod* selected by an inspector to store and visualize inspection findings will have a relationship to the preset patterns stored in the *RegroupingPattern* class.

5 Conclusion

A mandatory façade inspection program is essential to avoid façade debris-related accidents and incidents, but the current façade inspection program is experience-based and needs guidance for inspectors to conduct in-depth and comprehensive inspections. With the challenges identified from the shadowing work, we envisioned a 3D model-based automated checklist generation and flexible regrouping to guide the inspectors in practice. Major classes included in the ontology are provided in this paper. These are discussed in major categories to represent façades in general (including classes such as façade components, defect categories, and defect property sets and relationships between them), to enable generation of a checklist (including classes such as generator, façade sections, façade inspection form and its subtypes, etc.) and to regroup façade elements (including classes such as regrouping patterns that are storing preset hierarchies of defects or components). This paper is an outcome of ongoing research work. Currently, we're developing a functional prototype that uses the proposed ontology as an underlying data schema to generate customized façade

inspection checklists for given buildings and enable restructuring the inspection data based on inspectors' data restructuring preferences. The generality and extensibility of the ontology will be evaluated in user and synthetic tests with the prototype. The results of this work will be published in a journal paper. The work presented in this paper lays the ground for the following research on the implementation of reasoning algorithms for comprehensive checklist generation and flexible data regrouping with BIM for façade inspection projects.

Abstract –

Embedments (embeds) are used extensively in construction for the attachment of dissimilar construction materials, such as, concrete to steel and wood to concrete. Coordinating the layout, delivery, and placement of these embeds is a sensitive construction chore, one that if not done properly, can lead to considerable lost productivity, delayed schedules, and cost overruns. This coordination is further complicated by the fact that most embeds are installed in the project by one trade contractor to be used by an entirely different trade contractor later in the project. As a result, the construction manager undertakes routine inspections to minimize future complications if those embeds are missed or incorrectly placed. Therefore, it is crucial that the inspection process is as complete as possible to ensure a project's success. The construction industry is also shifting to a digital twin approach in the management of the construction process whereby parametric models are finding more use in the inspection process. Coupling this technology with augmented reality (AR) allows inspectors to use BIMs in unique and more informative ways. In this paper the researchers examine three different inspection processes, a traditional 2-dimensional paper inspection, an AR + BIM inspection, and an AR + BIM inspection with interactive queues. Quantitative data were collected with each method along with qualitative feedback from the participants to gauge perceived effectiveness of their inspection. Among the three methods, it was evident that the use of AR improved through its development. However, from the qualitative feedback, it was discovered that some visuals in the AR assisted inspection were distracting, leading the researcher to conclude that visual elements in AR can affect the inspection outcomes. Furthermore, the researchers discuss recommendations for using AR + BIM for embed inspections in the context of using assistive technology for that process.

Keywords –

Augmented Reality; Productivity; Inspections; Construction Quality

1 Introduction and Background

Coordination during the construction process involves risk and, in many cases, the practice of routine inspections enables a construction manager to manage this risk better than its competitors. The rewards for effectively managing construction risk are evident with increased profits for the construction manager [1]. The inspection process, regardless of what is being inspected, is a welcome process that minimizes cost and schedule impacts to a construction project [2]. The lack of good inspection practices, especially when multiple trade contractors are involved, compounds the problem. One such situation concerns the construction embedment (embed). Embeds serve to connect dissimilar parts of the project together, such as steel to concrete and wood to masonry. Their installation often relies on predicting, well in advance, what other materials will be affected if the embeds are not properly installed. Furthermore, it is ideal if they can be installed when the structure is being assembled and not afterwards [3]. Based on conventional structural design methodologies, if the embeds are not installed along with the construction of the structure several problems will arise [4][5], some of which include:

1. Drilling holes for a post-installation anchors that often compromises the internal structural reinforcing
2. Lost time related to re-design and retrofit of the structure for post-installation anchors
3. The added cost of re-design and specialized post-installation anchors

It is crucial that the inspection process happens, and that it is properly conducted. The research literature demonstrates that technology devices can be used as an assistive device for inspectors [6]. Technology devices using augmented reality (AR) as an assistive inspection tool is demonstrated in the research [7][8] and also has potential as an inspection tool where embeds are

concerned. AR expands a wearer's view by adding a virtual overlay to their *real-world* view. In doing so, the wearer is provided additional details that are otherwise not readily available. Adding this meta-information to a person's perception of the *real-world* view adds insights that are not available without the added virtual information [9]. Therefore, the use of AR within the inspection process is arguably a viable enhancement.

2 Rationale and Research Aim

Understanding that missing embeds directly impacts the cost, schedule, and quality of a project supports the need for better tools to improve the inspection process. This necessity alone is a strong reason for continuing research that improves the inspection process.

The research described in this paper is a continuation in the development of a prototype AR inspection tool [10]. The tool has been designed to assist an inspection of embeds with comparisons to the more conventional methods of visual examination using two-dimensional (2D) paper plans. This paper documents the iterations of design with recommendations for future design improvements.

3 Methodology

This paper describes three independent procedures for inspecting embeds and analyzes the differences between them. The methodology for all procedures was the same so that analytical comparisons could be made that would directly inform future iterations of an assistive device that could be used to improve embed inspections. Two variables were analyzed in this study: the AR visualizations and the participants. While the researchers realize that participant variance may reduce the validity of the results, the researchers did attempt to solicit participation from the same population (undergraduate construction management students). The differences within the population will be described later.

The study was conducted using a between-groups design. All groups were chosen to perform an inspection of demonstration embeds within a controlled experimental space. The inspection consisted of identifying if an embed was installed or missing – installation accuracy was not measure in this study. There are known accuracy errors caused by image drift and parallax with the *Microsoft HoloLens* that were defined in Kim & Olsen's research [10]. Therefore, for the purposes of this study and comparison, only the accuracy in identifying if an embed was installed or missing was measured. The method of inspection differed between the groups and became the independent measured variable of the study. The participants of GROUP 1 were selected to visually observe the demonstration embeds using 2D

paper plans. GROUP 2 was selected to use a *Microsoft HoloLens* (second generation) with AR visualizations developed using *Trimble Connect's* integration with HoloLens (<https://connect.trimble.com/integrations-overview>) as described in Kim & Olsen's research [10]. Lastly, GROUP 3 was selected to use the same *Microsoft HoloLens* as group 2 to conduct their inspection, but the AR visualizations were developed using *Enklu* software (<https://www.enklu.com/>). The differences between the AR visualization software will be described later.

3.1 Demographics

As previously mentioned, the researchers controlled the convenience sampling by selecting students from the same population where they had similar attributes. All students in all groups were postsecondary students in a construction management program in the Southeastern United States. The students were asked to participate as a part of their regularly scheduled class time. The students, at this point in their academic careers have taken plan reading courses, have an understanding of building information modeling practices, and several of these students have had a construction-related internship. Table 1 describes the academic classification of the students that participated.

Table 1. Participant's academic classification

Classification	GROUP 1	GROUP 2	GROUP 3
Freshman (first-year)	0	0	0
Sophomore (second-year)	0	0	0
Junior (third-year)	0	0	16
Senior (fourth-year)	10	16	9
Graduate (fifth-year +)	0	1	1
Population <i>n</i>	<i>n</i> =10	<i>n</i> =17	<i>n</i> =26

3.2 Setting

The experimentation was conducted in the same space as mentioned in Kim & Olsen's research [10] and is described again here. The indoor space is approximately 54'-0" long (16.5 m) and 12'-6" wide (3.8 m). The height of the room is 17'-0" (5.2 m) with no finished ceiling – all MEP equipment, conduit, and piping are exposed. On the long side of the room is a 30'-8" x 12'-6" (9.4 m x 3.8 M) window wall, which does not have any window treatments and allows an abundance of outdoor natural light within the space. Refer to Figure 1 for a composite layout of the experiment room.

Figure 1. Rendering of the experiment room

The room in Figure 1 has exposed masonry walls and provided a setting to place demonstration embeds on the walls of the space. A parametric model of the room was created in *Autodesk's Revit* and embeds were positioned throughout the room as shown in the closeup rendering of one side of the room (see Figure 2).

Figure 2. Closeup within the parametric model of experiment room showing embed placement

Some demonstration embeds were designed to simulate steel angles and others were designed to simulate flat plates. Upon completing the parametric model, the embed coordinates were loaded into a total station and the researchers positioned the demonstration embeds within the room to match their locations in the parametric model.

3.3 The Demonstration Embeds

The demonstration embeds were fabricated from rigid $\frac{1}{4}$ inch (6.35 mm) foam board and affixed to the walls of the experimentation space. Attention was given to having some of the embeds minimally contrast with the surrounding wall color of the experimentation space. It is reasoned that embeds on an actual construction project site are often difficult to find because they look similar in color to the surrounding structure that they are affixed to. Figure 3 shows an embed in the experiment space that contrasts with its surrounding color and Figure 4 shows an embed that minimally contrasts with its surrounding color.

Figure 3. (a.) Demonstration plate embed and (b.) actual plate embed with contrasting colors

Figure 4. (a.) Demonstration angle embed and (b.) actual angle embed with minimally contrasting colors

3.4 2D Embed Placement Drawings

The parametric model used to layout the demonstration embeds in the experimentation space was created through a laser scan of the space that was later converted into a parametric model using *Autodesk Revit*. This model was used to create a 2D paper plan set that GROUP 1 used for their inspection. A partial illustration of the 2D paper plan is shown in Figure 5.

Figure 5. Partial image of 2D embed placement drawings

GROUP 1 used these 2D plans for their inspection of the demonstration embeds in the experimentation space.

3.5 AR Visualizations

GROUP 2 and GROUP 3 used the AR headset to conduct their inspections. The difference between GROUP 2 and GROUP 3 was the AR visualization. Two different authoring tools were used to create the AR visualizations and are described in the next subsections.

3.5.1 GROUP 2 – Trimble Connect AR

GROUP 2's AR environment was authored using *Trimble Connect*. With this authoring tool, the parametric model is uploaded to a cloud site and processed using *Trimble Connect*'s proprietary software. The model can then be viewed in the Microsoft HoloLens once it is registered to the room's surroundings [12, p. 18]. In this experiment, the parametric model only included embed outlines and positional information so that the embeds, when viewed with the HoloLens would be superimposed over the real-world location of the demonstration embeds in the experimentation space. The student inspector would then be able to compare the AR view with the real-world view to assess an embed's installation state. A representation of the *Trimble Connect*'s AR visualization is shown in Figure 6.

Figure 6. Representation of the *Trimble Connect* parametric model AR view

3.5.2 GROUP 3 – Enklu AR

The AR environment for GROUP 3 was authored using *Enklu*. This authoring tool makes use of the *Microsoft HoloLens*' ability to "spatial map" (<https://docs.microsoft.com/en-us/archive/msdn-magazine/2017/january/hololens-introduction-to-the-hololens-part-2-spatial-mapping>) the surrounding experiment space. In short, it is scanning the walls, ceilings, and floors of the space to anchor or register [12, p. 18] visual elements to the real-world space. *Enklu* uses this data and presents it as a canvas upon which interactive AR elements can be added that the wearer of

an AR device can use. In this study, demonstration embeds were added as the AR elements – they were positioned in the "spatial map" so that the student inspectors could observe and compare the planned demonstration embed placement with its actual placement in the real-world. An illustration of the *Enklu* AR visualization is shown in Figure 7.

Figure 7. The *Enklu* AR view

Some technical limitations prohibit an actual *HoloLens* snapshot in this paper of the *Enklu* AR view. In Figure 7, when wearing the *HoloLens*, the yellow and green walls shown in this figure are not visible – the real-world walls are directly observed by the wearer.

The difference between the authored *Trimble Connect* AR experience and the *Enklu* AR experience is in the interactivity of each environment. It is intended that the differences between the two AR experiences is the independent variable that is measured. The differences are enumerated as follows (these differences were not measured independently for this study):

- The *Trimble Connect* AR visualization is static (no elements move).
- The *Enklu* AR visualization contains a pop-up menu that appears over a demonstration embed allowing the wearer to record the observed embed's installation state.
- The *Enklu* AR environment includes a prompting queue – there is a visual glowing dot that prompts the wearer where to find the next embed during the inspection process.

4 Data and Results

A total of 53 students ($N=53$) participated as representative inspectors for this study. GROUP 1 included 10 students ($n=10$), GROUP 2 included 17 students ($n=17$), and GROUP 3 included 26 students ($n=26$). The experiment was designed so that 14 demonstration embeds needed to be assessed by the students during their inspection. Each embed was

predetermined to have a specific installation state as follows:

- INSTALLED – the embed was observed to be installed in the experiment space
- NOT INSTALLED – the embed was observed to be missing from the experiment space

The results of the student's assessment were recorded and tabulated for errors in observing the accurate predetermined installation state of the embed. The error frequency is tabulated in Table 2 for each embed.

Table 2. Embed error frequency for each group

Embed ID	State	GR 1 (n=10)	GR 2 (n=17)	GR 3 (n=26)
Plate 1	Missing	10%	35.3%	11.5%
Plate 2	No Contrast	0%	29.4%	26.9%
Plate 3	Contrasts	10%	5.9%	3.8%
Plate 4	Contrasts	0%	5.9%	7.7%
Plate 5	Contrasts	10%	5.9%	15.4%
Plate 6	Missing	10%	58.8%	15.4%
Angle A	Contrasts	0%	5.9%	3.8%
Angle B	Contrasts	0%	0%	0%
Angle C	No Contrast	0%	5.9%	3.8%
Angle D	Missing	10%	47.1%	3.8%
Angle E	Contrasts	0%	5.9%	3.8%
Angle F	Contrasts	0%	5.9%	3.8%
Angle G	Contrasts	0%	11.8%	7.7%
Angle H	Contrasts	0%	5.9%	3.8%
Mean	--	3.6%	16.4%	8.0%

5 Discussion and Analysis

For the purposes of reviewing the results, the researchers assign GROUP 1 as the control group since their method of inspection closely resembles the traditional method of construction quality inspections [13]. Therefore, GROUP 2 and GROUP 3 represent the independent variables of the study and the topic of discussion in this section of the paper.

Reviewing the error frequencies in Table 2, it is apparent that the control group has a lower mean error frequency (3.6%) – the tests groups have higher error frequencies (16.4% and 8.0%). This is an indication that if the process of inspection is to be improved by introducing AR, there are some improvements that need to be made. This experimental study describes one incremental step toward resolving this issue.

The researchers conducted inspection testing with GROUP 2 about three months before engaging GROUP 3 with the same experiment. The intent was to learn from the results found in the experiment with GROUP 2.

5.1 Analysis of GROUP 2

It was discovered through experimentation with GROUP 2 that the AR visualization often interfered with the inspection process – causing a larger error frequency. This is evident in the embeds that were missing from the experiment space (Plate 6 and Angle D) along with the embeds that had no color contrast with their surrounding structure (Plate 2 and Angle C). Each of these embeds had much higher error frequencies when the AR tool was used. The researchers concluded through this data and through anecdotal feedback during the experiment that the *HoloLens* impaired the wearers vision enough to make the assessment problematic for these embeds. It was further commented by one student that the AR visualization “got in the way of seeing if the embed was there or not”. From this feedback and through analysis of the data, the researchers modified the AR visualization of the experiment before GROUP 3's turn to inspect.

5.2 Analysis of GROUP 3

The AR visualizations were re-designed using the *Enklu* platform. The researchers were attentive to the opacity of the embed visualizations – reducing the opacity enough to enable better inspection of the demonstration embeds. Cross comparing the error frequencies of GROUP 3 to the control group (GROUP 1) it is apparent that the error frequencies are more similar than those between GROUP 2 and the control group. While the control group's error frequency is still lower, the gap has tightened and GROUP 3's error frequency in most cases has dropped by half. The only exception to this is Plate 2 where the error frequency to that of GROUP 2 is nearly identical. In short, it appears that it is difficult to make an accurate assessment when the color of the embed matches its surrounding structure's color.

5.3 Limitations and Future Work

While the researchers sought to minimize the conditions that could affect the result of this study, it became apparent that some elements of the experiment should be considered if the study were to be repeated.

5.3.1 Lighting

The researchers acknowledge that lighting is a significant issue with AR [14]. In this study this element was not controlled. Although lighting (luminance) data was collected, it was inconclusive about how this may have affected the research results.

5.3.2 The Subject of Inspection

This study was intentionally limited in its scope; choosing only to analyze installation state of the embeds.

It is recognized by the researchers that installation accuracy is also a significant quality issue when embeds are concerned. However, as explained earlier there is an inherent limitation with the Microsoft HoloLens concerning image drift that makes a comparison of using AR for this type of inspection problematic. In the future, analysis of accuracy should be considered and added to the comparison once hardware improvements are made.

5.3.3 The Inspectors (Students)

This study used a convenience sample of students that were marginally experienced in the inspection of embeds. For the purposes of the methodology, students were consistently used throughout the three different studies to control for “experience” bias. Future iterations of this research should be conducted with willing and “seasoned” inspection practitioners.

5.3.4 Headset Design

The findings in this research lead to the conclusion that the AR visualizations interfere with the inspection process. This was discovered for both GROUP 2 and GROUP 3. The *Microsoft HoloLens* (second generation) has a flip visor that allows the wearer to remove the AR visualization by flipping the lens up allowing the viewer to see the real-world view unobstructed, see Figure 8.

Figure 8. (a.) HoloLens with visor down and (b.) HoloLens with visor up

Conditions in a future study should include this as an option for the student inspectors where a simple removal of the AR visualization could resolve the interference present in this study.

6 Conclusions

This is a continuing study that has evolved as newer iterations of AR technology, both hardware and software, have allowed for improved results when using AR as and

assistive technology. Aside from the limitations discussed in the previous section of the paper, the authors contend that a broader experimentation including revised hardware, the inspection and measurement of embed placement accuracy, and the timing of the accuracy (i.e. inspection before the embed is cast in-situ or afterwards) are all variables to be measured. The motivation to undertake this study emerged from the necessity to improved quality and productivity in an industry that is often viewed as failing in both [15]. It has been reasoned that one of the root causes for poor construction quality is the lack of proper inspections [1][3][4] and the authors contend that early inspections can help minimize or eliminate retrofit work that disrupts productivity.

During the experimentation the researchers observed that some of the student inspectors were overly distracted by the “new” technology. The authors contend that that distraction was a good thing and once the normalcy of AR technology takes root in the construction industry, we may see more innovative ways in which the technology can improve the industry’s reputation.

E-mails: h.ibrahimkhil@unsw.edu.au, x.shen@unsw.edu.au, khalegh.barati@unsw.edu.au

Abstract –

Construction projects are often suffered from time delay and cost overrun, unavoidably leading to underperformance and low productivity of the construction industry. Inadequate monitoring of construction progress is one of the key factors behind this scenario that has a detrimental effect on subsequent construction activities. Recent development in 3D Building Information Modelling (BIM) and laser scanning technology has made it possible to actively monitor construction progress. This paper aims to obtain timely and accurate progress information of construction activities through integrating mobile mapping techniques with as-built BIM. A novel method of construction progress monitoring to measure progress of work in terms of percentages, is presented. Having updated as-designed BIM model as well as construction site scan data, Hausdorff distance is introduced to filter out the noise and extract elements of interests from the site scan data. The extracted elements are then converted to as-built BIM model and compared with as-planned BIM model. Python script and Dynamo programming are used for color codes to indicate status of activities and obtain related progress percentages. A case study was conducted in the Engineering building at the University of New South Wales (UNSW) to obtain real site scan data. The result shows that the method has achieved an average of 95.9% accuracy in estimating progress percentages. In addition, the take-off quantities from the as-built BIM model could be used for several purposes, such as construction schedule update and procurement management.

Keywords –

Construction progress monitoring; Laser scanning; SLAM; Scan-to-BIM; Hausdorff distance.

1 Introduction

Construction industry is a major contributor to the global economy, accounting for around to 10% and 25%

of Gross Domestic Product (GDP) in both developed and developing countries respectively [1]. In Australia, the industry contributes about 9% to GDP, producing annual revenue of \$360 billion [2]. However, the industry's low productivity rate compared to other industries has remained a challenge for construction practitioners and researchers [3, 4].

One of the areas that has a major impact on low productivity rate is construction progress monitoring. Because the traditional construction progress monitoring, which is a manual observation and data collection process, is time-consuming, costly, error-prone, infrequent, and unsafe resulting in time and cost overrun in construction projects [5, 6]. A timely and accurate progress monitoring system not only contributes to successful completion of a project, but also helps to increase productivity and enhance safety performance of a project. For instance, using advanced reality capture technology contributes to workers at construction site exposed to COVID-19 hazards [6]. Therefore, measuring construction progress in a timely and reliable manner by implementing new techniques and technologies are vital in addressing the challenges in traditional system [7, 8].

The aim of this study is to use Simultaneous Localization and Mapping (SLAM) and scan-to-BIM techniques to obtain timely and accurately progress percentages of construction activities, which is used in schedule update. The study's key contributions are using mobile scanners, which improve usability while also minimizing noise; introducing Hausdorff distance to extract objects of interest from scan data while also filtering out the noises; and calculating work progress in percentages. A case study was conducted in engineering building at University of New South Wales (UNSW) and produced successful results.

The rest of the paper is organized as follows. A review of previous studies is discussed in section 2 followed by research methodology and the case study. Finally, the discussions and conclusions of the study are reviewed.

2 Literature Review

Automated progress monitoring using various methods and technologies has been widely studied in recent years to overcome the problems with traditional approach. This part of the paper provides information about available reality capture techniques, as-built BIM, and data-driven progress monitoring in previous works.

2.1 Reality capture techniques

Technology development recently resulted in several types of reality capture techniques using in data acquisition from construction sites. For example, imaged-based or photogrammetry, Laser Scanning (LS), Radio Frequency Identification (RFI), Ultra-Wideband (UWB), Global Positioning System (GPS), Wireless Sensor Network (WSN), and Unmanned Aerial Vehicle (UAV) [9]–[11]. The RFI, UWB, and GPS are found to be impractical for progress measurement of cast-in-place activities [10]. Laser scanning, photogrammetry, and RFI are preferred for progress monitoring [11].

The photogrammetry technique has widely used in progress monitoring but still there are associated problems: all photos and videos are affected by severe weather conditions, lighting and shadow [12, 13]. In addition, it is not capable of covering entire project and due to complexity of indoor environment limited studies have been conducted pertinent to indoor progress monitoring [14, 15].

The 3D laser scanning technique is comprehensive and accurate approach. However, errors in calibration, environmental factors' impact such as sun and wind on instrument movement and thermal expansion, surface reflection and dynamic field settings are certain drawbacks [16]. Additionally, several scanners are required to cover entire area [13, 15] and improvements are also needed to accelerate registration of multiple scans [17].

To overcome the problems of photogrammetry and static laser scanning approaches, numerous studies have been conducted using simultaneous localization and mapping (SLAM) technique in construction domain. For example, Kim et al. [18] introduced object recognition and navigation method based on SLAM that implemented and tested on a mobile network platform for 3D real-time data acquired from a construction site. Shang and Shen [19] studied integration of SLAM with UAV as pilot study for construction site real-time mapping. Asadi et al. [15] used SLAM technique in unmanned ground vehicle (UGV) for real-time image localization to automatically register site images to as-planned BIM model. Therefore, the SLAM could be used in progress monitoring to mitigate problems in static laser scanning and photogrammetry approaches such as time spent in registration of scans as well as available

noise in scan data [13].

2.2 As-built BIM

Building Information Modelling (BIM) provides an outstanding opportunity to the construction industry since almost all data acquisition technologies are integrated with BIM which provides a better platform for construction sites particularly for progress monitoring [16, 20].

Scanning data with BIM can be used in two different ways: scan-to-BIM and scan-vs-BIM. In the scan-to-BIM approach scan data from a construction site is first converted to a BIM model manually or semi-automatically before performing additional analysis [21]. This approach is often used for existing structures including historical buildings and could be applied in various phases of a construction projects as well [22].

In the scan-vs-BIM approach a scan data is aligned into coordinate system of a CAD model and further analysis is performed [23]. This approach has been widely used by scholars for the experiments to compare as-built with as-planned data [5]. The comparison of visualized as-built and as-planned construction data through BIM results in enhanced identification, communication, and analysis of discrepancies in progress [24]. In this study a scan-to-BIM approach is used to create as-built BIM model.

2.3 Data-driven Progress Monitoring

In recent years photogrammetric and laser scanning point clouds with BIM have been used to measure progress of construction works. For example, Bosche et al. [25] investigated the potential of laser scanned data for progress control by merging time-stamped 3D laser scan data with a 3D CAD model, which was later improved by Bosche et al. [26] as well. Similarly, Turkan et al. [27] used a 3D CAD model with 4D BIM to update project schedule automatically. Turkan et al. [28] used a 4D BIM model and laser scanned data to track progress of work. The result indicated reasonable and automated estimation of project progress for structural erection in terms of earned value. Golparvar-Fard et al. [29] used point cloud created from images in which progress was color coded. Martens [30] also indicated progress of work in color codes using Hausdorff distance in the method.

Pucko and Rebolj [31] and Pucko et al. [5] conducted studies with multiple scanners mounted in labors' helmets. Continuous modifications were captured with scanners and the as-built model compared with 4D BIM model for progress monitoring. Kim et al. [32] also used laser scanners to acquire data and compare the incomplete 3D data with 4D BIM model to propose a fully automated method for progress

measurement. Zhang and Arditi [17] conducted experiments in laboratory environments using point cloud to evaluate automatic progress control. There are several other studies used point clouds and BIM models for progress measurement. This study also uses SLAM-based approach utilizing point clouds and BIM model with below research methodology for progress monitoring. SLAM-based approach reduces noise and the time spent in registration of scans.

3 Research Methodology

The designed and selected research methodology for current study is divided into three phases: 1) digital twin in which as-designed, as-built and as-planned models are provided, 2) progress analysis that includes a model-to-model comparison and quantification of progress percentages, 3) schedule updates using obtained progress percentages from phase two. The entire research methodology diagram has shown in Figure 1. The study covers phase one and phase two while phase three will be studied in the future. These two phases are further described in below sub-section.

3.1 Data Filtration and As-built BIM

There are two steps that are used in data filtration: first, coarse and fine registration are carried out between construction site and benchmarking point clouds. Secondly, Hausdorff distance is introduced to extract object of interest from registered point clouds.

The benchmarking point cloud is a virtual point cloud created from as-design BIM model for construction elements that are under construction on jobsite. This point cloud is noise free and includes only objects of interest that will be extracted from scan data. Hausdorff distance is used to quantifying the similarity between two arbitrary point sets without necessity to establish the one-to-one correspondence between the point clouds. In mathematics, the Hausdorff distance measures how far two subsets of a metric space are from each other, or it shows the maximum deviation between two models. Given two nonempty point sets as below:

$$A = \{x_1, x_2, \dots, x_n\} \quad B = \{y_1, y_2, \dots, y_n\}$$

the Hausdorff distance between A and B defines as $H(A, B)$. Which $H(A, B) = \max(h(A, B), h(B, A))$

Where:

$$h(B, A) = \max_{y \in B} \left(\min_{x \in A} \|y - x\| \right) \quad h(A, B) = \max_{x \in A} \left(\min_{y \in B} \|x - y\| \right)$$

$h(A, B)$ and $h(B, A)$ are one-sided value from A to B and from B to A, respectively. In most engineering applications, the number of point sets obtained by 3D model is not identical, and it is difficult to establish one-to-one correspondence between the point clouds. Hence, the Hausdorff distance is suitable for measuring similarity between 3D models in engineering practices [30, 33].

The Hausdorff distance is used to filter the as-built point cloud against a benchmarking point cloud in this study as well. Following the Hausdorff distance, the RANSAAC shape detection algorithm is also applied to remove unnecessary points remained in the result of Hausdorff distance. Finally, the cleaned point cloud as a result of RANSAAC algorithm is converted to a BIM model called as-built BIM. The as-built BIM is later used in comparison with as-planned BIM model to indicate the status of activities and obtain progress percentages.

3.2 Progress Monitoring

Work progress is also monitored in two stages: determining the status of activities and calculating progress percentages based on take-off quantities.

The as-built and as-planned models are registered in same coordinate system using Autodesk Revit's shared coordinate system to determine status of activities in terms of ahead of schedule, behind of schedule or on schedule. Three different colors are used for color coding as below: red color is used to indicate behind of the schedule activities. Blue Color is used to indicate on schedule activities. No color or white color is used to indicate ahead of schedule activities. Python scripting and Dynamo visual programming were used to perform the task.

Following determining the status of activities, Dynamo visual programming is used to obtain volumes of the as-built elements and transferred it to Excel

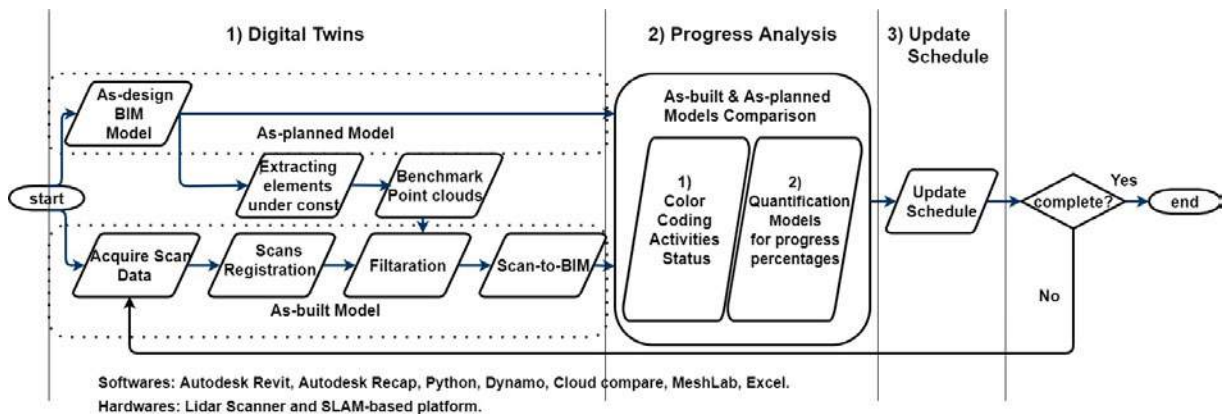

Figure 1. Proposed research methodology.

spread sheet. The obtained volumes are used in comparison with as-planned BIM model volumes to calculate progress percentages. A unique element ID is assigned to each element which contributes to both Python and Dynamo programming as well as calculating progress percentages.

4 Case Study

This case study was carried out in Civil Engineering Building (H20) at the University of New South Wales (UNSW). The study included two rooms, meeting room and its associated kitchen, each with an area of 58.78 m² and 21.56 m² respectively. The primary goal of performing the research in an existing structure is to validate the methodology. The as-designed model, which is a complete 3D BIM model of the building as shown in **Figure 2**, was produced in Autodesk Revit 2020 using correct room dimensions measured by hand with a tape measure. Site scan data were collected by Geo-SLAM ZEB-REVO laser scanner as shown in **Figure 3**.

Figure 2. Two different views of as-designed BIM model of building H20, room 402 at UNSW.

Figure 3. Point cloud data produced by the mobile handheld scanner for room 402 building H20 at UNSW.

The Geo-SLAM ZEB-REVO laser scanner is handheld, lightweight, and easy to use scanner that can perform a fully automatic scan. This laser scanner has maximum range of 30m, scan rate of 43200 points/s and relative accuracy of 1-3 cm. The SLAM condition is also shown

in color scale from blue to red as good to poor respectively [34]. The color was not considered in process of point cloud in this case study. The scan data were collected in less 10 minutes for the case study.

The progress of the work is measured by comparing the as-built and as-planned BIM models. The as-planned model is a subset of the as-designed BIM model that is intended for construction within a certain time frame. The as-built model is developed using scan data to show the construction site's status. It is assumed that an accurate as-designed BIM model exists, which is modified on a regular basis with change orders and contract modifications.

The study's focus is limited to the progress of the walls. Hence, the scan data was manipulated into four different cases to measure progress in different time periods. These four cases are: 1) not started with no progress; 2) partly completed with progress until the floor of larger windows on the south side of the building; 3) work progress until the floor of small windows on the west side of the building and 4) completed with 100% progress. Scan data for second and third cases shown in **Figure 4**.

Figure 4. Simulated point cloud data: (a) second case: work progress until the floor of windows on the south side of the building; and (b) third case: work progress until the floor of windows on the west side of the building.

4.1 Filtration and As-built BIM

A benchmark point cloud of walls was generated from as-design BIM model in Cloud Compare followed by coarse and fine registration with side scan data as shown in Figure 5 (a). Hausdorff distance was implemented in MeshLab to filter out noise and additional construction elements in the scan data such as columns, floor, ceiling, and furniture. **Figure 5** (b) depicts the result of Hausdorff distance.

Figure 5. Procedures of data processing: (a) Point clouds registration: red is benchmarking point cloud and RGB is site scan; (b) Result of Hausdorff distance; (c) Planes detection using RANSAAC algorithm; (d) Fourth case: result of RANSAAC algorithm; (e) Second case: result of RANSAAC algorithm; (f) Third case: result of RANSAAC algorithm; (g) Second case: as-built BIM; (h) Third case: as-built BIM; and (i) Fourth case: as-built BIM.

RANSAAC shape detection algorithm from Cloud Compare was also applied to eliminate residual noise from the result of Hausdorff distance. Figure 5 (c) shows the RANSAAC detected planes for both interested objects and residual noise. The residual noise in the shape of planes is removed and required planes are kept only. The product of the RANSAAC application is a cleaned point cloud that is ready to be converted to as-built model as shown in Figure 5 (d). Parts (e) and (f) display the results of RANSAAC algorithm applied to the remaining other two partially completed cases. The as-built BIM models for the three separate cases were produced manually in Autodesk Revit 2020 considering the worst cases as shown in [Figure 5. (g, h, i)] respectively.

4.2 Status of Activities and Progress Percentages

The status of activities related to the construction schedule is determined by comparing as-built and as-planned BIM models. Since the research was performed on an existing structure, the following two assumptions were considered in the case study: 1) two as-built BIM

model walls were approved as not yet completed or behind schedule, and 2) two as-built BIM model walls were accepted ahead of schedule. As-built and as-planned BIM models were registered in same coordinate system using Autodesk Revit shared coordinate system. Color codes were produced using Python script and Dynamo, as shown in Figure 6. Red elements indicate activities that are behind schedule, blue walls indicate activities that are on schedule, and no color or white color indicates activities that are ahead of schedule.

All the elements were assigned a unique ID starting at 100. The ID aids in comparison, data transfer to another environment, and schedule updates. To measure the progress percentages, the volumes of elements were transferred and compared to as-planned volumes, as shown in Table 1. A simple proportion was carried out considering as-planned values 100% complete in comparison. Activities 100,200,700 and 800, which are behind of schedule (B.S) and ahead of schedule (A.S) cannot be used in comparison. Hence, the progress is calculated for ongoing activities in different cases only. Ahead of schedule (A.S) activities could be used if the comparison is performed with as-designed model, which will be considered in future improvement.

Figure 6. Status of activities in the fourth case.

The total accuracy of the work is calculated by calculating the errors in each wall in all cases. In calculating progress percentages, the errors are either increment or decrement. It is worth noting that the scanning device's accuracy is not covered in this case study. Because of the increase or decrease in values, the absolute values of errors are taken. Subsequently, the average and total average values for all the errors are determined. Finally, as shown in Table 1., the total accuracy is calculated.

5 Discussion

The case study revealed that the new method of progress monitoring using Hausdorff distance and as-

built BIM can be used for completed and partially completed activities. This approach used a handheld scanner to collect data, which reduced the amount of noise as well as the time spent in registering multiple scans. The use of a mobile scanner and as-built BIM in progress monitoring, according to this report, not only improves measurement precision, but also contributes to resuming postponed projects, COVID-safe working, procurement preparation and a variety of other benefits.

The novel approach used in this study, which combined algorithms and modern technology, can provide the following advantages. These advantages include quickly extracting objects of interest, showing activity status, and obtaining progress percentages that assist project managers not only in assessing job progress but also in other phases of the project life cycle. In addition, using mobile scanner minimizes the drawbacks of photogrammetry and static laser scanning approaches.

The study like other research works, has some limitations. Some parts of the study such as registration, creating as-built BIM models in Autodesk Revit, and registering as-built and as-planned models in the same coordinate system, are still done manually. In addition, since Autodesk Revit does not allow to overriding color on a link model, the activities that are ahead of schedule are not colored as shown in Figure 6.

Table 1. Progress percentages and accuracy calculation

Accuracy calculation

6 Conclusions

Construction progress is still measured manually, which is biased and error prone and has negative impact on project success in terms of time, cost, quality, and safety. This research work with a novel method addresses this problem to obtain the accurate and reliable progress of work in terms of percentages.

The method was evaluated on real scan data in a case study, with various elements such as floors, columns, furniture, and kitchen items assumed as noises, yielding the following advantages.

Utilizing Geo-SLAM mobile scanner in progress monitoring system helps to gather data in different environments, reduces number of allocated resources, time and costs, and contributes to resuming projects and safe working environment. In addition, integrating Hausdorff distance and benchmarking point cloud makes it simple to remove noises and redundant elements from scan data to obtain objects of interest.

Project stakeholders could also see the status of the activities in visual format, and reliably calculate work progress in percentages, which is challenging task in traditional approach. The obtained progress percentages could also be used for automatic schedule updates, procurement management, contract dispute resolution, and project resumption after a breach of contract.

In future work, shortening filtration process, overriding a color to ahead of schedule activities, and application of the methodology in other tasks will be studied.

Abstract –

Three-dimensional (3D) printing is a branch of additive manufacturing (AM) that works by slicing a 3D computer-aided design (CAD) model into 2D layers and sequentially printing each layer additively until the entire object is obtained. There has been a growing interest in 3D printing in the architecture, engineering, and construction (AEC) industry because of its ability to lower costs, reduce waste, and simplify the supply chain. Due to the inherent nature of this technology, it requires a synergistic effort among experts in different disciplines such as architecture, material science, structural design, and robotics, to name a few. Previous studies have focused on developing, exploring, and investigating the architectural, materials, and structural aspects. However, the robotic technology aspect received relatively less attention. Thus, the objective of this study is to critically review the existing 3D printing robotic systems in the AEC industry and explicitly categorize them. At first, the literature related to 3D printing robotic systems in the AEC industry was studied, and the subjects which have not been discussed extensively were identified. Then, the gaps in the existing state of the art were identified, and lastly, a classification method was developed and discussed. To obtain the classification of the existing construction 3D printing robotic systems, five parameters were highlighted, namely fabrication place, fabrication type, materials used, 3D printer type, and 3D printing technology. In addition, the obtained classification was based on exploring the combinations of these parameters and their variations for existing applications in the AEC industry. By selecting the material that will be used, the application type, and other structural details, the printer details will be provided based on the developed classifications. The resulting classification could greatly assist and guide stakeholders' efforts to better understand and adopt 3D printing in current and future projects.

Keywords –

3D printer; robotics; classification; AEC industry.

1 Introduction

Three-dimensional (3D) printing is a method that has been highlighted in various fields and industries. From biology to engineering, 3D printing helps provide an automated method to build complex geometric shapes with the least amount of human intervention.

In the AEC industry, the adaptation of additive manufacturing started in 1998 by Khoshnevis [1]. Since then, creating and testing new materials, configurations of 3D printers, unique structural systems, and new application solutions were the new focus areas in the era of 3D printing [2].

Recently, the construction of 3D printing has evolved from an architect's modeling tool to produce a large-scale structure, especially after constructing the world's first 3D printing house (Canal House) in Amsterdam in March 2014 [3]. This is also evident from the spike in research related to 3D printing in the last few years [4,5]. The observed spike is potentially because 3D printing provides many advantages compared to conventional methods, including fewer chances of human errors, time and cost-saving and less wasted material in the whole building process [6]. Furthermore, 3D printing can also provide a reduction in work-related injuries as well [4]. As much as 3D printing showed many promising improvements to the current state of construction globally, more research is needed to improve the quality and the capability of the already existing systems.

Due to the variety of materials used in 3D printing, the scale of printing, and the purpose, different types of 3D printing robotic systems were developed. There are several parameters that distinguish one robotic system from another. The most important ones are fabrication place, fabrication type, materials used, 3D printer type, 3D printing technology, and 3D printing method. To select the appropriate 3D printing robotic systems, the right parameters should be selected. To assist 3D printing users in selecting the appropriate system for their application, this study provides a classification of 3D printing robotic systems based on existing applications in the AEC industry.

2 Literature review

Although conventional construction methods have remained relatively unchanged for decades, the new technology, 3D printing, guaranteed the capability of being an effective way to increase the project efficiency and profitability and having positive environmental impacts [6]. For those reasons and the increasing number of applications, 3D printing is receiving attention from researchers and practitioners in the last few years.

Many studies have focused on creating different structures, especially large-scale ones, enhancing their properties, and studying their printability and structural capacity. The study by Pessoa et al. [7] presented a review of the 3D printing application in the construction industry. The study concluded that 3D printing is still in an initial stage in the AEC industry. As mentioned in their study, a collaboration between the private sector and research groups counted as an essential step for developing full-scale solutions for 3D printing. Some of the examples in their study included that kind of close collaboration across the world. Another study developed by El-Sayegh et al. [4] provided a systematic review of 3D printing in the construction industry. Their research discussed and evaluated the different 3D printing techniques. It was focused on the 3D printing benefits, challenges, and risks and concluded that before confirming that 3D printing can become a viable solution in the construction industry, several challenges still need to be addressed.

Some review studies focused on a certain type of material, such as Mohan et al. [8], which focused on reviewing the material behavior spanning from the early age to long-term performance for extrusion-based concrete 3D printing. The study presented and discussed the printability and the structural capacity of the Extrusion-based 3D printing with concrete material. Another review paper by Ma et al. [9] focused on reviewing the existing 3D printing technologies of cementitious materials currently used. The three latest development of largescale 3D printing systems were summarized, and their relationships and limiting factors were identified. The study was concentrated on the printability and the structural capacity of each technology. On the other hand, Zhou et al. [10] focused on the 3D printing of polymer materials and reviewed the printability of this type of material. The study investigated the limitations of using polymer materials in construction 3D printing. In addition, Buchanan and Gardner [11] reviewed metal 3D printing techniques in construction. The printability and the structural capacity were discussed in detail. Their research was focused on the methods, the application, the challenges, and the opportunities of metal 3D printing.

In 2018, Ozturk [12] provided a review of different applications of 3D printing technology in industries other

than the construction industry to examine their attempts in the construction industry and provided an outlook on possible future application areas.

This resulted in the identification and classification of the state-of-the-art 3D printing technological developments for various industries and made projections on the possible adaptation areas in the construction industry.

Kidwell [6] analyzed progressive 3D printing companies that have effectively employed 3D printing technology on a full scale. This research aimed to examine the current uses of 3D printing technologies in construction and then highlight the best practices and applications while considering the technology's existing limitations and creating an outline for these applications. The study was focused on the type of materials, printability, and structural capacity. Duballet et al. [13] conducted a study on building systems related to concrete extrusion-based 3D printing techniques. The study highlighted specific parameters such as concerning scale, environment, support, and assembly strategies and proposed a notation system to classifying building systems depending on concrete 3D printing.

In 2016, Rogers et al. [14] Provided a research agenda for future studies on the impact of 3D printing services on supply chains by identifying types of 3D printing services available today and identifying the potential impacts of these services. However, this study did not provide any details regarding printability and structural capacity. Perkins and Skitmore [3] investigated the state of the art construction 3D printing practices and their future potential based on the review of relevant literature. In addition, the technology could be applied to construct buildings far more quickly and at a much lower cost. Their research described in detail the three main 3D printing methods used for cementitious materials: contour crafting, concrete printing, and D-shape. It concluded that approximately 30% of waste could be reduced by 3D printing, which makes it a very attractive proposition for construction.

The literature review thus confirms that as 3D printing is still in its infancy in the AEC industry, research is still focused on the materials used, printability, and structural capabilities. The research gaps found after reviewing the literature are:

1. Most of the studies were developed to review 3D printing based on the materials used and printer methods, the studies that review general 3D printing in construction are very few.
2. Most of the studies provide a 3D printing classification for a certain technology or technique; none of the studies provided a general 3D printing classification.

3 Research aim and objectives

This study will provide a classification of the existing 3D printing robotic systems in the ACE industry, focusing on the 3D printer's details and different applications. The following objectives will lead to achieving the mentioned aim of this study:

1. To explore the existing 3D printing robotic systems in the ACE industry.
2. To identify different applications of the analyzed 3D robotic systems.
3. To develop a classification of the 3D printing robotic systems.

The proposed classification will assist the building designers, and construction professionals choose the appropriate 3D printing robotic system(s) for their particular context and application.

4 Methodology

To achieve the abovementioned objectives, the following methodology is employed. First, a systematic literature review was done to collect the 3D printing robotic systems' details and their different applications. The literature was reviewed to collect the details of different 3D printing robotic systems used in construction. The collection process focused on the methods used in 3D printing and other parameters such as the material used, the area of the structure printed, fabrication place, fabrication type, and 3D printing technology. Second, application details were collected to show the 3D printing robotic system's capability. Lastly, based on the collected data, a classification was developed. The above mentioned methodology is shown in the form of a flowchart in Figure 1.

4.1 Data Collection and Preparation

There are a variety of 3D printing robotic systems, methods, and types used in the construction industry. It is very important to understand every aspect of these systems, methods, and types before choosing the right system for their context or application. Lack of such an understanding will not only lead to choosing the wrong method, system or type but also might have time, cost, and resource implications on projects. Therefore, to comprehensively understand and map these, this research was focused on collecting different parameters that may affect the selection of the proper robotic system, such as the materials used, fabrication place, fabrication type, 3D printing technology, and 3D printing method. Although this is not an exhaustive list of parameters, these are some of the most significant factors impacting the selection of the right 3D printing robotic system(s) as per the authors'

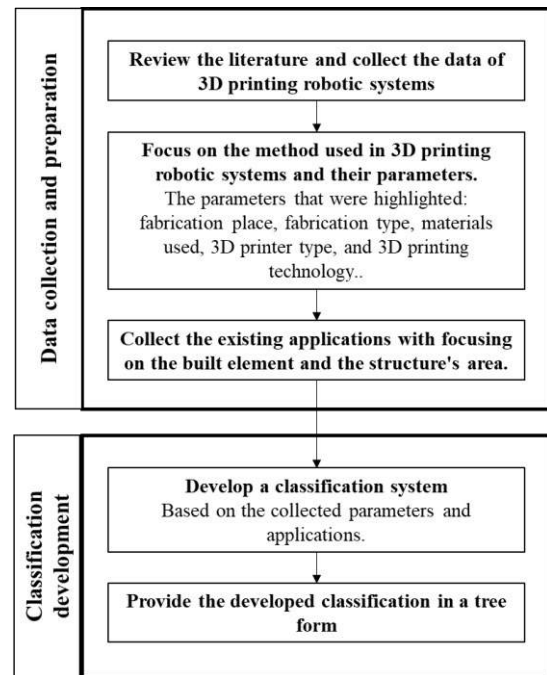

Figure 1: Steps involved in the proposed research methodology to develop a construction 3D printing robotic systems classification

and industry professionals' experience.

After collecting the existing 3D printing robotic systems in the AEC industry and their different applications, the following are the details of each parameter.

- **Material used:**

The existing materials used for 3D printing in the AEC industry are polymer, cementitious, and metal materials.

- **Fabrication place:**

According to the literature, it was found that the 3D printing structure can be fabricated either on-site or off-site where the most application was constructed.

- **Fabrication type:**

Based on different applications, it was found that there are two different fabrication types used in 3D printing, Additive Fabrication (AF), where the object or element is built by layering materials on top of each other, and Formative Fabrication (FF), where heat and pressure are used to form the material into the desired shape.

- **3D printing technology**

To meet the requirements of different materials used in 3D printing, various technologies have been developed. Based on [11] and according to ASTM Standard F2792, seven printing technologies have been developed for 3D printing until now [16]. The first technology is the Powder Bed Fusion (PBF), which is melting and fusing the powder material using a laser or electron beam. All PBF processes require that the powder material should be

spread over previous layers. The second technology is Vat Photopolymerization, in which a vat of liquid photopolymer resin is used to construct the model layer by layer. In addition, it uses liquid to form objects. Unlike the PBF technology, during the build phase, there is no structural support from the material itself, where the support is given from the unbound material. The third technology is Material Jetting, in which the material is jetted into the platform, then it solidifies. In this process, layer-by-layer, the material is extruded through a nozzle that moves horizontally across a platform to deposit material where needed. The fourth one is Material Extrusion which is the most commonly used technique. In this technology, by depositing the material through a nozzle layer by layer, in some methods, such as in the Fused Deposition Modeling (FDM) method, the material is heated. The nozzle moves horizontally, and after depositing a new layer, the platform moves vertically. The fifth technology is called Binder Jetting, which uses two materials to build the desired structure, namely a powder-based material and a binder. Typically, the binder, which acts as an adhesive between powder layers, is liquid, while the build material is powder. In a horizontal motion, a print head alternately deposits layers of build materials and binding materials, and when a layer of an object is printed, it will be lowered on its build platform. The sixth is Energy Deposition. In this technology, a nozzle is installed on a robotic arm with several axes, where melted material is deposited on the desired surface, where it solidifies. Although material extrusion is similar in principle to this process, in this technology, the nozzle can move in more than one direction. The seventh and last technology is Sheet lamination. This technology uses metal ribbons or sheets welded together with ultrasonic energy. During the welding process, computer numerical control (CNC) machining and removal of unbound metal are required. Metals such as aluminum, copper, stainless steel, and titanium are used in this technology [29].

- 3D printing method

Since the technology can be implemented in different techniques, different printing methods were developed for each technology. Based on existing applications for polymer materials, four different methods are used: Fused Deposition Modeling (FDM), Digital Projection Lithography (DLP), Paste Dispenser, and FreeFAB. For cementitious materials, there are five different methods: Contour Crafting, Concrete printing, D-Shape, Fused Deposition Modeling (FDM), and Fused material powder. Lastly, for metal materials, three different methods exist. These methods are Selective Laser Melting (SLM), Ultrasonic Additive Manufacturing (UAM), and Direct Energy Deposition (DED) [10].

This study focused on collecting the existing printing methods for each application and the details of each

parameter to demonstrate the ability of each printer. After collecting all these details, the classification was developed and summarized in the next section.

4.2 Classification Development

The classification with nine different levels was developed based on the collected data. Since the objective was to develop a classification for an AEC professional (or user) with minimal to no prior expertise in construction 3D printing, the classification levels were broken down into two parts: user selection and 3D printer details (Figure 2). Since the entire classification was too big, to better visualize it, it is segregated based on the type of material. Each of the different levels in the classification for each of the materials is shown in Figures 3 and 4. Each of the levels and components involved in the classification was already described in the methodology. To make the classification crisp and easy to view, abbreviations were used for different levels and components.

In order to select the appropriate 3D printing robotic system based on the developed classification, the user should select the type of material that they intend to use, decide if just an element or the whole structure will be built, the area of the structure, and similar application of what he/she wants to build. Based on their selection, the printer details (i.e., the printing method orienting technology, fabrication type, printer type, and fabrication place) are provided in the lower levels of the classification. It was mentioned before that the classification was built based on the previous application. The resulting classification for each material is presented in Figure 3 (for cementitious) and Figure 4 (for polymers and metals).

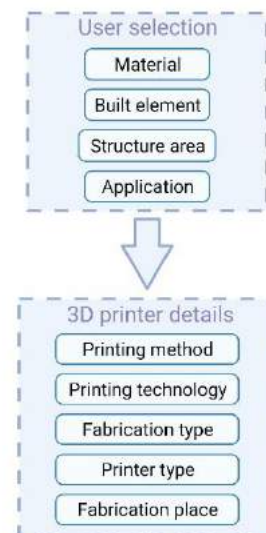

Figure 2: Classification levels (created using biorender.com)

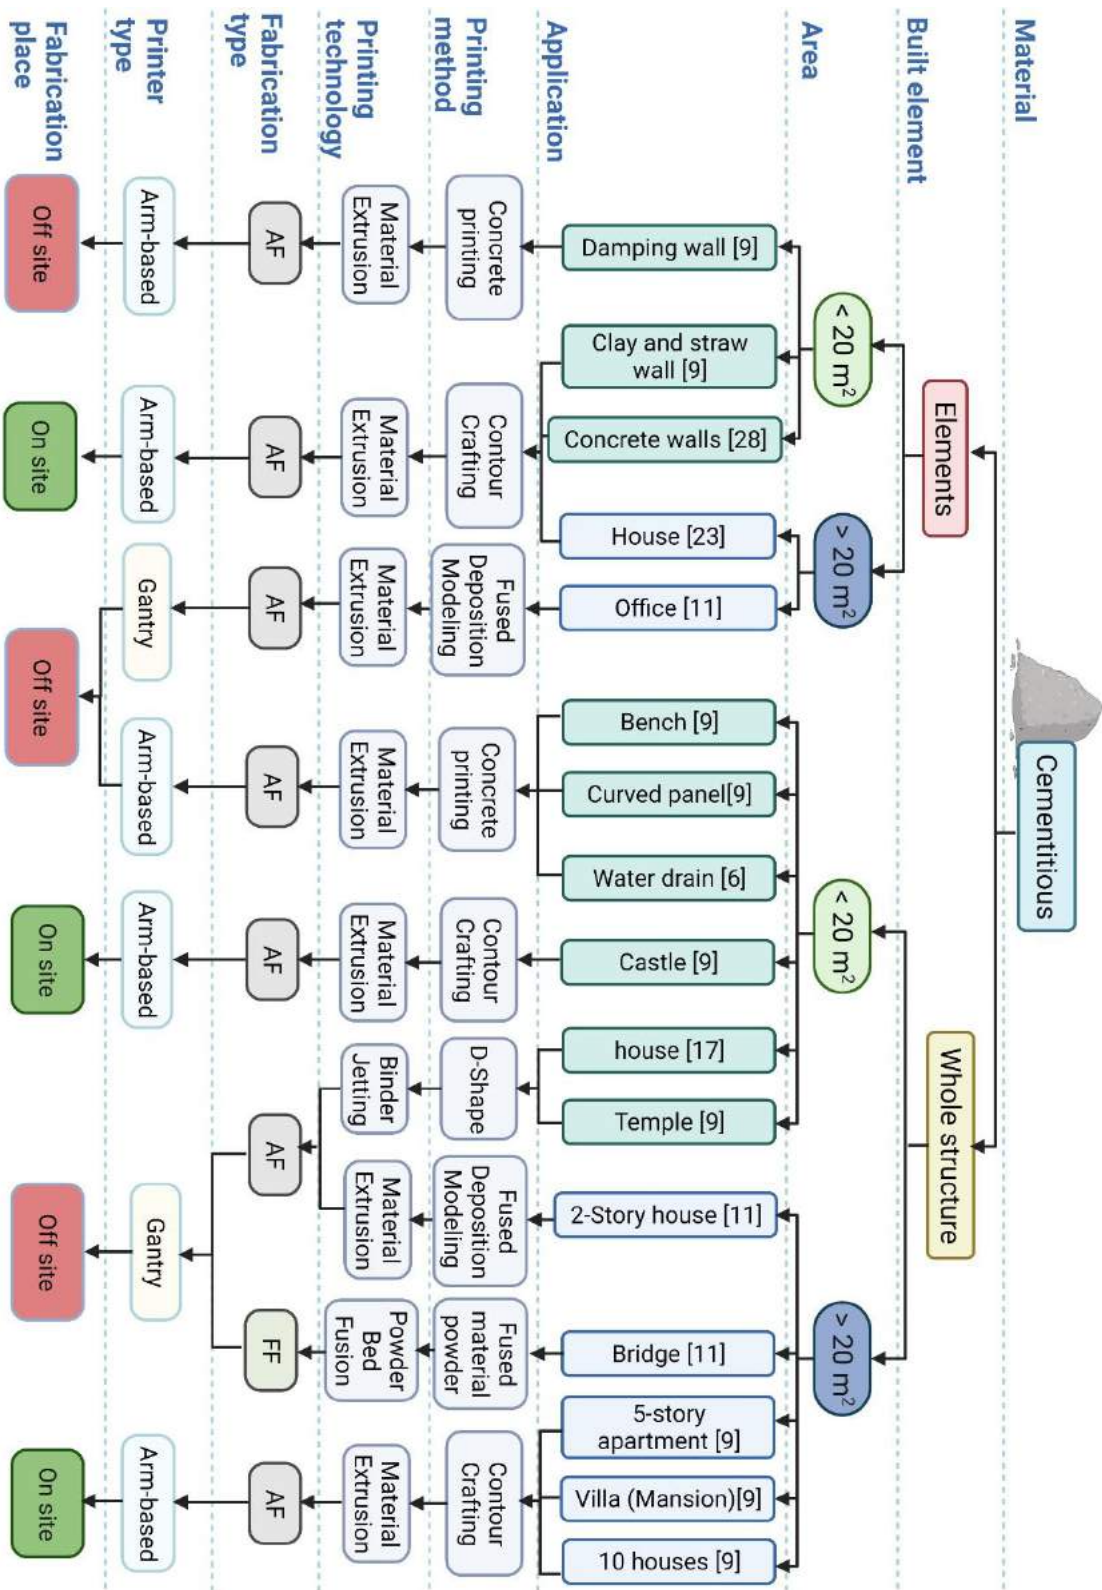

Figure 3: 3D printing robotic systems' classification of cementitious materials (created using biorender.com)

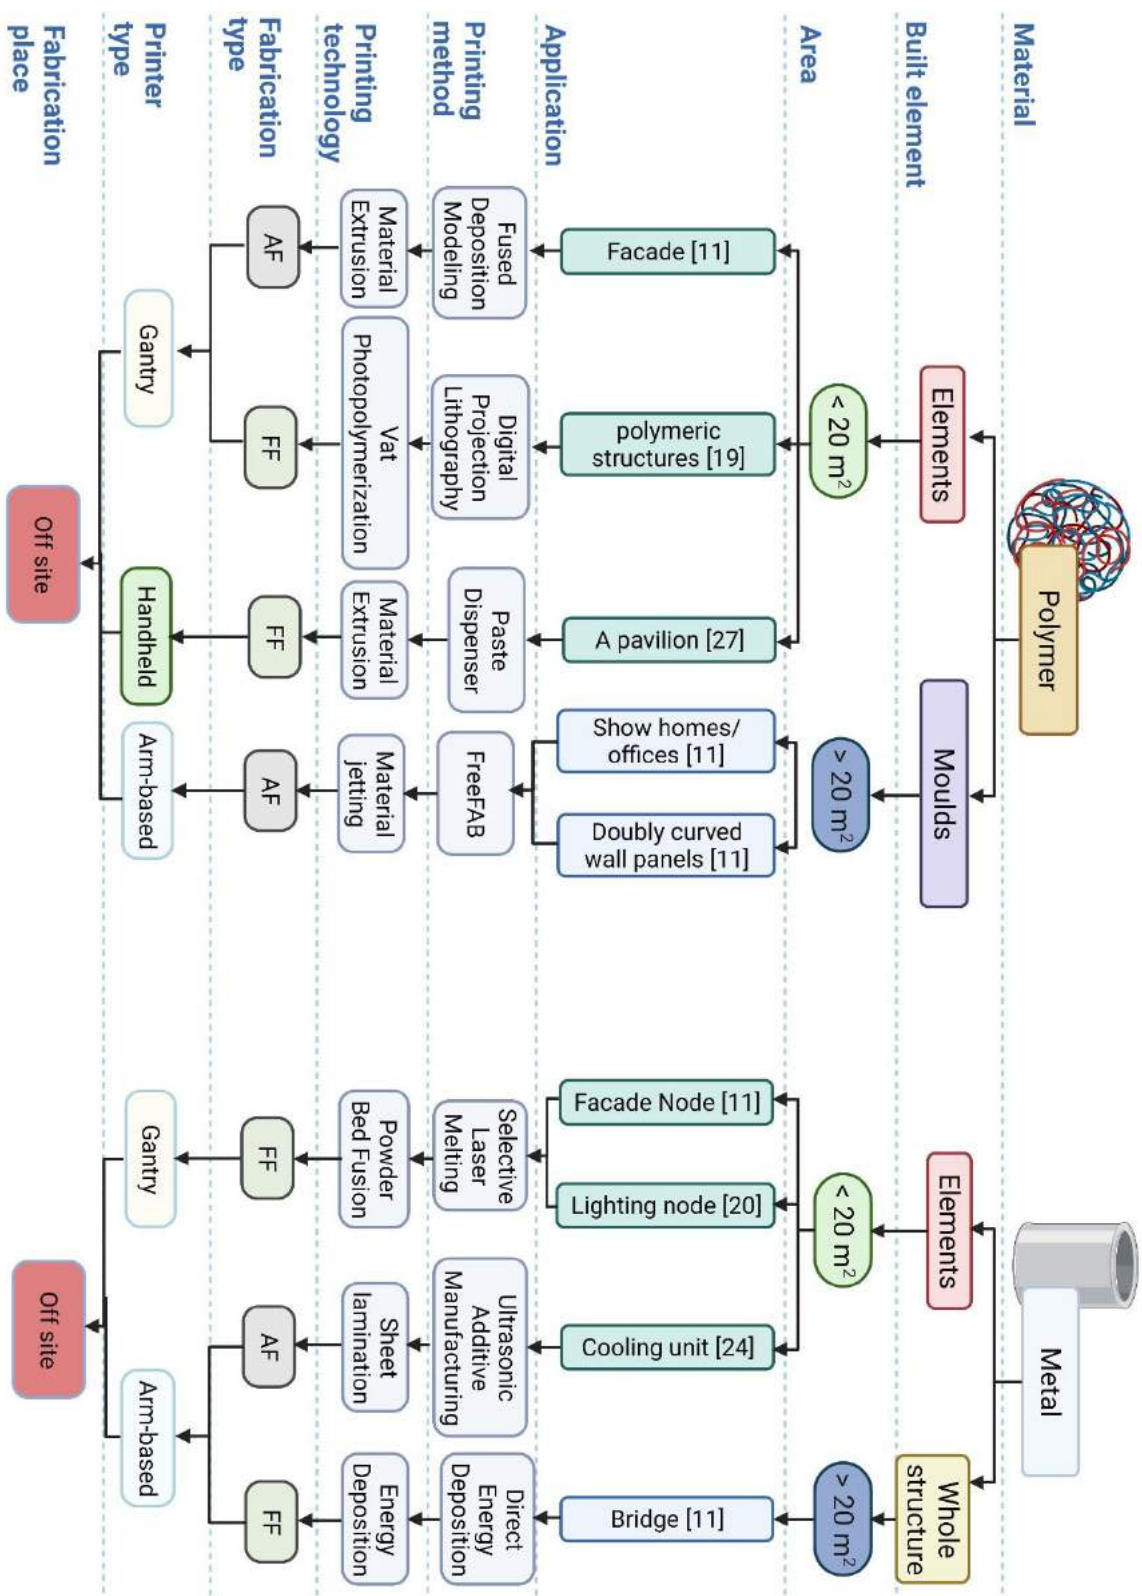

Figure 4: 3D printing robotic systems' classification of polymer and metal materials (created using biorender.com)

5 Results and discussion

In the resulting classification, 16 existing applications were collected for cementitious materials, while only five and four applications were collected for polymers and metals, respectively. Therefore, the most popular material used in 3D printing in the AEC industry is cementitious material. The use of polymer and metal materials is limited, especially on large-scale structures.

However, polymer additive manufacturing is the most common method because of its low cost and widespread equipment availability. Moreover, the developed classification showed that most 3D printed structures were printed off-site, and the most popular printer type is the arm-based. In addition, all the onsite implementations are arm-based using cementitious materials.

The presented classification was developed using the existing applications with full details of the nine levels. Some of the collected methods and applications were excluded because of the limited information (e.g., no application was found for the Selective Laser Sintering (SLS) method used for polymer materials, so this method was excluded. Also, the polymeric structures in [19] were excluded because it has no structural details). The developed classification can and should be updated when new applications surface.

Most of the studies proved that the AEC industry is trying to Investigate new ways for improving project efficiency, and using 3D printing can reduce time and cost and improve quality and labor safety. The developed classification can support the decision-making process to select the appropriate 3D printing systems in future projects.

6 Summary and Conclusions

This research developed a classification of the existing 3D printing robotic systems in the AEC industry. The literature was reviewed to demonstrate the current status of real-world implementation in the AEC industry. It was found that 3D printing is still in an early stage in the AEC industry. After reviewing the literature, data of different 3D printing robotic systems were collected. Then, different existing applications for each system were collected with providing its details to determine the capability of the system. The collection procedure focused on data from different 3D printing robotic systems based on parameters such as the materials used, fabrication place, fabrication type, 3D printing technology, and 3D printing method. There were three types of materials used in 3D printing in constructions, namely Polymer, Cementitious, and Metal. The fabrication place can be either on-site or off-site. There were two different fabrication types used in 3D printing:

Additive Fabrication and Formative Fabrication. In addition, there were seven different printing technologies: Powder Bed Fusion, Vat Photopolymerization, Material Jetting, Material Extrusion Binder Jetting, Energy Deposition, and Sheet lamination. After collecting all the needed data, a classification was developed, and the use of the classification was discussed. Due to the big size of the classification, it has been divided into smaller clusters based on the type of material. For each material, the classification represents the existing 3D printing robotic system's details. When new applications emerge, the classification should be updated. The developed classifications showed that the most used material in 3D printing in the AEC industry is cementitious. Although polymers are the most common material used in 3D printing in different industries, it is limited in AEC industry. The right parameters should be selected in order to determine the appropriate 3D printing robotic systems. In this instance, the developed classification is used. Based on selecting the material, the similar application, and other details from the first four classification levels, the 3D printing robotic system's details are obtained. The resulting classification could greatly assist and guide stakeholders' efforts to better understand and adopt 3D printing in current and future AEC projects.

Abstract –

The Jade University of Applied Sciences organised the digital business game "PING PONG", a BIM Game, to teach students the networked and digital planning methodology BIM. Building Information Modelling (BIM) should be the planning standard for construction projects and thus a fixed component of university education. For this purpose, an innovative and motivating teaching format was developed with the course PING PONG, which brings about an increase in the quality of teaching and the success of studies. Based on the Erasmus+ project "BIM Game" [1][2], this article describes in detail how a realistic BIM business game can be designed to test the most common BIM key technologies in a scientific environment and to anchor the processes of collaborative working more firmly in the brain. Furthermore, the didactic means and a work portal that were used to evaluate the decentralised project work and to pace the game are presented to shorten the complex, interdisciplinary and time-consuming planning processes through simultaneous project work.

Keywords –

BIM Game; Building Information Modeling; BIM; HOAI; game design elements; business game; integrated planning; decision-oriented planning

1 Introduction

Playful learning is the most intuitive form of learning that people know. Even at a very young age, new skills are learned through play and adaptation [3] [4]. The Building Information Modeling (BIM) Game makes use of this natural play instinct and thus provides a higher motivation to deal with the topic of BIM. This is the initial idea and motivation of the European-funded research project "BIM Game" organized and developed in cooperation with various universities, colleges,

training centres, and software companies from five European countries. Results were reported in the ISARC proceedings 2020 [1]. The BIM Game is developing further and is now incorporated into a regular lecturer at the Jade University of applied science, where the authors organized the digital planning game PING PONG. It was a three-day event to teach architecture students about BIM digital design methodology, but also to test new measures and tools to take the BIM game to a higher level.

2 The basic framework

The complex task of construction planning requires methodical knowledge, knowledge of general processes and structures as well as information about framework conditions such as laws, ordinances, guidelines, technical rules and specific information about the task. [5] The complexity of the planning and construction process has increased significantly in recent years, due to structural change in the construction industry and increasing competitive pressure. Factors such as increasing project sizes, more complex building geometry, hardly realisable time schedules and numerous requirements for the energy and resource efficiency of buildings lead to a growing number of actors involved in the project and thus different interests and process requirements. [6] This wide range of services cannot be offered completely by any one company, which is why construction projects are almost exclusively realised in cross-company cooperation. [7]

Decentralised planning becomes necessary as soon as a planning organisation divides the responsibility for planning tasks across its corporate hierarchy among several planners. (cf. [8] [9])

With increasing complexity, topics such as the integration of the actors involved in the project or the creation of a consistent and compatible data environment are becoming increasingly important. Especially in the

context of increasingly decentralised project cooperation, the aspect of cross-disciplinary and cross-application interaction and integration is becoming a central factor for the success of project-related cooperation and thus for the success of the project. Against this background, the question of integrated planning and the application of BIM has gained importance in recent years. [6]

Problem-solving in construction planning is predominantly done by methodologies without algorithms. Classical optimisation strategies cannot be applied due to mathematical non-scriptability and a lack of information [10]. In Germany, complexity is classically reduced by dividing construction planning tasks into the various service profiles according to the Fee Regulations for Architects and Engineers (HOAI). [11] The HOAI distinguishes between activities and results (cf. HOAI § 15 Para. 2). Listed are those activities which, in connection as a bundle of activities, produce a result as a prerequisite for decision-making (**decision-oriented planning**). [5] The decision itself is not part of the service profile of a particular institution, since as a rule the decision-maker and the institutions preparing the decisions are not identical or should not be identical (**independent planning**), i.e. the contractor will bring the respective result of a service phase into the decision-making process with the client. [5] The designation of the results of the individual service phases is the same for all service profiles of the specialist planners involved in the object planning so that the individual activities of all participants can be integrated into specific phases in each case (**integrated planning**). [5] The activities described in the HOAI do not change as a result of new methodological approaches such as BIM, as the activity descriptions of the HOAI continue to be existential for construction planning. However, the service phases can mix or overlap or be carried out simultaneously instead of sequentially. The following figure (Fig. 1) shows this partially simultaneous arrangement in the familiar bar representation of a network plan.

Fig. 1: Semi-simultaneous phase arrangement [7]

Simultaneous processing (*Simultaneous Engineering*) and the diverse networking and feedback of problem-solving cycles lead to a phase overlap in planning. In addition to positive effects on the quality of planning, this

also opens up great potential for shortening planning periods. [7] The time-saving potential can be used, for example, to compress interdisciplinary subject areas that are traditionally only dealt with sequentially (one after the other) due to mutual dependencies.

These more complex subject areas, whose problems are to be solved primarily through iterative interactions with various subject experts go beyond the "normal" lecture content in the academic training of architects. However, a digital business game offers ideal conditions to train interdisciplinary and parallel collaboration on the project. For this playful way of learning, in addition to the usual assessment criteria for **results**, further assessment criteria e.g. **ideas**, **activities**, **decisions** and **interactions** need to be created to specifically guide and assess the students in a short time frame (Fig. 2).

Fig. 2: Required evaluation criteria for digital business games in construction planning

3 PING PONG – a digital business game

The first decentralised and at the same time international business game was held at the Jade University of Applied Sciences over three days: 18 architecture students learned about the design and planning tools of the BIM methodology. Under almost real competition conditions four groups of up to five people planned a campus café for the university with the possibility of playing PING PONG; time limitation: 55 hours. In each group, responsibilities were divided and players took over different roles to learn and understand integrated planning processes. Cooperation within the group was decentralized, all students worked from home, planning took place directly on the 3D model. One of the motivating aspects of the game was the competition character of the event. Each group was in direct competition with the other groups, intermediate results from other groups were published partially to increase the pressure on the participants. The instructors came into play as coaches and trainers, helping the groups to overcome problems and difficulties, motivating and pushing them to new achievements. In the role of the client, the teachers invited the groups to have interim discussions and requested performance levels. Hereby aspects of independent planning could be trained.

The clock was ticking: Results had to be delivered precisely and, above all, on time. This was ensured by a

work portal that controlled the entire game, structured process steps and requested efficient and decision-oriented planning. Time flew by, the conference rooms were open around the clock for discussions and meetings, and finally, after three exhausting working days full of activities, decisions and interactions exciting designs (like shown in **Fig. 3**) were presented and awarded.

The playful competitive atmosphere motivated all participants. It lowered the fear of using new technology, trained digital communication and provided insights into the benefits and performance of various digital planning tools.

Fig. 3: Final Design presented by: Melissa El Haddad, Anna-Lena Laube, Lisa-Marie Schlott, Christine Büch

3.1 Learning objectives

The primary learning objective of the PING PONG game is to understand and apply the digital planning methodology BIM. In a realistic simulation of a planning competition, this knowledge must be derived and evaluated on the students' design. In direct collaboration with group members and exchange with the client, the students plan and develop their ideas and use the appropriate digital tools.

3.2 Structure and boundary conditions

A total of 18 students from the architecture program took part in the course. Based on a self-assessment to be submitted in advance, they were divided into four teams of approximately equal strength. The boundary conditions were shaped by corona-related limitations: Participants worked from home. Various videoconference rooms were available during the game. In addition to a computer with webcam and microphone, the following software applications were part of the players' basic equipment:

1. Modelling and visualisation software
2. Web-based data management / cloud / CDE
3. Cost estimation software
4. Collision detection software
5. IFC Viewer

6. BCF application

The game was initiated by two introductory meetings that started three weeks before the workshop. This introduction was used to explain the process and organization of the game and to provide an overview of the software applications used in the game. For this purpose, video tutorials on how to use and install them were made available. The project description, competition overview, design manual, and modelling guidelines were also uploaded for review. Three days before the start of the game, the teachers conducted a software check of all players to ensure that all installations were completed successfully and that the technical requirements for participation were met. The total playing time was 55 hours. During this time, virtual meeting rooms within a Zoom conference were available to participants. The final submission of results was scheduled for the third day followed by presentations of the results and an award ceremony. A few days later the event was concluded with a final debriefing session in which the participants reflected on what they had learned.

4 Didactic means

The PING PONG course was characterized by a clear game structure, its rules and a process landscape that automatically demanded results. This gave the event transparency and orientation. The clear time constraints and the compact workshop format helped to create an intensive working atmosphere. At the same time, the event was directly related to practice, because the BIM Game was a true-to-life simulation of a restricted interdisciplinary planning competition, organized according to RPW 2013 [12], to show the students realistic conditions.

This was achieved within the game through a coordinated diversity of methods and tools. Different digital applications had to be used to solve the tasks. Conversations, group work, activating questions as well as client meetings (shown in **Fig. 4**) were different formats in which students had to use their knowledge, repeat and adapt it to the respective situation, thus cognitively consolidating information. In addition, the game structure included the possibility to improve already submitted performances afterwards. This repetition option served to reflect on one's performance and was used by all groups.

The participants received feedback through the regularly held client meetings. Here, the teachers were able to give feedback, check learning objectives, request additional services if necessary and make demands on the planners. Outside of the client meetings, the teachers were "coaches" and looked over the shoulders of the students. In this role, they gave help and tips, motivated

and listened. This division led to a clear understanding of the roles in the cooperation with the students to distinguish the different forms of pedagogical support in terms of content and concepts.

The game was didactically condensed in very different ways. Above all, the format of a time-limited compact workshop led to the development of a very intensive working atmosphere. The competitive spirit of the participants was awakened and a team-building effect was created that motivated each individual - including the teachers - and thus produced excellent results.

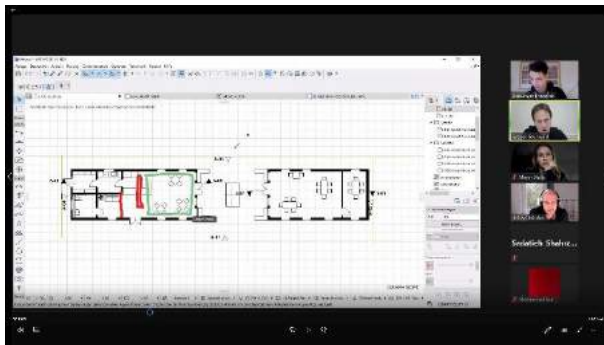

Fig. 4: Corrections to the model in the client meeting via screen sharing of the conference system

4.1 Didactic structure

The PING PONG game was developed through the application of Constructive Alignment. This learning goal-oriented didactics goes back to John Biggs [13]. Biggs suggests aligning learning objectives, assessment form and teaching and learning activities. In this respect, the learning objective was defined first (see 3.1 Learning Objectives).

In the following step, formats had to be found that could make learning progress visible. The idea was to integrate the examination in the form of a project presentation within a competition process. In this way, it was possible to measure the teaching and learning success and thus obtain feedback on the achievement of the objectives. The playfully structured presentation within an architectural competition made the participants forget the exam situation and achieved good results.

In the third step, the teaching and learning activities were placed in the game setting. Instructions for action, modelling guidelines, short tutorials, coaching talks, presentations, but also a mutual helping of the students, i.e. a variety of coordinated methods, were used for this.

The preliminary introduction to the game was an important tool for initiating the game. To reflect on what was learned, a debriefing was held one week after the end of the game, according to Hattie rank 1 for successful learning [14].

4.2 Learning processes

Sustained learning only takes place when several channels are simultaneously absorbed during information intake, if active information intake is repeated at a later time and if students feel exposed to a moderate stress situation in a safe environment.

The work portal described below is based on the following findings:

- Support of verbal and written knowledge exchange with students
- Repetition effect: Voluntary repetition in the active absorption of information
- Establishment of a moderate stress situation in a safe environment

"If you want to explain something to someone else, you have to understand it yourself beforehand, e.g. you have read or heard it. Anyone who tries something out or applies it already associates the entire sequence of events with the actual information, which is why the result is more firmly anchored in the brain than if they had merely observed the same result with someone else." [15]

"The more often managers can practice dealing with stress in a safe environment, the more confidently they will later apply what they have learned in their professional lives." [16]

5 Work portal

The Business Process Management System (BPMS) Bizagi steered the business game phases, from modelling to executing and evaluating processes. Key elements provided within this BPMS are a process engine where the process models are executed and a web-based work portal for user's interaction providing means to manage a worklist, taking and completing tasks, among other functionalities. [17]

5.1 General concept

For the integration of the work portal into the runtime system of a .NET framework, the "Bizagi Suite" offers three packages (*Modeler*, *Studio* and *Automation*). The *Bizagi-Modeler* supports the modelling of processes based on "Business Process Modeling Notation 2.0" (BPMN2.0) to visually document, simulate and optimise business processes. *Bizagi-Studio* includes low-code

software for automating business processes and Bizagi-*Automation* transfers business logic to a digital (working) platform on which technical and human activities are executed and orchestrated. Furthermore, the Bizagi-*Automation* package implements the business processes on different information technology (IT) systems, such as desktop computers or mobile systems. For a better understanding, the differences between BPM and BPMN2.0 are briefly explained below.

5.1.1 BPM

"Business Process Management (BPM) is a systematic approach to capture, design, execute, document, measure, monitor and control both automated and non-automated processes to sustainably achieve objectives aligned with business strategy. BPM involves the deliberate and increasingly IT-enabled determination, improvement, innovation and maintenance of end-to-end processes." [18] Here, "end-to-end process" always stands for the holistic process view, i.e. from the start to the end of a work sequence. [19]

5.1.2 BPMN2.0

If the overarching view is reduced to pure process modelling, the meaning of the acronym BPM changes to "Business Process Modeling". In addition to process logic, this involves the technically correct representation of "lived" work sequences. "Business Process Model and Notation" (BPMN) is a standard for visually representing process logic. BPMN is used to communicate a variety of information to a variety of audiences. Through multiple diagrams, BPMN covers different types of modelling and thus enables the modelling of end-to-end processes. [20] Originally, BPMN was developed only to be read by humans. With BPMN 2.0, mapping to the execution language WS-BPEL (Web Services Business Process Execution Language) was established to make the existing process semantics also machine-readable. [20]. BPMN 2.0 thus offers a standardised process language that can be read and interpreted by humans and machines. [19] (Further information of the BPMN2.0 process semantics see [21] [22].)

5.2 Implementation into the game

Bziagi's process engine ran the BPMN2.0 process model locally. The work portal was accessible via HTTP (Hypertext Transfer Protocol) and guided the participants (shown as groups in **Fig. 5**) and the contest organizers (shown as the client in **Fig. 5**) transparently and sequentially through the game, which is structured as follows:

- Phase-0: Project initiation
(Target working time (tw): 1 hour).

- Phase-1: Concept
(tw: 5 hours, through simultaneous processing)
- Phase-2: Design
(tw: 5 hours, through simultaneous processing)
- Phase-3: Evaluation
(tw: parallel to the further course of the game)
- Phase-4: Feedback
(tw: 1 hour)
- Phase-5: Presentation
(tw: max. 5 hours)

Fig. 5: The technical BPMN2.0 process model on which the work portal is based and the processing progress visible to all groups (green markings)

After completing phases 1 and 2, the results of all groups were displayed in the work portal. The competitors could then decide to either go to a well-deserved end of work, start working directly on the following phase or improve their results (cf. **Fig. 6**). Improving the results inevitably led to an increased workload (outside the target working hours) or reduction of the target working hours of the subsequent phase. All groups chose improvement (a voluntary repetition of previous performance), through an increased workload.

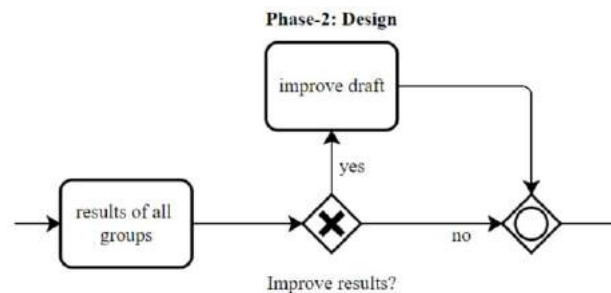

Fig. 6: Extract from the technical process model; competitors' decision to voluntarily improve results

Overall, all groups had to complete the same tasks in the same target work time. Task distribution and result retrieval were done automatically and successively through the work portal. Only those who had uploaded all the required results could close the current activity and start a new one. There was no "back button" so that only the final results to be assessed had to be uploaded. As soon as an activity was completed, the results were saved

in the work portal and the competition progress was displayed to all competitors in real-time (cf.

Fig. 5 the green markings).

Thus, participants were guided through the game, driven to precise performance formulation and on-time submission. However, due to a large number of tasks and mandatory deadlines, students were forced to reduce target achievement criteria, either in design quality, detailing of construction, cost calculations, or sustainability information. There was not enough time to meet all criteria. This led to an unusual stress situation for the students and they had to practice dealing with this dilemma by setting priorities and also accepting cutbacks in the project.

5.3 Framework conditions and targets

There were clear targets for the architectural design, called in and checked by the work portal: regarding the costs, an upper limit of a maximum of 500.000 EURO was set, for the planning of the design a deadline of 3 days. In addition to the modelling guidelines, the design manual and the spatial pilot, the quality objectives in terms of functionality, sustainability and design qualities of the building were defined by an exposé distributed at the beginning of the game with the following weighting:

- Functionality (factor 5)
- Design quality (factor 3)
- Economic sustainability
 - Costs according to DIN276 [23] (factor 4)
 - Collision-free planning (factor 1)
- Ecological sustainability
 - Energy efficiency (factor 2)
 - Proportion of renewable raw materials (factor 2)

The BIM process focused on the creation, handling and overlay of IFC (Industry Foundation Classes) models as well as model-based clash detection and documentation via BCF (BIM Collaboration Format). The logic of the functional BIM process is shown in **Fig. 7**. The points in it are briefly explained below:

1. Employer's Information Requirements (EIR)
2. BIM execution planning (BEP)
3. Create IFC models
 - 3.1. Architecture
 - 3.2. Structural engineering

4. Overlay IFC models (coordination model)
5. Collision Detection
6. Documentation of collisions via BCF

Iterative planning processes and under consideration of different interests, the design was developed in such a way that as many of the required goals as possible were achieved. Regular discussions with clients were steered by the work portal, enforcing client participation and thus forcing decision-oriented planning. With the quality objectives, the game was given clear evaluation benchmarks that both provided orientation in the decision-making process during the entire game and regulated the comparative evaluation of the results at the end.

Fig. 7: The functional BIM process logic of the business game

5.4 Evaluation

The assessment of the competition performance was divided into two parts. Firstly by assessing the group results as *soft facts* and secondly by assessing the *hard facts* taking the content of the uploaded files in the work portal into account.

Evaluation criteria for the *soft facts*:

The IFC models were presented as the final group result by the respective competitors. The evaluation was made subjectively by the clients, based on the functional and design quality of the building as follows:

- **Functionality:**
Fulfilment of the spatial programme, utilisation concept/utilisation offer, spatial formation, orientability and traffic organisation in the interior, accessibility from the outside, structuring of open space quality.
- **Design quality:**
Quality of the urban planning and building design concept, building quality, design of the building structure and the individual areas, quality of the open space.

Evaluation criteria for the *hard facts*:

- BCF files as a result for economic sustainability

and as evidence for the model-based interactions as well as the decisions during group processing

- Building costs as a result of economic sustainability and as evidence of cost activities
- A/V-value as a result of the evaluation of energetics and as evidence of Computer-Aided Design (CAD) activities
- Sustainability index as a result for the evaluation of the share of renewable raw materials of the building shell and the proof of CAD activities
- IFC models of the architecture and the structure as a concept idea in phase 1

6 Conclusion

As Building Information Modeling is set to become the design standard for construction projects, academic training must teach digital design methodology. However, it is important not to limit training to the simple application of the individual tools, but to understand that the introduction of the methodology creates new work methods and processes that need to be mapped. The business game PING PONG described aims to test the most common key BIM technologies in a scientific environment so that users can experience the most common digital technologies individually. By solving technical problems independently, the procedures of the model-based coordination process can be anchored more firmly in the brain. This refers especially to the cooperative, interdisciplinary and parallel way of planning, decision-oriented and integrated. These new challenges must be experienced and tried out rather than described in theoretical treatises. Because experience shows that the advantages of BIM can simple be read, but not simply applied. That is why the business game PING PONG is an excellent way to gain initial experience playfully, in protected laboratory conditions. The student evaluation confirms this assumption: 100% of the evaluators think that the practical relevance of the course has become clear, and it is also unanimously certified that the theoretical content was better understood through the exercises. 83.3% think that they have learned something new.

7 Suggestion on further research

With the second business game "JADE WORK", the BIM game was held for the second time and was opened to students of the Department of Civil Engineering and external participants. By including students from other faculties and players from the private sector, the real-life conditions of the game could be intensified. The high level of interdisciplinarity in the groups led to new, detailed impulses through additional expertise, while the external participants in turn benefited from the digital

competence of the students. It should be noted that the BIM Game is an experimental field that can be continuously supplemented and enriched with further aspects. Be it through the integration of life cycle assessment (LCA) to take greater account of sustainability aspects in the design, or the remuneration of services through the billing of fees to focus more strongly on aspects of construction management. The chosen innovations are strongly subject to the respective thematic focus of the game and are of course also dependent on the game duration. This business game could, for example, be conducted internationally in one day due to the different time zones. The great success of the business game motivates to develop it further, to continue the event and to make it a permanent part of the teaching. Extending this to a whole semester is also one of the plans of the authors.

Abstract –

Circular economy (CE) strategies have been considered to help reduce global sustainability pressures in different sectors; however, there is a gap about how they could be used to contribute to the Architectural, Engineering and Construction (AEC) domain. Past research used lifecycle assessment (LCA) methods or experts' opinions to partially identify the benefits and drawbacks of specific CE strategies or approaches adopted in construction projects. This study presents a systematic literature review to identify the scope of key approaches to construction circularity. From a rigorous selection and review of 40 journal articles, this study identifies 15 key approaches that emerged from the state-of-the-art. These approaches represent the efforts of using digital technologies, comprehensive mapping and assessment methods, and material experiments to allow construction circularity from 5 different perspectives: material design, building design, construction and facility management, urban sustainability development, and system precondition, which emphasize the communication between project stakeholders concerning what, how and when the materials should be used within the estimated number of life cycles. Findings reveal the importance of integrating the stakeholders, service centers and recycling plants, transportation networks, and local authorities to work together to deliver construction circularity at micro, meso, and macro levels. The legal, risk, financial (funding and taxes), and contractual frameworks need to be further studied to fully explore the different opportunities of circular strategies and approaches in the AEC domain.

Keywords –

Circular economy; Construction circularity; Sustainability; Digital enablers; Reuse and recycle

1 Introduction

The AEC industry is one of the most resource-intensive ones. It is responsible for 35 % of all solid waste and 42% of primary energy demand in Europe [1]. The concept of circular economy (CE) (slowing, narrowing, and closing resource flows) [2] and associated strategies help stakeholders redefine the workflows in the industry towards sustainable projects in terms of reduced greenhouse gas emissions and minimized resource use. Understanding the CE strategies used in the AEC domain is not easy, especially considering construction projects' high complexity and uncertainty nature. However, the term “circular buildings” or “construction circularity” received increasing attention in recent years [3]. There has been no standardized way of defining and evaluating construction circularity as circularity encompasses every possible interaction and process related to a given material from material extraction to project demolition in the AEC context. Summarizing the existing guides to circular cities, such as the CE guidance for construction clients by UK Green Building Council [4] and ISO/TC 323 standard by International Organization for Standardization [5], construction circularity could be understood as the goal of designing out wastes and pollution and keeping construction materials in use through strategies including reuse, repair, recover, restore, refurbish, remanufacture and recycling to reduce environmental impact, emissions and improve sustainability. Despite the great potentials of CE strategies, past research focused on investigating the lifecycle assessment (LCA) methods or experts' opinions to partially identify the benefits and drawbacks of the

specific CE approach adopted in construction projects. An overview of exactly what and how the different available approaches could contribute to CE remains missing from the existing body of knowledge but requires systematic investigations.

To address this gap, this study adopts a systematic literature review method to find a total scope of key approaches to CE. The remainder of this paper is structured as follows. Section 2 describes the review methodology, followed by the detailed findings of key approaches in Section 3. Section 4 concludes the study together with a discussion of the findings and future work.

2 Methodology

This study adopted the systematic literature review method for the identification of key approaches to CE. As theoretically defined by Wolfswinkel et al. (2013) [6], a systematic literature review method is used to comprehensively search the relevant body of literature in the easily accessible publication databases with comprehensible search rules or search criteria. Therefore, the method is considered suitable in this study for assessing the details of the scientific publications related to the CE. The publication database of the Web of Science Core Collection was scanned for the retrieval of the literature across publication years ranging from 2011 to 2021. The search rules were used to ensure the relevance of the selected literature to the detailed topics of CE (presented in Table 1). To be specific, the dimensions of “How”, “Where”, and “When” CE could be achieved were investigated in parallel using the connecting logic operator “AND”. Within each dimension, the keywords, such as “Reuse” and “Recycle” concerning “How” CE could be achieved, were connected using the logic operator “OR”. Using the search rules, the initial search returned 146 journal articles. This number was reduced to 45 by filtering to specific fields in Web of Science. The selected fields were civil engineering, construction building technology, and architecture. Fields such as navy engineering and agricultural engineering were excluded. Next, the first author read the full contents of the 45 articles in-depth and examined whether the contents were aligned with the key approaches to CE. Articles that only provided literature review analysis were excluded. In the end, a total of 40 articles were selected.

From the in-depth review of the 40 articles identified, the authors first derived five categories to which the emerging key approaches would belong. Then the 40 articles were coded to link main research findings with specific key approaches in each category. The coding processes were set up for iterative modifications and

enlargements to reduce personal bias as much as possible. Throughout the content review analysis stage, various thematic codes were inductively derived and led to 5 categories: 1) material design, 2) building design, 3) construction and facility management, 4) urban sustainability development, and 5) system precondition. Each category contains a conceptual grouping of the key approaches to CE. For the convenience of coding and easy understanding of the key approaches, each article was exclusively assigned to one category based on its most significant circularity concepts. A description of the key approaches is provided in the following section.

Table 1. Search rules used in Web of Science

How (OR)		Where (OR)		When (OR)
Reuse Recycle Reduce Refurbish Recover Restore Regenerate Circular	AND	Building Housing Infrastructure	AND	Design Production Manufacturing Installation Construction Maintenance Operation End-of-life Deconstruction Demolition

3 Findings

Five categories and fifteen key approaches to realizing CE resulted from the coding process during the systematic review. The probabilistic distributions of the articles by regions, journals, and years are presented in the supplementary file [i]. The list of these approaches is shown in Table 2.

3.1 Material design

In this broad category, the emerging material design solutions for CE include LCA-based design for reuse and design through waste recycling, focusing on investigating CE strategies on a building material or a relatively micro level.

(1) LCA-based design for reuse

Unlike conventional LCA applications that focus on evaluating the environmental impact of building materials from existing use, the LCA-based design for reuse emphasizes the impact when the materials originated from prior buildings will be reused again in future buildings. New equations for the allocations of impacts of a building component over the building use cycles have been recently proposed to account for the material reuse potential, which could be adapted based on the existing LCA guides and norms (e.g., Product Environmental Footprint Category Rules Guidance [7]).

ⁱThe supplementary file can be accessed via: <https://bit.ly/3o6ZNO2>

For example, De Wolf et al. (2020) [1] proposed a distribution allocation method that distributed the impacts of production and end-of-life stages in proportion to the number of life cycles of reused building components and tested it for the loading bearing components of an office building project (Kopfbau Halle 118 in Switzerland). Their LCA calculation results incentivized design with upstream reuse and downstream reuse [1]. Oh et al. (2016) [8] and Saint et al. (2019) [9] conducted similar LCA analyses for the optimal sustainable design of the concrete-filled steel tube

columns and the solar water heater, respectively. Their findings indicate that the LCA-based design could reduce the energy payback period, greenhouse gas emissions, and building maintenance and operational costs. These studies manifested the importance and usefulness of new material design methods based on LCA and reuse concepts; however, the primary challenge behind using LCA-based design for reuse is the difficulty of estimating and predicting the number of life cycles that building components can be reused.

Table 2. List of key approaches identified from the reviewed literature

Category	Key approach	Supporting literature
Material design (micro level)	LCA-based design for reuse	[1], [8], [9]
	Design through waste recycling	[10], [11], [12], [13], [14], [15], [16], [17], [18], [19], [20], [21]
Building design (meso level)	Design with reuse	[22], [23], [24]
	Design for deconstruction	[25], [26], [27]
	Circularity evaluation	[28], [29], [30]
Construction and facility management (project management level)	Lean construction	[31]
	Service life prediction	[32]
	Digital coordination platform	[33], [34], [35]
Urban sustainability development (macro level)	User-centered community design	[36]
	Sustainable requalification	[37], [38]
	Urban circularity mapping via open data	[39], [40]
	Nature-based design	[41], [42]
System precondition (system boundary level)	Product-service business model	[3], [43]
	Closed-loop supply chain network	[44]
	New role definition	[45]

(2) Design through waste recycling

Unlike most dominating design practices that favor using new materials, design through the waste recycling approach focused on discovering the methods and benefits of using recycled materials. An intense claim has been around the quality of construction material wastes following the local building codes, which could lead to the instability of final recycled products to affect the physical and mechanical properties of buildings. However, recent studies have revealed the satisfactory mechanical performance of construction materials recycled from wastes that meet design intents. Examples include recycling wood wastes in cement composite materials for a newly designed wood wool cement board [10], recycling aggregates from crushed ultra-high durability concrete as a substitute for the natural aggregate to deliver high performance concrete under extremely aggressive exposure conditions [11], embedding granulated recycled particulate material additives into 3-D printer materials, concrete and pavement [12], incorporating fine recycled aggregates from demolition waste in rendering mortars [13], developing building bricks using steel industry electric

arc furnace dust as admixture into standard clayey raw materials [14], recycling carbon-fibre and glass-fibre reinforced thermoplastic composite laminate waste into high-performance sheet materials [15], recycling the industrial by-product in the stabilised rammed earth materials [16], recycling the limestone, siliceous concrete fines and shatterproof building glass from demolition waste in new blended cements [17], designing exterior cladding using recycled textiles and drinking water treatment wastes [18], recycling rammed earth from heritage building for future building purposes [19], recycling wood and biopolymer for particleboards to replace the conventional panels made of synthetic polymers and virgin wood particles [20], and recycling glass waste in preparation of the gypsum composites for construction [21]. These studies were primarily conducted through rigorous and comparative lab experiments combined with environmental impact analysis, ensuring the proper characterization (e.g., thermal conductivity, surface roughness, loading capacities) of recycled materials for building needs. Besides, these materials have been demonstrated as environmentally benign alternatives to reduce up to 95%

of environmental impacts compared to conventional material design and usage scenarios.

3.2 Building design

In this broad category, the emerging building design solutions for CE include Design with reuse, design for deconstruction, and circularity evaluation, focusing on investigating CE strategies on a building system or a relatively meso level.

(1) *Design with reuse*

Unlike the conventional design of building systems and structures that focuses on assessing the structural properties of newly manufactured building elements, the design with the reuse approach highlights the reuse of a stock of reclaimed elements to ensure optimal structural geometry and topology. This approach is slightly similar to the LCA-based design for reuse approach, both of which need to rely on accurate estimation of reuse cycles; however, the latter one does not extend to the reuse of the entire modules or assemblies without much reprocessing for future projects [22, 23, 24]. Brütting et al. (2019) [22] innovated a train station roof structure of complex layout by reusing the disassembled electric pylons from a power transmission line in Switzerland, which reduced an up to 63% environmental impact when compared with a same weight-optimized conventional design. With the same idea of such large-scale reuse applications, Chen et al. (2020) [23] and Nijgh et al. (2020) [24] designed brick-lined railway tunnels and a steel-concrete demountable car park building, respectively, which enabled great adaptability of large-scale building systems by reusing the disassembled elements.

(2) *Design for deconstruction*

Design for deconstruction is a design approach to extend the service life of the different elements of a project (e.g., building components), which is different from the design with reuse approach that usually sources reused elements from other deconstructed or demolished projects. The essential idea behind the design is the consideration of deconstruction, which is a process of reclaiming building materials and elements “as-is” (e.g., windows, doors) [25], but it is always challenging to perform. Eberhardt et al. (2018) [26] have found that the material composition significantly influences the deconstruction performance. Besides, different technological tools have been developed to facilitate the design for deconstruction. For example, Sanchez et al. (2019) [27] proposed a semi-automated selective deconstruction programming approach to optimize the disassembly sequences, which was based on 4D BIM that collected the appropriate level of details of deconstructed building information (e.g., the exact location of nails in wood framing). These semi- or fully- automated technical methods could increase the efficiency of deconstruction planning and design for deconstruction;

however, they have not been widely studied, and case studies have been lacking in the existing literature.

(3) *Circularity evaluation*

Circular evaluation is the approach to ensure the technologies, processes, and materials are appropriate to meet circularity needs. A few circularity evaluation frameworks and taxonomy of circular indicators have been established based on best practices of using general CE concepts; however, they do not comprehensively inform the specific design and technical requirements of buildings. Finch et al. (2021) [28] developed twenty circular performance criteria for the external functional layers of New Zealand light timber platform framing, which covered a wide range of characteristics (e.g., thermal resistance, waterproofing) of recycled and reused materials. Besides, there are individual circularity indicators used for different circularity aspects. For example, the embodied greenhouse gas emissions indicator was investigated to map the circularity performance of four Danish projects [29]. For wastes and demolition, the indicator of waste diversion rate was calculated to assess the effectiveness of waste management in the residential construction sector in Australia [30]. The results from these evaluations helped project owners determine economic benefits from reuse and recycling and helped local government and regulatory bodies benchmark and develop circular construction programs and policies for sustainable urban development.

3.3 Construction and facility management

In this broad category, the emerging construction and facility management solutions for CE include lean construction, service life prediction, and digital coordination platform focusing on investigating CE strategies on a project management level.

(1) *Lean construction*

Lean construction principles and methods are not new in the construction domain, including pull planning / reverse engineering, takt planning, and the Last Planner® System. However, the interaction between lean construction and CE has not received much attention until recent time. Benachio et al. (2021) [31] suggested incorporating reversible building design processes into the design for deconstruction processes in which a design could consider all life cycles of building elements and guarantee their high reuse potential in future projects. From the selected literature, only one article discussed lean construction to achieve circularity [31]; therefore, the lean construction methods seem to receive much less attention when compared to the other key approaches.

(2) *Service life prediction*

Service life prediction is an inevitable part of life cycle assessment and is aligned with life cycle costing. The building lifespan has significant effects on the

overall environmental performance of a building. For example, the longer the lifespan and more reuse cycles, the less embodied environmental impacts [32]. Therefore, an accurate prediction of the life span of building elements and the number of life cycles is considered essential to allow a reliable planning process for CE. Detailed mathematical prediction models were not seen from the selected articles, but it is likely they were excluded earlier during the literature search. However, many LCA-related case studies in the selected literature referred to norms and standards (e.g., ISO 15686 Part 2 and Part 8 [32]) to predict the service life of building elements.

(3) *Digital coordination platform*

A digital coordination platform approach is required not only for a Construction 4.0 context but also for a circular construction one, centered around applying BIM technologies to enhance the information exchange and decision-making processes with quick information updates in circular projects. The practical implementation of a digital coordination platform can be carried out using different software solutions and plugin functions. Eray et al. (2019) [33] and Fagnoli et al. (2019) [34] developed BIM-based solutions to connect the 3D information of building elements with the building facility management needs and the adaptive reuse plans, which gave more certainties to stakeholder communication and established clear agreements. Besides, blockchain technology (i.e., a distributed ledger system) has become an emerging topic in circular construction. For example, Kouhizadeh et al. (2019) [35] analyzed multiple case studies of blockchain adoption for circularity purposes. They found that leveraging blockchain with RFID, QR codes, and other sensors could prevent data falsification among stakeholders and increase traceability of reused and recycled materials. They also found that a particular form of blockchain-based contractual system, the Ethereum-based smart contract, could trigger automatic payments and automatically store protocols with material contractors in the construction supply chain. Compared to the other key approaches, the development of BIM-based or blockchain-based digital coordination platforms to realize CE was not seen extensively in the existing literature.

3.4 Urban sustainability development

In this broad category, the emerging urban sustainability development solutions for CE include user-centered community design, sustainable requalification, urban circularity mapping via open data, and nature-based design, focusing on investigating CE strategies on a macro level, e.g., urban, city, and country level.

(1) *User-centered community design*

A user-centered community design approach is an

opportunity to drive design in response to user needs and improve circularity and sustainability. The engagement with inhabitants and users is important from the early project planning phase. Lucchi and Delera (2020) [36] enhanced the historic public social housing community in Milan by involving inhabitants to provide knowledge of the local social-economic conditions for selecting appropriate sustainable retrofit solutions. The findings indicate that participatory actions are also important for empowering the environmentally responsible design for public housing neighborhoods.

(2) *Sustainable requalification*

A sustainable requalification approach focuses on the requalification of services and physical spaces to improve social aggregation for a new suburb and urban metabolism. Mami (2014) [37] suggested making communities (in Italy) independent from the view of waste disposal and instead promoting the self-sufficiency principle (e.g., smaller and cheaper transportation service networks and plants work together to enable waste cycle management that transforms wastes into useful resources). Considering the same principle, Serena and Altamura (2018) [38] prepared a harvest map in the area between Como and Milan to identify, within the network of local companies, waste materials that could be used in the recovery of a historical Villa on the Lake Como constructed with load-bearing stone masonry and wooden floors. The requalification of services and physical spaces enhanced the service and space integration for circularity, but the distance between plants and the quality of transportation infrastructure becomes fundamental to affect the environmental and economic outcome of using the approach.

(3) *Urban circularity mapping via open data*

Urban circularity mapping via open data is an approach that spatially models the building blocks in an urban area and quantifies their environmental requirements or impacts. Following this idea, Marcellus-Zamora et al. (2020) [39] used geo-referenced data on reused construction and demolition wastes in LEED databases to quantify the waste material flow (e.g., how many materials have been recycled or reused) in the city of Philadelphia. Their findings, which showed that 77% of the sampled buildings had materials with recycled contents, have incentivized future data collection for tracking the material recycle and reuse. Using a slightly different quantification approach that is based on BIM and GIS, Stephan and Athanassiadis (2017) [40] developed a high-resolution model to map out the embodied energy intensity of the city of Melbourne considering the typology, geometry, and age of each building in the municipal's open database. However, the urban circularity mapping is quite challenging in many places due to the lack of a local open database and the lack of the computational power to complete the

quantification process for all building stocks. Nevertheless, it provides a great opportunity to inform city and urban planners to rebuild cities and communities towards sustainability by looking at the environmental performance of each building.

(4) Nature-based design

At the urban level, the nature-based design approach concerns using nature-based solutions to reorganize the relationship between the built environment and the ecological environment. For example, Mussinelli et al. (2018) [41] advocated the integration of trees, water bodies, and other natural green areas with the urban infrastructure to support urban regeneration. A more specific application of this approach was illustrated in the study of Sierra-Pérez et al. (2018) [42], where they introduced the cork insulation boards as a natural material solution for retrofit building design in the Barcelona metropolitan area to reduce environmental impact and retrofitting cost, considering that cork is a very interesting forest-based material for many industrial sectors as a natural and renewable material. The nature-based design provides a great opportunity for one sector (e.g., the cork oak forest sector) to diversify its market and produce materials that fit into another sector (e.g., the housing sector). This potential synergy is also highly relevant to the sustainable requalification approach as the interaction of sectors and companies should not be neglected.

3.5 System precondition

In this broad category, the emerging solutions for establishing critical system preconditions for construction circularity include product-service business model, closed-loop supply chain network, and new role definition, focusing on investigating CE strategies under particular system boundaries.

(1) Product-service business model

A product-service business model has become an important precondition for smooth implementation of circularity approaches because of the redefined material value proposition (e.g., leasing and sharing), new ways of building, and the change in the ownership of materials. Based on structured interviews, Kanters (2020) [3] found that the product-service business model is required by the circular material providers to offer a service with long-term responsibility. It also means that the building owners and tenants do not need to own building materials if they do not want to own them. For the business model to succeed, the challenge is that the providers have to ensure the services are well-designed to meet clients' needs [43] and preferably have a long lifespan.

(2) Closed-loop supply chain network

A Closed-loop supply chain network is required to support the circular material flows that optimally locates the industrial facilities and plants to manufacture and

distribute products and collect and recycle end-of-life products. Using the mixed-integer linear programming (MILP) model, Accorsi et al. (2015) [44] optimized the geographic location of raw material suppliers, manufacturing plants, distribution centers, collection nodes for wastes, landfills, and recycling centers together with the optimization of the allocation of transportation flows. The supply chain network coupled with the transport geography is a fundamental precursor to realizing construction circularity.

(3) New role definition

A new role definition is necessary when defining the supply chain network towards circularity and project stakeholder collaboration processes [45]. As new rules and procedures are adapted for circular strategies, new roles must be established and defined accordingly. Based on the analysis of multiple case studies concerning the coordination of reuse of building materials, van den Berg et al. (2020) [45] found that new roles of "separator" demolish subcontractors were created for demounting, selecting and delivering reused materials for other project sites. How effective the coordination activities and construction circularity should depend on whether the new roles are aligned with the circularity approaches and contractual terms.

4 Conclusions and future work

This study takes a systematic literature review to find an overall scope of key approaches to construction circularity. From the 40 selected publications, five broad categories representing different levels of circularity implementation: 1) material design, 2) building design, 3) construction and facility management, 4) urban sustainability development, and 5) system precondition, were identified. Those categories were further decomposed into 15 key approaches to realizing CE.

The current body of knowledge concerning construction circularity emphasized the new experiments and LCA analysis heavily to validate the potential of recycled and reused materials regarding their environmental performance and mechanical properties. However, this review finds that the other emerging but less studied topics (i.e., reflected in less than two articles), such as the lean construction methods, the digital coordination platform, and the urban circularity mapping via open data approach, etc., are worth considering to realize construction circularity. This review finds that BIM-based and blockchain-based platforms could increase the traceability of reused and recycled materials, which in turn facilitates the communication between project stakeholders concerning what, how, and when the materials should be used within the estimated number of life cycles. At the urban level, industrial symbiosis through nature-based design and sustainable

requalification is needed for connecting the demolition sites, recycling plants, and construction project sites to allow efficient use of resources. New business models and new role definitions are also required to support the implementation of circularity in construction.

Besides the identified mainstream key approaches from the selected literature, researchers mentioned the importance of establishing revised legal and contractual frameworks and renewed material certification systems for reusing and recycling materials. For example, the Australian draft standard for recycled structural timber does require further treatment; however, treatments typically have a specified effective lifespan, which could impose a high legal risk for local builders. Besides, local government funds and tax policies lacked discussion in the literature, but they are considered important drivers. However, these legal, risk, financial and contractual topics have not been systematically investigated and require more expert knowledge and future research work.

Although different approaches to construction circularity seem to have their respective potentials, it remains difficult to devise a complete circular construction approach that treats all aspects fairly. Overall, this review shows the necessity to integrate stakeholders, service centers and plants, transportation networks, and local authorities to realize construction circularity at the micro, meso, and macro levels.

Abstract –

Offsite construction (OSC) has demonstrated various benefits, but its wide adoption is constrained by complex and dynamic supply chains. It is vital to establish a comprehensive performance measurement system for OSC supply chains, which however has seldom been explored in detail. This paper aims to identify the key performance indicators (KPIs) of OSC supply chains through a systematic review of the literature published from December 2000 to March 2021. A total of 65 KPIs were extracted from 84 articles, including 35 economic, 19 social, and 11 environmental KPIs. A consistent KPI framework was initially proposed to describe how the KPIs jointly assess OSC supply chains. The results indicate that previous research mainly focused on the economic aspect of OSC supply chains while social and environmental performance were largely overlooked. Under each aspect, several indicators were ascertained as frequently cited KPIs, while some others received relatively little attention. This paper contributes to a better understanding of OSC supply chain performance by investigating current measurement efforts from a multidimensional perspective. To practically develop a quantifiable assessment method, further research should build on the framework and pay more attention to the overall or total performance and the neglected KPIs, particularly in social and environmental aspects.

Keywords –

Offsite Construction; Supply Chain; Key Performance Indicators; Performance Measurement

1 Introduction

Offsite construction (OSC) transfers onsite activities into a controlled manufacturing environment [1], with many benefits such as shortened construction time, improved productivity, better quality and enhanced sustainability [2]. However, a wider take-up of OSC is constrained by its complex and dynamic supply chains that feature complicated and interdependent processes,

including design, manufacturing, transportation, storage, and assembly of building components, elements or modules [3, 4]. Regarding OSC, the lack of a comprehensive supply chain performance measurement could result in sceptical attitudes of stakeholders towards this innovative construction method without a clear vision of its superiority. Performance measurement for OSC supply chains is therefore growing important, which helps determine how successful organisations attain their objectives and highlight improvement opportunities [5].

Previous research proposed diverse performance metrics ranging from fundamental ones including cost, time and quality [6, 7] to more sophisticated ones including stakeholder satisfaction, technology transfer, partnering, and carbon emissions [8-10]. These studies focused on specific segments of OSC supply chains and partly evaluated the economic, social and environmental performance. However, fragmentation in using these indicators may not achieve satisfactory results, as different stakeholders often emphasise their individual performance rather than the whole supply chain. Scholars stressed the importance of simultaneously rather than separately considering the three pillars above to enhance OSC supply chain systematically [5, 11]. As such, there is an urgent need to develop a holistic framework based on KPIs to evaluate the overall performance efficiently.

This paper aims to identify existing KPIs of OSC supply chains through a systematic literature review. The remainder is structured as follows. Section 2 describes the research methodology and procedure. Section 3 synthesises published literature and demonstrates the extracted KPIs in economic, social and environmental aspects. The findings and discussion are presented in Section 4. Finally, Section 5 concludes the research implications and recommends future directions.

2 Methods of Review

The performance measurement is suggested to use composite indicators, and frameworks with a systematic perspective are recommended to guide the analysis. Ahi and Searcy [12] extracted 2555 unique performance metrics of supply chains through a structured content

analysis, the majority of which fall into the groups of economic, environmental social focuses. Pan, Zhang, Xie and Ping [13] developed a set of KPIs from the economic, social and environmental perspectives to benchmark modular integrated construction projects. The Triple Bottom Line (TBL), which systematically examines the social, environmental and economic impacts, is therefore recognised as a sound starting point for developing comprehensive performance metrics [14, 15]. This research adopted TBL and identified KPIs of OSC supply chains drawing on a comprehensive review of related articles. A three-stage review following the systematic literature review method was proposed (Figure 1) [16].

Figure 1. Main stages of research procedure

In Stage 1, a comprehensive paper search was conducted using Web of Science and Scopus. The search strings combined OSC related keywords like “offsite construction”, “prefab*”, “industrial* construction”, and “modular construction” (see Pan, Zhang [17]); supply chain related ones like “supply chain*” and “value chain*”; and KPI related ones like “key performance indicator*”, “performance metric*”, “performance measurement”, “performance evaluation”, “performance assessment”, “driver*”, and “critical success factor*”. 265 papers were retrieved and screened to collect articles that: (i) were published in peer-reviewed journals or conference proceedings; (ii) were in engineering and construction management field; and (iii) were written in English. For comprehensive coverage, a snowballing search was conducted to collect relevant articles outside the scope of the predefined search strings [18]. Finally, 84 articles were considered eligible, including 74 from the initial screening and 10 from the snowball search.

In Stage 2, a preliminary analysis was performed to classify the selected papers according to year, location, source and research method. These results clarified the previous research process and expedited to assess the main issues in supply chain performance measurement.

In Stage 3, KPIs were extracted through content analysis and organised based on the concept matrix according to Webster and Watson [16]. The initial indicators were catalogued against the citing sources, and those with similar meanings were merged. Then, the KPIs were classified based on TBL and further clustered into different performance fields. For prioritisation, the KPIs were ranked based on the frequency of occurrence.

3 Review analysis and findings

3.1 Profiles of publications

The included articles were first analysed in terms of year, location, journal, and research methods. Figure 2 illustrates the annual distribution of the 84 included articles from 2000 to 2021. The number of publications remained low for 14 years, with a sharp and progressive increase since 2014. Figure 3 shows the geographical distribution of the articles based on the author affiliation. Hong Kong SAR (21 articles; 25%) accounted for the largest number of publications, followed by Australia (15, 17.8%) and Mainland China (11, 13.1%). As for publication sources (Figure 4), Journal of Construction Engineering and Management, Journal of Clean Production, and Construction Engineering and Economics were the leading sources of research in performance measurement for OSC supply chains. Figure 5 indicates that most of the included articles (39) adopted hybrid research methods, followed by case study and literature review. Interview was also widely adopted (36) but commonly together with other research methods.

Figure 5. Research methods

3.2 KPIs of OSC supply chains

This study aims to identify KPIs that are indicative of the performance of OSC supply chains in terms of a certain activity or as a whole. Results indicate that limited publications have provided a comprehensive list of KPIs. Most articles (86.9%) mentioned economic KPIs, while 56.0% and 31.0% of articles considered social and environmental KPIs, respectively, as illustrated in Figures 6-8 and described below.

3.2.1 Economic KPIs

To indicate OSC supply chains' economic success, KPIs were found related to ten performance fields: namely, cost, time, quality, productivity, flexibility, efficiency, predictability, reliability, leanness, and utilisation (Figure 6).

Cost performance was pointed out as the most significant performance field in the economic aspect. The most frequently mentioned KPI in this field was lifecycle cost (e.g., [19]), which can be further measured by the associated cost across the entire supply chain. The breakdown of lifecycle cost, accounting for a large portion of cost performance, were described as process-based costs, including assembly cost (mentioned in 16 articles), transportation cost (14), inventory-related cost (13), production cost (7), and overheads (7) that support the processes of creating a product or service (e.g., [20]). Instead, other researchers used resource-related cost,

including KPIs of labour cost, capital cost, and material cost (e.g., [9]). The remaining KPIs included cost variance (18), return on investment (12), and financial strength (6). Cost variance that ranked third according to the frequency of occurrence in the retrieved papers presents deviations of actual cost against planned budget or benchmark (e.g., [8]). Since the promotion of OSC supply chains can only be realised when stakeholders earn benefits [21], return on investment measuring the value-added benefits has attracted great attention (e.g., [22]). Last but not least, financial strength mentioned in six papers was significant to the success of OSC deliveries, due to the high initial investment and financial pressure faced by suppliers (e.g., [23]). There is overlap between various cost performance indicators, and different stakeholders should deliberate on the selection of KPIs according to their business goals.

Time performance accounted for the second large portion of economic performance. Literature in the supply chain field identified time-based competition as a management area to evaluate OSC supply chains' responsiveness, representing less process time and a shorter order fulfilment cycle [24]. Time-related KPIs of OSC supply chains are listed in reverse order based on the frequency of occurrence: time variance, cycle time, assembly time, delivery time, ontime delivery rate, and manufactory time (e.g., [25-27]). To ensure the ontime delivery, stakeholders can use these KPIs in combination to measure time performance of each stage against cycle time or planned schedule, thus helping them develop appropriate responsiveness interventions.

The third performance field was productivity. It measures the quantity of products and services obtained through unit resource expenditure, such as labour productivity, equipment productivity, and material and energy productivity (e.g., [28, 29]).

Flexibility, the ability to meet varied customer requirements and frequent order changes, ranked as the fourth performance field. On the one hand, flexibility is manifested in responding to varied customer requirements, indicating the balance between customisation and standardisation (e.g., [9, 23]). Standardisation may ensure efficiency but might sacrifice customisation, while customisation can be challenging to scale. On the other hand, flexibility is the possibility to address short term changes and external disruptions. As such, the importance of supplier and material alternatives, inventory buffer, and other performance regarding responsiveness to changes were emphasised in 19 articles (e.g., [30, 31]).

Quality ranking the fifth place consists of two aspects: the major one being defects and rework, and the other being compliance with building specifications. The terms extracted from the selected publications, such as quality-reduced defects, cost of rework, changeover cost, and

quality cost, were listed under the group of defects and rework (e.g., [9, 29, 30]). In case of product defects, extra money and time need to be spent, affecting the operations of downstream activities. Besides, quality was also described as compliance with codes and standards, though rarely mentioned [29].

Figure 6. KPIs of OSC supply chains in the economic aspect

The following field was efficiency, measuring how companies and processes harness resources to achieve the highest output with the least inputs. The efficiency-related KPIs focus on resources optimisation for specific operations across supply chains. According to the results, researchers paid particular attention to the efficiency of site layout (13), purchasing procedures (12), and design approval (7), as listed in descending order [9, 32, 33].

The final four were less-mentioned performance fields. Predictability mentioned in 17 articles is critical to stable delivery by forecasting and planning time, cost, and demand of OSC supply chains [30]. Reliability was discussed to reflect the accurate and stable delivery of suppliers' products and service. Terms like accurate, reliable and timely time and material flows were identified as conducive to business continuity [25]. Accurate documents, such as accurate delivery notes, stock records and working instructions, was seen as a contributor to delivery accuracy [34]. The penultimate performance field was leanness, reflecting the item-level management and automation level in OSC supply chains

[35]. In the last performance field, worker, energy and material, equipment utilisation were identified as major KPIs, which could be calculated as the rates of utilised resource against the total available time/volume of resources for a project [26].

3.2.2 Social KPIs

Concerns about the social performance of OSC supply chains have been increasing in recent years. The extracted social KPIs were clustered into the following five performance fields: impact on project, impact on industry, information flow, employee concerns, and impact on community (see Figure 7).

One of the most significant social performance fields was the impact on project. The social KPI, collaboration and coordination, was most frequently mentioned in the retrieved papers. Enhanced by advanced technology, it has provided an innovative way that stakeholders could pool their resources and knowledge together and work towards the overall goals of the entire process rather than their own goals [7]. The second KPI was trust and long-term relationship. Trust between various participants was proved helpful in smoothing the construction process, thereby increasing supply efficiency and allowing flexibility when facing uncertainty [36]. In addition, long term bonding between suppliers and contractors leads to greater synergy, transparency, openness, sharing and trust [37]. Researchers increasingly valued the partnership and meanwhile concerned about conflicts and disputes that damage the cooperative relationships. Therefore, the ability to solve conflicts and disputes was regarded as the third KPI in the performance field [38]. Following that, stakeholders' satisfaction that reflects their level of satisfaction with the finished product or services, ranked as the fourth KPI. The least mentioned KPI in this performance field was about accident, which together with conflicts and disputes were considered to damage the stakeholders' satisfaction and may have severe social impact [36].

Social performance regarding the impact on industry was viewed equally important as they affect the industry's decision on the OSC adoption. KPIs in this field focused on technology and innovations application (32), which stimulates the development of OSC by improving productivity [26]. In the following KPIs, the second KPI of government support and the fourth one of regulation and standards development, are also significant incentives to promote OSC [36]. Competitiveness and leadership mentioned in 7 articles ranked the third place, as products competitiveness and enterprises' leadership are a necessary piece of organisational success [9]. Next two KPIs (i.e., research and development, intellectual property protection) indicate the stakeholders' attitudes towards and investment in technological upgrading of OSC supply

chains [39, 40].

Information flow was analysed as a performance field closely bound to information technology. It included information sharing and communication [36], information visibility and traceability [35], information security [41] and information transparency [42]. Especially information sharing and communication, the KPI representing the exchange of data between various organisations and professionals is a significant indicator of the cooperation level and further contribute to the success of OSC supply chains.

Next performance field was employees' concerns, including health and safety and job satisfaction [37]. As labour shortage has become severe in the construction industry of many developed economies, the improvement of work conditions is crucial to establishing OSC supply chains [36]. Companies that take measures to increase their job satisfaction by improving workers' welfare and career development will in return have a positive impact on the corporate image and project profits [36].

Impact on the local community received relatively less attention. Projects which rely heavily on local areas' infrastructure should serve the local community [43]. Corporate responsibility measures stakeholders' commitments to supporting local general welfare undertakings and complying with laws and regulations [37], while impacts on local economy measures how a project influences the fiscal revenue and employment in the region [44].

Figure 7. KPIs of OSC supply chains in the social aspect

3.2.3 Environmental KPIs

The environmental KPIs involved four performance fields: waste and pollution, resource use and recycling,

environmental commitment and greenhouse gas emissions (Figure 8).

First, the major environmental concern was waste and pollution generated in the whole supply chain, as it could reduce the industry's and community's willingness to uptake the OSC approach. As such, it is essential to take waste-related KPIs (i.e., waste disposal, waste reused and recycled) [45] and pollution-related KPIs (i.e., water pollution, air pollution, and noise pollution) into environmental consideration when establishing OSC supply chains [43].

Resource consumption accounted for the second large portion of environmental performance. The extraction and processing of building material may result in soil degradation, water shortages, and global warming. The reduction in the consumption of water, energy and other natural resources is a measure of the environmental capability of resource saving and recycling [36].

Environmental commitment was another important performance field, including environmental statutory compliance and environmental targets and activities. The former one refers to compliance with environmental legislation, policies and standards, helping avoid adverse environmental impacts [46]. The latter one is to measure impacts on the achievement of environmental goals [36]. Companies throughout OSC supply chains are the mainstays to improve environmental performance and are responsible for publishing their environmental goals.

The last performance field about greenhouse gas emissions was regarded as one of the commonly tracked environmental impacts in the construction industry. Greenhouse gas emissions are usually converted into carbon accounting for measurement. The primary step to keeping them at an acceptable level is estimating carbon accounting throughout the whole supply chain [47].

Figure 8. KPIs of OSC supply chains in the environmental aspect

4 Discussion

This study identified a holistic list of KPIs for OSC supply chains through a systematic literature review. All the identified KPIs covering economic, social, and environmental aspects can be structured as illustrated in Figure 9: (1) the radial direction indicating the hierarchical relationships between a particular indicator and higher-level performance; (2) the circular direction describing the clusters of KPIs that assess a specific performance field and aspect. Figure 9, taking the environmental KPIs as an example, shows that the environmental aspect (inside layer) is comprised of four performance fields (middle layer), under which there are a total of 11 environmental KPIs (outermost layer). Similarly, economic and social KPIs are also distributed accordingly, and the specific KPIs of the outermost layer are described in the sections above.

The KPIs are intended to be broadly applicable, but there are some overlaps and limitations. For example, lifecycle cost can be regarded as the sum of each process's expenditure [20]. Whether to use lifecycle cost or some specific process costs depends on different stakeholders and segments of OSC supply chains [43]. Besides, previous research mainly focused on the economic performance of OSC supply chains rather than social and environmental aspects, which underscores the deficiency in these two core areas of current measurement efforts. With the occurrence count of each KPI, this study not only identified common KPIs, but also found that several KPIs received relatively little attention in the past. In addition, modular construction representing the highest level of OSC is the main trend. Research on supply chain performance measurement for modular construction should build on that of OSC supply chains and deliberate on the differences with component, element and system delivery.

The proposed KPIs derived from various publications enhance the knowledge base of OSC supply chains. However, the presented work is only a fundamental step to establishing a bespoke performance measurement toolkit or method. Several improvements for future research have been identified as follow. First, researchers should consider the entire spectrum of supply chains and the overall performance, particularly in social and environmental aspects [11]. Second, as these KPIs are only derived from literature and lack practical verification, it requires triangulation of multiple forms of evidence subject to validity testing, such as interviews and questionnaire surveys [7]. Third, a quantitative analysis should be conducted to evaluate the interaction and relative importance of the proposed KPIs [33]. It is meaningful but challenging to explore how to balance the KPIs to attain the best sustainability performance. Finally, empirical research is required to validate the proposed framework.

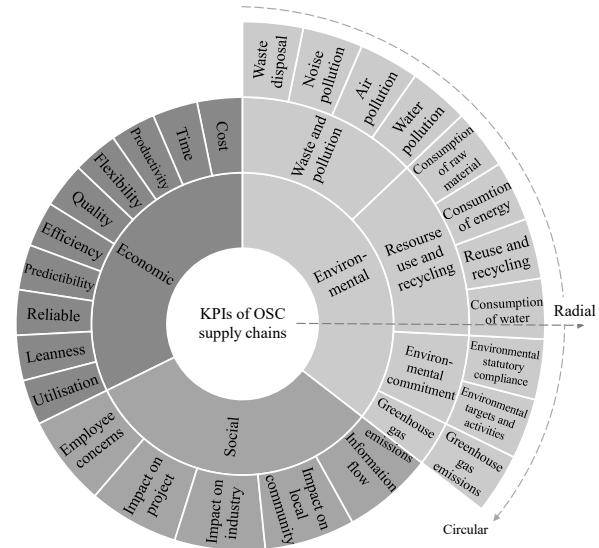

Figure 9. The framework of OSC supply chain KPIs (take environmental KPIs as an example)

5 Conclusions

This research attempts to provide a systematic review of existing publications on KPIs of OSC supply chain and suggest future research. An initial performance measurement framework, consisting of 35 economic, 19 social and 11 environmental KPIs, was developed to demonstrate how they jointly measure the performance of OSC supply chains. Although the framework is intended to be broadly applicable, organisations should select the most appropriate KPIs to evaluate whether their performance is in line with goals. In addition, more attention should be paid to the neglected KPIs, especially in social (e.g., job satisfaction and impact on local economy) and environmental (e.g., pollutions and greenhouse gas emissions) aspects, to support the enhancement of OSC supply chains in a systematic and sustainable manner.

This review contributes insights into the strategic considerations of performance measurement but is still far from meeting requirements for practice. Consistent performance measurement based on the initial framework should be further refined to support the industry's and community's decision making on OSC supply chain selection and evaluation. As discussed, future research focusing on modular construction will validate and transform the selected KPIs into a total factor or a multidimensional assessment method, with quantifiable or qualitative descriptions of the indicators and the weighting system. The proposed measurement will be verified using real-world cases to demonstrate how OSC supply chains could benefit the construction industry, local community and ecological environment.

Abstract –

Typical construction project management and production management courses teach the critical path method, in which only the precedence constraint is considered while scheduling activities. By contrast, the tri-constraint method is an object-based scheduling method that considers activity precedence, resource constraints, and spatial availability. However, the tri-constraint method is only taught at few universities to date. This paper outlines the creation of a new curriculum to teach the theory and application of the tri-constraint method. The paper describes a proposed five-lesson, flipped-classroom curriculum for teaching the tri-constraint method. In class one, we introduce students to the limitations of the critical path method. In class two, we teach the fundamental algorithm behind the tri-constraint method. In classes three to five, we demonstrate how the tri-constraint method can be scaled using a BIM-based smart scheduler, in partnership with the software company ALICE Technologies Inc. During this period, students learn how to model constraints, generate millions of schedules, and explore tradeoffs and interventions for further schedule optimization. The paper concludes by describing how the curriculum was implemented in Autumn Semester 2020, summarizing preliminary qualitative feedback from the students, and reflecting on future improvements. The proposed curriculum is now available for usage or adaptation by the broader construction informatics research community to be integrated into construction project and production management courses.

Keywords –

Education; Generative construction scheduling; Tri-constraint method; Critical path method; Automation

1 Introduction

Creating a schedule is one of the most important

steps in the planning phase of a construction project: in the planning phase it shows the scope of the work, enables coordination of all project participants and is the basis for estimating costs and the duration of the project; in the execution phase it provides information on when, by whom and by when the work must be carried out, but also enables monitoring of the projects' progress. Moreover, it is often used for contractual matters, for example as a basis for claiming liquidated damages in case of delays.

To develop these schedules, most construction management programs teach students the critical path method (CPM). CPM was developed in the 1950s [1], [2] and has been widely accepted due to its applications in planning, scheduling, and control [3]. Scholars found that by the early 2000's, CPM was used to produce 80% of all construction schedules [4]. It is the most common scheduling approach in the United States [5] and the United Kingdom [6] for planning and controlling construction projects [7]. In a survey of Engineering News Record Top 400 Contractors, 98.5% of the participating companies used CPM in their projects [8]

However, scholars increasingly note the limitations of CPM for production management in construction. Today, schedules are developed without considering the resources systematically while scheduling. Afterwards, a resource levelling process is performed to prevent an over-allocation of resources. The new distribution in turn affects the previous schedule, which must then be adjusted again, making the process of creating a reliable schedule an iterative task. Furthermore, CPM often does not take advantage of digital technologies such as Building Information Modelling. For example, 4D BIM does not automatically generate the sequence of production but instead acts as a visualization or check of the proposed CPM sequences. The four most relevant limitations can be summarized as 1) initial reliance on assumption of unlimited resources, 2) no consideration of spatial or location-based constraints, 3) lack of automation, and 4) lack of dynamic change process (i.e. changes require many laborious steps). Due to space limitations, we refer readers to Dallasega et al. [3] for a comprehensive summary of CPM limitations.

One emerging alternative to CPM is the Tri-Constraint Method (TCM) [9], [10]. In TCM, precedence, resource availability and spatial constraints are operationalized into the following formal scheduling constraints: precedence, discrete resource capacity and disjunctive constraints. This allows TCM to systematically consider precedence, resource and spatial constraints when scheduling activities. As a result, scheduling no longer requires an iterative process to consider resources. By combining the mechanisms that resolve the constraints with mechanisms that vary the feasible sequences of activities, TCM is able to loop through a predefined algorithm and create multiple feasible schedules. In doing so, it allows the selection of the most optimal of all feasible schedules for a given project [9]. The systematic consideration of resources right from the start makes the scheduling process more structured and transparent and facilitates automation. With powerful computers, numerous reliable schedules can now be created and compared in less time.

One application to apply the TCM is already on the market. ALICE, a cloud-based scheduling software, uses TCM for the generation of schedules. When uploading a BIM model, the software automatically determines the precedence relationship between the elements. Then, each element can be assigned a recipe that describes the sequence of activities to create the element. Each activity can then be assigned resources (labor, material, equipment) and productivity rates or durations. The software then automatically generates multiple schedules that can be compared and analyzed. By parameterizing using production rates and the BIM model, changes to schedules or resources can be quickly incorporated into a new schedule.

However, a corresponding change in how construction management (CM) programs teach construction scheduling has not followed. CM classes can be reluctant to integrate these new approaches into their curricula for various reasons. First, new methods such as TCM and new software such as ALICE may have only recently attracted the interest of industry and the academic world lacks broad expertise in these areas [11]. There may be fear of teaching a new method that might not ultimately be successful. Finally, and most importantly, CM programs often are not able to make room for new content in existing curricula because they already have a tight timetable and also do not have sufficient time and resources to create a new curriculum [12].

It is important that CM programs do not fall behind industry implementations. CM curricula has an important role to play in researching these new methods and technologies, demonstrating their applicability and their benefits for industry, and thus supporting and motivating industry to apply new methods. University

education is also a good starting point to provide students, future employees of the industry, academic foundations and technical knowledge about different innovative approaches that may support or shape their future careers. Software companies can offer guides, tutorials, training materials and seminars on how to use their tools that are tailored for companies. However, these cannot be directly integrated into existing university curricula, as they focus on the practical application of their tools in the industry and can remain a “black box” to practitioners. There is need for teaching of the fundamental principles and theoretical knowledge behind such algorithms, alongside some practical introduction to software applications.

Based on the above, this paper proposes a 5-week curriculum for teaching the TCM within an existing CM course on construction scheduling. We created and implemented a 5-week curriculum that teaches the fundamentals and limitations of the CPM, the theoretical foundations of the TCM, and an introduction to the software ALICE for further exploration of how such theoretical foundations can be operationalized in practice. The objective of this paper is to share the basic learning objectives and course structure of the proposed curriculum, along with preliminary feedback from the first implementation of the curriculum in Autumn 2020. The long-term goal of this work is to share the curriculum for use and adaptation from the broader CM educational community. All course lessons, teaching notes, exercises and presentation templates are freely available online [13].

2 Departure and Approach

The Tri-Constraint Method (TCM) is a new generative planning method that is specially adapted to the conditions of BIM-based construction planning. It is applied in the form of an automated event simulator, using three fundamental constraints in the execution of a construction project to determine the sequence of activities and their start and end dates [9]. These constraints are mechanisms that prevent the execution of an activity at a given time [9]. The basic unit of work within the TCM are referred to as operations. An operation describes the work of a crew on a component of an element [9]. The three fundamental construction constraints of TCM are:

- Precedence constraints - relationships used to define logical links between activities, analogous to the traditional planning approach. They are not dependent on the current moment or current constraints and can be displayed using a graphical representation such as a network diagram [9]. An example of such a precedence constraint is the condition that foundations must be built before the

overlying columns can be placed. If this restriction is violated during planning, physically unfeasible schedules will be created.

- Discrete resource capacity constraints - depend on the current point in time. They take into account the availability of discrete resources and therefore cannot be represented in a network diagram [9]. Discrete means in this case that these resources can be available in integer quantities greater than or equal to 1 [9]. Examples of such resources can be workers, tools or materials. If this restriction is violated during planning, resources may be over-allocated and operations may not take place as planned.
- Disjunctive spatial constraints - prevent operations from taking place at the same time and place. Disjunctive means that either one option or another option is chosen, but never both at the same time. To take this restriction into account in planning, TCM considers the available space as a unary resource. It therefore takes values between 0 (entire space occupied) and 1 (entire space not occupied) [9]. This restriction is therefore also dependent on the current time and cannot be represented using a network diagram. Examples are two otherwise independent activities taking place in the same place. If this restriction is violated, their workspaces will overlap. On the construction site, this could reduce the productivity and increase the probability of onsite accidents.

Based on these constraints, the actual schedule of the project is generated using a generative algorithm that can generate millions of scheduling sequences. This is based on the event simulator of Waugh, where operations are moved from a TODO list, via a CANDO and a DOING list to a DONE list by iterating over time. Due to space limitations, readers are referred to the work of Morkos [9] and Waugh [14] for detailed description and further discussion about the automated/generative scheduling algorithm.

To the knowledge of the authors and in conversation with ALICE technologies, the TCM is currently only taught at two universities – ETH Zurich and Stanford University. The first author had previously attempted to teach the TCM in 2018 and 2019 courses at ETH Zurich. Feedback was that these specific lessons were interesting and showed promise, but the unstructured nature of the assignments was difficult and hard to implement. Furthermore, the lead author wanted to go deeper into the theoretical exploration of how the TCM works instead of only practical applications. Due to practical constraints, the course only had a limited period of time to teach the TCM. Any proposed curriculum needed to be streamlined so that it could be

effectively taught in a 5-week timeline. Furthermore, the course should engage with latest trends in pedagogy including the use of a flipped classroom for active and problem-based learning.

The overall approach to this work can be summarized as the development of a scalable project-based curriculum for CM courses that teaches the theory behind TCM and highlights its advantages over traditional planning methods. The aim is to ensure that a long-term learning effect is achieved among students. In addition to this theoretical perspective, the application in practice shall also be addressed. This is important in order to enable them to apply TCM in their upcoming professional life with the appropriate tools such as the ALICE software and thus to plan projects more successfully. The curriculum should be embedded in an existing management course in order to introduce students to the TCM method and its application with ALICE within a few weeks.

3 Proposed Curriculum

The developed curriculum has a total length of five lecture weeks with two lectures of 45 minutes each per week. On the one hand, this ensures that, from the perspective of the lecturers, there is sufficient time for teaching the contents. On the other hand, there is enough time for a spaced repetition of individual topics, and to review the topics in the context of assignments. Since the curriculum is closed in itself and only lasts about one third of the usual 14 weeks of lectures during a semester, it can easily be integrated into already existing courses at other universities.

The flipped classroom approach is used for the individual lessons. Therefore, each topic is introduced and deepened over three sessions: Pre-Class Homework, Lecture, Post-Class Homework. In the first Pre-Class Homework session, the new content is delivered through papers and videos. Afterwards, obligatory multiple choice and text questions ensure that the students have done their homework and come to the lecture with the basic understanding of the topic. The acquired knowledge is then deepened in class by repeating and discussing the new content and by doing in-class activities. Following the lecture, students work in groups on the Post-Class Assignments, where they are asked to solve more complex problems. The repetition of each new topic three times over a two-week period through different approaches is designed to ensure a long-term learning effect.

3.1 Lecture Plan and Learning Objectives

Table 1 gives an overview of the contents of the five lessons. These are divided into two blocks: Lectures 1 and 2 serve to impart theoretical knowledge. In the first

lecture, the traditional planning method will be presented and in the second lecture TCM will be introduced. Lectures 3 to 5 focus on the practical application of TCM with ALICE. In these, both interactive demonstrations of ALICE by the teaching staff are given and the students work independently with the software. For the In-class activities, a simpler LEO 1 model is used to demonstrate features of ALICE and for the Post-class activities, a more complex LEO 2 model is used to show a more extensive and more relevant use of the software later in practice (see Figure 1).

Table 1. Summary of course structure and learning objectives.

No.	Lecture Title	Learning Objectives
1	Traditional Project Scheduling	<ul style="list-style-type: none"> • Understand the theory behind traditional scheduling • Apply traditional scheduling to a simple example • Describe the limitations of traditional scheduling
2	Tri-constraint Method	<ul style="list-style-type: none"> • Differentiate between planning and scheduling • Comprehend the effects of the 3 constraints on scheduling • Understand and apply the scheduling algorithm of TCM • Analyze benefits and drawbacks of TCM
3	Introduction to ALICE	<ul style="list-style-type: none"> • Implement basic features of ALICE (Plans, Models, Supports, Recipes, etc.) • Identify the association between ALICE and CPM • Create independently a non-resource-constrained schedule using ALICE
4	Modelling Constraints in ALICE	<ul style="list-style-type: none"> • Develop an ALICE model with consideration of the tri-constraints • Understand factors that influence the creation of

		schedules with TCM <ul style="list-style-type: none"> • Create feasible schedules with realistic activity durations. • Analyze and compare multiple schedules using ALICE
5	Optimization in ALICE	<ul style="list-style-type: none"> • Learn how to influence schedules and optimize them for a specific goal • Describe the advantages of parameterization and automation of scheduling using a tool such as ALICE.

In Lesson 1 (Traditional Project Scheduling), the objective is for students to understand and independently apply traditional planning methods in combination with CPM. This helps to ensure that all students have the same level of knowledge about planning methods currently used in practice, while independent application enables them to recognize and discuss the limitations of these methods.

In Lesson 2 (Tri Constraint Method), the students are introduced to the TCM without any advanced visualization technology (e.g. no BIM interface). Students are introduced to the influence of the three fundamental constraints on the schedule, the significance of the distinction between planning and scheduling, and the exact mechanisms of the scheduling algorithm. The advantages of TCM compared to the traditional methods are discussed.

In Lesson 3 (Introduction to ALICE), the students are introduced to the ALICE software. Here the students should learn the basics of the ALICE software, before the consideration of resources or the optimization of schedules is dealt with. The objective is therefore to explain how ALICE works and to enable students to enter required inputs themselves in order to create a basic schedule. The students are asked to build a simple schedule using the recipe function in the LEO I BIM. To achieve this simplification, this first schedule is based on priority relationships only (similar to how the CPM works) with no consideration of resources.

Figure 1. The LEO 1 (above) and LEO 2 (below) models used in the curriculum.

In Lesson 4 (Modelling Constraints in ALICE), students begin to explore more advanced possibilities to create schedules using ALICE software. Specifically, resource constraints are introduced when creating schedules with ALICE. Furthermore, students learn how to specify the duration of single activities parametrically using productivity rates and other element properties (e.g. volume, lateral surface) in ALICE. As a result, the students created a more constrained (and likely longer) schedule for the LEO 1 model according to TCM during this lecture. The reasons for the longer scheduling time are discussed with the class.

In Lesson 5 (Optimization in ALICE), the students begin to explore factors that have large influence on schedule duration. By adjusting the input parameters in ALICE, the students begin to develop intuition on how to optimize schedules in terms of duration, costs or use of resources. Especially the larger Post-Class model LEO II enables a thorough exploration of how optimization changes the overall schedule outputs.

4 Implementation and Assessment

Once the proposed curriculum was designed, the authors sought pre-implementation feedback to assess the quality of the curriculum. For pre-implementation assessment, the authors presented the curriculum in a video conference with three employees of ALICE Technologies Inc., including Dr. Rene Morkos the inventor of TCM and founder of the company. During the discussion, the general structure of the curriculum and the most important lecture contents were presented. The feedback positively emphasized that first a theoretical introduction should be given and then the software should be used first (M. Faloughi, personal communication, May 20, 2020). It had been a recurring problem with the ALICE training that some users had not internalized the theory behind TCM. With regard to the theoretical contents, almost everything important is included in the curriculum and the quantity is appropriate for the planned 5 weeks (R. Morkos, personal communication, May 20, 2020). One key feedback was that the limitation of sequencing with traditional methods should be dealt with more clearly (R. Morkos, personal communication, May 20, 2020). This was then included in the full course implementation.

The authors implemented the curriculum as part of the larger course Lean, Integrated and Digital Project Delivery at ETH Zurich in Autumn Semester of 2020. This is a 4-credit course (corresponds to 120 hours of workload for the total course) for graduate students that introduces students to newly emerging trends in the construction industry, such as Lean Principles, BIM, parametric scheduling and Integrated Project Delivery. Due to COVID-19 restrictions, the first lesson was presented in person while the following four lessons were presented via Zoom.

During implementation, the teaching team collected student feedback in order to conduct a post-assessment of retained learning. Three surveys were conducted before, during, and after teaching the curriculum to assess learning. Data from these surveys are currently under statistical analysis with the expectation they will be included in a future full-length journal paper. To further assess the student experience in learning the curriculum, the teaching team reviewed qualitative feedback obtained from the yearly course evaluation. These are summarized below:

- “The organization surrounding ALICE and the TCM was done pretty good”
- “For some tasks with ALICE more time would be nice during the lecture to better understand the tasks. It was sometimes a little of a rush”
- “The frequent guest presentations bring this course very close to the industry which I thought was also very good as most other courses in civil

engineering are too theoretical to really be able to see it in the perspective of the industry itself. For example, I really liked the use of ALICE as this is a software that is also used on construction sites and not just a tool used to instruct students.”

- “I think explaining ALICE and the short exercises in class was really great and should be unchanged.”

In addition, the general experience for students in the course was positive. For example, the evaluation question “how satisfied were you in general with the course unit?” received an average response of 4.7 (n = 28), where 5.0 is the highest possible score and represents that a student is “very satisfied” with the course. However, the curriculum for TCM only represented 5 out of 13 lectures in the overall course, so it is not possible to say if TCM is a primary cause of the strong student evaluations.

5 Discussion and Conclusion

Reflecting on the first implementation of the proposed curriculum, the following limitations were noted. The curriculum places high demands on the teacher to incorporate a flipped classroom approach into their teaching. Additionally, the hiring of teaching assistants will be necessary to support the classroom activities. The teaching staff has to prepare for the implementation of the curriculum, such as contacting ALICE, preparing the models, arranging the groups for group work, adapting the documents etc. Additional time and effort are required as ALICE is a software that is constantly evolving. Furthermore, the curriculum demands a collaboration with ALICE, so if a collaboration for any reason is not possible anymore, the curriculum cannot be successfully implemented without major modifications. However, ALICE Technologies Inc. has expressed a willingness to partner with universities in order to facilitate students learning about their generative construction scheduling approach.

A further structural limitation of the curriculum is that it is very precisely structured, as a lot of content has to be taught in a very short time span. As a result, students do not have much freedom to explore the application on their own. If the number of students is small and the necessary resources (time and teaching assistants) are available, it is recommended not to use the prepared models for each lesson, but to provide the students with an unprocessed model that they can work on throughout the curriculum.

Beside the mentioned limitations and possible implication difficulties, we expect that this curriculum will motivate CM programs to include TCM into their courses and foster the spread of TCM and/or other novel scheduling methods. This in turn can enable students as future project managers to question the traditional

scheduling method and seek more efficient approaches. Future planned research will include a statistical analysis of pre- and post- learning retention regarding the TCM and automated or generative scheduling techniques.

Overall, the proposed curriculum can give the students a solid knowledge of the theory behind TCM and its automated application with ALICE. In addition, the flipped classroom approach allows an efficient use of the lecture and enables to dive deeper into the topic and reflect critically on the acquired knowledge. This is enhanced by the basic structure of the curriculum that additionally encourages students to make connections between the taught topics. Further, by teaching each new topic over a period of three weeks and thus ensuring spaced repetition, there is potential for the achievement of a long-term learning effect; however, more research is needed to confirm this. With the above-mentioned aspects, we believe this curriculum enables a high-quality teaching of a novel scheduling approach. Future research will quantitatively assess student learning from this first implementation.

6 Acknowledgements

The authors would like to thank Dr. René Morkos, Mazen Faloughi, and Jennifer Woodford from ALICE Technologies for their feedback in the development of the curriculum.

The curriculum has been designed to be shared with other CM course instructors. All course lessons, teaching notes, exercises, grading templates, and presentation templates are freely available online at <https://www.research-collection.ethz.ch/handle/20.500.11850/482232> [13].

E-mail: hala.nassereddine@uky.edu, mbh.93@uky.edu

Abstract –

The increased complexity of construction projects coupled with the increase in customer expectations has fueled electrical contractors' interest in innovation as a source of competitive advantage. Emerging technologies such as Augmented Reality and Digital Twins have recently gained momentum in the electrical construction industry. While these emerging technologies provide a novice approach to visualizing construction work, most of their use-cases are based on Building Information Modelling (BIM). Therefore, to unlock the full potential of emerging technologies, it is important to properly allocate and leverage BIM resources on a construction project. Therefore, this research aims to provide electrical contractors with a set of tools to understand and leverage their BIM resources before and during construction. To achieve the research objective, a survey was developed, and 23 complete responses were collected to identify factors that impact the actual percentage of electrical contractors' BIM Efforts. The survey results were augmented with follow-up structured interviews with subject matter experts having electrical and BIM experience. BIM practices collected from the interviews were grouped into three categories: people, process, and technology. The study aims to provide electrical contractors with a set of tools to leverage their BIM resources before and during construction. This study also highlights some of the ongoing challenges faced by electrical contractors when managing BIM changes during project execution.

Keywords –

Building Information Modeling; Electrical Contractors; BIM Effort Factors; Best Practices

1 Introduction

Building Information Modeling (BIM) is a construction industry evolution that transformed the use of analog drawings into digital electronic BIM. It is defined by the National BIM Standard-United States

(NBIMS) as “a digital representation of physical and functional characteristics of a facility. As such it serves as a shared knowledge resource for information about a facility forming a reliable basis for decisions during its lifecycle from inception onward” [1]. Autodesk defines BIM as “an intelligent 3D model-based process that gives architecture, engineering, and construction (AEC) professionals the insight and tools to more efficiently plan, design, construct, and manage buildings and infrastructure” [2].

BIM can benefit all parties and stakeholders of any construction project, and subcontractors are no exception. BIM process can provide subcontractors with more control over their project, especially on cash-flows, service levels, resources, and change orders [3]. The 3D model-based BIM process helps MEP professionals in designing, detailing, and documenting building systems, all of which leads to improved accuracy, reduction in clashes, optimization of building system designs, improved collaboration and data sharing, and an increase in the transition from design to construction [4].

For mechanical and plumbing, BIM and 3D models did become the new norm; however, for electrical contractors, the use of BIM is still expanding [3]. Major reasons for this delay include the lack of standards, specifications, and software for rendering an intelligent electric design model in BIM [5], in addition to the size of electrical elements where modeling larger elements such as duct systems and air handlers are approachable options, while smaller elements such as electrical switches and outlets might prove more challenging [6]. This generated extensive industry effort to further promote BIM with electrical contractors, develop appropriate software and add-ons, identify industry practices, and provide BIM-friendly data beyond dimensions for elements like switch gears, pumps, and motors [4] [7].

[8] developed a survey targeting electrical contractors who are members of the National Electrical Contractors Association Construction (NECA) to study the state of practice of BIM adoption in 2009. Results showed that most companies using BIM are medium or large sized and they mostly use BIM on healthcare and commercial

projects. Electrical contractors preferred to model rigid components such as branch and feeder conduits and valued clash detection the most.

[9] conducted another research to study the state of practice of BIM with electrical contractors in 2014 through a survey distributed to members of the National Electrical Contractors Association (NECA), ELECTRI International, and Federated Electrical Contractors (FEC). This study showed an increase in the adoption of BIM in the electrical construction industry and an increase in BIM knowledge. Forty-one percent of study participants reported that MEP specialty trades lead the modelling coordination effort, 35% said general contractor, 14% mentioned electrical consultants. The study also suggested that it is safe to assume that the majority of staffing for BIM implementation is three or fewer.

BIM can result in major gains for electrical contractors. However, to create the 3D models, electrical contractors need to spend more time and resources on 3D modelling than traditional 2D drawings [3]. Different factors exist that affect the time and effort needed by electrical contractors to implement BIM and conduct 3D modelling. Such factors are not always internal, but they go beyond the company. This makes it impossible to isolate external factors and variables that affect the use of BIM for electrical contractors [10] [11]. Most recently, [6] investigated the impact of design and scope changes on the modelling performance of electrical contractors. Building on the existing work performed in the area of BIM modelling for electrical contractors, this research, sponsored by the National Electrical Contractors Association, aims to provide electrical contractors with a set of tools to leverage their BIM resources before and during construction.

2 Research Method

The methodology employed to achieve the research objective consists of five tasks. The first task consisted of synthesizing existing work on BIM. The review of literature allowed for the identification of key variables for allocating BIM efforts and a survey, acting as a foundation for the data collection efforts of this research, was designed to gather qualitative data from electrical contractors. The survey consisted of four phases: 1) contractor data, 2) project information, 3) parties' relationships, and 4) BIM. The first section included company-specific questions and the three remaining sections asked project-specific questions. Once the survey was developed, a pilot version was distributed to the Task Force supporting this research effort. Seven experts reviewed the survey and made a valuable contribution to the research effort. The survey was then polished and fine-tuned before mass distribution. The

survey was transcribed into Qualtrics, a digital survey platform, and into an excel spreadsheet for ease of use. The Task Force supported the researchers in their data collection effort and distributed the survey to member companies of the National Electrical Contractors Association (NECA) and companies in their network soliciting their participation in the study. Once data was collected, statistical analysis was performed in the third task to identify factors that can impact electrical contractors' BIM effort.

The outcomes of the survey informed two questions on BIM best practices and BIM challenges which were further pursued in the fourth task with follow-up online meetings and interviews with industry practitioners and subject matter experts who have electrical and BIM experience. Structured interviews were conducted through NECA with nine electrical contractors and 14 subject matter experts having, on average, 20 years of electrical experience and 10 years of BIM experience. The interview data was then analyzed as the last task and recommendations on best practices and areas of improvement were formulated.

3 Survey Results and Analysis

A total of 23 complete responses were collected throughout the survey.

3.1 Characteristics of Electrical Contractors Surveyed

The annual electrical and low voltage systems *revenue* of the 23 electrical contractors who took the survey was uniformly distributed across the four revenue categories: 30% of respondents selected less than \$50 million, 22% between \$50 and \$100 million, 26% between \$100 and \$250 million, and the remaining 22% of responses came from contractors with revenue over \$250 million. This distribution expresses a general view of the use of BIM in the electrical construction industry. Compared to the 2014 study, the results of this survey indicate a balanced representation of companies of various sizes, highlighting the growth of BIM in the electrical construction industry.

Despite the equal distribution of companies in size, the *annual revenue of projects using BIM* varied within the industry. Of those who responded to the survey, 22% said that the annual revenue of projects using BIM within their company is less than \$100 million, 13% selected between \$10 and \$25 million, 13% between \$25 and \$50 million, 30% between \$50 and \$100 million, 13% between \$100 and \$250 million, and 9% over \$250 million. This unequal distribution shows that the frequency and types of projects on which BIM is used vary within the electrical construction industry.

At the portfolio level, the bulk of the 23 electrical contractors (61%) indicated that they develop all their BIM models *in-house* and very few electrical contractors (9%) *outsource* BIM. Respondents were asked about the breakdown of their BIM efforts between *detailed* and *coordination* across their project portfolio. On average, the majority of the 23 electrical contractors who participated in the survey reported that they spend more time on the BIM detailing efforts than the BIM coordination efforts.

Respondents were asked to report the number of full-time BIM modelers employed within their company. To get a better understanding of this variable, the number of full-time BIM modelers was plotted with respect to the size of the company Figure 1. The gray circles in Figure 1 represent individual responses and the green circles represent the average per category of size. Compared to the 2014 study [9] the data displayed in Figure 1 indicates that electrical contractors have been investing more in BIM as the number of BIM modelers has. The graph shows that larger companies hire more full-time BIM models with the average number of Full-time modelers ranging between 2 for small companies and 15 for larger companies according to the survey results. This observation was tested statistically using a correlation test and a positive correlation was detected between the two variables.

3.2 Characteristics of Collected Projects

Main features of the data collected from the three remaining survey sections are presented here where respondents were asked to provide information on one complete construction project. Data collected from 23 construction projects is described in the following sections. It is worth noting that respondents have selected an exemplary project to use for the survey. Thus, the results displayed in this paper represent data collected from good projects.

3.2.1 Relationships with Stakeholders

An example of the data collected here is presented for the relationship between electrical contractors and project owners. This section of the survey asked respondents to select a particular project for which they were asked if they had previously worked with the same owner before and 78% of respondents said yes. This 78% of the respondents were then asked to assess their past relationship with the owners using a five-point Liker scale of poor (1), fair (2), good (3), very good (4), and excellent (5). On average, these respondents reported that they had a very good relationship. Then all survey respondents were asked to evaluate their relationship with the owner of the project they have selected for the survey and on average, respondents said that they had a very good relationship with the owner.

The same type of questions was asked to assess the relationships of electrical contractors with the Architect/Engineer (A/E), general contractor (GC), and other trade partners on the project.

Figure 1. Number of full-time BIM modelers vs size of electrical contractors

3.2.2 Electrical Contractors' Perspective on Design

Respondents were asked about the design quality of the project they selected for the survey. Their perspective was measured on a five-point Liker scale of very poor (1), poor (2), average (3), good (4), and very good (5). The aggregated data indicated that the quality of the design is perceived as average by electrical contractors. It is important here to note that the projects respondents selected for the survey were exemplary projects.

Respondents were also provided with five design issues and were asked to indicate if they have experienced any on the project they selected for the survey. The results of this data show that 87% of the projects experienced design coordination, 83% additions, 74% deletions, 52% design errors and 43% reworks.

3.2.3 Electrical Contractors' Use of BIM

Respondents were asked to specify how BIM was used on the selected project Figure 2. The majority of respondents indicated that they have used BIM for 3D coordination and clash detection, MEP coordination, As-built drawing model, and drawings derived from the models.

3.2.4 Actual Percentage of Electrical Contractors' BIM Efforts

Respondents were asked to indicate the total actual project hours and the total actual hours spent on BIM. From these two variables, the *actual percentage of electrical contractors' BIM efforts* was calculated as follows: The actual percentage of electrical contractors' BIM efforts equals the actual hours spent on BIM divided by the total actual project hours (for electrical

contractors). The collected data shows that the percent effort of BIM ranges between 0.15% and 6.71% with an average of 2.94%. The actual percentage of electrical contractors' BIM Efforts is a key variable in this study and is used (as shown later) to identify the factors that can impact electrical contractors' BIM efforts.

Figure 2. Electrical Contractors' use of BIM

3.2.5 Distribution of BIM Resources on Construction Projects

Respondents were asked to specify the number of full-time and part-time BIM modelers used on the project used for the survey. Each set of a circle and cross corresponds to a project. Figure 3 shows that the data can be split into two groups. The first group highlighted here has an average project size of 12.8 million dollars, an average of two full-time BIM modelers and 1 part-time BIM modeler per project. The average percent BIM effort of this group is 2.83%. The second group highlighted to the left includes two projects with an average size of 190 million dollars, 13 Full-time BIM modelers on average and 4 part-time. The average percent of BIM effort for this group of large projects is 4.06%.

3.3 Statistical Analysis

The survey data was analyzed using three statistical tests: correlation test, Mann-Whitney-Wilcoxon (MWW) test (the non-parametric version of t-test), and Kruskal-Wallis test (the non-parametric version of ANOVA). All key findings are presented below, and significance for all three tests is reported at the 95% confidence level.

3.3.1 Impact of Company Profile on BIM Efforts

- There exists a positive correlation (0.48) between the *annual electrical and low voltage systems revenue* and the *percentage of in-house BIM models*. On average, larger electrical contractors tend to develop BIM models in-house.

- There exists a strong positive correlation (0.81) between the *annual electrical and low voltage systems revenue* and the *annual revenue of projects using BIM*. On average, larger electrical contractors tend to use BIM more than smaller electrical contractors.
- There exists a strong positive correlation (0.68) between the *annual electrical and low voltage systems revenue* and the number of *full-time BIM modelers*. On average, larger electrical contractors tend to hire more full-time BIM modelers
- There exists a strong positive correlation (0.84) between the *annual revenue of projects using BIM* and the number of *full-time BIM modelers*. On average, electrical contractors with a higher revenue generated from projects using BIM tend to hire more full-time BIM modelers.
- The percentage of BIM models created *in-house* by electrical contractors is, on average, significantly higher than the percentage of *outsourced* models.
- Considering the portfolio of construction projects, the percent effort spent by electrical contractors on *detailing* is significantly higher than the percent spent on *coordination*.
- On average, there exists a strong positive correlation between the *annual electrical and low voltage systems revenue* (size) of electrical contractors and the *actual percentage of electrical contractors' BIM efforts*. Larger electrical contractors spend more time on BIM on their construction projects.

3.3.2 Impact of Electrical Contractors' Relationships with Project Stakeholders on BIM Efforts

- There exists an inverse correlation (-0.39) between the *actual percentage of electrical contractors' BIM efforts* and their *past relationships with A/E*. The better the relationship with A/E on previous projects, the lower the percent BIM effort spent by electrical contractors on future projects with the same A/E.
- There exists an inverse correlation (-0.47) between the *actual percentage of electrical contractors' BIM efforts* and their *current relationship with A/E* on the project. The better the relationship with A/E on the ongoing project, the lower the percent BIM effort spent by electrical contractors.
- There exists an inverse correlation (-0.31) between the *actual percentage of electrical contractors' BIM efforts* and their *past relationships with GC*. The better the relationship with GC on previous projects, the lower the percent BIM effort spent by electrical contractors on future projects with the same GC.

Figure 3. Overview of the allocation of electrical contractors' BIM resources on construction projects

- There exists an inverse correlation (-0.42) between the *actual percentage of electrical contractors' BIM efforts* and their *current relationship with GC* on the project. The better the relationship with GC on the ongoing project, the lower the percent BIM effort spent by electrical contractors.
 - There exists an inverse correlation (-0.42) between the *actual percentage of electrical contractors' BIM efforts* and their *current relationship with the other trade partners* on the project. The better the relationship with the trade partners on the ongoing project, the lower the percent BIM effort spent by electrical contractors.
 - There is a significant relationship between the *actual percentage of electrical contractors' BIM efforts* and the following *BIM applications*.
 - MEP Coordination
 - Understanding Constructability
 - Digital Fabrication/Pre-fabrication
 - Design Collaboration
 - Visualization
 - Handover of Model to Contractor
- Projects that use the above-listed BIM applications result, on average, in a need for electrical contractors for a higher percent of BIM effort needed to manage the project.

3.3.3 Impact of Design on BIM Efforts

- There exists an inverse correlation (-0.42) between the *actual percentage of electrical contractors' BIM efforts* and the *quality of design*. The better the quality of design, the lower the percent of BIM effort spent by electrical contractors.
- The more *design issues* experienced on the project, the higher the percent of effort needed from electrical contractors to manage the BIM models.
- There is a significant relationship between the *actual percentage of electrical contractors' BIM efforts* and *design coordination issues* experienced on the project. Projects that experience design coordination issues result, on average, in a need for electrical contractors for a higher percent of BIM effort needed to manage the project.

3.3.4 Impact of BIM applications on BIM Efforts

- The more *BIM applications* used by electrical contractors on the project, the higher the percent of effort needed from electrical contractors to manage the BIM models.

3.3.5 Impact of Updating BIM during Execution on BIM Efforts

There is a significant relationship between the *actual percentage of electrical contractors' BIM efforts* and the following reasons for electrical contractors to *update BIM models during execution*:

- Design Changes
- Incomplete information in the model by other trades
- Owner's request
- Incomplete information in the model by the electrical contractor

Projects that experience any of the above-listed reasons for updating BIM models result, on average, in a need for electrical contractors for a higher percent of BIM effort needed to manage their BIM effort.

4 BIM Best Practices for Electrical Contractors

Electrical and BIM subject matter experts were asked during the interviews to share practices they have found to be successful in managing the BIM effort during project executions. The feedback collected from the 9

interviews was consolidated into three major themes: People, Process, and Technology (Figure 1). The following sections synthesize the best practices and lessons learned shared by the interviewees and provide electrical contractors with an overview of current BIM practices that can guide their implementation. The outlined practices also assist the electrical contractor in mitigating the impact of the project variables that have a significant impact on the percent effort spent managing BIM during execution.

4.1 People

The people-related practices that assist electrical contractors in managing their BIM effort during execution are summarized in this paper. The analysis of interview data showed that five best practices were collected at two levels: 1) internal to the electrical contractor and 2) at the interface between the electrical contractor and other project stakeholders. Practices are discussed in the subsequent sections.

4.1.1 Maintain Strong Relationships within the Electrical Team

Establishing and maintaining a solid working relationship between the project management team, BIM team, and field operations team is key to managing BIM efforts. Trust must be built between these three teams internally. The BIM modelers should be the link that connects the field to the office and need to communicate with the electrical team regularly (weekly conversations, daily huddles, etc.) to ensure alignment among the team members. Project managers also play a critical role in supporting the electrical team and enhancing its performance but establishing parameters for modelers to use consistently during the duration of the project, and thus, reducing errors, mistakes, and potential rework.

4.1.2 Hire the Right BIM Modelers

Developing and maintaining a good BIM model is not a simple task and the knowledge, attitude, and expertise of BIM modelers has a significant impact on the success of the construction projects. Interviewees noted that BIM modelers need to be able to get buy-in from the field operations team. They need to be detail-oriented with electrical background and field experience either directly or vicariously by working closely with the field workers. BIM modelers have to collaborate with the foreman and the people who are boots on the ground installing the electrical work. This collaboration brings invaluable knowledge and feedback for a modeler because it captures constructability knowledge and streamlines the as-built phase.

4.1.3 Empower Field Workers

Interviewees noted that electrical contractors need to

empower field workers to be accountable. If workers see discrepancies between the model they are using in the field and actual conditions of other trades, they can send the electrical contractor an image of what is in the field along with an image of the model. The electrical contractor will then follow up with the GC.

4.1.4 Build Strong Relationship among Stakeholders

In addition to establishing and maintaining strong relationships internally, the relationship at the interface between electrical contractors and other project players is paramount. Having the right players who are updating models regularly is critical. Moreover, communication between project participants is essential especially when new changes are to be made in the model. Interviewees stated that receiving a notice of an upcoming change from the A/E, GC, or trade partner would help electrical contractors be prepared to fit the changes within their schedule and communicate the changes to the field.

4.1.5 Have the Right Entity Lead the BIM Coordination Effort

The project person/entity leading the multi-trade BIM coordination effort and setting the expectations plays a key role in the successful management of BIM. The leading entity should hold project team members accountable and leverage the available tools.

4.2 Process

People-related practices shared by the 14 interviewees are outlined in the next sections.

4.2.1 Start Right: Invest in Project Setup Standards

When embarking on a new construction project, the electrical contractor needs to start right. The following practices were consolidated from the interviews to assist electrical contractors in laying the right foundation to start the BIM process:

1. Ensure that control is set for the site and facility.
 - Get the control points on site before any layout. Ensure control points are in a location that will not be disturbed throughout the construction of the project. This process is time consuming, but if done properly it can be very rewarding.
 - All teams need to agree to the same three points of column line intersection point offsets.
 - Make sure all layout teams check in on every level of the project and have the same coordinates on their machines. Documents these check-ins.
 - Place the control points in the model.
 - When control is set properly for the project, all subs will take control from the same points to start.

2. Use an object to verify the placement of the structural and architectural models in the Navis Model respective to the column lines and elevations. This should be done against a corner just on top of the floor. When all trades align, then you should be good to start modeling.

4.2.2 Implement BIM Resolution Workflows

Electrical contractors are encouraged to implement a BIM issue resolution workflow where they document the issues, who is responsible to resolve them, and how they were resolved. This process is similar to maintaining an updated constraint logs for BIM issues encountered during project execution. To maximize the value of these practices, it should be applied to everyone on the project including the owner, A/E, GC, and trade partners.

4.2.3 Develop Standard Operating Procedures

Developing standardized processes plays a major role in enabling continuous improvement and sharing knowledge. Among the process-related practices discussed is the development and use of BIM Standard Operating Procedures (SOP). Interviewees highlighted the need to standardize processes internally especially as the team grows, streamline documents into a centralized reference, and set up modeling templates for the project (use the same families and annotations for example).

4.2.4 Establish Modeling Guidelines

Establishing modeling guidelines and rules at the front end of the project for all participants who need to develop, use, access, or update the BIM models is important to build standardization, transparency, traceability, and accountability into the project. Some suggested modeling practices shared by the interviewees included:

- Hold an internal kick-off at the beginning of every project to establish the modeling guideline for the project.
- Provide NWC files that include model parameters to field workers to give them all the information they need to do the installation.
- Isolate modelers from working on top of each other.

4.2.5 Manage Data

To create a reliable BIM dataset, it was recommended that electrical contractors keep a rework log to track BIM time that is out the expectancy of the electrical contractor (time that wouldn't have been budgeted to begin with).

4.2.6 Provide Training

Interviewees encouraged electrical contractors to provide training videos to ensure the cohesion of the BIM team.

4.2.7 Keep Yourself In Check

Interviewees emphasized that trades need to run clash detection between themselves and other trades and resolve any clashes prior to uploading the models and before the coordination meeting. Coordination meetings are to handle difficult challenges that need the team to solve them.

4.3 Leverage the Use of Technology

The technology-related practices fall into two major categories: leverage cloud-based technology and utilize new technologies.

Regarding cloud-based technology, interviewees shared the following practices:

- Cloud-based software such as BIM360 and Procore enable models to be centrally located, enhance documentation sharing, and allow access to the most current information instantly.
- Leverage cloud-based workflows for more streamlined processes and allows multi-regional teams to work together.
- Use cloud-models internally.
- Interviewees also noted the the benefits of using new technology to help manage an up-to-date and accurate model such as productivity applications and 360 photographs/video and laser scanners to help confirm the install

5 BIM Challenges for Electrical Contractors

Interviewees also shared the following major challenges faced by electrical contractors when managing BIM changes during project execution:

- Trades using a different technology (i.e., 2D vs 3D) and different file formats being shared.
- How frequently do trades update their models (i.e., every few hours or every week for instance).
- Base model does not get updated after contract execution.
- Agreement of model ownership.
- Lack of accuracy of the trades.
- Sign-off dates can be aggressive.
- BIM coordination process begins on an incomplete design.
- Design changes need to cascade to the prefab team and the field before installation.
- Receiving feedback from the foremen is as good as the information provided to them.
- Scope creep.
- What is contractually required by the GC and what is required or requested by the electrical operation team needs to be clearly defined.

- The actual set-up of the model.
- Time commitment and investment into developing the BIM model before execution.

6 Conclusions

This research aimed to help electrical contractors understand the factors that impact the level of effort needed to develop BIM models and to provide the electrical contracting community with best practices to efficiently manage and update BIM models during execution. Following a literature review, a holistic survey was developed and a total of 23 completed responses were collected. The static analysis of the collected data showed that the following project variables have a significant impact on the actual percentage of electrical contractors' BIM efforts: past and current relationships with project A/E and GC, current relationships with project trade partners, design quality, design coordination, MEP coordination, and the use of BIM for visualization, design collaboration, digital fabrication and prefab, handover of the model to the contractor, and understanding constructability. Follow-up interviews were conducted to collect further details from electrical contractors on their uses and perceptions of using and managing BIM during construction. Shared BIM practices were grouped into people, process, and technology practices. Ongoing BIM challenges were also shared by the interviewees, highlighting areas in need of improvement.

It is important to recognize that BIM practices vary across electrical contractors and given the uniqueness of every company, future work could focus on studying a company's BIM database to develop accurate models to help the company better estimate its BIM efforts. Additionally, while data was collected for the Level of Development (LOD) of BIM, the responses collected for each level did not enable the analysis of this variable. A trend was however detected showing that projects with LOD greater than 350 result in greater efforts. Future research can analyze the LOD for major electrical assets and their impact on the overall electrical BIM efforts.

7 Acknowledgment

The authors wish to thank the National Electrical Contractors Association (NECA) for sponsoring this research effort under the Russell J Alessi Early Career Award. NECA, composed of its 136 independently chartered chapters across the country, supports the electrical contracting industry through advocacy, research, continuing education, promoting effective labor agreements, hosting trade shows, and offering management training. More details about NECA can be found at <http://www.necanet.org>.

In addition, thanks are due to the task force for their guidance and support through the project and to the electrical contractors and respondents who participated and supported this research effort.

Interactions Between Construction 4.0 and Lean Wastes

Mahmoud El Jazzar ^a and Hala Nassereddine ^a

^aDepartment of Civil Engineering, University of Kentucky, USA
E-mail: meljazzar@uky.edu, hala.nassereddine@uky.edu

Abstract

Lean construction and Construction 4.0 are two prominent concepts challenging traditional practices in the construction industry. The continuous increase in competition and the demand for more efficient project delivery with less waste is pressuring construction companies to adopt these concepts. Body of literature have discussed the benefits of each separately, however, very few have discussed the interaction effect between them. Therefore, using literature, this paper investigates the impact of Construction 4.0 technologies on the eight types of Lean Construction waste. To achieve the research objective, the eight types of waste and the seven Construction 4.0 technologies were first defined. Then, A two-dimensional matrix was generated using 54 research articles to visually represent how each of the seven Construction 4.0 technologies can eliminate certain types of waste. While the impact of Construction 4.0 on waste elimination varies among the technologies, it can be concluded that Construction 4.0 supports Lean waste elimination. Future research should investigate the relationship at different phases of the project including design, and operation. Also, it should investigate additional technologies.

Keywords –

Lean construction; Construction 4.0; Industry 4.0; Construction Waste; Construction Technologies

1 Introduction

The traditional construction management system is characterized by a high level of waste resulting in low productivity, cost overruns, and delays [1]. As a legacy industry, researchers and practitioners started a journey to change the status quo and find a better management system to improve the construction industry. Inspired innovations in manufacturing, Lean Construction emerged as a new paradigm that challenges the traditional approach to construction. According to [2] “Lean is a way to design production systems to minimize waste of materials, time, and effort to generate the maximum possible amount of value”.

The Lean philosophy started to be adopted by the construction sector in the mid-1990s as a new approach

to improve productivity and eliminate activities that do not add value for the customer, thus reducing and eliminating waste[3]. [4] defined waste as the inefficient use of equipment, material, and labor that results in the overutilization of resources needed to construct a facility. [5] offered a generic definition stating that waste is what can be eliminated, including activities, resources, and rules, without reducing customer value.

According to [6], 68% of the time is wasted on non-value adding activities, resulting in poor construction project performance. [1] added that 90% of onsite tasks fall under two types of activities: non-value adding and non-value adding but required activities. [7] showcased that the non-value adding activities consume 9.4% of the project budget, leading to budget overruns. Researchers have well documented that waste, in all of its forms hinders, project workflow, lowers productivity, and increases overall project cost [8]. Therefore, it is crucial that practitioners and researchers identify where improvements are needed in the construction processes in order to minimize the sources of waste, and thus, eliminate waste.

Taiichi Ohno, chief engineer at Toyota, identified the following seven types of waste in production in 1988: defects/rework, overproduction, waiting, transportation, inventory, movement/motion, and over processing [9]. A few years later, Womack and Jones added the eighth type of waste, non-utilized workers talent [5]. Researches noted that identifying and defining different types of waste in construction is a strategy to eliminate them [9].

As Lean continued to gain momentum in the construction industry, manufacturing was undergoing another major transformation through the fourth industrial revolution (Industry 4.0). [10] defined Industry 4.0 as “a new technological age for manufacturing that uses cyber-physical systems, Internet of Things, Data and Services to connect production technologies with smart production processes”. The core of this revolution is based on connectivity and interaction between machines and humans through different technologies: Robotics, Augmented Reality, Simulations, The Cloud, Big Data, Internet of Things, Cybersecurity, Additive Manufacturing, horizontal and vertical system integration [11].

Building on the gains of Industry 4.0, construction researchers began to investigate the potential of Industry 4.0 in construction, and as a result, the concept of

“Construction 4.0” emerged to encompass emerging technologies [12].

While various research efforts have discussed how Industry 4.0 technologies can increase and support Lean manufacturing effectiveness by eliminating waste [13], research has not yet explored the connections between Construction 4.0 and Lean construction and how it can be leveraged to eliminate waste. Therefore, this paper investigates how the Construction 4.0 technologies can help eliminate construction waste. To achieve the research objective, a comprehensive literature review was performed using 65 papers that discuss the eight types of wastes in Lean Construction and the different Construction 4.0 technologies. Next, a matrix was developed based on the research corpus to map the interactions between the two variables and showcase how each of the Construction 4.0 technologies assists in reducing wastes at the construction phase.

2 Literature Review

2.1 Eight Types of Waste

The eight-waste taxonomy was identified by [5][14] for manufacturing, and then later, was adopted by other industries including healthcare, financial, IT, and services [9].

Various studies attempted to expand Ohno’s list of waste. For instance, [15] identified information waste as the loss of talent, capabilities, and behavioral waste. The authors also considered the “failure to speak and listen” as the greatest waste of construction. [16] suggested another type of waste known as “making do” which occurs when a task has started without its predecessors being ready. The author also noted that “making do” is the most critical type of the construction industry.

Given that Ohno’s seven types of waste and Womack and Jones’s eighth waste are the most discussed in the body of knowledge, the matrix presented in this paper is based on Ohno’s taxonomy while taking into consideration the peculiarities of construction.

Construction waste as derived from literature are known as (DOWNTIME):

- **Defects/rework:** it refers to the incorrect work that needs to be repaired, reworked, or replaced. This type of waste covers a major spectrum of construction problems including repair work, work defects, and retesting tasks [17].
- **Overproduction:** it is the process of fabricating material too early, ordering extra material, or delivering activities too early, thus, creating idle periods [17].
- **Waiting:** it occurs when crews wait for long-lead items to arrive, or due to unrealistic schedules, or

when prerequisites are not ready [9][18].

- **Non-Utilized/Unused talent:** it refers to non-utilized employee talent and skills [5].
- **Transportation:** it refers to the unnecessary transportation of people, tools, equipment, or products. It involves unnecessary transportation from the site to the material laydown area [18].
- **Inventory:** it refers to the excess storage of material on-site or at the fabrication yard, work in progress, and unused tools.
- **Movement/Motion:** it refers to unnecessary movement of workers within construction site [19].
- **Extra/Over-processing/Unnecessary work:** it refers to doing things that need not be done, or excessively performed, for example, excessive training time, excessive use of equipment, long approval process which will not add a value to a process [17].

2.2 Value and Waste

[20] thoroughly discussed the concept of value and waste in construction and highlighted the importance of identifying customer(s) value before proceeding with any efforts to minimize waste. In addition, the author explained waste elimination cycle and how the efforts to focus on waste elimination alone could lead to the creation of additional waste and not necessarily lead to delivery of customer value. On the other hand, [21] highlighted the challenges in identifying and delivering value since it is dependent on the type of customer(s), which in many cases could lead to conflicts to identify which is more valuable such as choosing between comfort and cost.

2.3 Construction 4.0

Inspired by Industry 4.0, the term “Construction 4.0” emerged in the 21st century construction research corpus [12]. Current research highlighted the lack of a consensus on a single formal definition for Construction 4.0 [12][22][23]. However, various authors and organizations attempted to define it. For instance, the European Industry Construction Federation (FIEC) defined Construction 4.0 as the counterpart of Industry 4.0 in the Architecture, Engineering & Construction (AEC) industry and it refers to the digitalization of the construction industry [24][25]. While the definition of Construction 4.0 varies among different researchers and organizations, there is agreement that the adoption of Construction 4.0 will shift the construction process, organizations and project structures from a fragmented to an integrated state [25].

2.4 Construction 4.0 Technologies

A review of the literature identified a wide set of Construction 4.0 technologies. This paper focuses on seven of the most frequently discussed Construction 4.0 technologies [23], namely: Integrated Building Information Modeling (iBIM), 3D printing (3DP), Artificial Intelligence (AI), Augmented Reality (AR), Virtual Reality (VR), , Drones, and Robotics.

To understand the impact of Construction 4.0 technologies on different types of construction wastes, it is important to first understand and define the technologies. Therefore, a brief introduction to these technologies is provided.

- **Integrated Building Information Modeling (iBIM)** is considered the higher level of traditional BIM that is integrated and fed by information from different technologies via the cloud [26].
- **3D Printing (EDP)** is the process of creating a complex, physical 3D object from a CAD model. This technology is being used in different industries including healthcare, automobile, as well as the construction industry on mainly small and medium-sized scales [27][28].
- **Artificial Intelligence (AI)** is the simulation of human intelligence processes by machines [29]. Machine learning is considered one of the components of AI where a machine learns from a set of data using statistical methods.
- **Augmented Reality (AR)** is a data publishing platform that allows the user to display information, engage and interact with the published content, and collaborate with others in real-time from remote locations [30].
- **Virtual Reality (VR)** is a computer-generated simulation in which a person can interact with artificial 3D objects with the aid of a 360-degree visions headset [31].
- **Robotics** are machines that can perform or replicate human actions. Currently, they are being used in in the vertical construction sector [32].
- **Drones** are unpiloted small sized aircrafts that are remotely controlled. In recent years, their use in construction has been on the rise for various applications such as surveying and progress monitoring [33].

It is important to note that while each of these technologies has its own attributes, iBIM is considered central to the digitization of the construction industry and in achieving Construction 4.0 integration [34]. Although this paper investigates how each Construction 4.0 can eliminate construction waste, the authors recognize that Construction 4.0 is not about an individual technology, but rather the integration of various technologies. . While

the matrix presented next is two-dimensional, the connectivity between Construction 4.0 needs to be considered to get a full read of the impact of Construction 4.0 and construction waste.

3 Methodology

To achieve the research objective, a literature review was performed using Google Scholar to identify papers that showcase the implementation of Construction 4.0 technologies mainly in the construction phase of the construction project. The reviewed documents included articles, company reports, and conference proceedings. Moreover, the search looked for words in the title, abstract, and keywords of the articles, such as “technology”, “iBIM construction”, “Drones Construction”. Furthermore, the results were restricted to English language, limited to 2021-2017 with some exceptions to highly cited papers.

4 Construction 4.0 and Construction Wastes Interaction Matrix

The search resulted in a total of 54 research papers related to Construction 4.0 technologies that were reviewed, analyzed, and mapped onto a matrix as shown in Figure 1. The top row represents the eight types of waste and the first column lists the different seven Construction 4.0 technologies. Examples of the interactions presented in the matrix are briefly discussed in the next sections.

4.1 Integrated Building Information Modeling (iBIM)

iBIM is considered the core for Construction 4.0 implementation and it plays an essential role in providing a medium of communication between different technologies supported by Internet of Things and Big data [12][22][23][34]. Although the term “BIM” is mentioned in the selected papers, the applications reviewed and discussed in this work refer to iBIM because they showcase the implementation of an advanced form of BIM which communicates with different types of technologies via active cloud links. For instance, [35] showcased an iBIM and RFID workflow use-case which improves material flow processes where the aggregated collected information helped in creating short-term look-ahead plans that assisted in minimizing inventory, improving construction workflow, and minimizing waiting, defects, and material transportation. Having a proper material management and tracking system benefits the overall construction process, and minimizes overproduction and over processing. [36] presented how iBIM can be used to implement a digital

Lean construction management system. As a result of this implementation, the construction team were able to utilize the potential of digital pull planning and the model data, to perform accurate resource planning, and make decisions on site based on the performance data collected via different handheld tools. This study showed how

iBIM plays an important role in minimizing overproduction, over processing, inventory, transportation, movement, and waiting. Additionally, the implemented tool helped enhancing the construction team decision making skills.

	Defects	Over production	Waiting	Non-utilized/Unused talent	Transportation	Inventory	Movement	Over processing
 iBIM	35,36,54,55,56,57,58,59	35,36,52,53,54,55,56,57,58,60	35,36,52,53,54,55,56,57,58,60	36	35,36,52,53,54,55,56,57,58,60	35,36,52,53,54,55,56,57,58,59,60	35,36,52,53,54,55,56,57,58,59,60	35,36,52,53,55,56,57,58,60
 3D Printing	27,28,38,39,41,61,62,63,64	27,28,38,39,41,61,62,63,64	27,28,38,39,41,61,62,63,64	27,28	27,38,39,41,61,62,63,64	27,28,38,39,41,61,62,63,64	27,38,39,41,61,62,63,64	27,28,38,39,41,61,62,63,64
 AI	43,44,45,66	47	43,44,47,45,65,66		43,44,47,45,65,66	46	43,44,45,46,65,66	45,47,65,66
 AR	48,49,50,51,67,68,69	49,50,67,68	48,49,50,51,67,68,69	48,49,50,51,67,68,69	50,51,49	49	48,49,50,51,67,68,69	48,49,50,51,67,68,69
 VR	50,70,71,72,73	50,70,71,72	50,70,71,73	50,70,71,72,73	50,70		50,70,71,72,73	50,70,71,72,73
 Drones	74,75,76,77,78,79,80,83	74,75,78,80	74,75,76,77,78,79,80	76	74,78,80		74,76,77,78,79,80,83	74,75,77,78,80
 Robotics	81,82,83,84,86,87	82,83	81,82,83,85,86,87		83,87		81,82,83,84,85,86,87	81,82,83,85,87

Figure 1- Construction 4.0 technologies and Waste Interaction matrix

4.2 3D Printing (3DP)

Different research papers have showed the positive effects of using 3DP in construction either through simulation or Value Stream Mapping [28][37] or by showcasing real projects physically [27][38][39]. 3DP helps in minimizing unnecessary movement, waiting, transportation, and inventory, by using less material inventory and workers [27][39]. In addition, the technology minimizes traditional concrete defects like honeycombing because it doesn't require the use of frameworks. Moreover, defects that may occur while *printing* can be easily spotted and treated before printing another layer [37][38]. Furthermore, 3DP reduces overproduction and over processing because the speed of printing can be controlled [40][41]. Furthermore, 3DP is help to build more talent among workers because it pushes them to learn new technical digital skills [27][39].

4.3 Artificial Intelligence (AI)

AI is considered one of the core technologies for Construction 4.0 [22][23]. The current application derived from literature mainly focused on safety improvement and inspection [42][43][44][45]. When spotting unsafe workers behavior, AI could alert

operation center which allows to prevent injury and as a result prevent defects, and waiting [45]. In addition it can be used for various inspection applications which will help to detect defects and the proper intervention required which will help in minimizing transportation, over processing, and movement [43][44]. Also [46] showcased how AI can be used to minimize inventory and highlight long lead items that needs attention, in addition to detecting any potential future risks, whether environmental, legal, or financial by analyzing the material suppliers' data. Finally, [47] showcased how AI can minimize over production by optimizing project duration and properly levelling the project resources.

4.4 Augmented Reality (AR)

[48] showcased how AR can be used with BIM for on-site safety management to help workers visualize danger spots and proactively avoid potential accidents, thus, eliminating possible defects that might occur due to accidents, waiting, and unnecessary movement. The author added that the technology can be used to fetch model data and superimpose it on the real-world environment to inform better decisions that can help in quality inspection and lower approval times, and eventually reduce over processing. [49] demonstrated the use of AR to provide construction personnel all the information needed to perform the work (drawings,

material type and availability) which leads to reduction in overproduction, inventory, and unnecessary transportation of materials and equipment on site. It is worth mentioning that in all the reviewed papers, there was a consensus that AR enhances workers skills, decision making, and safety [48][50][51]

4.5 Virtual Reality (VR)

[50] demonstrated the use of VR to train workers on operating various construction equipment such as cranes and excavators. The training allows workers to safely test different scenarios before performing the work on site, thus, enhancing workers talent and judgment. Understanding the risks and limitations in training also assists in minimizing other types of waste during construction such as unnecessary movement, over processing, transportation, and defects. Similarly, [72] presented how VR can be used to train young wood carpenters. The results of this study suggested that VR training is more efficient than traditional video training and helps trainees to better understand the process and its perquisites, which results in reductions in defects, waiting, over production, and over processing.

4.6 Drones

[78] presented various applications for drones in construction such as surveying and structural inspection, progress monitoring. The authors also discussed the integration of drones with AR to create real virtual scenes that can enable construction managers and teams to plan material and worker flow on site, in addition to identifying any potential risks, thus, minimizing rework, overproduction, over processing, waiting, movement, and transportation. Furthermore, [74] demonstrated how drones can be utilized to improve construction workflow and safety which will help to minimize over processing, over production, waiting, transportation, movement, and defects.

4.7 Robotics

[83] presented painting robotic applications in construction that aim to improve the construction process and its productivity, reduce site congestion, and lower operation time, all while delivering better quality. The technology is also perceived to reduce safety risks associated with work near edges or at high places. It can be thus concluded from this work that robotics can reduce waste such as defects, overproduction, over processing, waiting, transportation, and movement. Additionally, [87] demonstrated how robotics and AI can be integrated to perform earthworks in a dam project to accurately detect the compaction quality of the rockfill materials in real-time and assess the compaction quality of the entire work

area to provide feedback on the poorly compacted areas in order to help crews to make corrective actions. This application highlights the potential of robotics to minimize defects, overproduction, over processing, waiting, transportation, and movement.

5 Discussion and Limitations

Based on the literature and the resulting matrix, it can be concluded that the implementation of Construction 4.0 technologies helps in minimizing the eight types of waste in construction. The analysis also showed that some technologies have more potential to reduce waste than others. For instance, iBIM was shown to minimize all types of waste, while Robotics which does not have interactions with all eight wastes, specifically it doesn't impact inventory non-utilized talent. While the level of interaction between Construction 4.0 and waste varied, in general, different technologies had an impact on at least six types of waste.

The matrix proposed in this paper is theoretical and is based on the 54 reviewed papers and only seven Construction 4.0 technologies. Moreover, as noted earlier, the two-dimensional matrix does not clearly show the connectivity between the various Construction 4.0 technologies. Research limitation can be summed up by the number of papers which represent a sample of the current research related to implementation of Construction 4.0 technologies. Additionally, the waste discussed in this paper are mainly wastes encountered on the jobsite during the construction phase. Other phases of the project life-cycle such as design and operation have not been discussed.

6 Conclusions

This research aimed to study the relationship between Construction 4.0 and Lean Construction by investigating the impact of Construction 4.0 technologies on reducing construction waste. Implications of seven Construction 4.0 technologies on eight types of waste were identified through a thorough review of 54 articles. A two-dimensional matrix was generated to visually represent how each of the seven Construction 4.0 technologies can eliminate certain types of waste. While the impact of Construction 4.0 on waste elimination varies among the technologies, it can be concluded that Construction 4.0 supports Lean Construction and waste elimination. Future research can address the limitations of this work by analyzing other Construction 4.0 technologies and their connectivity, considering other phases of the construction lifecycle such as design and facility management, and conducting prototypes or applications that specifically showcase the implications of Construction 4.0 on waste.

Abstract –

Digital twin technologies have been widely used among different industries, for which different conceptual models and system architectures have been proposed. However, the processes are required to establish a digital twin for intended use cases have not been fully studied. This study adopts a systematic literature review analysis focusing on case studies on digital twin models, highlighting the practical steps in developing a digital twin and the challenges faced by various researchers in this field. After a rigorous selection of relevant literature, a total of 23 scientific publications were systematically reviewed. The literature focused on recent publications (2016-2021) to convey updated information regarding the developments of digital twins in the construction domain. The findings synthesized the main processes of establishing and using digital twin technologies in the AEC industry, including the data acquisition processes, data transmission processes, data modeling processes, data integration processes, and the servicing processes. Although digital twin models could improve the stakeholders' decision-making processes, several challenges regarding data integration and data security still exist in the current applications. The digital twin models require people with the right skills to construct them, a large amount of funds, and the latest technologies with higher computational power to successfully develop them.

Digital twin technologies; Use cases; Information integration; Stakeholder collaboration; Sustainability

1 Introduction

The advancements of BIM applications have changed

how the information could be generated, stored, and exchanged amongst the various stakeholders in the construction industry. However, digital technologies are evolving with the advent of the Internet of things (IoT) and Artificial Intelligence (AI) agents such as Machine Learning, Deep Learning, Data Analytics, etc. The evolution of BIM should be carefully considered in conjunction with these emerging technologies [1]. Artificial intelligence improves the sharing of information, helping to reduce the cost to the consumers and lesser impacts on the environment, adding 10% to the United Kingdom (UK) economy by 2030 [2]. According to Sacks et al. (2020) [3], the digital twin models, Automated Project Performance Control (APPC), Construction 4.0, automated data acquisition technologies have been emerging areas of research in the AEC industry.

National Aeronautics and Space Administration (NASA) has been using digital twin models from earth to control and run simulations of their spacecraft for accurate mapping [4]. The digital twin models in the aviation industry are used to twin models of aircraft and airport models, in the latter to facilitate the tracking and efficient control of luggage. The manufacturing industry creates digital twin models for small components and large factories. These digital twin models are also used for safety and logistics maintenance while maximizing the efficiency of the products [5]. For example, in the automotive industry, Tesla uses this technology to transmit the performance data from its vehicle to the 'mothership'. The automotive industry has already established synchronous data transmission between their cars and factory to improve the efficiency of products [6]. Digital twin models in the health and well-being industry have been used for planning and performing surgeries, detecting stress levels and emotional changes, tracking fitness, predicting the occurrence of illness, and

customizing recommendations for an individual [7], [8].

The digital twin models also have been used for transportation management, energy usage optimization, asset anomaly detection, resource and logistics planning, safety monitoring, event prediction, and running simulations [9]. These emerging use cases generate a large amount of data from multiple sources, which needs to be stored and shared while ensuring safety and security [2]. The digital twin models could be used within a smart city, which facilitates connectivity using IoT devices. This helps to enhance the services, utilities, and infrastructure by testing various transportation scenarios [10], [11].

The current activities related to developing the digital twin models in the construction industry are at an early stage. There have been contributions from the academic community to exploit digital technologies and BIM in recent years. This has further led to the development of conceptual frameworks for the digital twin. The developments heavily rely on the performance of BIM and integrated IoT technologies. The application of digital twin models would help to address many of the construction-related problems.

Fuller et al. (2020) [10] reviewed the developments made across various industries on digital twin models using the emerging technologies and the challenges encountered by them. Boje et al. (2020) [12] summarized BIM applications and how they could pave the way for the concept of semantic digital twin models in the construction industry. Lu et al. (2020) [13] illustrated a clear road map for digital twin developments in the UK, which promoted the implementation of digital twin models at the city level. Compared to these studies, this paper adopts the systematic literature review analysis to summarize the practical steps to develop a digital twin and identify the challenges various researchers face in this field. This study highlights both the potential and the challenges of using digital twin technologies in the construction industry. The various digital models, data sources, and transmitting networks required to create a digital twin are demonstrated. The findings from this systematic review would provide insights into the future implementation of the National Digital Twin Program and Gemini Principles in the UK.

This study is not limited to the concepts and terminologies on digital twin models but emphasizes the important processes required to develop digital twin models within the construction industry. This further helps in understanding the benefits and challenges faced by the various researcher.

Section 2 provides a comprehensive summary of the definitions of digital twin from various industries. Section 3 describes the methodology of the systematic review. The detailed findings from the review analysis are included in Section 4, followed by the conclusions

and future research in Section 5.

2 Understanding digital twins

2.1 Definitions of digital twin

NASA provided the first definition of digital twin in 2012. Though the exact definition of a digital twin has not been unified in the current literature, researchers could still refer to the definitions from various domains and industries to find the commonalities. A list of the definitions is summarized as follows:

- (1) Aerospace domain: A digital twin is a multiscale, multi-physics and probabilistic simulation of an asset integrated using the sensors and physical models to duplicate its corresponding flying twin [4].
- (2) Infrastructure service domain: A digital twin is a dynamic representation of an asset or a process in a digital form representing all the features in the built environment [14].
- (3) Manufacturing domain: A digital twin is a digital representation of a component or an asset that helps to optimize the manufacturing process by predicting the performance of the machine [15].
- (4) Healthcare domain: A digital twin is a virtual replica helping to monitor and evaluate in real-time without being in close proximity to the physical object [16].
- (5) Construction domain: A digital twin is a realistic digital representation of physical assets, distinguishing itself from other digital models due to its connection to the physical twin [3].

By summarizing these definitions, the main components for generating digital twin models include 1) the physical elements/assets, 2) the linked data, and 3) the virtual models. The digital twin models in various industries more or less have the same features and purposes of applications, providing dynamic and real-time information for the planning and control processes. Sensor devices such as RFID and laser scanner equipment are integrated with the digital model to act as a constant source of communication with the real world. By adding artificial intelligence or big analytics, the digital twin applications could further expand the potential to enable autonomous decision-making.

2.2 Resolving the misconceptions of digital twin and BIM

The digital twin technologies have been widely used among different industries, for which different conceptual models and system architectures have been proposed. However, this gradually led to some misconceptions and misunderstandings within a specific

industry [10]. The very basic idea of using the digital twin technologies in the construction industry starts with using the BIM-based platforms and collaborative models to improve construction and design methods. The construction documents, specifications, and 3D design models are federated in BIMs instead of using spreadsheets and 2D CAD drawings [12]. To show the actual reflection of the physical assets at any given time as in line with the digital twin modeling concepts, the BIMs need to be continuously updated using the information collected from the sensors or ubiquitous IoT devices. However, there has been a lack of efforts to connect BIMs to digital twin models. The associated large amounts of BIMs and sensor data could be stored in the cloud or in relational databases to be further used for data analytics and machine learning applications to support decision-making, e.g., predictive maintenance of the HVAC systems [13]. The comparison between the use of BIM and digital twin modeling is illustrated in Table 1.

Table 1. The comparison of BIM and digital twin

	Building Information Modelling	Digital Twin Modelling
Purpose	Used to enhance efficiency during design, construction, and throughout building lifecycle [17][18].	Used to enhance operational efficiency by predictive maintenance and monitoring assets [19].
Feature	Real-time data flow not necessarily required [20]	Real-time data flow required for simulations [21].
Data exchange standard	IFC, COBie, etc., to support design information exchange [22].	Standards to support wireless sensor network transmission of information [23].
Main users	Architects, engineers, developers, and facility managers [24].	Facility managers and equipment engineers [25].

3 Methodology

This study takes a systematic literature review method to synthesize the potential and challenges of using digital twin technologies in construction projects. The literature for this research was acquired through the academic search engine database (i.e., Web of Science used in this study) and focused on the last 5 years

(publication year ranging from 2016 to 2021). The database has the feature of customizing the search preferences. The search keywords were “digital twin in construction” or “semantic web” or “artificial intelligence” or “construction 4.0” or “BIM” or “building information modelling” to rectify the new advancements about the scope of research. It is also worth noting that this study considered the terms “cyber-physical model and system”, “virtual twin”, and “smart cities” as a digital twin application when used in a similar context. The initial search found that 6980 articles were published in the field of digital twin applications, out of which 4490 were published since 2019. Although many articles have been published on this topic, the authors further refined the search to journal and conference articles only in the “civil engineering domain” by the Web of Science search engine. Besides, with an in-depth review of the abstract of the articles from the refined search, 23 articles were left for the systematic review analysis. In addition, reports from government and non-government organizations were used as a reference to support the triangulation of the literature. This study also included recent publications on digital twin use cases from other industries as a reference to help the authors verify and validate the terminologies and concepts.

It is noted that the literature review did not intend to include all the work published on the digital twin applications in the construction industry as this is not an exhaustive review. Also, this review focused on articles published very recently (2016-2021.June) to convey the most up-to-date information concerning digital twins.

4 Findings

The systematic review identified and synthesized the main processes of establishing and using digital twin technologies in the AEC industry (Table 2), including the data acquisition processes (Section 4.1), data transmission processes (Section 4.2), data modeling processes (Section 4.3), data integration processes (Section 4.4) and the servicing processes (Section 4.5). The potential and challenges of implementing digital twin technologies were discussed in Section 4.6.

4.1 Data acquisition processes

The data acquisitions processes aim to collect the data from various sources in different types and available in distinctive formats. The data can be the geometric information, environmental conditions, scheduling parameters, and functional capabilities [26]. The data can be collected using radio-frequency identification (RFID), sensor systems, images and videos, quick response codes (QR), and related IoT devices [27]. The data collected from various sources need to be processed to ensure systematic data mapping. The data can be processed

using data fusion, blockchain, and edge computing algorithms to be converted into a readable format such as Extensible Markup Language (XML) and My Structured Query Language (MySQL) [28]. For example, for the digital twin of the West Cambridge site, which has assets in quite a large number, the data regarding the

environment and the physical elements were acquired from sensors deployed on the site. The other information was acquired using MySQL from the space management system (SMS), asset management system (AMS), and building management system (BMS) at the Cambridge University [13].

Table 2. Establishing and using digital technologies

Data acquisition	Data transmission	Digital modeling	Data/model integration	Service/objective	Reference
QR codes, RFID, IPC, sensors	WAN, LAN, Internet	3D geometric model, kinematic model	Virtual environment platform	Simulation and optimizing model	[21], [23], [29]–[32]
GIS, Sensing images, sensors, BMS data	Internet	BIMs, CIMs	Cloud computing	Monitoring and controlling of the physical city	[12], [13], [19], [25]
Real-time sensors, QR codes, Building management system, space management system, etc.	Internet, WLAN	BIMs	Machine learning, data analysis, and simulation engines	Anomaly detection for built asset monitoring in operation and maintenance	[11], [14], [24], [28], [33]
Geospatial datasets, demographic and climatic conditions	Internet	BIMs	Cloud computing, big data	Running Simulations for urban planners	[34]–[37]
Thermal imaging camera, data sets, IoT sensor devices, AI	Internet	CIMs, BIMs, thermography map	Machine learning algorithms	Energy planning renovations, simulation models	[38]–[41]

4.2 Data transmission processes

After data are systematically acquired, they need to be transmitted for modeling. The transmission of data from the real-world physical asset to the digital replica and vice-versa is the most critical part of developing a digital twin model. This phase provides insights into the physical element and helps to automate the system wherever applicable. A two-way mapping (i.e., a transmission) layer is required between the physical asset and the virtual model.

The transmission of the data could be done using short-range technologies such as Wireless Fidelity (Wi-Fi), Near Field Communication (NFC), Bluetooth, etc., and for wider ranges, the third-generation (3G), fourth-generation (4G), Wide Area Network (WAN), Long Term Evolution (LTE) wireless telecommunication technology could be used [20]. Wireless Local Area Network (WLAN) is the most widely used technology, but it has security issues. According to Silva et al. (2018)

[42], Light Fidelity (Li-Fi) and Low Power Wide Area Network (LPWAN) are good alternatives due to their transmission efficiency. Moreover, the IoT devices help exchange data from the physical assets to the virtual models, and in turn, the virtual models are updated according to the data input from IoT devices [9].

Lu et al. (2020) [13] developed a Wireless Sensor Network (WSN), which was supported by IoT devices along with QR codes for managing the network of asset information for the transmission phase. The IoT devices used in this study were Monnit wireless sensors with a 1-min heartbeat. These sensors were used to capture data regarding the temperature, humidity, and motion at different locations. The data were uploaded to the gateway nodes using radio frequency, which were eventually sent to the Sensor Manager through the internet from the gateway nodes. QR codes were scanned by the maintenance personnel using the App Redbite Solutions [13] to update the information and transfer it to the asset management platform. The data from the asset

manager and sensor manager were eventually collected and updated to the AWS DynamoDB for communicating with the digital models.

4.3 Data modeling processes

The data modeling processes consist of developing 3D or nD models in Building Information Models (BIMs) or higher-level city information models (CIMs) representing the physical elements in the real world. The digital replica of a physical asset for the digital twin needs a definition. The definitions for digital replica can be composed of data from BIMs, Geographic Information System (GIS), IoT sensors, asset management systems, weather data systems, cost/scheduling/safety management platforms. However, the data should be aligned to the intended use of the digital twin.

The digital models could be done using photogrammetry, drones, vehicle-based scanning devices, laser scanners, and digital cameras for generating highly detailed models. Besides, the digital design models of the proposed site, Mechanical, Electrical and Plumbing (MEP) components, and BIMs could be created using Autodesk Revit and other BIM authoring software.

4.4 Data integration processes

Once the modeling processes are completed, all the associated data are stored, analyzed, processed, and updated as changes occur. Since a large amount of heterogeneous data are generated and used, it is essential to have appropriate storage and integration. It is evident from various literature that researchers have used different platforms to ensure an effective and secured data management system. Cloud storage has been considered an effective option. The dynamic linking of different knowledge engines (KEs) to the physical elements helps gather the information continuously. The KEs are driven by the target domain knowledge, and the information is stored under them. The KEs are dependent upon the intended use of the digital twin.

The digital models created in BIM software could be exported to Industry Foundation Class (IFC) files. The IFC files could be integrated with the data stored in the DynamoDB, which translates data at a semantic level; a relationship between the data in DynamoDB using a set ID and the objects from the BIMs based on the globally unique identifier (GUID) was established to do so.

4.5 Providing services via the digital twin

When data are integrated and stored properly, the knowledge from the KEs is interpreted, enabling the exchange of information between the physical assets and the model. End-users and FM professionals play an

important role in the decision-making processes. Moreover, regular feedback should be fed into the KEs from the people and professionals to enhance the FM functions.

In the following case study, the digital twin models were used for various servicing scenarios:

- (1) Monitoring the ambient temperature and humidity of the working spaces.
- (2) Maintenance planning optimization by using data from the building management systems and failure/maintenance logs.
- (3) Allocating resources by prioritization of the maintenance tasks.
- (4) Energy planning at an urban level for achieving low carbon output.

Similar applications on future projects having identical attributes could be done to contribute to the initiative of the National Digital Twin. These servicing use cases assisted the stakeholders' decision-making processes and enhanced the relationship between the end-users and buildings. After reviewing multiple case studies, it was found that the data acquisition, data transmission, modeling, data integration, and servicing processes compose the whole picture of digital twin modeling. However, the specific methods to conduct each process differ and depend upon the intended use of the digital twin models.

4.6 Evaluating digital twin applications

4.6.1 Potential of the applications

The data collected from digital twin models can be used for emergency and crisis planning and managing assets [26]. The data updates from the digital twin models help to portray the issues and constraints to various stakeholders, such as predicting the conditions of a physical asset, predicting energy consumption while maintaining the environmental codes, monitoring the structural health of the infrastructure assets, predicting structural life. When combining the data with AI algorithms and data analytics, these digital twin models are useful for forecasting or back-casting. In those cases, the future state of an asset can be determined and compared against a desirable planned state.

Besides the predictions, the digital twin models help stakeholders choose the right design solutions for a structure with low carbon emission and clean energy. Specifically, the iterated possible design solutions could be quickly produced to facilitate the generative design when simultaneously considering the environmental, cost, and schedule benefits.

The data updates are also helpful in monitoring the construction workforce in real-time, which continuously provide feedback about the construction workforce when exposed to risks related to the body segments.

Particularly in dangerous sites such as nuclear power plants, a constant real-time update about the installation work is necessary to protect workers from hazards and minimize human interventions.

The digital twin models allow the involvement of the wider audience in assisting urban planning and designing practices by utilizing the data such as the preference of citizens and material usage prioritizes. Since the data are collected from the citizens or the end-users, the digital twin models could efficiently bridge the gap between the people and buildings/cities. This would provide the required agility and customization whenever needed. At the city and urban level in general, digital twin models link the various buildings and citizens together to generate a unified federated model to ease the convenience of managing the city developments.

4.6.2 Challenges of the applications

Across the literature, it is noted that the basis for developing digital twin models for specific use cases is the data, and data integration is critical for a successful implementation of the digital twin while being linked to the physical assets. However, the major challenge remains the integration of data from multiple technology sources in different formats.

The data required for the digital twin models are stored in disparate systems, and at times, it is challenging to determine whether the data from one machine is the same as on the other. The data sources are usually heterogeneous. Furthermore, there could be a difference in the nomenclature of the database from system to system. The synchronization of data to ensure continuous feedback loops is also a challenging task. Since the digital twin models monitor the assets in real-time, it is necessary to have a continuous stream of information without any breakdowns. The quality of data collected should meet the requirements of the intended use. The quality of data can deteriorate while extracting it from the source or while transforming it.

The digital twin requires data to be transmitted from the physical asset to the digital replica in real-time, which involves a significant amount of cost and time. These economic aspects have not been justified. Many studies have linked the IoT with the digital twin as the devices are getting cheaper and their applications more user-friendly. Nevertheless, the problems of linking the IoT data with the digital models persist. The formats of BIMs and the semantic web data of the IoT devices still need to be further standardized and developed to integrate the data. However, in terms of data standards, the manufacturing, aerospace, and healthcare industries have made more significant progress in this field.

Digital twin models are exposed to cyber threats; thus, data protection and privacy are key priorities [43]. Since the data is sensitive, it needs to be protected; otherwise,

it could lead to trust issues. The digital twin models should be used following a common data transmission and exchange standard.

Installation and maintenance of the sensors on a construction site is a concern to a few. There are always chances of sensors getting damaged or stolen from construction sites. Moreover, these devices generate a large amount of data that needs to be stored, filtered, and matched with the BIM models. Besides, the physical assets in the construction industry need to last for decades, making the lifecycle maintenance a critical task.

The construction industry is complex and involves multiple stakeholders; therefore, all the project members must work collaboratively. Furthermore, the involvement of multiple stakeholders might lead to a longer time to construct the physical asset and digital twin models. The digital twin models require people with the right skills to construct them, a large amount of funds, and the latest technologies with higher computational power to successfully develop them.

5 Conclusions and future work

Digital twin-related topics have recently gained great attention in the AEC industry to improve data processing productivity. This study conducted a systematic literature review to understand the practical steps to develop a digital twin application to enhance construction integration and the challenges faced by various researchers in this field. Firstly, a comprehensive summary of the definition of digital twin from various industries was provided. Secondly, the method for systematic review was presented, and 23 articles were narrowed down for detailed analysis. The results presented the main processes of establishing and using digital twin technologies in the AEC industry, including the data acquisition processes, data transmission processes, data modeling processes, data integration processes, and the servicing processes. In the end, the digital twin application potentials and challenges were summarized. In the future, the digital twin applications should consider the collaborations among different stakeholders to ensure the proper time for model development. The ACE industry should focus on the training and development of skilled professionals specifically for digital twin applications. The related parties should also pay enough attention to the budget planning during decision makings.

Analyzing the Impact of Government-driven BIM Adoption: Introducing the Case of South Korea

Donghoon Ji^a and Yelda Turkan^a

^aSchool of Civil and Construction Engineering, Oregon State University, United States of America
E-mail: jid@oregonstate.edu, yelda.turkan@oregonstate.edu

Abstract

Unlike what South Korea have accomplished in the Architecture, Engineering and Construction (AEC) industry, current situation of Building Information Modeling (BIM) adoption in South Korea is still challenging. To identify the impact of government-driven manners on BIM adoption, this study presented the status of BIM application in South Korea. First, BIM adoption plans from 2010 to 2020 is described in chronological order. Second, statistical data of public projects from 2010 to 2020 regarding BIM application is presented and analysis based on the relationship between BIM adoption plans and statistical data was carried out to identify drawbacks and required improvements of BIM adoption plans. Third, two cases of Incheon International Airport and Godeok Bridge were introduced to represent the actual level of BIM application in South Korea. It can be identified that 1) mandatory BIM adoption is not effective for the expansion of BIM implementation, 2) current adoption plans exclude private projects which have greater amount than public projects and 3) stakeholders in South Korea have competent capacities of BIM despite challenging circumstances. Lastly, implications to improve government-driven BIM adoption were addressed.

Keywords –

BIM, BIM Adoption/Implementation, South Korea

1 Introduction

Architectural, Engineering and Construction (AEC) industry in South Korea has achieved a significant growth since the late 1960s, when South Korea's industrialization began. According to the 2020 Engineering News Record (ENR) report [1], there are 12 South Korean contractors ranked in the top 250 in global rankings and their total revenue is \$24,595.5 million, which accounts for 5.2% of international revenue of the top 250 contractors (Table 1).

Table 1. Global Market Share of the Top International Contractors in 2019

Contractor Nationality	No. of Firms	Int'l Revenue	
		\$ mil.	%
European	45	236,218.9	49.9
Chinese	74	120,005.7	25.4
American	35	24,648.5	5.2
South Korean	12	24,595.5	5.2
Turkish	44	21,639.2	4.6
Japanese	13	19,433.6	4.1
Australian	5	8,703.4	1.8
Indian	5	6,786.0	1.4
All Others	17	11,037.4	2.4
All 250 Firms	250	473,068.1	100.0

However, when it comes to Building Information Modeling (BIM) adoption, South Korean AEC industry is behind despite the formal, government driven BIM adoption plan [2][3]. South Korean government has launched BIM adoption plans for the public sector AEC projects in 2010 and demanded full BIM implementation for all public projects by 2016 [4]-[6]. Unfortunately, this plan was not as successful due to a variety of reasons including the readiness of the AEC industry in South Korea. Accordingly, the government revised their BIM implementation plan in 2020, which will be discussed further in the next section.

This paper examines the current level of BIM adoption in South Korea as it has features of both government-driven efforts and challenges faced by the AEC industry and by analyzing this circumstance, it may be possible to better understand and possibly improve the success of government led BIM adoption programs. Accordingly, this study analyzes the current level of BIM adoption in South Korea to identify the impact of government-driven plans on implementing BIM. In sections 2 and 3, the BIM adoption plans in South Korea are described in chronological order and statistical data from South Korean BIM projects are

analyzed to identify the impact of government-driven BIM adoption plans. Section 4 describes two projects that implemented BIM, namely, Incheon International Airport and Godeok bridge projects, to showcase the level of BIM adoption for different types of projects in South Korea. Finally, the government-driven BIM adoption plans and possible ways to improve such plans are discussed and conclusions are drawn.

In 2012, Lee et al. published the results of their survey presenting the status and future expectations of implementing BIM in South Korean AEC industry [7]. The research identified that South Korean AEC industry has high level of competency to utilize BIM and positive perception of BIM adoption. However, throughout the years between 2012 and 2020, BIM adoption in South Korea has failed to yield successful results, therefore follow-up research to analyse the overall BIM adoption in South Korea is needed. In addition, South Korean government conducted a study to review their previous BIM adoption plan while establishing a new BIM adoption plan [2]. However, the research mainly focused on the articles from the BIM adoption plan in terms of their weakness and areas for improvement, thus, it does not provide a comprehensive analysis such as the effectiveness of the BIM adoption plan. Therefore, by reviewing the government driven BIM adoption plans in South Korea and the associated statistical data published since 2011, this study provides not only the recent status of BIM adoption in South Korea but also a look into government-driven BIM adoption plans.

2 BIM Adoption Plan in South Korea

In South Korea, the Ministry of Land, Infrastructure and Transport oversees and regulates all construction and civil engineering projects and most of the public construction and civil engineering projects are controlled by the Public Procurement Service, a department in South Korean government. The Ministry of Land, Infrastructure and Transport establishes the masterplan for BIM adoption and the Public Procurement Service provides detailed plans and guidelines to accomplish the masterplan.

The first BIM implementation plan in South Korea was established in 2010 [5][6]. The Public Procurement Service published the BIM adoption plan and guidelines for public projects based on the Ministry of Land, Infrastructure and Transport's masterplan. Starting with public turn-key projects over 50 billion KRW (approximately 50 million USD), the Public Procurement Service had planned to mandate BIM for all public projects regardless of their cost. Also, this plan proposed the expansion of BIM adoption to all stages of a project including bidding, planning, design,

construction, and management. Details regarding the 2010 BIM adoption plan are presented in Table 2.

Table 2. BIM Adoption Plan in 2010

Year	2011-2012	2013-2015	2016-
Target	Public turn-key	Public project	
Cost	Over 50 billion KRW		All projects
Application stage	Design stage		All stages

Unfortunately, the 2010 BIM adoption plan was not as successful due to several reasons. First, the plan was set for 5 years, a relatively short time period, and the stakeholders in South Korean AEC industry was not ready to immediately start utilizing BIM [2][8]. As a result, the plans for updating and expanding the 2010 adoption plan in 2016 did not proceed. To overcome these shortcomings and improve the level of BIM adoption in South Korea, in 2018, both academic institutions and the South Korean AEC industry invested into research to supplement the plan. The government, both the Ministry of Land, Infrastructure and Transport and the Public Procurement Service, established a renewed, ten-year roadmap plan for BIM adoption in 2020 [2][9]. The main objective of the 2020 plan is to supplement the progress achieved with the previous plan to enable continuous expansion of BIM implementation throughout the whole lifecycle of infrastructure projects. A more gradual transition was pursued by adding additional details to the previous plan, which is expected to serve as a buffer prior to full BIM adoption. Under this new plan, public projects over 30 billion KRW are mandated to utilize BIM in the design stage and projects under 30 billion KRW are mandated to partially utilize BIM targeting architectural and structural design or during the schematic design phase. BIM adoption plans regarding public projects from the Korea Land & Housing Corporation (LH), a public enterprise for the development and management of public housing, were also established. Furthermore, BIM implementation plans for the private sector have been added to expand BIM utilization to private sector projects. The details of the 2020 BIM adoption plan are presented in Table 3.

Table 3. BIM Adoption Plan in 2020

Year	2021-2023	2024-2026	2027-2030
Public project	1) over 30 billion KRW		
	Design stage / All construction works		
	2) 20 billion~30 billion KRW		
	Design stage / Architecture and Structure		
LH project	3) 10 billion~20 billion KRW		
	Schematic design / Architecture		
	50% of new projects (25% in 2021)	100% of new projects	
*Private project	No Plans	**Total floor area over 10,000m ²	***Total floor area over 2,000m ² (500m ² in 2030)

*Not mandatory
 **Officially referred to as a project of cooperation with relevant specialized engineers
 ***Officially referred to as a project with resident supervisor

3 Status of BIM Projects in South Korea

In this section, the status of BIM implementation in South Korea is analyzed using statistical data from 2011 to 2020. The data for this study is limited to the annual statistical source published by the Public Procurement Service [10]. During the period from 2011 to 2020, right after the 2010 BIM adoption plan was activated, the public projects which were mandated to use BIM is relatively scarce [9] except for the projects executed by the Public Procurement Service. The statistical data for this study present the total number of Public Procurement Service's projects and their net cost as well as the projects that applied BIM and their net cost. Following the 2010 BIM adoption plan, the projects that used BIM in 2011 and 2012 are public turn-key projects over 50 billion KRW. Likewise, the projects that used BIM from 2013 to 2020 are all public projects over 50 billion KRW as the target cost in the 2010 plan have remained the same after 2015. The statistical data are presented in Table 4.

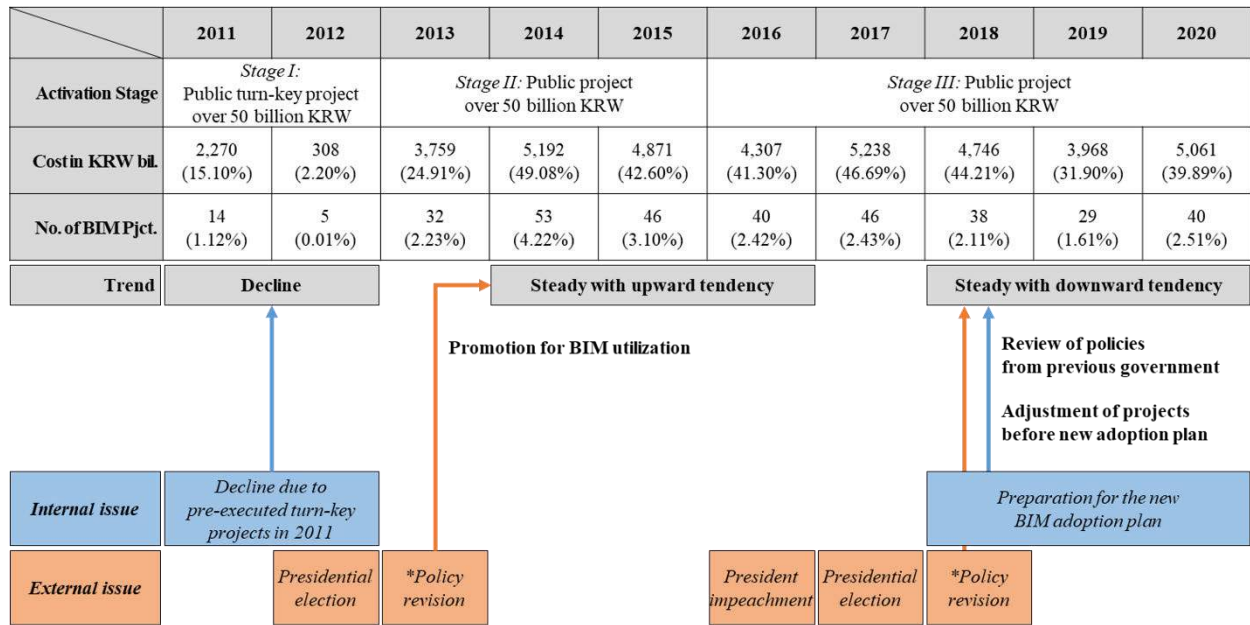

Based on the data presented in Table 4, Figure 1 represents an aggregated timeline from 2011 to 2020, which includes both internal and external issues related to the BIM adoption plan and the AEC industry in South Korea. Figure 1 indicates that there has not been a significant change in net cost or the number of projects using BIM. For instance, focusing on the 2014 to 2020

period, net cost of the projects that used BIM has slightly decreased (from 5,192 billion KRW to 5,061 billion KRW) while the number of projects using BIM have also decreased from 53 to 40. This result aligns with the characteristics of government-driven public projects. In general, public projects based on government plans maintain a constant proportion each year without drastic changes. So, although BIM has been mandated and utilized in public projects, it is difficult to achieve gradual increase in BIM adoption since public projects hold their proportion each year.

Table 4. Cost and Numbers of BIM-applied Projects

Class	Total Project		BIM-applied Project	
	Net Cost (KRW bil.)	No. of Projects	Net Cost (KRW bil.)	No. of Projects
2011	15,033	1,250	2,270 (15.10%)	14 (1.12%)
2012	14,009	1,151	308 (2.20%)	5 (0.01%)
2013	15,089	1,433	3,759 (24.91%)	32 (2.23%)
2014	10,579	1,255	5,192 (49.08%)	53 (4.22%)
2015	11,435	1,483	4,871 (42.60%)	46 (3.10%)
2016	10,428	1,651	4,307 (41.30%)	40 (2.42%)
2017	11,218	1,891	5,238 (46.69%)	46 (2.43%)
2018	10,736	1,801	4,746 (44.21%)	38 (2.11%)
2019	12,438	1,799	3,968 (31.90%)	29 (1.61%)
2020	12,686	1,593	5,061 (39.89%)	40 (2.51%)
Average	12,365	1,531	3,972 (32.12%)	34 (2.22%)

In addition, in the 2010 BIM adoption plan, the project cost, which was over 50 billion KRW, was overestimated. There are limited number of stakeholders who have the capacity to manage projects over 50 billion KRW and if this condition remained the same, only those stakeholders would have utilized BIM in their projects. Moreover, the target cost translates into a small number of target projects, 2.22% of all public projects. In the 2020 plan, the project cost target has been adjusted, increasing the percentage of target projects compared the total number of projects to 4.56% (for projects that are 30 billion KRW) and 12.64% (for project that are 10 billion KRW). Thus, the new 2020 BIM adoption plan is expected to provide improved results compared to the previous adoption plan.

* In this figure, the word 'Policy' refers general policies related to the AEC industry

Figure 1. Timeline of BIM adoption in South Korea

4 Case Studies

This section introduces two BIM-applied projects in South Korea as case studies, Incheon International Airport project and Godeok Bridge project [11]-[13]. These projects were the grand prize winners of Korea BIM Awards in 2019 and 2017, respectively, hosted by buildingSMART Korea. Through this section, details regarding the BIM application for each project are presented.

4.1 Incheon International Airport

Incheon International Airport project, which was planned in 5 stages, launched in 1996 and the first stage, construction of Terminal 1 and related facilities, was completed in 2001. After the first stage, Stage 2 proceeded from 2002 to 2008 and focused on the construction of the Concourse (Auxiliary Terminal) and related facilities to cope with the increased demand. During this stage, BIM was partially applied for the first time and mainly used for quality management and coordination of complex structures and Mechanical, Electrical and Plumbing (MEP) components. In terms of BIM application, Stage 2 was mainly planned as a testbed to evaluate the feasibility of using BIM, and based on this experience, BIM was actively applied starting in Stage 3.

Figure 2. Incheon International Airport

Stage 3, construction of Terminal 2 and related facilities, was carried out from 2009 to 2017. The main objective regarding BIM application was to utilize BIM actively throughout the project. Accordingly, BIM was used for design and the scope of the design included not only the Terminal 2 but also every road, railway and other transportation facility on the site. As in Stage 2, overall management of design, construction and quality was achieved using BIM. Moreover, Stage 3 utilized as-built BIM in Level of Development (LOD) 300 and LOD 350 for managing construction procedure and schedule. Throughout Stages 2 and 3, BIM was utilized in 20 activities (17.86%) out of a total of 112 activities and it is estimated that it produced cost savings of 11.7 billion KRW, 0.15% of the total cost.

Stage 4, the expansion of Terminal 2, is scheduled to proceed from 2018 to 2024 and this stage has been planned to utilize BIM only during design by excluding all traditional 2D documents. Stage 4 also utilizes as-built BIM in LOD 300 and LOD 350 for overall management. Furthermore, Stage 4 has its objective for being a testbed for the-state-of-the-art technologies for BIM such as using Virtual Reality (VR) and Augmented Reality (AR), and mobile data management systems that are accessible via smartphones and tablets. During Stage 4, the goal is to utilize BIM in 62 activities (57.94%) out of total 107 activities and it is expected to result in 48.4 billion KRW in cost savings, 1% of the total project cost. The details regarding Stages 2, 3, and 4 are provided in Table 5.

Table 5. BIM Implementation for Incheon International Airport (Incheon International Airport Corporation 2019)

Stage	Stage 2 (2002-2008)	Stage 3 (2009-2017)	Stage 4 (2018-2024)
Target	Concourse	Terminal 2	Terminal 2 Expansion
Objective	Testbed of BIM	Active BIM	Full BIM design Testbed of add-ons
Content	- Partially applied BIM - Quality management of complex structure, MEP	- BIM-based design - Quality management of complex structure, MEP - As-built BIM for process and schedule management	- Full BIM design - As-built BIM for process and schedule management - VR/AR for virtual completion - Mobile management
BIM Activity	20 activities (17.86%) <i>achieved</i>		62 activities (57.94%) <i>expected</i>
Cost Saving	11.7 billion KRW (0.15%) <i>achieved</i>		48.4 bil. KRW (1.00%) <i>expected</i>

The case of Incheon International Airport indicates that the level of BIM implementation in South Korea is advanced for larger projects. Contents of the case study, from traditional BIM applications (e.g., quality management of complex features and schedule management using as-built BIM) to adoption of new technologies (e.g., virtual completion with VR/AR and mobile management with portable devices) give a hint about the level of BIM adoption in South Korea. However, since this project is regarded as the flagship BIM project in South Korea, another project which represents an average case is discussed next.

4.2 Godeok Bridge (Tentative Title)

Godeok Bridge is a reinforced concrete, cable-stayed bridge and planned to cross the east of the Han River, Seoul. This six-lanes bridge has the maximum width of 30.6 meters and the total length of 1,725 meters, with 1,000 meters of the main bridge, 725 meters of two connection bridges and additional 1,645 meters of two interchanges. Godeok Bridge project, which is the fourteenth sector of the Sejong-Pocheon Highway, started in December 2016 and is estimated to finish in December 2022.

Figure 3. Godeok Bridge

Godeok Bridge project utilized BIM in the design stage. The original design of two pylons of the bridge became an issue in terms of the constructability. The lower part of the pylon had a multi curved surface, which could cause poor quality at intersections between the deck and the pylon. Therefore, BIM was used to review the alternative designs of pylons considering structure stability, economic feasibility, and design aesthetics. Also, reinforcing bars on these intersections were coordinated using Nemetschek's Allplan Engineering 2017, a class coordination software.

In addition, a 4D as-planned BIM was applied to perform the construction simulation of this project. The simulation focused not only on the overall process but

also the connection between the main bridge, two connection bridges and two interchanges. The result from this simulation provided the base line for developing the actual construction schedule.

Lastly, with Bentley's LumenRT 2017, Godeok Bridge project established the BIM-based VR environment for the design review and evaluation. This approach enabled every stakeholder to have access the as-planned bridge design easily enabling them to have a better understanding on this project. Moreover, the VR environment was utilized for safety briefings and education for the workers enabling them to experience their workplace and activities virtually.

Although the case of Godeok Bridge is a good example for BIM-applied civil infrastructure projects, it represents an average BIM adoption level in South Korea. Like most other projects implementing BIM, BIM use is limited to the design stage and the most common BIM applications such as constructability review and clash detection are utilized.

5 Implications

This study identified the impact of government-driven BIM adoption in South Korea. Although mandatory BIM adoption plans for public projects may accelerate BIM adoption, it is not effective in terms of the expansion of BIM use across the AEC industry since the portion of public projects is not expected to increase. In addition, the target project cost in BIM adoption plans have a huge impact on the results as a high ceiling would result in a smaller number of target projects and stakeholders as there are limited stakeholders with adequate capacities for utilizing BIM. Furthermore, since there is a close relationship between public projects and government policies, the continuity or success of BIM implementation based on public projects is not guaranteed due to frequent changes in government.

Second, current BIM adoption plans exclude private projects which make up a significant portion of all construction projects. In South Korea, net cost of private projects is 200% to 300% greater than that of public projects. Private projects are more flexible than public projects regarding progress during the project and clients often ask for more benefits (e.g., cost saving, schedule reduction, quality increase). Consequently, private projects have great potential for BIM application, and excluding private projects in the BIM adoption plan would negatively impact the widespread adoption of BIM across the AEC industry.

Lastly, it can be concluded that South Korean AEC industry has sufficient capacity to utilize BIM despite the challenging circumstances. From both cases in Section 4, successful adoptions of traditional BIM

applications in the design stage can be identified. Furthermore, there are possibilities for the advanced BIM adoption such as BIM application in the construction stage and adoption of BIM-based advanced technologies. To sum up, current insufficiency of BIM adoption in South Korean AEC industry results from inappropriate BIM adoption plans from the government as AEC stakeholders in South Korea have competent abilities to implement BIM. So, efforts to utilize the capacities of BIM stakeholders in effective ways are needed to improve existing government-driven BIM adoption.

In order to overcome the drawbacks summarized above and improve the current government-driven BIM adoption plans, a robust, long-term masterplan which is authorized by the government could be a potential solution. This masterplan would need to be consistently operated without being affected by changes in the government or other policies. Also, continuous expansion of the scope of BIM applications and motivation for active stakeholder engagement should be considered.

One example that can be added to the BIM adoption masterplan is a method of reward based on the performance of BIM applications for both public and private projects, such as direct rewards of subsidy or indirect incentives of tax benefits or bidding advantages. Especially, direct/indirect financial assistance for stakeholders could help avoid poor profitability of BIM application for them especially for the first few projects, which is one of the main obstacles for implementing BIM. In the meantime, to leverage rewarding contents properly, a reasonable amount of subsidy and incentive has to be set [14]. Also, equitable evaluation criteria under precise analysis to distribute rewards effectively are needed. These criteria have to consider both quantitative features such as cost savings, coverage ratio and qualitative features such as performance against capacity and client satisfaction.

6 Conclusions

The AEC industry in South Korea has made remarkable achievements as 5.2% of the total revenue of the global construction industry belong to South Korean contractors. However, compared to those achievements, the current level of BIM adoption is behind. BIM adoption in South Korea is relatively new, and the first government led BIM adoption plan put in place in 2010. Accordingly, this study analyzed the current status of BIM adoption in South Korea to identify the impact of government-driven plans on implementing BIM.

The BIM adoption plans in South Korea from 2011 to 2020 were presented and compared. The first BIM

adoption plan in 2010 set out for the full BIM adoption starting in 2016, by expanding on the types of target projects and project cost. However, from 2010 to 2015, the first plan failed to provide the expected results due to its short period and low BIM capacities of the South Korean AEC market at that time. The 2020 BIM adoption plan was established to improve the previous plan by gradually expanding the types and sizes of projects over the years. Next, the status of BIM projects in South Korea was analyzed using the statistical data from 2011 to 2020. The data pointed out that the BIM adoption plan did not have much effect as there has not been significant changes in net cost or the number of BIM-applied projects. Reasons for this result are related to the characteristics of public projects. The government controls the number of public projects. It is impossible to expand BIM adoption if only public projects are mandated to use BIM. Additionally, mandating only the very high-cost projects use BIM have resulted in limited number of target projects and stakeholders to participate in. Finally, Incheon International Airport was presented as a case study as it represents the best BIM application case in South Korea. The case study implies that BIM capacities of South Korean AEC industry are sufficient despite the challenging circumstances and methods to leverage their competent BIM abilities in effective ways, which could help improve government-driven BIM adoption.

This study suggests a robust, long-term masterplan, which covers both public and private projects, to overcome the shortcomings from government-driven BIM adoption. This masterplan needs to guarantee a consistent operation without being affected by internal/external issues. Also, continuous expansion of BIM adoption and motivating stakeholders with various incentives should be considered. Specifically, direct/indirect financial assistance based on the BIM application performance, such as direct rewards of subsidy or indirect incentives of tax benefits or bidding advantages, can be added. To leverage the contents of rewarding, details such as the amount of subsidy and incentive, evaluation criteria to distribute rewards have to be considered.

This study analyzed the impact of government-driven BIM adoption. In addition, implications to improve BIM adoption can be specified further by future studies. Meanwhile, this study has insufficient considerations of qualitative features of BIM application among BIM-applied projects, such as level and performance of application, in order to supplement qualitative considerations, surveys on the details of BIM-applied projects should be conducted.

E-mail: roghieh.eskandari-toushmanlou.1@ens.etsmtl.ca, Ali.motamedi@etsmtl.ca

Abstract –

The development of new visualization technologies, such as Mixed Reality (MR) and Augmented Reality (AR), has enabled many applications to improve our daily life. For example, AR has been used in landscape assessment by overlaying virtual objects on a real-world scene to enhance the user's experience. For many advanced visualization scenarios, the virtual removal of objects is done to prevent their intermingling with the existing objects, which could lead to inaccurate visualizations. Diminished Reality (DR) is the technique of virtually removing and seeing through undesired objects in an environment in real-time. The main objective of this paper is to review recent studies to provide an overview of the main procedures, techniques, and applications of DR. In this regard, this paper investigates definitions of DR, its enabling technologies, and its potential applications. It also discusses the current challenges of using DR systems in the Architecture, Engineering, and Construction (AEC) industry.

Keywords –

Diminished reality, Augmented reality, Construction Visualization, See-through vision, AEC industry, interior design, landscape simulation.

1 Introduction

Many new computer devices and software products have been introduced to the consumer market with the development of extended reality (XR) in recent years. XR refers to the environment that is generated by computer graphics and wearables to blur the line between a virtual environment and the real-world using human-machine interactions [1]. It consists of all the different forms of computer-altered reality, such as Virtual Reality (VR), Augmented Reality (AR), and Mixed Reality (MR).

VR can be defined as a 3D computer generated environment, with which a user can connect and interact through various input and output devices in real time [2]. VR systems require the use of a Head-Mounted Display (HMD) device, such as Oculus [3], HTC Vive [4], and Google Cardboard [5] or an immersive combination of projection screens such as CAVE (Cave Automatic

Virtual Environment [6]) to generate realistic sensations, such as images and sounds. AR generally refers to a technology that can display virtual objects onto the physical world in the form of an overlay to provide an enhanced experience[7]. AR adds more depth of relationship with the real environment, which VR systems lack, by adding computer-generated content to the real world. However, the fact that in AR scenarios the real and virtual worlds are separated decreases the level of user immersion. MR overcomes this challenge by merging the real and virtual worlds. In MR, the user can execute practical scenarios and experience interactions between virtual and real objects [8]. There are many practical applications of XR, and it has been implemented in various fields, namely Architecture, Engineering, and Construction (AEC) [9], retail industry [10], manufacturing training [1], marketing [11], entertainment [12], and medical science [13].

DR is a technique to visually diminish or see-through an object by recovering the background images of the area that is occupied by the object [14]. To date, various studies have explored the development of DR technology and its potential applications. The motivation for this research came from the lack of attention paid to DR applications and challenges. The main contribution of this paper is to provide a review of DR technology and the extent to which it has already influenced various applications, and the existing challenges to be addressed in the AEC industry.

2 Review Methodology

This research is the initial stage of a comprehensive research project to develop a framework to implement a DR technology in the AEC industry. A "mixed methods systematic review" was implemented as the strategy to discover the knowledge gaps in this domain by summarizing and evaluating the evidence [15].

The overall process of review consists of four stages i.e., identification, screening, eligibility, and inclusion. In this research snowballing technique is used in

combination with the systematic literature review method to ensure all key articles were covered. By using the mixed methods of review strategy, 65 key articles were filtered for the review of the DR techniques, in different applications. As shown in Figure 1, 11% of studies are conducted for the application of AEC industry. This paper will review the DR technique, challenges, and opportunities in the AEC industry.

Figure 1. Number and percentage of the DR applications in 65 papers.

3 An Overview of Diminished Reality Techniques

To eliminate an object from a scene, the background information must be acquired from the scene using sensors such as cameras. Diminished reality techniques are classified according to the background recovery techniques used to fill in the space, namely inpainting-based diminished reality (IB-DR) and observation-based diminished reality (OB-DR). The inpainting-based diminished reality (IB-DR) technique fills the Region of Interest (ROI) with a plausible texture estimated from pixels surrounding the region or image patches around the ROI [16]. IB-DR approaches are basically based on computer vision and image processing techniques for object removal and reconstruction [17].

In observation-based diminished reality (OB-DR), the concealed view is recovered using the background observation results. Existing OB-DR approaches use multi-view-based procedures to get information about the occluded background. These methods give more convincing results than IB-DR methods, since they use the real scene behind the occluded objects. OB-DR can be classified into two categories depending on the

background observation methods used: pre-observation-based diminished reality (POB-DR), real-time observation-based diminished reality (ROB-DR).

In POB-DR methods, the background is observed beforehand that is without the presence of the objects to be diminished. For example, Kido et al. [18] used a 3D model of the hidden background, which was generated in the pre-processing step to rebuild the DR background.

In this category, the model of the environment is reconstructed before the real-time procedure. Therefore, a high-quality DR result is expected. However, the time interval between the pre-observation stage and the DR processing stages may cause photometric and geometric differences between the physical and virtual scene [19].

In the case of ROB-DR, the background is observed in real-time using additional cameras. For example, Kameda et al. [20] used several surveillance cameras in the scene for seeing through the walls in real-time. This paper will review OB-DR methods including ROB-DR and POB-DR methods.

This paper will review OB-DR methods including ROB-DR and POB-DR methods. According to Mori et al. [14], the general approach for implementing a DR system is divided into four steps: scene tracking, object detection, background generation, and composition. (See Figure 2).

Figure 2. Overview of the general process of the DR system.

3.1 Scene tracking

In each DR system, to achieve the 3D recovery of a scene, the geometry of all the cameras is required, including the main camera and the background observer camera. Scene tracking can be classified into a fixed viewpoint and free viewpoint, depending on the camera movement. Six degrees of freedom (6 DoF) camera pose estimation including three elements for the position and three elements for the orientation of the camera relative to the object is performed. Scene-tracking methods can be classified into marker-based tracking and marker-less tracking approaches.

Marker-based tracking relies on explicit image patterns placed in the scene to estimate the camera pose. While these methods are fast, robust, and low-cost, they suffer from limitations, such as requiring uniform lighting conditions and recognizable markers that contrast strongly with the environment [21].

To avoid using such markers, several studies have focused on developing efficient marker-less tracking methods. Marker-less methods can be divided into sensor-based and vision-based methods. In sensor-based methods, positioning methods and sensors are employed to estimate the camera pose [22]. As for vision-based approaches, computer vision and image-processing techniques are used for camera pose estimation and tracking. While vision-based methods are more accurate and reliable than sensor-based methods, they are currently more complicated to implement and require a 3D model of the environment.

3.2 Object detection

The detection of the object to be diminished have become challenging procedures in DR [23]. Some studies used the manual detection of objects. In these methods, the ROI is determined by users to find their desired object. Manual detection of ROIs can be applied in the static environments where the target objects and cameras are not moving [14]. Some other studies tried to use automatic or semi-automatic methods for the object or ROI detection. In these methods, various features have been used for object detection, such as Haar-like features [24], histograms of oriented gradients [25], and CNN-based (Convolutional Neural Network) object detection algorithms [26]. Deep learning-based object detection is capable of detecting ROIs in dynamic scenes. For example, Kido et al. [18] utilized deep learning methods such as MobileNetSSD to determine ROIs of moving objects. There is also another category in DR studies that recovers the background without determining the ROI in the image. In this category, background images are overlaid on the user's perspective view. Even though this method decreases the computing cost of determining

ROIs, it may result in unexpected artefacts surrounding the objects to be diminished [14].

3.3 Background generation

The background information must be registered to the user's viewpoint in a 3D scene. The information for the background generation can be sourced from surveillance cameras [28,29], a panorama image [29], depth camera on the HMD [30], handheld RGB cameras [18], RGB cameras mounted on a drone [31], and 3D laser scanners [32].

There are two approaches for background generation including: (1) 3D modelling and rendering, and (2) Image-based rendering (IBR). The former approach is a traditional way for the real scene simulation. In this approach, the geometric and illumination information of the scene is recovered in the modelling section using common methods such as Structure from Motion (SfM) and texture mapping. Then, the new viewpoint image is generated using the reconstructed scene from the modelling process. While the 3D modelling and rendering method is capable of completely displaying the scene's geometric information, it is extremely complicated, and requires high processing time and computational cost. Otherwise, 3D modelling and rendering methods result in non-photorealistic outputs with low computational cost.

On the other hand, IBR methods can directly generate the scene using acquired images. In these methods, new views are generated from a set of input images by transferring pixel values of the input images to their positions in the new views [33]. Rendering results in IBR methods are photorealistic because they are produced directly through input images. However, despite the traditional 3D modelling and rendering methods that enabled the users to see the background scene from any random viewpoint, IBR methods cannot continuously achieve random viewpoints because of the limitation in the input image viewpoints. Most common techniques in the IBR methods are light field rendering [34], unstructured lumigraph rendering (ULR [35]), and view-dependent texture mapping (VDTM [36]).

3.4 Composition

Composition is a post-processing step that is required to improve the DR result and decrease inaccuracies that may occur between the projected ROI in the current frame and the recovered background model. This process is also called seamless cloning in some studies [37]. In this procedure, the local differences are corrected in the boundary of the ROI and interpolated inside the ROI. The result is then added to the recovered background model to compute the corrected values. Composition process improves the DR results by reducing the visible seams in

the stitched frames and adjusting the light mismatches. In this regard, alpha-blending processing [38] is more commonly used in DR studies. It produces new blended pixels by combining weighted background and foreground pixels. The results in DR studies indicate that alpha blending is computationally inexpensive and produces efficient solutions in dynamic scenes [39].

4 DR and Displaying Devices

Devices in DR studies can be used to display the main view, in which a user can see the results of the DR system, and the background view that observes the hidden background view. For the main view, research on diminished reality uses different display devices, such as head-mounted display (HMD) devices, hand-held display devices, and web cameras.

In several studies, HMD devices were used to implement and display DR effects. DR systems involved with Video See-Through-HMDs (VST-HMDs) devices provide users with immersive displays. On the other hand, Optical See-Through HMDs (OST-HMDs) are physically not applicable in a diminished reality system since pixels cover the real world in a semi-transparent manner [40]. Although this feature of OST-HMD devices was beneficial in the applications that aim at removing undesired objects semi-transparently (e.g. in [30]).

HMDs are not the only devices that are used in DR applications. Kameda et al. [20] proposed a new visualization method with a handheld mixed reality (MR) device that is a camera attached to a handy subnotebook PC (HPC). Handheld MR devices are more useful for realizing see-through vision in outdoor environments.

For background observation in DR studies, imaging sensors, namely fixed or moving RGB cameras and RGB-D cameras are more commonly used. However, the use of a 3D laser scanner to measure point cloud data of the background scene has also been emphasised [32].

5 DR Applications in AEC

DR is applied to simulations of various scales ranging from small-scale interior design applications to large-scale landscape assessments.

5.1 Interior Design Simulation

DR can improve the communication efficiency of design participants during the design process. DR function is used to display indoor renovation plans in a single-user MR system by Zhu et al. [41]. They later used a collaborative design system that allows multiple people to participate in the same MR environment simultaneously during the early design

stage [30]. This study used a combination of the point clouds as a large-scale mesh of environment and BIM data as a 3D modelling of the complex objects for the background reconstruction. The BIM model production and modification for the DR background creation is time consuming and requires more resources than other methods such as point cloud. However, it is suitable for complex physical objects.

5.2 Landscape Simulation

DR momentum is also observed in urban design in the case of building, removing, or replacing a new construction. In an attempt to retain a good landscape, stakeholders must use simulation to plan potential landscapes with the innovative designs. By overlaying a 3D design model onto the physical world, AR can be applied to evaluate the potential landscape on a vast scale. DR, on the other hand, can be used to visually remove the structures during development. Inoue et al. [42] used DR for building and vegetation designs simulation. Kido et al. [18] presented a DR system to remove moving objects and immobile exterior structures in real-time for onsite landscape simulation. Yabuki et al. [32] developed a point cloud-based DR system to remove the outdoor buildings in real-time and facilitate landscape simulation. Fukuda et al. [43] developed an AR/DR system, in which the green view index is measured simultaneously with the DR simulation in an urban and planting design application.

6 DR Challenges in AEC

Determining efficient approaches at each stage of the DR processing, such as scene tracking and background recovery, is important due to the diversity of applications in this domain.

6.1 Registration and Alignment Issue

An accurate registration and alignment of the camera's position and orientation is an important challenge in implementing AR and DR techniques in outdoor environments. In many studies, special equipment or artificial indicators are utilized to estimate the camera pose. For example, Yabuki et al. [32] used feature points on video images and known points in point cloud data measured by a 3D laser scanner to get an accurate registration for DR simulation in urban areas. Calibration markers are also useful in camera pose estimation. Kameda et al. [20] used distinguishable structures of buildings, so called landmarks, as calibration markers. Texture of these markers is required to be updated to deal with the illumination changes in the outdoor environment. Surveillance cameras embedded in

the environment are useful to update these texture changes in the landmarks.

Stable tracking is difficult in an outdoor environment due to the illumination inconsistencies in the image and the existence of various sources of noise. Therefore, maintaining stable tracking over an extensive period can be a critical problem to improve the user experience of outdoor AR/DR systems [42].

An efficient method of background reconstruction is very important for diminished reality in the AEC industry applications. Discontinuity will appear at the boundaries of the reconstructed background and the rest of the reference view without a proper reconstruction. Multi-camera approaches are advantageous by allowing real-time updates of the background. However, they require additional cameras, are less flexible than single-camera techniques, and require a more elaborate setup [44]. In addition, existing multi-view geometry-based DR techniques used depth searching in overlapping areas of each image, making it impossible to see the image from different angles. These methods are computationally expensive because of using several cameras.

6.2 Illumination Consistency

Illumination consistency between the run-time processing and 3D virtual model of the background environment is another challenge in DR systems. To solve this issue, Fukuda et al. [45] used deep learning algorithms during the DR simulation to achieve this illumination consistency. Liu et al. [46] solved the problem of illumination consistency in AR and MR using surrounding light estimation in the real environment. Most POB-DR systems managed only static scenes under consistent illumination conditions since they assumed that the object elimination is done instantly after background observation or is performed in indoor environments. IBR methods can help solve these practical problems in POB-DR [39].

Inconstant illumination and noises are also affecting the stable object tracking in the outdoor environment. Inoue et al. [42] used perspective n-points (PnP) problems to estimate camera motion in an outdoor environment. PnP is a problem of estimating the camera pose from n 3D-to-2D point correspondences. In this method, the n 3D points are in advance defined as tracking reference points and their corresponding 2D points are traced by estimating the optical flow. Liu and Chen [40] applied a fast colour correction at high frame rates to compensate for the lighting changes that may occur between scanning and run-time.

6.3 Heavy Data

In outdoor environmental applications, utilizing effective strategies to overcome the challenges of treating

vast amounts of data and considering a wide field of view is essential. For instance, in architectural and urban applications, loading a 3D city model is heavy and time-consuming on mobile devices and tablet computers, which makes these devices less applicable than a laptop PC in DR simulations for architectural and urban design applications. Therefore, a distributed computing system available over the internet, such as cloud computing would be a good option for these applications [18].

To summarize, existing DR approaches generally rely on one or more of the following assumptions: multiple viewpoints, planar surfaces, limited camera movement, markers for pose estimation, simple backgrounds, or existence of a pre-scanned models without objects to be removed. However, several studies attempted to solve the aforementioned challenges.

7 Conclusion

This study reviewed previously published articles found in the literature to propose a three-part overview of the various DR applications. The first part focused on the definition and influences of DR, the second categorized the enabling technologies in DR, and the final part introduced applications of DR in the AEC industry and existing challenges. This study has found that there are numerous applications for DR, for instance, AEC industry, autonomous cars, entertainment, and visuo-haptic systems. DR presents many challenges, such as difficulties of processing a large amount of data for large-scale environments, registration and alignment problems, and illumination consistency. Nevertheless, several studies attempt to solve these challenges. In general, this research extends our knowledge on the relevance of DR in various applications and presents a general workflow for implementing a DR solution.

Abstract –

Adoption of digital fabrication (dfab) in AEC promises great advantages in productivity, sustainability, and new design and delivery opportunities. Companies are interested in adopting dfab, but lack an overview of emerging dfab technologies and their use potential, as well as tools to evaluate their match with the own needs and business interests. Based on a qualitative analysis of five emerging dfab technologies, we developed an easy-to-use scoreboard to guide firms' decision-making when adopting dfab technologies towards industrial implementation.

Keywords

Digital fabrication, additive manufacturing, technology transfer, technology adoption

dfab lack an overview of emerging dfab technologies and their use potential, as well as tools to evaluate their match with the own needs and business interests.

In this study, we seek to understand the relevant key parameters of interest for such an evaluation tool, particularly in the case of additive concrete dfab technologies. Our assessment is based on researcher and industry interviews at the Swiss National Center of Competence in Research (NCCR) dfab, a leading dfab research center. We synthesized our findings in an evaluation framework to create a comparative overview of dfab technologies and assess the prospective users' needs. Based on this framework, we developed an easy-to-use scoreboard to guide firms' investment decisions in further R&D aiming at adopting dfab technologies towards industrial implementation.

1 Introduction

Adoption of computationally driven manufacturing in the AEC industry, commonly called digital fabrication (dfab), promises great advantages in productivity, sustainability, and new design and delivery opportunities. Dfab is defined as a fabrication or building process relying on a seamless conversion of design and engineering data into digital code to control manufacturing devices [1]. Particular attention is given to dfab technologies for additive manufacturing using concrete, the world's most-used building material by volume and a major contributor to global CO₂ emissions. Many such dfab technologies are currently developed worldwide in research centers but these are often in pre-commercial development stages (e.g. in demonstrators or exploratory pilot projects). Overall adoption of advanced dfab technologies by industry is lagging due to challenges with technology transfer from research to industry.

For firms in search of innovative technologies to bring to market, the diversity of potential solutions presents a challenge. Companies with interest in adopting

2 Point of departure

In many industries, the shift toward digitalization and automation has fueled the development of new processes, new products, and an increase in productivity. By contrast, the AEC sector has lagged in automation and digitization in the past decades [2]. With the shift of the AEC sector towards industry 4.0 now accelerating, dfab technologies are on the rise in construction [3]. Dfab can contribute to increasing productivity and sustainability in AEC by its potential to improve construction quality and speed, workplace safety, waste reduction, and resource efficiency [4]–[6]. After roughly two decades of experimental research in construction-scale dfab, a variety of dfab technologies are now approaching maturity levels sufficient for industry implementation. Evidence of this can be seen in an increasing range of additive production methods developed by several research centers and companies worldwide, encompassing a multitude of materials and processes [7], [8]. However, industry uptake of advanced dfab technologies is still slow, despite their many potential advantages. Adoption is lagging due to challenges with technology transfer from research to industry [9], [10].

This transfer challenge has multiple reasons, but we found the following two of particular importance in the context of the NCCR dfab. First, for firms in search of innovative technologies to bring to market, the diversity of potential solutions presents a challenge. Second, firms lack an overview of the application potential of emerging dfab technologies, and tools to evaluate their match with the own needs and business interests.

Little research has looked into how to overcome these challenges by systematically matching industry needs and technology properties. In order to address this, we ask the following questions:

- What are properties of dfab technologies that matter for industry?
- How can these properties be generally described in a manner so that firms can evaluate and compare dfab technologies?

3 Research method

3.1 Methodology

Dfab in AEC is a nascent research area where quantifiable data is lacking. Therefore, we chose a qualitative research approach. Grounded Theory (GT) is a common qualitative method well suited to investigate our stated research aims [11]. GT is based on the analysis and categorization of qualitative data, such as interviews, notes, and observations. The qualitative data is analyzed in an inductive “open coding” process in which relevant categories are developed directly from the content of the data rather than from pre-existing theory or hypotheses. Theoretical sampling, i.e. the targeted collection of additional data as the theory develops, allows the researcher to focus the inquiry on data that has relevance in the area of study. The focus of the method is on developing a system of categories in order to develop theory from qualitative case [12].

3.2 Data collection

We conducted a total of ten semi-structured interviews. First, through our network, we identified five technologies of interest and initial contact persons for each technology. Then, in a first round, five interviews were led with six researchers leading dfab technology developments (one interview per technology). Interview questions aimed at understanding the technologies, the processes and the properties of their results, along with implementation limitations and opportunities. In a second round, five additional interviews were led (two additional researcher interviews, one industry partner, one external technology consultant, one industry expert not directly related to the technology research). The second set of interviews served to better understand more

specific technical aspects, industry needs, and future development potential towards industrial processes. The interviews were recorded and transcribed with the interviewees’ permission.

Relying on more than one data source is important to ensure the validity in qualitative research [13]. For this reason, the interviews were complemented by direct observation of processes and analysis of images and video recordings of experiments (due to Covid-19 restrictions, some direct observations had to be cancelled and were replaced by the analysis of video material). In addition, the review of scientific publications on the technologies contributed to a more complete understanding.

3.3 Data Analysis

The collected data was analyzed to distill relevant evaluation criteria to assess and compare the different dfab technologies. In a first step, we investigated the data for different recurring topics of importance. Out of this, we identified a first set of categories with which we sorted the dataset. In a next step, the information was compared, discussed and interpreted. This inductive process led to a first comparative overview of parameters relevant to the dfab processes and/or the resulting products. Through further iterative consolidation and refinement of the parameters, a set of eleven key parameters emerged that reflected the important aspects of the dfab technologies found in the data. These key parameters were summarized and classified in the presented evaluation framework. To make the framework applicable for industry, we developed a scoreboard to help industry rate their own needs and compare these needs to the characteristics of available dfab technologies.

Preliminary validity checks were performed with industry partners and the involved research teams of the assessed dfab technologies to see whether the proposed framework and scoreboard can accurately reflect their point of view.

4 Evaluated dfab technologies

4.1 Overview

This study evaluates five experimental manufacturing technologies currently under development at ETH Zurich. Albeit these technologies have certain similarities (e.g. they are all forms of additive manufacturing with concrete), there is a great variance in their processes and properties. As such, they can be classified as following under three categories: direct extrusion, 3D-printed formwork and slip-forming. To understand, compare and develop generalizable evaluation criteria, the respective technologies will be explained in the following chapters.

4.2 Description of technologies

4.2.1 Example 1: Direct Extrusion of Concrete

Concrete 3D-printing is directly layering small-aggregate concrete or mortar. The resulting layer thickness is usually in the range of a few centimeters. Here, a special concrete mix is needed: malleable enough to be extruded and adhere to the previous layer, yet firm enough to be able to support its own weight as well as the weight of the subsequent layers. To achieve this, accelerators are typically added at the extrusion point (nozzle) when printing the concrete to precisely control the setting behavior. Adding reinforcement in the layered is a challenge not yet fully resolved. One approach to achieving structural performance is to print cavities to place reinforcement and cast conventional concrete, using the printed concrete shell as lost formwork.

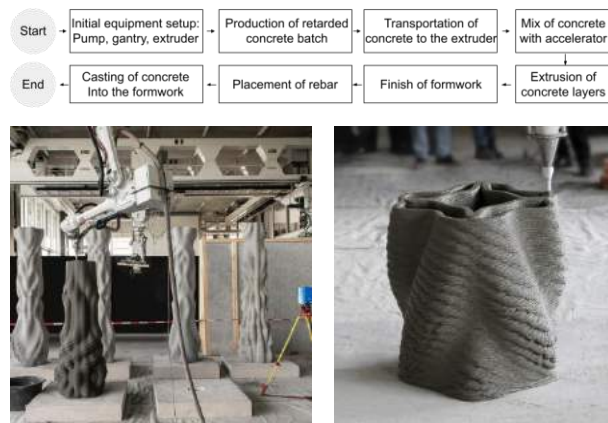

Figure 1. Concrete extrusion printing, process map and production images (credit: digital building technologies, ETH Zurich)

4.2.2 Example 2: FDM 3D-printed formwork

In this example, FDM technology is used to produce concrete formwork for complex shapes from thermoplastic material. After printing, the formwork is placed in a container filled with either sand or water simultaneously while pouring the concrete to overcome hydrostatic pressure. Self-compacting concrete is used to avoid possible damage of the thin formwork due to vibration. For stabilizing the formwork, printed support structures can be used. Generally, the formwork is destroyed during removal. Depending on the filament used, the material can be recycled and re-used for formwork printing. For more complex or fragile shapes, a dissolvable formwork material can be used, such as Polyvinyl Alcohol (PVA), a water dissolvable and biodegradable material [14].

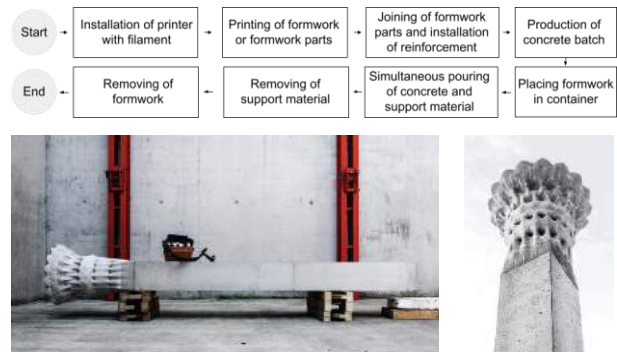

Figure 2. FDM formwork process map and results (credit: digital building technologies, ETH Zurich)

4.2.3 Example 3: Simultaneous FDM 3D-printed formwork

A system named “Eggshell” combines 3D-printing of thermoplastics (FDM) for formwork but pouring concrete simultaneously. By using set-on-demand concrete, hydration is controlled precisely during construction, reducing the volume of poured concrete in its fluid state at any given time. This minimizes the hydrostatic pressure, allowing for the use of thin-walled, material-saving formwork. Once the concrete is hardened, the formwork is removed and recycled [15]. The system allows standard reinforcement to be placed before or after casting and the use of post-tensioning in a post-production step.

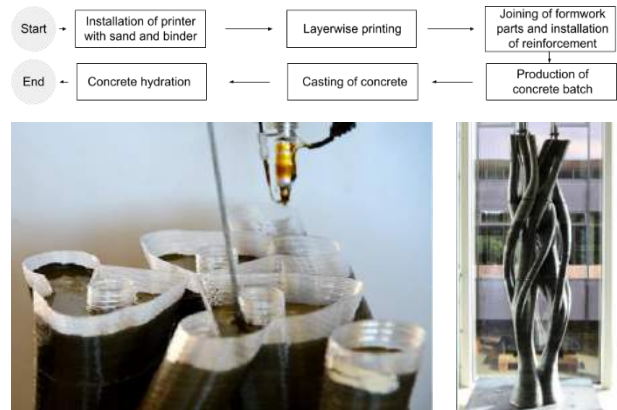

Figure 3. “Eggshell” process map and production (credit: Gramazio Kohler Research, ETH Zurich)

4.2.4 Example 4: Binder jet 3D-printed formwork

In this example, the process of binder jetting layers powder material (often sand) over a workable area and selectively bonds it using particular agents. Repeating this process several times leads to creating a 3D structure with sub-millimeter resolution. During printing, the powder bed acts as a support structure, allowing for overhangs and internal voids. Through the process of selectively binding, binder jetting has the great advantage

of not demanding an auxiliary support structure. At the end, the unbound material is removed and can be re-used [16]. The printed form acts as a stay-in-place or removable formwork which can be filled with a self-compacting concrete or shotcrete and reinforced conventionally and/or with the use of fibers.

Figure 4. Process map and result of binder-jet printed formwork (credit: digital building technologies, ETH Zurich)

4.2.5 Example 5: Concrete slip-forming

Smart Dynamic Casting (SDC) is a small-scale concrete slip-forming process allowing for changing cross-section during the forming process by means of a flexible or movable formwork [17]. SDC uses a computational interface to integrate slip speed, material feed and cross-section change. A set-on-demand concrete mix is used to control material setting at an exact and predictable point in time. SDC allows for the waste-free fabrication of bespoke concrete columns and reinforcement is placed prior to slipping. The technology was demonstrated to fabricate 15 bespoke mullions for DFAB HOUSE [18].

Figure 5. SDC process map and production (credit: Gramazio Kohler Research, ETH Zurich)

5 Results

5.1 Evaluation framework

We identified eleven parameters relevant to evaluate the match of a given dfab technology with a prospective user's needs. We also found three clearly distinguishable top categories under which to group these parameters: resources required by the process, the final product properties, and manufacturing at the interface between the product and processes (Fig. 6). The following subsections detail the categories and key parameters.

Figure 6. Evaluation Framework

5.1.1 Properties

Product properties strongly influence the application potential of dfab technologies. We identified four parameters pertaining to the finished product properties.

Freedom of Design – Dfab technologies can achieve a higher flexibility in design compared to traditional means of construction, where non-standard, geometrically complex design elements are typically material-, time- and cost-intensive. Typical design examples are undercuts, internal voids or cantilevers. Still, dfab technologies vary in the degrees of freedom they allow. Therefore, freedom of design can strongly determine the possible uses of a dfab technology.

Surface Quality – Surface quality affects durability for exterior elements, dimensional imprecisions can preclude use of the technology where tight tolerances are required, and the visual surface quality can be decisive for architectural applications. In the investigated dfab technologies, surface quality differs largely, displaying a rough, layered appearance, a microstructure from 3D printed formwork, a smooth extruded or a customized

finish. Surface quality is specific to each dfab process and affects both performance and market acceptance.

Multifunctionality – Dfab allows the construction of multi-functional building elements that combine varying functions such as structural stability, insulation, electrical or HVAC integration, and acoustics and daylighting. Examples are an anti-slip surface on a concrete stair, or the use of internal voids for the integration of building systems in a slab to reduce build-up height. Multifunctionality depends on the properties of the dfab application and can be a significant value-add.

Structural Properties – Dfab allows optimizing geometry precisely for specific load cases. This can increase structural efficiency and reduce material consumption. However, structural properties of concrete products are also highly affected by the type of reinforcement, which can be challenging to integrate in an additive concrete dfab. Options include ductile (e.g. fiber-reinforced) printing material, pre-placed rebar, post-tensioning, or adding reinforced concrete in pre-printed voids. Concrete dfab products vary in structural performance and therefore in their potential application.

5.1.2 Resources

A quantitative understanding of construction speed and cost is an important decision-making factor for early adopters when comparing dfab technologies and conventional construction processes. This is generally described by productivity, which measures output for a given input [19]. The input is mostly denoted in either time or total costs, which in itself usually contains workforce, material, and equipment costs. In addition, to estimate and optimize resource requirements more precisely, a qualitative understanding of the dfab process and its individual steps is important.

Time – Labor productivity is one of the most frequently used productivity measures in construction, since labor is usually the driving cost factor [20]. Accordingly, output per unit of time is an important factor for the industry adoption potential of a future industrial dfab process. However, additional factors need to be considered, since processes are a combination of automated and manual tasks [6]. E.g., for the analyzed additive processes, total production time consists of the processing speed dictated by the technology, equipment preparation (set-up and calibration), material preparation (formwork, concrete or reinforcement), manual tasks (formwork assembly, placing of reinforcement or casting of concrete), and concrete curing time.

Workforce – Dfab offers potential to increase process automation and reduce process supervision requirements,

impacting both labor costs and the required skillset of the workforce [21]. Therefore, despite uncertainties due to the early technology development stage, workforce is a key parameter for dfab adoption.

Material – Dfab technologies tend to be highly dependent on material properties. In the additive dfab technologies, the primary mortar or concrete material used is highly specific to each technology, with processing steps strictly coordinated based on the material properties. In addition, formwork print materials require equal consideration. Overall, material properties affect production speed, cost, and sustainability.

Equipment – Dfab technologies require specific production equipment, varying widely in complexity and ease of use. The investigated types of dfab exemplify this: direct extrusion requires a feed system and a mortar extrusion nozzle attached to a robot; printing formwork requires a filament or binder jet printer; slip forming uses a movable formwork and automated feed system. Furthermore, systems require differing degrees of integration between the individual parts controlled by integrated software, e.g. between the formwork printer and casting system, or the reinforcement and production system. Equipment is a central agent of dfab and a major cost-driver relevant for adoption decisions.

5.1.3 Manufacturing

The Manufacturing category subsumes key parameters of the manufacturing technology itself, pertaining to both the process and the resulting product.

Production Procedure – The production procedure is determined by the complexity of the manufacturing technology. Factors this complexity include the set-up of the production site, the number of required production steps, and the number of independent suppliers. Some technologies offer alternative sequences, such as pre-printing vs. simultaneous printing of a formwork or different reinforcement options. Understanding the production procedure is relevant for assessing the ease of adopting a technology and integrating it into established workflows and existing supply chains.

Scalability – Understanding scalability is a key parameter in technology adoption decisions. It describes whether a technology can be scaled in physical size, production volume, and product range for industrial production. Upscaling typically requires changes to the manufacturing set-up, e.g. to handle large material quantities, ensure robustness, and enable variation. As a result, the full-scale production process may differ substantially from earlier developments. Factors inherent in each dfab technology can hinder or enable upscaling.

Versatility – Versatility measures the potential of a dfab technology to produce different results and process different materials. Typically, early-stage dfab technologies are first implemented in exemplary prototypes or proof-of-concept applications. By default, these implementations do not cover all future capabilities of an emerging technology. Since some technologies offer a wider set of future applications, the number of manufacturing options a dfab technology affords could strongly affect the adoption potential.

5.2 Technology positioning scoreboard

Figure 7. Radar chart showing comparison of several technologies and industry need

Based on the evaluation framework, we designed a scoreboard to easily assess prospective dfab adopters' needs and market demands for a specific use case, and to evaluate them against a range of potential technology solutions for further development towards successful industrial application. We developed a detailed four-point rating scale for each of the eleven key parameters to provide a balanced evaluation of both potential product properties (what is the quality and function of the product) and process factors (how does the process work and what resources are required). The tool creates an easily readable radar chart to compare the user's own demands with potential new technology solutions, or to compare several technologies to each other (Fig. 7). The complete table of scoring categories for each key parameter is shown in the Appendix.

In a subsequent step, the scoreboard was tested by the researchers developing the five technologies by rating their own technology using the scoreboard. For

comparison, one industry partner not directly related to the research was asked to rate their process independently. Fig. 6 illustrated the result of the scoreboard testing. The industry rating (continuous line) represents the industry needs perspective, while the technology self-assessment by technology developers (dashed lines) opposes the range of available technologies. Therefore, the chart can support the industry participants in choosing one or several technologies for further consideration.

6 Discussion

6.1 Contribution and relevance

The contribution of this paper is a high-level, qualitative tool that serves to identify 1) industry needs, and 2) technology capabilities in the context of early-stage development of dfab for construction. The proposed framework and scoreboard are an attempt to provide technology providers and prospective adopters with the simplest possible way to understand and compare complex and developing technologies. The eleven categories should enable them to assess the complete picture and respective trade-offs between different dfab alternatives versus traditional construction processes. Albeit informed by the analysis of a limited range of examples, the framework is intended to be applicable also more generally across emerging technologies, materials and processes.

While the current tool allows a qualitative rating of all categories, the parameters relating to resources could be quantified. This has been done for early-stage dfab, e.g. in the productivity assessment by Garcia de Soto et al. [6]. However, quantifying the productivity of early-stage technologies necessarily leaves out qualitative factors that may bear potential to improve the future productivity of a technology regardless of current inefficiencies. There is great potential for future research to unify the qualitative and quantitative perspectives.

Future development scenarios of the scoreboard include an open-access online tool available to both industry and technology developers for self-assessment. In the longer term, the rating tool could be combined with a database of recorded technology and needs ratings.

6.2 Limitations

This is a purely qualitative study. In this early research phase, we only evaluated five exemplary technologies in one research center, and we studied only one class of dfab technologies, additive concrete manufacturing methods. While the variance in the technologies and processes allowed for some preliminary conclusions, a more diverse sample of technologies should be analyzed going forward. A quantification of some of the categories (e.g.

productivity measures) would further strengthen the research going forward and allow users of the framework a more informed decision making process. In addition, we see the need to expand the rating system to include more explicit sustainability parameters to reflect the increasing significance of this topic in technology investment decisions.

7 Conclusion

This research presents a preliminary industry evaluation tool for advanced dfab technologies to guide their investment decisions. We developed the framework with eleven evaluation categories by analyzing five different additive concrete dfab technologies using grounded research methodology. We then condensed this in a simple evaluation scoreboard to help industry compare their own needs with potential dfab technologies to meet them. While the tool with its categories is intended to work in a generalized way for various dfab technologies, this needs further verification through more research.

Appendix: Key parameter scoring categories

Freedom of Design	1	low - 1 type of geometry, no degrees of freedom	only one type of geometry can be produced with limited variations
	2	moderate - 2 degrees of freedom	only one type of geometry can be produced but more than 1 degree of freedom can be adapted (e.g. height and diameter)
	3	high - multiple degrees of freedom	customizable geometry (e.g. cross-section, height, custom angles, etc.)
	4	very high - all geometries possible	multiple types of geometry can be produced with multiple degrees of freedom, e.g. free-form, one-off geometries
Quality	1	low - high geometrical variations	very low quality (e.g. very high variations in geometry relative to model >10%, low surface quality (underground))
	2	moderate - moderate geometrical variations	moderate quality (e.g. variations in geometry relative to model <5%, low surface quality)
	3	high	quality and tolerances of high quality, e.g. architectural finish
	4	very high - no variations	very small dimensional variations relative to model, better surface quality than feasible with state-of-the art technologies
Multifunctionality	1	no function integration	no additional function
	2	partial function integration	little/peripheral additional functions, surface patterns
	3	high functional integration	integration of a central/substantial function
	4	fully integrated system	fully integrated system (e.g. plumbing, electricity, ...), multiple functions
Structural properties	1	low - e.g. underground	low structural performance, additional reinforcement required to provide load bearing capabilities
	2	moderate - e.g. partition wall	moderate structural performance, e.g. load-bearing wall for single-story structure or non-loadbearing wall
	3	high - e.g. column, load-bearing wall	good structural performance, e.g. load-bearing column, walls or shear walls
	4	very high - highly optimized structures	High-performing structure with optimized properties according to loading scenario; e.g. graded assemblies, material-optimized structures
Scalability	1	low	not scalable in geometry and mass
	2	moderate	scalable in either geometry or mass
	3	high	scalable to multiple components / a family of products
	4	very high	scalable to almost any product
Versatility	1	low	only one specific application possible
	2	moderate	one specific application with variations possible
	3	high	different applications possible (e.g. columns, walls, façade panels)
	4	very high	almost any application possible (fully versatile tool that can process multiple materials)
Production procedure	1	complex	lots of steps and support structures required, multiple independent suppliers/contractors
	2	moderate	moderate number of steps and support structures required, some specialized materials/sources
	3	simple	simple process with small number of production steps, little additional support structures required
	4	very simple	very few production steps, no additional support structures, fully integrated supply chain
Equipment	1	highly complex	highly complex equipment required (e.g. high investment costs, highly skilled labor required, frequent maintenance)
	2	complex	complex equipment required (e.g. moderate investment cost, substantial training of workers required, maintenance)
	3	moderately complex	specialized equipment required; can be operated by workers with little additional instruction or training, moderate maintenance costs
	4	not complex	no complex equipment required; no additional training required, no specialized skills required to operate
Material	1	very expensive	very high material costs (e.g. unique superplasticizer required)
	2	expensive	high material costs (e.g. multiple additives required)
	3	moderate	moderate material costs (e.g. special concrete mix)
	4	cheap	low material costs (e.g. no special mixes, recycled materials can be used)
Workforce	1	very high	highly labor intensive
	2	high	requires manual tasks and/or permanent supervision
	3	moderate	low/occasional manual tasks, moderate supervision
	4	low	fully automated with minimal supervision
Time	1	very high	fabrication time substantially higher than usual
	2	high	fabrication time higher than usual
	3	moderate/neutral	fabrication time slightly higher or equal than usual
	4	low	fabrication time lower than usual

Quantifying the complexity of 3D printed concrete elements

Abstract -

Freedom of shape enabled by 3D concrete printing (3Dcp) is often mentioned alongside productivity, technology progress, material optimization, and other benefits of the technology. When doing so, printed structures are described using qualitative terms such as “complex”, “double-curved,” and “geometric freedom”. However, such descriptions depend on the aesthetics and the observers’ interpretation, which renders an objective comparison between concrete objects difficult. To alleviate the ambiguities with such qualitative comparisons, this study proposes a quantitative metric consisting of two complexity coefficients – Intrinsic Complexity Coefficient (ICC) and Fabrication Specific Complexity Coefficient (FSCC). The ICC considers the concrete elements’ geometry using shape coefficient and mean curvature, whilst the FSCC defines the elements’ complexity within the context of 3Dcp (ease of printing, resolution). Thus, the ICC can be used to compare printed elements and the FSCC to determine which element is easier to print. Within this study, 10 pillars with varying complexity were designed and then graded according to the two complexity coefficients. Further, this evaluation was employed to adjust the construction duration consumed when calculating the productivity of elements produced using 3Dcp and traditional construction techniques. In such a way, the coefficients allowed to incorporate geometric complexity when comparing the productivity of various construction techniques, illustrating just one of many applications for ICC and FSCC.

3D Concrete Printing, Digital Fabrication, Freedom of Shape, Quantification of Geometric Complexity

1 Introduction

One of the most significant advantages of 3Dcp is its ability to create concrete elements of great geometric freedom. This is particularly relevant as traditional construction techniques fail to do so because of difficulties in manufacturing complex formwork, which is conventionally made from plywood, steel, or aluminum. On top of that, formwork sizes are standardized, which further limits the variety of shapes that can be manufactured. This is done to maximize their reuse, thus, minimizing the formwork cost per element. Nevertheless, even with simple shapes, formwork costs are significant and may account for 35-54% of the total construction cost and consume 50-75% of the total construction time [1].

Further, concrete is a convenient material to use with various formwork shapes due to its ability to flow into place before curing. However, this free-flowing ability is often not used to its full potential with conventional rectilinear

and cylindrical formwork. This opportunity seems wasted even more since 3D parametric modeling tools provide architects and structural engineers with enhanced design flexibility.

At this moment, concrete elements of conventional shapes can still be produced more productively using in-situ or precast methods when only the construction phases are considered [2]. More comprehensive studies have shown that alternative methods, such as the Mesh Mould [3], become more feasible when the complexity increases [4]. This leads to believe that rather than perceiving 3Dcp as a replacement for conventional construction techniques in normal ambient conditions, it should currently be perceived as an alternative for specific jobs that, for instance, require the ability to build geometrically more complex shapes. However, due to difficulties in quantifying the complexity of such shapes, printed elements that differ from conventional forms, such as a straight wall, are described only using qualitative terms like “complex”, “double-curved” and “geometric freedom”. Such descriptions are greatly dependent on the aesthetics and the observers’ interpretation of the complexity of a given element. Therefore, any analysis of how complex the respective elements are, is highly subjective. On top of that, it is difficult to provide a fair comparison between 3Dcp and traditional methods of production as it is not always possible to capture the added benefit of printing complex geometries. Thus, this study proposes two coefficients aimed to quantify complexity and allow the above-mentioned comparisons.

Of course, 3Dcp offers other benefits besides from creating more geometrically complex elements. Nevertheless, exploring these benefits is outside of the scope of this paper.

2 Methodology

This study proposes two coefficients for evaluating the geometric shape complexity of a concrete element. First, the Intrinsic Complexity Coefficient (ICC) captures the geometric complexity of the element itself while the Fabrication Specific Complexity Coefficient (FSCC) relates to how difficult the element is to print. This section describes how the two coefficients are derived and how they can be applied to a productivity analysis using an example of 10

pillars designed within this study.

2.1 Designing 10 Pillars with Varying Geometric Complexity

10 pillars were designed as part of this study using Rhino 6, a 3D computer aided design software, and its in-built plug-in Grasshopper, a visual programming environment [5]. These pillars, shown in Figure 1, display varying levels of geometric complexity that can be created using 3Dcp. All of the pillar designs stem from the same parametric Grasshopper script [6], in which multiple parameters such as the degree of the NURBS curves, radius of cross sections at different heights, and number of side ornaments were varied to create 10 different pillars. The pillars are not designed to carry any axial, shear, bending or torsional loads and are intended for architectural purposes only. Design was limited so that that overhangs could not be printed at angles greater than 10.6° due to printing and material constraints. All pillars are 200 cm tall, with a varying diameter from 25 to 44 cm.

Figure 1. 10 pillars of varying geometric complexity

2.2 Intrinsic Complexity Coefficient

To counter the ambiguity that stems from describing concrete shapes using qualitative terms, we introduce a quantitative geometry-specific Intrinsic Complexity Coefficient (ICC). We suggest that the ICC is dependent on the local geometries that make up the elements. More specifically, we classify the local geometries using the Shape Index (SI) and the mean curvature of the local geometries. The reasons for choosing these parameters and how they are combined are described in the following sections. The conceptual make-up of the coefficient can be seen in Figure 2.

By employing the ICC, a more systematic method of comparing different concrete elements can be introduced. This is relevant, for example, for comparing the levels of development of 3Dcp technology over time, which can

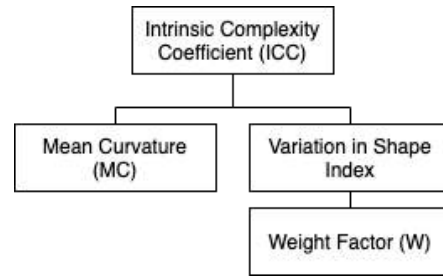

Figure 2. Components of the Intrinsic Complexity Coefficient (ICC)

be done by noting the range in ICC of elements that the technology is able to manufacture.

2.2.1 ICC: Shape Index, SI

The Shape Index (SI) is a non-dimensional and scale-invariant coefficient in the range $[-1, 1]$ [7]. The lower end of the range (-1) represents a spherical cup (concave) while the higher (1) a spherical cap (convex). The shapes with an SI in between the two limit values vary, representing shapes such as a rut, saddle, ridge, dome etc. The index describes the shape of a local geometry using the principal curvatures of the locality (Equation 1) [7]. Instead of using several values to describe a local geometry, SI provides a single encompassing index that reflects the shape of the local geometry independent of its size.

$$SI = \frac{2}{\pi} \arctan\left(\frac{k_2 + k_1}{k_2 - k_1}\right) \quad (1)$$

where $k_1 \geq k_2$ and k_1 and k_2 describe principal curvatures.

For the ICC, we calculated the SI of each pillar at equally spaced points on the pillars' surfaces. In this study, we used 5050 points as the computing power did not allow for more. However, in the future, a specific number of points per surface area should be chosen for more consistent comparisons. The SI was used to map the variation in local geometries for each pillar by obtaining ranges of the SI. The ranges with at least 1% of the total points were used for further calculations thus discarding local geometries that appeared in insignificant amounts. For each range the mean curvature was calculated and the percentage of points in a certain range was used to obtain the weight factor. This is explained in detail in section 2.2.3.

2.2.2 ICC: Mean Curvature, MC

To understand why curvature can serve as a relevant metric in determining the complexity of an element, we first define what constitutes a simple shape. In this regard, straight lines and flat planes intuitively seem like the most

simplistic shapes in 2D and 3D spaces, respectively. More complex shapes are achieved from altering a line or a plane, which can be observed in the increase in difficulty in the mathematical expressions of such elements. Based on this, a parameter like the curvature, which describes the extent of which a shape differs from a flat object (i.e., line or plane), can be used to describe the complexity of a shape. Two types of curvatures are defined in differential calculus: intrinsic and extrinsic [8]. Intrinsic curvature relies solely on the algebraic properties of the surface itself and does not require any knowledge of how it is embedded in the surrounding space. A type of this curvature is the Gaussian Curvature. In simple terms, it describes whether an object could be transformed into a flat plane without stretching the surface of the respective object. If the Gaussian Curvature is zero, one of the principal curvatures must have been 0 and the surface can be rolled out into a flat plane. To demonstrate, we can imagine a sheet of paper rolled to form a cylinder. Although the cylinder is curved, the paper can easily be laid flat, thus, the Gaussian Curvature equals zero. Within the context of this study, we would consider a cylinder to have a higher curvature than a plane, thus, the extrinsic curvature is more appropriate than intrinsic when considering the local geometries.

The extrinsic curvature can be described using the mean curvature, which is the average of the two principal curvatures (Equation 2). It describes the curvature of an element based on its surface properties and the fashion in which it is embedded in space.

$$MC = \frac{k_1 + k_2}{2} \quad (2)$$

where k_1 and k_2 are the principle curvatures.

2.2.3 ICC: Weighing and forming the coefficient

As some of the local geometries are more ubiquitous in the concrete element than others, we introduce a weight factor, W , that is dependent on the number of respective local geometries in the element ($n_{local\ geometry\ l}$). It is defined as the natural logarithm of the percentage of shapes that are within the respective SI range squared (Equation 4). To not skew the results by local geometries that appear only a small fraction of times, only the ranges with at least 1% of the total measured local geometry count are included. For a similar reason, the natural logarithm is squared to make sure that the coefficient scales over a greater range and gives greater weight to local geometries that are more present within the element.

$$N_l = \frac{n_{local\ geometry\ l}}{n_{all\ local\ geometry}} * 100\% \quad (3)$$

where $N_l \geq 1$. N_l is the percentage of local geometries representing a specific local geometry l and n represents number of local geometries.

$$W_l = \ln(N_l)^2 \quad (4)$$

where W_l represents the weight of the local geometry shape l .

In addition, the average mean curvature for every SI range is calculated by summing all the mean curvature values for every local geometry within a range and then dividing by the number of local geometries within the same range (Equation 5).

$$MC_l = \frac{\sum_{i=1}^{N_l} MC_i}{N_l} \quad (5)$$

Once the average mean curvature value for points in an SI range is obtained, we multiply the value with the weight for the respective range. These multiplication values for all SI ranges are then added together to find the ICC. The code for obtaining the values for calculating the ICC can be located in [6].

$$ICC = \sum_{l=1}^L (MC_l * W_l) \quad (6)$$

2.3 Fabrication Specific Complexity Coefficient

While the ICC can assist in comparing produced elements, it cannot be used to determine which design is easier to fabricate using 3Dcp. Therefore, we suggest a Fabrication Specific Complexity Coefficient (FSCC) to measure how complex the printing process of a concrete element is.

To better illustrate the need for such a coefficient, we can imagine a cone-like concrete element. The ICC would be the same regardless of whether the cone is placed standing on its larger base or on its smaller base. However, if the cone had to be printed standing on its smaller base, gradually increasing in size as the element is printed, it would be more difficult to fabricate than if the cone was placed on its larger base. This demonstrates the need for FSCC. Using both coefficients in junction can be useful when comparing existing 3Dcp technologies - their capability of creating an object of a certain ICC by using effort described by FSCC.

FSCC is suggested to be a function of how easy the element can be printed (i.e., ease of printing) and how well the final element will reflect the parametric model (i.e., resolution). The breakdown of the FSCC is shown in Figure 3.

These properties were obtained by performing simulations in Grasshopper. They are described in greater detail in the following sections.

Table 1. Properties used in the simulation to quantify the ease of printing, where t is curing time in minutes[9]

	Property	Quantity
Element Geometry	Object Height	2m
	Object Diameter	25 – 44cm
Printer Properties	Layer Height	1cm
	Printer Speed	0.5mm/s
	Specific Weight	20.2kN/m ³
	Young's Modulus	0.0781 + 0.0012 * t MPa
Material Properties	Shear Modulus	$\frac{0.0781+0.0012*t}{2.6}$ MPa
	Yield Strength	5.984 + 0.147 * t KPa
	Coef. of Thermal Expansion	0.00001°C ⁻¹

Figure 3. Fabrication-Specific Complexity Coefficient, FSCC

2.3.1 Ease of printing, B

The ease of printing is dependent on a multitude of variables such as the:

- material properties (yield strength, Young's modulus, stiffness and the rate of change of these properties over time while the material solidifies),
- printer properties (rate of extrusion and printed layer dimensions),
- geometry of the element (size and curvature).

To account for all of them, we used a simulation script in Grasshopper created by Witteveen+Bos, Karamba3D, Nanyang Technological University, and used in studies at the Eindhoven University of Technology (TU/e) [9]. It analyzes when a printed element would buckle during the printing process and accounts for the variables mentioned above. In this study we focused on the height of the element that can be printed before it buckles as the output of this simulation. The original authors of the simulation empirically found that when using their materials and technologies an element would buckle when the displacement exceeds 1 cm. For simplicity, all the properties used in the simulations in this study are the same as originally assigned by the authors of the simulations. The only exception is the printing speed, which was decreased to exemplify the difference in the height that can be printed before an element buckles. These parameters are shown in Table 1.

These properties can be adjusted based on the materials and technologies used. Similarly, the 1 cm limit for buckling varies based on different properties. Because of this variability, the same concrete element can have a different ease of printing and, thus, a different FSCC if the elements are manufactured at different facilities, unlike the ICC, which remains the same.

2.3.2 Resolution, R

Similar to how a picture's resolution determines how well details are visible in a photo, the dimensions of the printed layers determine how well the final printed element will resemble the parametric model. It is important to account for this, as the height of the printed concrete layers can restrict how geometrically intricate a printed concrete element can be. Thus, we suggest considering the volumes of the parts of the printed element which differ from the parametric model. This idea is demonstrated in Figure 4, which shows pillar 10 if it would be printed with a layer height of 4 cm. The green color indicates the excess printed concrete and red color shows the concrete missed in relation to the parametric model.

Figure 4. Extra concrete printed (green) and concrete missed (red) for pillar 10 if it would be printed with a layer height of 4 cm

To achieve a measure of resolution, we created a Grasshopper script [6] which identifies these parts (of extra concrete and omitted concrete) and adds their volumes. In this script, it is assumed that no sagging of concrete occurs. The percentage difference of concrete volume in the parametric model and the printed element is used as the final value.

2.3.3 FSCC: Combination of the parameters

Both the ease of printing (B) and the resolution (R) are expressed as percentages before they are used to calculate the FSCC. In the former case, the height at failure is used to calculate the height left until the top of the element. This difference is then used to measure what percentage of the pillar was left until completion as shown in Equation 7.

$$B = \frac{h_{total} - h_{failure}}{h_{total}} * 100\% \quad (7)$$

where h_{total} is the height of the pillar and $h_{failure}$ is the height at which the pillar will collapse (obtained from the simulation [9]).

Similarly, to account for the resolution, the volume of the concrete that is printed and/or omitted with respect to the parametric model is expressed as a percentage fraction of the total concrete pillar volume (Equation 8).

$$R = \frac{V_{extra} + V_{omitted}}{V_{total}} * 100\% \quad (8)$$

In both cases, the larger the value, the greater the complexity of the element that the parameter is describing. Finally, the FSCC is obtained by multiplying both results as shown in Equation 9.

$$FSCC = B * R \quad (9)$$

A larger FSCC indicates greater complexity in 3D printing an element.

2.4 Productivity Analysis

An example of the use of the ICC is within productivity analysis. Productivity data can be adjusted using the ICC to provide a fairer comparison between different production techniques. When producing more complex elements (or elements with a higher ICC), the process is more productive as, in this time, a more complex design is achieved than that of a simpler one (e.g., circular column). Thus, a scaling factor is introduced to reduce the time to account for the added complexity in the productivity comparison. The scaling factor, f , is obtained as shown in Equation 10.

$$f = ICC + 1 \quad (10)$$

The adjusted time is not meant to be a reflection of real-life production duration, but a measure used for comparing productivity. It is calculated as shown in Equation 11.

$$T_{adj} = \frac{T}{f} \quad (11)$$

where T_{adj} is the adjusted time, T is the real-life duration of production and f is the scaling factor.

3 Results

Pillars of varying geometric complexity were designed with Rhino 6 and Grasshopper [5]. The following sections show the complexity analysis of these pillars as outlined in the Methodology, as well as the implementation of ICC in productivity analysis.

3.1 ICC – Results

The shape index was obtained by following the process outlined in Section 2. Although variance of SI was not directly used in obtaining the ICC, the weight factor is influenced by how varied local geometries are. The ICC will be increased in value when there is a larger variety in the shapes of local geometries in the object. This is confirmed in Figure 5 where the relationship between variance of the shape index and pillar number is illustrated. A general trend can be noticed, where, with the exception of pillars 5 and 6, the variance of the shape index (SI) increases with the pillar number, similar to how the ICC increases with the pillar number (Figure 7).

Figure 5. Variance of Shape Index for Pillars 1-10

The mean curvature was obtained in Grasshopper and is shown for each pillar in Figure 6.

The results for the shape index as well as the mean curvature were weighed and combined to give the values of the Intrinsic Complexity Coefficient (Figure 7). It can be seen that although shape index variance was very low for pillars 5 and 6, the mean curvature is the highest for these pillars, resulting in comparable values for their ICC. This shows the trade off between variation in local geometries and mean curvature that we had during the design of the 10 pillars. This is because printing an object with many

Table 2. Pillar parameters required for the FSCC

Pillar #	Volume difference (%) (Layer h = 1 cm), R	Height at failure (cm)	Percentage of total height not reached (%), B	FSCC	Rank
1	0.10	192	0.04	0.00	1
2	0.10	168	0.16	0.02	2
3	0.18	168	0.16	0.03	3
4	0.60	172	0.14	0.08	4
5	0.45	156	0.22	0.10	5
6	0.84	152	0.24	0.20	7
7	0.79	144	0.28	0.22	8
8	1.07	144	0.28	0.30	10
9	0.55	140	0.30	0.17	6
10	1.27	156	0.22	0.28	9

Figure 6. Mean Curvature for Pillars 1-10

different local geometries that would also have large mean curvatures was not a viable design option due to the restrictions on maximum printing angle for the 3D printer at the Besix3D facility [10].

Figure 7. ICC and FSCC of each pillar

Pillars 9 and 10 obtained the highest values for the ICC, as they incorporated both varied local geometries and large mean curvature. Pillars 1 and 2 had the lowest ICC values as expected due to their simple design (circular pillar and rectangular pillar with rounded corners).

3.2 FSCC – Results

The parameters for each pillar required for obtaining the FSCC are listed in Table 2. By multiplying the percent volume difference with the percentage of total height left

to print, we can obtain the FSCC. Similarly, we display these coefficients in Figure 7 to visualize the differences in the fabrication complexity between the different pillars.

As expected, the FSCC for the first two pillars is the lowest. These pillars could also be constructed using in-situ and precast construction techniques with no foreseeable difficulties. Pillar 8, is the most difficult to construct as per the FSCC.

The results show that the ICC and FSCC have an R^2 value of 0.60, meaning that 60% of the FSCC data can be explained by the ICC.

3.3 Productivity Analysis

Data from a productivity study that compared the productivity of constructing a column with 3Dcp, precast and in-situ techniques [2] was employed. The data was adjusted using the scaling factor obtained from the ICC. By implementing this scaling factor, the increased complexity - the increased ICC value - for the 3Dcp columns was taken into account, acknowledging the added benefit of the design for the 3Dcp columns, thus, providing a fairer comparison between the three production techniques. Although the elements in this study are of a different design than in the productivity study, the production time for 3Dcp is more dependent on the printing speed and volume of material used. As the dimensions are comparable between the 10 columns designed as part of this study and the Concrete Choreography columns used in the productivity study [2] [11], the duration can be assumed to be the same for this analysis. Results can be seen in Table 3.

The time (T) is taken from the productivity study [2], the ICC for the in-situ and precast columns is assumed to be 0.105, which is the same as the ICC for pillar number 1, as all of these are circular columns of relatively similar size. The factor f and $T_{adjusted}$ are calculated as outlined in the previous section.

It can be seen that after scaling, 3Dcp becomes the more productive production method for some of the columns.

Table 3. Scaled time of production

Method	T(h)	ICC	f	$T_{adjusted}(h)$
In-situ	54.2	0.105	1.11	49.05
Precast	50.7	0.105	1.11	45.88
		0.105	1.11	53.39
		0.140	1.14	51.75
3Dcp	59.0	0.258	1.26	46.90
		0.267	1.27	46.57
		0.385	1.39	42.60
		0.404	1.40	42.02
		0.645	1.65	35.87
		0.668	1.67	35.37
		0.965	1.97	30.03
		1.071	2.07	28.49

Productivity of in-situ is exceeded for pillars with ICC 0.258 and higher and productivity of precast is exceeded for pillars with ICC 0.385 and higher.

4 Limitations

There are several limitations to this study. First, the coefficients were created empirically by considering the factors that influence complexity and describe a 3D shape. All of the decisions made in the creation of the coefficients had logical reasoning as well as were generally backed by mathematical theory. However, this approach could have resulted in a biased and partial selection or omission of elements that make up the ICC and FSCC, as well as the way the coefficients are weighed.

Second, the ICC is made to evaluate curved designs. If a design would include sharp edges and straight planes, the ICC would be significantly lower. This is because in this study we define the opposite of complexity to be a straight line or plane. Thus, for future studies, another element in the ICC should be introduced to consider a design with straight edges to also be of a certain complexity.

Third, only 10 elements are evaluated raising concerns of a lack of statistical relevance. Although the obtained results follow expectations and work well with the designs in this study, the coefficients should be tested on more elements of different dimensions and designs to verify their functionality or find ways to improve them.

Last, in the productivity analysis several values were approximated or assumed based on similarity, such as the ICC values of the in-situ and precast columns or the printing time for the 3Dcp pillars. Nevertheless, these are reasonable and the printing time for the 10 pillars is more likely overestimated than underestimated due to the Concrete Choreography columns [2][11] being larger. Thus, in reality the 3Dcp pillars' values for $T_{adjusted}$ would likely be lower than what they are in this study, resulting

in 3Dcp still proving to be more productive than traditional methods for pillars with higher ICC.

5 Discussion

This study offers two coefficients - ICC and FSCC - the former to quantify the complexity of concrete elements and the latter to quantify the effort in producing them using 3Dcp. Within the scope of this study, the coefficients proved effective, providing results that aligned with expectations and could be employed for productivity analysis.

The relationship between the ICC and FSCC was explored. For the 10 pillars used in this study, it was found that ICC and FSCC had an R^2 value of 0.60. The coefficients are not strongly correlated, yet show a generally similar trend where 60% of the variation in the ICC can be explained by the FSCC values. This supports the idea that for 3D printing concrete elements, the shape/design of the element (as long as it fits within the constraints of the printer, such as overhangs and maximum angles) does not directly impact the difficulty of printing. This contrasts with traditional methods, where generally, an increase in shape complexity results in increased difficulty in production, leading to additional costs.

The FSCC results also align with our expectations, as they generally increase with the ICC of the pillar. It is important to note that the coefficient does not only depend on the design but also the materials used and the printer's parameters, such as speed of extrusion, as they are significant factors in the buckling simulation. Thus, FSCC can be considered a good representation of the difficulty of the exact manufacturing process planned - specific to the facility, technology, and materials chosen. This enables to use FSCC for choosing the printing process for a specific object, including the choice of material and printing settings. Furthermore, FSCC can be used to compare 3D printing technologies and their development by looking at how FSCC would decrease for the same concrete element when printed with improved materials/printers. In future studies, FSCC could be created for various techniques (e.g., in-situ, precast) to allow direct comparison and aid in choosing a production method.

The coefficients were only tried on the 10 designed pillars, but they can also be applied to other construction elements. The transferability was not explored in this study, but we expect no significant difference of the ICC and FSCC's applicability for different elements. The only issue that may arise is that the coefficients are not normalised, thus, elements might be difficult to compare if the objects are of very different dimensions.

Lastly, productivity analysis was carried out for the 10 pillars as well as columns constructed with in-situ and precast methods. The results showed that, after scaling, 3Dcp does, in fact, become more productive than in-situ

and precast methods for pillars with higher ICC values. This aligns well with expectations, as pillars with the two lower ICC values could be produced using traditional construction techniques and would likely be less costly and time-consuming than if produced with 3Dcp. However, the pillars with higher ICC values would be extremely difficult, if not impossible, to produce with the traditional methods. Thus, the analysis supports the notion that for more complex designs (higher ICC) 3Dcp is more productive than traditional construction methods. It needs to be taken into account that many values used in this analysis were approximated. To obtain the exact values, the pillars would need to be printed, and the process for calculating the ICC would have to be carried out for the circular column of the exact dimensions as used in the productivity study [2]. The example was shown as a preliminary attempt at considering complexity within productivity, with the hope to aid in the implementation of such creative and original designs in construction projects.

6 Conclusions and Outlook

Overall, the two complexity coefficients - ICC and FSCC - are a good start in quantifying the complexity of concrete elements, yet require further testing and perhaps alterations. With parametric design as well as different manufacturing methods being developed and implemented in industry, it is important to perform not only a qualitative but also a quantitative comparison between designs and production methods. An example of how ICC could be employed in productivity analysis was shown, providing results that aligned with expectations. The adjusted time showed that after scaling, for pillars with higher ICC values, 3Dcp is the more productive method of construction when compared to precast and in-situ.

In future studies, the coefficients could be improved by changing the way the weights of the variables are distributed, as well as by altering the variables that were included in the coefficients. Nevertheless, for the scope of this study, the ICC and FSCC can be considered an appropriate representation of the complexity of a concrete element and the ease of manufacturing it using 3Dcp.

7 Acknowledgements

This research was funded by the NYUAD Post-Graduation Fellowship 2019-2020. We also want to thank Aayush Aayron Deo for assisting with printing small-scale plastic prototypes of the pillars used in this study.

Email: nawal.alhanaee@moid.gov.ae, Tahani.Yousuf@moid.gov.ae

Abstract

A significant advancement has been contributed by the break-through technologies like smart contracts and blockchain in banking industry, healthcare industry, and construction industry (Zhang 2020). Blockchain can be defined as the distributed public ledger that records all data transaction that is exchanged and shared between the parties within the systems (CEMEX Ventures 2020). The blockchain offers various opportunities and advantages for all the involved parties within an enterprise (Penzes 2018). A synchronized and secure record of transactions are provided to the involved parties. The confirmation of all participants within the system is required in order to finalize the data transaction (Nicosia 2019). Every sequence of transaction is recorded by the blockchain ledger, from beginning to end, in certain irreversible and verifiable records of all transactions which are ever made. There are abundant areas of application of blockchain technology. Smart contract has an important role in the digitalization of conventional paper contracts and provides grounds for the application of blockchain technology (Strategy 2019).

This research intends to evaluate the use and application of smart contract, via blockchain technology, in the construction and infrastructure industry of the COVID-19 pandemic. Current COVID-19 pandemic condition has resulted in wider range of negative impacts on the construction sector in UAE, thereby affecting large parts of UAE economy (Gupta et al., 2020). There has been identified significant need of development and implementation of effective digital tools for data management that require least resources. In doing so, the concept of blockchain technology has emerged and investigated by the scholars in construction sector (Salama & Salama 2018). By employing the concepts of smart contracts under blockchain technology, the construction sector in UAE can be improved (Constructible 2020). This may also result in alleviating the negative impacts of COVID-19 in construction sector of UAE. The research findings will be important for the

professionals in construction sector of UAE and in delivering the concept of blockchain technology for construction industry.

Keywords –

Smart Contract; Blockchain technology; COVID-19; Civil Transaction Code

1 Introduction

A smart contract can be defined as the computerized transaction protocol that is run on blockchain public network and seeks to replicate legally binding contracts through a code (Level X Supply 2020). Instructions and clauses could be coded in the program (Dubai 2016). When the coded contractual conditions are met, the program is executed which pertain that the smart contracts are self-enforcement (Duy et al., 2018). Smart contracts enable automatic data transfer and embedding of payment amounts, allowing digital transaction information exchange among the contract parties after the instructions are reached. Due to their binary logic, smart contracts are decisive and the contract conditions function depends on coded scope satisfaction (Chamola et al., 2020).

Construction sector in UAE has been constantly advancing and revolutionizing and with the involvement of digitalization, the prospects in construction sector has become significantly efficient (Salama & Salama 2018). Further inclusion of information technology and other digitalization aspects in the construction sector have been focused after the global pandemic situation due to COVID-19. Blockchain technology has resulted in bringing the smart technology back to the business sectors and construction industry has been efficiently advantaged through this technology (Nicosia 2019). Smart contract is also defined as the digital contract which serves its purpose when the predefined conditions are met. According to Penzes (2018), Ethereum platform was one of the first blockchain related application which possessed the potential to execute computer scripts and codes on the blockchain. The code was secured on the blockchain and the input conditions

came from the blockchain as immutable data. Blockchain technology, implemented in the construction sector of UAE, is predicted to save over \$ 3 Billion USD, as forecasted by the whitepaper of the Dubai Future Foundation (DFF), Center for the Fourth Industrial Revolution UAE (C4IR UAE), and World Economic Forum (WEF) (Anderson 2018). The amount forecasted is another noteworthy figure for the construction of another skyscraper project. The integration of blockchain technology has also been predicted to eliminate 77 million work hours per year and 398 million printed documents – thereby saving money, time and resources. In UAE, more than 100 stakeholders from 60 governmental and non-governmental entities have been exploring the implementation prospects of blockchain technology (Dubai 2016).

In the face of COVID-19 pandemic, governments around the world have efficiently introduced measures to protect the economies, businesses and citizens. In UAE, numerous measures have been undertaken that are vital to the construction sector of UAE (Bishr 2019). The construction industry is vital for the economy of UAE and COVID-19 has significantly impacted the construction sector UAE, thereby negatively influencing the economy. Various negative impacts on the construction sector in UAE have been highlighted which include disruption events and traditional delays contributed by the breach of contract by one of the parties (AlTaei et al., 2018). Moreover, suspension claims are another emerging issue contributed by COVID-19 in the construction sector of UAE. Some developers may look to suspend their contracts due to the uncertainty of COVID-19 pandemic (Hargaden et al., 2019).

2 Methodology

2.1 Research Design and Approach

Primary research design has been selected for this research with a qualitative approach. Justification for the use of primary research design in this research can be attributed to the requirement of analysis of perspectives and views of professionals in the construction sector regarding the implications of use of smart contracts under blockchain technology. Expected implications of this technological approach in the construction sector can be perceived positive since various negative influences have been identified on data storage, exchange and management which has resulted in delays in construction projects and suspension claims.

Qualitative approach has been identified effective for the researches conducted under

exploratory paradigms (Thomas & Magilvy 2011). Qualitative approach facilitates an in-depth analysis of research problem being addressed and also facilitates the researcher to integrate their own perspectives and views (Tesch 2013). There are various advantages of qualitative approach such as presence of large amount of data, it provides a detailed and in-depth analysis of the qualitative data, and also encourage the participants of the study to expand their responses (Silverman 2016). These advantages of qualitative approach are the major justification for selection of qualitative approach for this research.

2.2 Sampling and Participants

Random sampling strategy has been applied in this research and the population targeted for interviews included professionals working in the finance and information technology department of the UAE organization. Simple random sampling approach provides the equal opportunity to each of the participant from the target population (Thomas & Magilvy 2011). Randomly chosen sample from the target population represent the total population in an unbiased fashion. Before the selection of sample participants, it was ensured from the participants that their construction company has been using blockchain technology for smart contracts. Selection of random sampling strategy for this research can be attributed to the unbiased representation of total population by the selected sample. Sample of two participants was selected for the interviews. Before conducting the interviews, informed consent as approved was taken from each of the participant to ensure complete ethical compliance.

2.3 Data Collection and Instrument

Researcher selected telephonic semi-structured interviews as the instrument for data collection and participants were interviewed for 10 minutes. Telephonic interviews were recorded and transcripts were generated from the recorded data. Primary data has been therefore collected in this research which ensured that each participant's views and perceptions, associated with the use of blockchain technology, have been reviewed and their experiences and behavior has been reviewed. This resulted in-depth evaluation of responses of participants to the questions. There are various advantages of semi-structured interviews which is why researcher has selected this approach of primary data collection. It allows the interviewees to respond efficiently to each of the questions of researcher. Moreover, it encourages two-way communication between the participants and interviewer which enables demonstration of various aspects related with the research problem being explored. Semi-structured also allow the respondents

to open up to the sensitive information that has been investigated however, no significant sensitive questions have been involved in the interviews. Semi-structured interviews enable efficient collection qualitative data and enable comparison of this data with the past researches. Primary qualitative interviews enabled collection of sufficient data as required for this study which was later analyzed by application of qualitative data analysis technique.

3 Data Analysis

Primary data collected through semi-structured interviews has been analyzed through application thematic analysis technique. Application of thematic analysis technique in this research can be justified with the reason that it enables familiarization of the data collected through interviews as well as allows researcher's own perceptions and opinions during the interpretation stage (Guest et al., 2011). For the analysis of qualitative data, thematic analysis technique is widely applied in the researches, particularly in case of data collected through interviews and discussion (Braun & Clarke 2012). Thematic analysis technique enabled thorough review of interview transcripts multiple time and familiarization with the collected data, which eventually results in extraction of potential themes which have been presented in the findings section.

4 Ethics

Research ethics are the codes and norms that a researcher is required to follow at each stage of the research to ensure integrity and quality of the research (Thomas & Magilvy 2011). Since the research was primary in nature, ethical compliance was followed in terms of beneficence, informed consent, confidentiality, and anonymity. Under the confidentiality ethics, participants' as well as organization's private data was protected and secured. Moreover, pseudonyms were assigned to each of the participant. Approved written informed consent was received from each of the participant as well as the research institute for the execution of this research project. During the interviews, no sensitive question was investigated from any of the participant.

5 Limitation

Research encountered certain limitations which narrowed down the scope of the research to significant extent. The major limitation was the global pandemic situation caused by COVID-19 which restricted the activities of researcher such as selection of interview setting that was convenient for the participants. Moreover, time constraints resulted in conduction of only 10-minute interviews with the participant.

6 Findings

Both participants belonged from the similar organization; P1 from the IT department and P2 from the finance department. Both participants were interviewed separately so that their responses can be efficiently recorded, analyzed and interpreted by the researcher. Interview questions are presented in the appendix 1. Participants were initially investigated whether they are aware of the idea of blockchain technology and smart contracts. According to the response of P1, "blockchain technology, as I perceive, is in digital journal form that enables digitalized management of data and the provenance of the digital asset." P1 also stated that the company has implemented the smart contract and blockchain technology after the pandemic condition due to COVID-19. Response of P2 was also similar and both respondents were identified to be well-aware of the blockchain technology, its application and the possible advantages their company may have in future due to implementation of this technology after the pandemic condition is over. Both participants responded that their company significantly advantaged from the smart contract strategies under the blockchain technology. P2 also quoted that "for all the aspects of construction project, blockchain technology can create single source of truth and this can be combined with the 'Building Information Modelling'. Such model can complement the activities of IT specialists and can become trusted digital twin of an asset, which may support the construction and design along with maintenance and operation."

Participants were investigated about the Emirates Blockchain Strategy 2021 and its impacts on their company's performance during COVID-19 pandemic. the strategy was highlighted to be based on the four major themes including happiness of citizens and residents, improvement in governmental transactions, improvement in the legislative compliance, and improved leadership.

Participants were investigated about the prospective implications they consider and associated with the implementation of blockchain technology. According to the P1, "traceability and transparency is predicted to be improved with the blockchain technology and in my opinion, smart contracts in construction sector are required to be managed through digital means of data gathering, storage and exchange. Current pandemic condition is challenging for the construction sector and it has restricted the conventional means of project compliance with the contract details." P2 added "there are various implications predicted and associated with the

blockchain technology. These include transparency in the data exchange, easy tracking of the data associated with the project details, and sustaining the credibility of the data”.

Participants were investigated about the perceived and observed negative impacts of COVID-19 pandemic on the construction industry in UAE and how their company has been affected. Participants counted various negative impacts on the construction sector in UAE which included halting of the spending on new projects, suspension of salaries, suspension of new projects (as responded under the reference of EMAAR Dubai). P1 also stated that “the COVID-19 pandemic has threatened the UAE construction sector by restricting the activities of project management at each level. UAE Construction Industry Think Tank has issued the white paper under which, all the construction companies have been addressed to adopt digitalized methods of project execution in different departments.”

Participants were investigated whether application of blockchain technology has affected citizens and residents in UAE. Responses were affirmative as the respondents stated that the employment of blockchain technology-based construction project contracts had positive impacts on the citizens and residents of UAE. According to P2, “payment delays were mitigated by the use of blockchain powered contracts in construction sector which was based on automated payment mechanisms. Also, this claim is made by the proponents of disruptive technology that involvement of blockchain technology in construction is going mitigate the issues contributed by the COVID-19 pandemic.”

Participants were investigated for the implications of the use of blockchain technology in improving government efficiency. According to the response of P2, “among the Middle East countries, UAE stands among the top countries that has adopted technology in its diversity of business sectors. Emirates Blockchain Strategy 2021 has been launched to mitigate the payment delay issues in construction sector and to convert 50% of the government transactions into the blockchain platform by 2021. The Strategy is expected to improve the data management and reduce the incidences of payment delays in the construction projects thereby improving government efficiencies in the UAE construction sector.”

Advancement in the compliance measures of legislative frameworks has also been predicted with the Emirates Blockchain Strategy 2021 as it aims to enable 50% of all the transactions through blockchain technology. This point was also affirmed by the participants indicating that the strategy may have direct impact on the compliance issues of legislations and regulations in the construction sector.

Furthermore, participants also indicated that the management and leadership aspects in their companies were improved and positively influenced by the application blockchain technology.

7 Data Analysis and Discussion

Data analysis has been conducted via application of thematic analysis technique. Four stages were followed for the application of thematic analysis by the researcher. Familiarization with the data, identification of common meanings and patterns, extraction of meanings, and development of potential themes. Three potential themes have been generated from the analysis of participants’ responses. These themes included happiness of citizens and residents, improvement in governmental transactions, and improvement in the legislative compliance.

Theme 1: Impacts of Application of Blockchain Strategy 2021

According to the responses of the participants, delay of the payments was one of the major issues in the infrastructure and construction sectors which eventually results in the project completion. According to the responses of the participants, mitigation of the issues related with payment delays was the major aspect that resulted in smooth conduction of construction projects and improved (Dubai 2016). The blockchain in smart contracts is associated with the elimination of all the uncertainties and ensuring transparency of the transactions. The smooth conduction projects in the construction sector has resulted in making residents and citizens contented with this technology (Salama & Salama 2018). The satisfaction level of consultants, contractors, stakeholders and subcontractors has also been approached and increased via use of blockchain technology in smart contracts for the construction projects (Ahmadisheykhsarmast & Sonmez 2018). Smart contracts using blockchain technology also help in the management of list of goods in the supply chain and how much payment has been made for these goods. Once the payments are made, shipments of the smart contracts are ensured (Gupta et al., 2020). A significant and positive impact is made on the project progress and may also speed up the delivery process. Contractors, consultants, and stakeholders play an important in the construction sector and their demands must be resolved (Zhang 2020).

Theme 2: Improvement in Governmental Transactions

From the responses of the participants, it has been reviewed that the Blockchain Strategy implemented by the UAE government has significant positive influence on the governmental transactions.

One of the major aims of the governmental Blockchain Strategy 2021 in the UAE is associated with the improvement governmental transaction systems (Krishnan et al., 2020). According to the responses of the participants, the Strategy is developed to capitalize on the blockchain technology for 50% of the government transactions. Analysis of responses of the participants indicate that the application of blockchain technology under the governmental strategies for UAE is directly associated with the impacts on the governmental efficiencies and reduction in payment delays, thereby positively influencing the UAE economy. Analysis of the responses of participants has also indicated that UAE government has efficiently launched the strategy even though the state is going through severe pandemic situation. COVID-19 pandemic has significantly affected the current situation in construction sector (Gupta et al., 2020). Thus, UAE government was required to go digital for various tasks associated with the construction project (Penzes 2018).

Information management through technological means has been substantially approached via blockchain technology (Bishr 2019). Presence of multiple players in the construction sectors require information management through efficient means and a reliable infrastructure while going through the phases of construction project (Anonymous 2020). One of the participants also highlighted the importance of building information modelling that has been considered to conduct efficient application of centralized building information model. In this modelling prospect, blockchain technology has been assessed to sort any legal issues that might be encountered, while managing all the information transactions (Dubai 2016). While addressing the various advantages of blockchain technology in construction industry, reliability of construction logbooks was recognized to become improved with this technology.

Theme 3: Improvement in Legislative Compliance

By the use of schemes under 2021 Strategy, there has been observed significant compliance with the legislations and policies in the UAE, implemented for the construction sector (Anderson 2018). The primary legislating regulation currently being followed in the construction sector is the Civil Transactions Code which covers the section on construction and general contract principles. According to the analysis of responses of the participants, Civil Transaction Code is being efficiently followed under the Blockchain Strategy 2021 (Nicosia 2019). The federal law has been further

required to be complied upon efficiently by the contractors and consultants. The Blockchain Strategy 2021 would further improve the working efficiencies of employees in the IT and finance despite the various challenges posed by global pandemic situation (Luo et al., 2019).

8 Conclusion and Recommendation

Blockchain Strategy 2021 implemented by the UAE government has been reviewed in this study. The use and implications of blockchain strategy in management of smart contracts in the construction sector have been evaluated through primary data collected through interviews. Participants of the research belonged from IT and finance sector of a construction company and had substantial knowledge of the application of blockchain strategy in the construction sector. Thematic analysis has been applied on the research findings which resulted in formation of three main and potential themes; impacts of application of Blockchain Strategy 2021, improvement in general transactions, and improvement in legislative compliance.

Research findings suggest that digital means of information management strategies were required urgently in the construction sector of UAE. Moreover, with the global pandemic situation, application of digital means of data storage, exchange and management was also required crucially. COVID-19 has impacted the overall operations and functions in the construction sector resulting in delay in the payments, suspension claims, and suspension of various large-scale projects due to restricted activities. With the implementation of Emirates Blockchain Strategy 2021, research highlighted the importance of economic stability through construction sector in UAE. Among the several advantages identified by the blockchain technology in smart contracts management, traceability of the of the proposed work would become easy, as suggested by the participants. This tracking and traceability would also result in further identifying all the detail the construction process is going through in different phases; such as their quantities, the origin, distribution of materials, quality, used machineries and the construction techniques.

Based on the findings of this research, certain recommendations can be made for the construction sector. Professionals in the IT departments of construction sector must comply with the legislative framework currently followed i.e., Civil Transaction Code, which ensures efficient transaction methods of payments to be followed (Strategy 2019). Furthermore, professionals in the construction sector can also employ various other digital platforms of data

management and use digitalized strategies and software (Luo et al., 2019). By developing competent framework for the construction industry, policymakers may also address the effective application of blockchain strategy in the small and medium sized construction companies.

Abstract –

The availability of inspection robots in the construction and operation phases of buildings has led to expanding the scope of applications and increasing technological challenges. Furthermore, the Building Information Modeling (BIM) based approach for robotic inspection is expected to improve the inspection process as the BIM models contain accurate geometry and relevant information at different phases of the lifecycle of a building. Several studies have used BIM for navigation purposes. However, the research in this area is still limited and fragmented, and there is a need to develop an integrated ontology to be used as a first step towards logic-based inspection. This paper aims to develop an Ontology for BIM-based Robotic Navigation and Inspection Tasks (OBRNIT). The semantic representation of OBRNIT was evaluated through a case study. The evaluation confirms that OBRNIT covers the domain's concepts and relationships, and can be applied to develop robotic inspection systems.

Keywords –

Ontology; BIM; Robotics; Navigation; Inspection

1 Introduction

Inspection is indispensable in the construction industry. Robots are used to automate the process of inspection during the construction and operation phases. The use of advanced technologies (e.g. scanners, sensors) has made the inspection process more accurate and reliable [1]. The complexity of the interactions with the surrounding building environment is the main challenge for inspection robots [2]. To overcome this challenge, an ontology can be used as a basis for the robot's task planning and execution. The robotic system utilizes and processes the ontology as the robot's central data store [3]. To accomplish the tasks correctly, the autonomous robot needs to deal with high-level semantic data along with low-level sensory-motor data. Therefore, a variety of knowledge, including the robot low-level data related

to perception and high-level data about the environment, objects, and tasks, needs to be integrated [4].

Building Information Modeling (BIM) is an approach to model all the information related to buildings by representing the geometrical and spatial characteristics, and is supported by the international standard *Industrial Foundation Classes* (IFC) [5, 6]. BIM models comprise useful information about the building environment, which can help the inspection robot to overcome task complexity. On the other hand, the Robot Operating System (ROS) [7] uses several navigation methods, such as Lidar Odometry and Mapping (LOAM) and Simultaneous Localization and Mapping (SLAM), which help the robot to build its map based on the collected data about the environment [8]. Regarding the different lifecycle phases, BIM models of a building include as-designed at the design phase, as-built at the construction phase [9, 10], and as-is at the operation and maintenance (O&M) phase. These models should be considered in the navigation and inspection processes. It should be noted that each of these models has several versions and should be continuously updated to reflect design, construction, renovation, and repair changes in the different phases of the lifecycle. Mismatches between the as-designed BIM model (or as-built BIM model) and the as-is state of the surrounding environment can create problems during the navigation and inspection tasks.

The navigation concepts in this paper are based on using the semantic knowledge and the BIM concepts for navigation tasks. The BIM-based approach is also expected to improve the inspection process. The robotic task must be performed in such a way that the process considers reliability, repeatability, and safety. Therefore, it is necessary to enhance operational consistency in the inspection environment [11]. Robotic systems' capabilities have progressed over time, and these systems have become dependent on multiple components with diverse functions. In most developed systems, the modules are created independently by different individuals with different technical expertise. Thus, a clear definition of the relationships between the system's various components is needed. The system's structure

and related components must have a straightforward design and documentation to solve this problem [3]. A clear and accurate description of the environment and the task can help the robot to achieve the tasks more autonomously [12]. The robot declarative knowledge represents the task's objects, properties, and objects' relationships in a semantic model [13]. The robot can use this declarative knowledge to perform the task more accurately. However, the research in this area is still limited and fragmented, and there is a need to develop an integrated ontology to be used as a knowledge model for logic-based inspection of building defects. The objective of this paper is to develop BIM-based ontology to cover the different types of information and concepts related to robot navigation and inspection tasks. The ontology is called OBRNIT (ontology for BIM-based robotic navigation and inspection tasks). OBRNIT covers the high-level knowledge of the robot comprising robotic and building concepts, and navigation and inspection information. The use case context is an inspection robot that is navigating in a building with partial knowledge of the environment because of changes in the available information due to construction and renovation scheduling issues, unexpected obstacles in the building, etc.

2 Methodology Workflow

The methodology for developing OBRNIT is METHONTOLOGY, which is clear, well-documented, mature, and based on the experience of other domains ontology development [14]. OBRNIT development based on METHONTOLOGY includes the initial, development, and final stages. The best practices and knowledge in the robotic inspection domain are used to develop OBRNIT. The initial stage involves steps to specify the scope, main concepts, and the taxonomies of OBRNIT. The scope of OBRNIT is defined based on the requirements. Research papers, textbooks, and online resources are used as sources for the requirements (e.g. properties). The ontology needs to cover all the concepts about the robot characteristics, building characteristics, and inspection and navigation tasks. The competency questions are defined as a part of the requirements of the robotic inspection domain [15]. Furthermore, this step helps to consider the size of the development and the level of detail that needs to be covered in OBRNIT. The next step is defining the concepts and taxonomies for OBRNIT. The data related to OBRNIT are gathered in this step. Communication with experts and end-users along with getting feedback from them is essential at the whole cycle of this stage. The development stage is devoted to constructing and verifying the initial structure of OBRNIT. In the first step of the development stage, the conceptualization model is clearly represented and

implemented in a formal language (e.g. OWL) to be later accessible by computers and used by different systems [16]. The development of OBRNIT involves reusing and adapting BIM concepts. Building Element Ontology (BEO) [17], which is based on the IfcBuildingElement subtree in the IFC specification and ifcOWL ontology [18], is a good starting point for including the relevant BIM concepts to OBRNIT. The ontology integration in the METHONTOLOGY method can be done at the conceptualization level [19]. The ontology integration method is selected in this research as it saves the effort to reuse and adapt the components that are needed to complete OBRNIT [20]. The next step of the development stage is verifying the developed ontology. Based on the consistency rules and competency questions, this process examines the ontologies from the technical perspective. The final stage is to add new, or modify existing, relationships, and validate OBRNIT with experts and end-users through evaluation questions. In this stage, the ontology is improved with the suggestions of the domain experts and end-users to fulfill the real-world requirements. OBRNIT evaluation is done through a case study. The final step is documenting the developed OBRNIT.

3 Developing OBRNIT

Some concepts from BIM and KnowRob ontology [21] are used as parts of this study. Protégé [22] is used to develop OBRNIT and to integrate it with BEO [23]. HermiT OWL Reasoner is used for identifying subsumption relationships and consistency evaluation. The current version of OBRNIT is available at <https://www.obrnit.info>.

OBRNIT covers four main groups of concepts including: (1) robot concepts, (2) building concepts, (3) navigation task concepts, and (4) inspection task concepts, which are explained in the following sections. Figure 1 shows the main concepts and relationships of OBRNIT. Color coding is used to group the concepts pertaining to each of the four groups. The relationships between concepts show how the ontology components are semantically interrelated. The types of relations used in the developed ontology are: *is*, *has*, *uses*, *affects*, *performs*, *causes*, *captures*, *has state*, *has time*, *has target*, and *measures* (e.g. thermal camera *measures* temperature).

3.1 Robot Concepts

The robot concepts of OBRNIT cover the main functions of a robot along with the related knowledge of the inspection and navigation tasks. Declarative abstract knowledge about the tasks and environment should be encoded in the robot controller and used to determine proper actions for a specific task.

KnowRob ontology represents semantic models using object detection applied to the acquired point clouds enriched by encyclopedic, common-sense, and action-related knowledge [24]. From the BIM point of view, this ontology is primitive and does not provide full support of building elements. For example, the concept of a wall is only mentioned as a part of the edges of a region's surface and does not have dimensions, material, connectivity, type, etc. Walls may play a major role in inspection and navigation tasks because they define the boundaries of robots' movements or can be obstacles, or the main target of inspection. Other building elements, such as ceilings, columns, and windows, are not covered in KnowRob.

As shown in Figure 1, mobility and sensing are the two main functions of robots. The mismatches between the path found based on the non-updated BIM model and the as-is state of the surrounding environment will cause an obstacle for the robot movement, and consequently its performance. Robot concepts cover basic attributes (e.g. type, size), robots' performance (e.g. movements, degrees of freedom (DOF)), robots' constraints (e.g. safety distance), and sensors for navigation and inspection tasks. The DOF define the modes for the motion capability of the robot. The types of robots considered in OBRNIT are UAV and UGV. UGV refers to any type of crawling, climbing, and other ground-based robots. The movement of UAVs is in the 3D spaces of the building. However, UGVs move following the floors and may be able to climb the stairs. In this case, there are some constraints on the movement, such as the maximum height of a stair step that they can climb. Also, the flying movement of a UAV has constraints, which mainly depend on the size of the UAV.

Sensors can be used for inspection (e.g. RGB camera, thermal camera) and navigation purposes (e.g. depth camera, GPS). LiDAR and cameras are two different types of sensors. Cameras collect images, which can be RGB/depth/thermal images. LiDAR scanners is a remote sensing method, which collects point cloud from the environment. The accuracy and field of the view of the robots' sensor, as well as its type, affect the robot's inspection performance.

3.2 Building Concepts

The BIM model can provide information about the environment of the robotic inspection. Every building element that affects the robot navigation and inspection processes should be included in OBRNIT. As explained in Section 2, the integration process starts with integrating BEO. The required concepts, which are not included in BEO, are added from ifcOWL ontology or defined based on the required concepts for robotic navigation and inspection. The process of integrating BIM concepts with OBRNIT aims to link the available

BIM concepts with the developed OBRNIT concepts, including related building concepts (e.g. BIM mismatch concepts), robot concepts, and inspection and navigation tasks concepts. Some research focused on robots that can open a closed-door with specific access control or use a handle, knob, or button. For example, Cobalt Access [25] can open locked doors by using the door's access control reader. However, passing through locked doors without human intervention is still the main issue for most robots. The state of the door can be open or closed, locked or unlocked, mechanically locked, or electronically locked.

Building concepts of OBRNIT includes the following: (1) Concepts reused from BEO ontology; (2) Concepts reused from ifcOWL: Some necessary concepts, which are not included in BEO (e.g. the *space* concept), are added from ifcOWL. HVAC elements are also added from ifcOWL in order to consider HVAC system defects; (3) Concepts adopted from Building Management Systems (BMS): Some concepts related to the state of the door are required for navigation purposes. These concepts are adopted from BMS; and (4) New building concepts defined based on OBRNIT needs: These concepts include BIM mismatch concepts. In addition, the following relationships are defined to link building-related concepts to navigation and inspection concepts: (1) Relationships to define the links between spaces for navigation paths (e.g. door-corridor), (2) Relationships to define a BIM object as the point of interest of inspection, and (3) Relationships to define obstacles or constraints for the robot movement (e.g. a narrow door). Furthermore, the mismatches between the as-designed or as-built BIM model and the as-is state of the surrounding environment should be semantically represented in OBRNIT. Identifying the potential types of mismatches is the first step to define a logic-based robotic inspection system that can reduce delays and reworks. Also, the information about the path has a major role when the goal is finding the optimal route and avoiding collisions with existing barriers. Spaces in the building (e.g. rooms) can be used to generate nodes for generating the path of the robot. The dimensions of a space can be used to define these nodes inside or on the edges of the space. The main building spaces for robot path planning are rooms, corridors, and stairs.

The mismatches between the information in the available BIM model and the reality cause navigation problems for robots. In some cases, the lack of adequate communication in the design phase, insufficient documentation, or errors of the contractor can turn into unexpected results including information mismatches between the as-designed BIM model and the as-is state of the building. The same problem can occur in the operation phase, where renovation issues can cause mismatches between the non-updated as-built BIM and the as-is state of the building. The assumption in

OBRNIT is that the path planning is based on a reference BIM model, but this model is not as-is and reliable. The semantic mismatch between the as-designed BIM model (or as-built BIM model) and the as-is state of the surrounding environment could be caused by one of the following problems: (1) there is an object in the BIM model, which does not exist in reality. This problem can be the result of design changes during the construction phase (e.g. removing a door) where the changes are not applied in the BIM model; (2) there is an object in the building which is not included in the last updated BIM model; or (3) there is a discrepancy between the BIM model and the actual building with respect to objects' attributes, such as location or dimensions. As shown in Figure 1, these problems that the robot can face in a building are classified as missing objects, unexpected objects, and non-conformity issues. Each of these issues could be linked with fixed or mobile objects. For instance, building elements (e.g. access points) can be missing objects, and furniture and temporary structures (e.g. falsework) can be unexpected objects. Also, classes related to non-conformity should cover material issues, unexpected states (e.g. damaged building element, a closed-door which is expected to be open), and deviation in location or deviation in dimensions (e.g. narrow door), etc. Each of the main mismatch entities has one or more causes and effects. A narrow door (i.e. deviation in dimensions) or a closed-door (i.e. different states from what is expected) are examples of non-conformity that can cause problems for a robot during its operation.

3.3 Navigation Concepts

The navigation task in OBRNIT refers to the act of performing navigation by the robot. As shown in Figure 1, navigation concepts cover the main information related to the path of the robot including nodes and links, which can be used for path planning. The navigation task has a network, and it uses the information of this network for path planning. Different types of navigation sensors can be used including GPS, LiDAR scanner, and depth camera. A path has attributes including the length, direction, and buffer-width. A node can be the origin or destination of a path, or a way-node on the path. Spaces (e.g. room, corridor) and access point elements of a building (e.g. doors, windows) can be nodes of a path. For example, if a robot must move from a corridor to a room, the center point of the corridor is the origin node, the center point of the room is the destination node and a door of the room is a way-node. Positions of the way-nodes vary based on the obstacles on the way of the robot. These obstacles may be unexpected objects detected by the robot. New links on the path connect these way-nodes to the origin and the destination nodes and each other [26]. Links connect nodes and define the direction of the path. Examples of links are the links connecting a

window to a room (in case of UAV), a door to a corridor, or a door to a room, based on the defined building elements and spaces. Links can be horizontal or vertical (e.g. stairs' links are vertical). The state and dimensions of access points (e.g. doors and windows) are important to enable the robot movement over the path.

3.4 Inspection Concepts

Inspection is the main task of the robot in OBRNIT and is mostly performed using vision sensors (e.g. LiDAR scanners, cameras). The attributes of inspection-related tasks of OBRNIT are defined based on common defects in buildings [27]. The inspection task has an inspection method, which can be visual inspection or a method for the measurement of physical conditions (e.g. broken glass) or environmental conditions (e.g. temperature). The method of inspection is based on the sensor's measurement and acquired datasets. Measurement devices for inspection include radio-frequency ID (RFID) readers, image sensors (i.e. RGB and thermal cameras), and LiDAR scanners. Images and point clouds can be used to detect surface defects, deformations, non-conforming elements, etc. Computer vision methods can be used for anomaly detection on the collected data. Also, the information of computer vision methods can be used for obstacle detection and navigation tasks.

The point of interest of the inspection task is defined based on the inspection purpose, which can be general scanning, inspecting mechanical systems (e.g. HVAC), or detecting building defects. General robotic scanning aims to update the BIM model or to collect data of a hazardous building, which is unsafe to inspect by human inspectors. The malfunctions of the HVAC system affect the environment temperature and air quality. Defected HVAC elements or related building elements (e.g. improper insulation) can be evaluated by thermal cameras. In the case of inspecting building defects, specific building elements are the points of interest, and each of them can be a target for the inspection task. Some issues related to non-conformity can be considered as building defects. Furthermore, the detected defects can be used to update the available BIM model to create an up-to-date as-is BIM model.

4 Case Study

Figure 2 shows a hypothetical case study of using an inspection robot to find the leakage in one of the rooms on the 9th floor in a building at Concordia University. The aim of the case study is to demonstrate the applicability of OBRNIT based on specific information about the building extracted from a BIM model and information about the inspection robot. The assumption is that the robot partially knows the environment based on a non-

updated BIM model. After defining the inspection point of interest in Room 9-215, which is leakage in the ceiling, the robot should navigate to reach this point of interest to perform the inspection task. Path planning is based on a reference as-built BIM model. The inspection robot will use an image sensor to capture images of the ceiling. The FLIR PackBot robot [28] is assumed as the robot used in the case study. The robot type is UGV, and it has horizontal and vertical (e.g. climbing the stairs) mobility.

Examples of BIM-based information include the objects in Room 9-215 and the inspection point of interest, as well as the spaces/objects from the elevator on the 9th floor to the door of Room 9-215. The origin node is in front of the elevators on the 1st floor, and the destination node is inside Room 9-215. The path has three parts. The first part is the vertical movement in the elevator from the origin node to the 9th floor. The second part of the path is the horizontal movement from the 9th floor elevator hall to the door of Room 9-215. The shortest path (Path A) uses Corridors 9-A1 and 9-A2 (Nodes 2, 3, 4, and 7). However, this path is blocked with scaffoldings, which are used for a renovation project, and create an obstacle for the robot. Therefore, the robot must follow a longer path (Path B) to reach the room. The robot could obtain information about the scaffoldings from an up-to-date BIM model, if available, or from its sensing ability. Having an up-to-date BIM model (i.e. as-is model) results in a higher confidence level with respect to obstacles. After detecting the obstacle, the robot should replan a new path (Path B).

The involved corridors to reach Room 9-215 in Path B are Corridor 9-A1, Corridor 9-A3, Corridor 9-A4, and Corridor 9-A2, which contain Nodes 2,3,4,5, 6, and 7. The last part of the path is the horizontal movement inside the room from the door to the destination node (i.e. the inspection point of interest). The robot will learn from performing the navigation task. After finding the mismatches with the as-built BIM model (i.e. the scaffoldings), the robot should store them as a reference point for performing the next tasks.

The case study demonstrates that OBRNIT can answer all the competency questions and it covers all the concepts necessary for the planning of the robotic building navigation and inspection. The case study also shows how several concepts are extracted from the BIM model of the building. Examples of these concepts include concepts related to the navigation task (moving to the specific floor and the specific room, and then moving to the point of interest in the room), as well as the inspection task (orienting the camera to the leakage area based on the field of view and collecting images). Integrating mobility characteristics of the robot and the knowledge about the surrounding environment can help the robot define the appropriate path based on the robot type and constraints. The robot can benefit from the BIM model to define the path based on defining the nodes and links of the path. In addition, the robot can benefit from the BIM model information to locate the inspected objects. Furthermore, the ontology can help the robot use a suitable sensor for the specific inspection task.

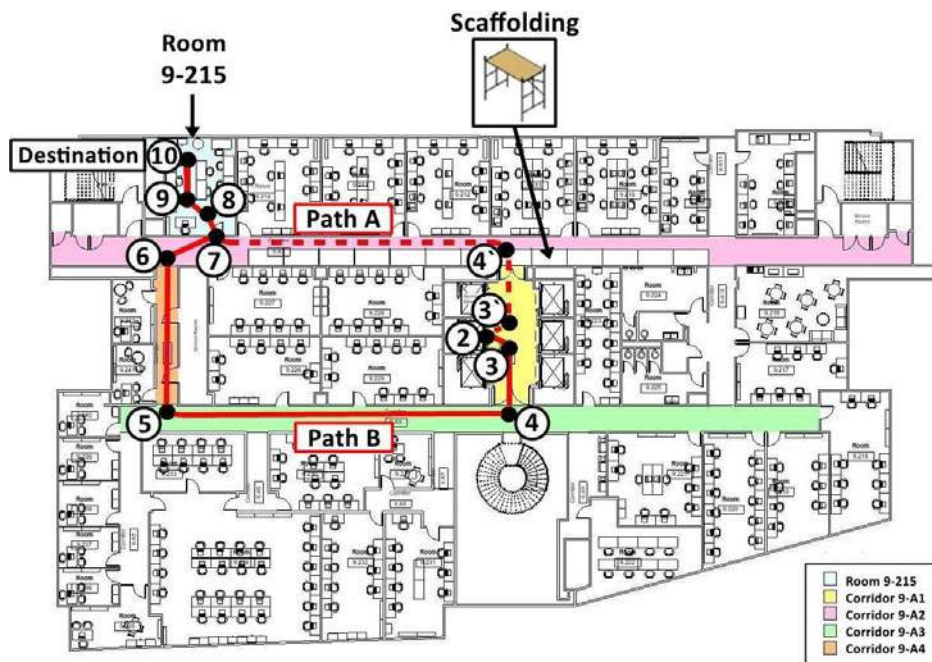

Figure 2. Case study of using an inspection robot

5 Conclusions and Future Work

This paper developed an integrated ontology, called OBRNIT, to extend BIM applications for robotic navigation and inspection tasks. OBRNIT comprises high-level knowledge of the concepts and relationships related to buildings, robots, and navigation and inspection tasks. BIM is considered as a reference that is integrated with the knowledge model. The application of OBRNIT was investigated in a case study. Based on the evaluation, OBRNIT was able to give a clear understanding of the concepts and relationships in the domain, and it can be applied for developing robotic inspection systems. OBRNIT is expected to provide the following benefits: (1) capturing the essential information from BIM can help to develop a seamless knowledge model to cover the missing parts of BIM; and (2) OBRNIT can be used as a first step towards logic-based inspection, which can help robots to perform inspection tasks autonomously without the help of human judgment.

Future work will focus on further development and implementation of OBRNIT to integrate it with low-level robotic capabilities to make the robot more autonomous. The abstract knowledge can be combined with robot action-related procedural knowledge to make the tasks executable [13].

Value Stream Mapping of Project Lifecycle Data for Circular Construction

Abstract –

With the aim of shifting from the traditional linear flow of resources in the construction industry into a circular model, several studies have focused on the reuse and recycling of construction and demolition waste. The present study focuses on the End-of-Life (EoL) decision-making for built facilities, including buildings and infrastructure, to support such a shift. We look at the involved EoL decisions through the lens of ‘information requirements’ and try to envision an information supply chain, in parallel with the facilities’ lifecycle stages, to support such decisions. We examine available data acquisition techniques, data analysis tools, and information standards that can help in creating and maintaining an up-to-date view of the built facility’s materials/components/subsystems and their location, condition, residual value, remaining life, second life attributes, etc. through digital twins. We suggest a value stream map for capturing and updating such information and identify technological requirements and barriers to its realization in practice.

Keywords –

Construction Supply Chain; Circular Economy; Digital Transformation of Construction; Value Stream Mapping; Digital Twins

1 Introduction

The construction industry is the largest consumer of raw materials globally. Most existing buildings and civil infrastructure follow the conventional *cradle-to-grave* model and are typically not designed to be ‘deconstructed’ or ‘disassembled’ so that their subsystems, components or materials can be reused or recycled ultimately. Construction, Renovation and Demolition (CRD) waste accounts for 20-40% of the total urban municipal waste. The majority of CRD waste is often sent to landfills, instead of being recycled and reused. CRD waste

recycling rates are only 16% and 37% in Canada and the US, respectively [1]–[3]. The large amount of CRD waste sent to landfills results in wastage of resources and becomes a challenge for landfill operation. Improper disposal of CRD waste can cause land depletion and deterioration, and the transportation process can also negatively affect the urban environment in terms of noise pollution and gas/dust emission [4]. Therefore, appropriate CRD waste management is essential for mitigating the negative impacts caused by such waste.

The so-called ‘3Rs’ principle, referring to *Reduce*, *Reuse*, and *Recycle*, is currently the main guidance for CRD waste management [5]. Several factors can affect the recycling and reuse of CRD waste, such as the regulatory framework, local CRD waste recycling system, and recycled product market [6]. CRD waste generation can be significantly reduced by design error detection and waste management using technologies such as Building Information Modelling (BIM) [7]. When joined with other technologies, BIM can also help control CRD waste throughout various phases of procurement, construction, operation, and eventually, End of Life (EoL) of buildings and infrastructure. During the construction and operation phases, a more holistic approach to evaluating the effect of recycled/reused content on embodied energy should be utilized for providing a broader view of the impact throughout the project whole lifecycle. Previous studies suggest that material substitution can decrease embodied energy by approximately 20% or more [8], [9]. Therefore, evaluating the trade-offs between embodied and operational energy in this context would be required for decision-making with regards to reusing/recycling some building materials [10].

As the AEC/FM (Architecture, Engineering, Construction/Facility Management) industry is highly fragmented, capturing project lifecycle data for facilitating circular construction is difficult; and the need for efficient information sharing and exchange between various stakeholders throughout the lifecycle is evident. With Industry 4.0 revolutionizing the use of sensors and

the Internet of Things (IoT) in the building and infrastructure sector, there is a massive amount of data generated during various phases of the built facility's lifecycle, as related to various components, systems, and subsystems. In many cases, this data is passively stored in the form of construction production reports and/or maintenance records. However, big data analysis tools and technologies present an opportunity to turn this large volume of data into useful information and knowledge extraction for various purposes, including reduction, reuse and recycling of CRD waste.

Moving from a linear to a circular supply chain can be considered a paradigm shift for the built environment. The implementation of deconstruction practices depends on several factors, including improvement of deconstruction techniques' maturity and management, augmentation of deconstruction awareness among stakeholders, advancement in environmental regulations [11], and effective collection and management of lifecycle data for EoL decisions.

Value Stream Mapping (VSM), as an effective lean-management tool, can help to identify the opportunities and prevent wastage of the information and data generated throughout the lifecycle, which is essential for EoL decisions. Accordingly, this paper looks at the whole project lifecycle of building and infrastructure (here referred to as 'built environment' or 'built facility') through the lens of circularity to identify EoL decision-making information requirements as well as opportunities to collect and store such information. The main objective of the study is to propose a roadmap to the value-stream mapping of built facilities' lifecycle data through the design, construction, operation, renovation, and deconstruction phases based on the 3Rs principle (Igwe et al., 2020). The emphasis of this paper is on the reuse of building systems, subsystems, and components, as well as the recycling of materials.

2 Construction Project Lifecycle and Circularity

A better understanding of reclaiming building and infrastructure materials and components is required to establish an effective deconstruction planning process. Additionally, the built facility's characteristics play an essential role when it comes to disassembly. Such characteristics, at a high level, can be classified into the following groups: (i) *transparency*, i.e., the level to which building systems can be identified and accessed easily; (ii) *simplicity* i.e., the straightforwardness of connection system as well as limited types of materials being used; (iii) *use of homogeneous materials* rather than mixed material grades or composite materials; (iv) *safety*, i.e., avoiding the use of hazardous materials; (v) use of *standard and regular* (i.e. repetitiveness of

elements), rather than non-standard components; and (vi) *components' sizes*, i.e., the use of a limited number of components with large dimensions rather than smaller ones. Figure 1 summarizes building characteristics for easy (and difficult) disassembly/deconstruction.

Figure 1. Building characteristics and their influence on 'deconstructability'

Beyond these rudimentary characteristics, however, there is a large number of aspects of the project lifecycle that can affect EoL reusability and recyclability of materials, components, sub-systems, and systems as explained below.

2.1 Design for Disassembly and Deconstruction

In response to the high consumption of resources and low recycling rate within the construction industry, the idea of Design for Deconstruction (DfD), which requires detailed planning early on at the design phase, was established. DfD proposes alterations in the building design that lead to an EoL dismantling in a coordinated way. It can also offset the incurred building removal costs through salvaged material and lesser use of landfills [11].

Different materials typically vary in terms of reusability and recyclability. Wood is a perfect building material for reuse. Wooden structures can be disassembled in a scheduled manner to protect lumber, doors, windows, and other components in their complete functional form. An evaluation of different wooden building types, performed by [12], indicated that light-frame wood structures are most difficult to disassemble due to small member sizes and effective use of fasteners, and post-and-beam wood structures are the simplest to

disassemble. Brick, on the other hand, has an excellent salvage value as long as lime mortars are used, since they can be easily removed. However, the choice of Portland cement mortar makes it challenging for bricks to be salvaged. Steel structures can also allow recycling of material, but concrete is difficult, as in-situ concrete cannot be recovered. Precast concrete components are considered reusable due to their standard (modular) sizes and the option of connecting them using fasteners. Table 1 summarizes the recommendations for DfD using wood, steel, masonry, and concrete structural systems.

Table 1 Recommendations for DfD using different building materials [13]

Material	Recommendations
<i>Wood</i>	<ul style="list-style-type: none"> • Use screws and bolts instead of nails • Consider using lime mortars • Use robust moisture management techniques to protect the wood from decay and insect damage • Use timber-frame construction instead of dimension lumber
<i>Steel</i>	<ul style="list-style-type: none"> • Identify grades and shapes directly on members • Use bolted connections • Use precast decks
<i>Masonry</i>	<ul style="list-style-type: none"> • Avoid cast-in-place members • Allowance should be given for thermal movement at connections to avoid cracks in members • Permanently label each member. The label should include concrete strength and member reinforcement
<i>Concrete</i>	<ul style="list-style-type: none"> • Avoid using mortar • Avoid using grouted reinforcement • Investigate using mechanical fasteners in place of mortar to secure blocks

2.2 Procurement and Offsite Manufacturing

Since the construction industry has lower productivity than several other industries such as manufacturing, offsite construction (OSC) has been attracting attention to accelerate project schedule, reduce project costs, and minimize weather impacts on traditional stick-built construction processes. Besides these advantages, the OSC is meant to help with waste reduction through factory production processes, as well as reuse and recycling of materials and components, due to the essentially different nature of offsite and prefabricated construction. The OSC inevitably disrupts traditional construction project planning and management by adopting three phases: (i) manufacturing; (ii) logistics; and (iii) assembly process on-site. While

phases (ii) and (iii) can also be discussed from the CRD waste management perspective, the focus here is on the manufacturing phase. To improve the manufacturing process in a factory, OSC adapts Design for Manufacture and Assembly (DfMA) methods and integrates the procedure with BIM to support the OSC design process [14], [15].

As a continuous effort to improve productivity by focusing on the planning, monitoring, and control of the manufacturing process, researchers have adopted several technologies such as tracking components through Radio Frequency Identification (RFID), audio signals, Machine Learning, simulation models, and optimization algorithms [16]–[18]. These works have also proposed an integrated production planning and control system based on the application of advanced technologies used to collect the production data (e.g., process times of workstations to complete one single module component and locations of modules). In addition, lean tools and techniques have been adopted in the manufacturing phase to reduce waste [19]. Most importantly, OSC significantly increases the potential of the components' re-use at the facility EoL.

While OSC material properties can be tightly controlled as part of the factory manufacturing process, the quality of their on-site assembly should also be closely audited during the operation, since it has a significant effect on the building performance, e.g., energy use [20]. This information, however, will be also extremely helpful for the EoL decision making, by providing a full history of the materials and systems' exposure and performance.

2.3 Construction, Installation, and Commissioning

Tracking and tracing technologies such as RFID can be used as an automatic data collection and local storage solution during and following the construction. RFID tags can be permanently attached to the facility components and the tag's memory can be populated by accumulated lifecycle information of the components, taken from a standard BIM database, as proposed by [21]. The memory space on the tag can be virtually partitioned into fields such as component ID, specifications, installation status, and other relevant data. This information is used as a kind of component passport to enhance lifecycle processes [21]. The same approach can be extended to bulk materials (e.g., steel bars). Iacovidou et al. (2018) explored the potential pre-conditions for RFID to facilitate construction components reuse. They developed guidelines for promoting their redistribution back to the supply chain [22]. Focusing on the construction phase, tags or barcodes attached to material or components can be automatically scanned upon arrival on site through readers fixed at the gate. This can be

helpful for site management, by helping to locate the materials/components on a large site, to monitor the progress of installation, or to improve the quality control process as described by Montaser and Moselhi (2013). But under a circular scenario, the mission of such tags can be extended throughout the facility's lifecycle, towards the EoL.

2.4 Operation and Maintenance

The application of preventive and predictive (rather than reactive) maintenance will help to reduce the waste by extending service life of components, systems, and subsequently, the entire facility. On the other hand, the reuse/recycling of building and infrastructure materials and components can pose potential challenges during the facility's operation phase, especially with regards to their effect on energy consumption vis-à-vis new materials with high thermal properties. Therefore, the availability of data regarding materials and their properties is critical to ensure they can meet new and more stringent energy efficiency requirements [23], [24]. To this end, information sharing and data exchange proposed in the design and construction phases can facilitate early evaluation of the effect of different recycled materials on energy performance.

On the other hand, the applications of big data analytics in built facilities' maintenance management practices are emerging [25], benefiting from the adoption of Artificial Intelligence (AI) and machine learning techniques. These applications initially focus on the use of statistical data-mining techniques to identify trends and patterns for reoccurring repairs based on failure modes (causes), rate, and effects [26]. With the growth of AI, there is now a shift towards using big data analytics in the development of failure detection mechanisms and tools to improve the reliability of components and systems [27], [28] and reinforce the adoption of data-driven predictive maintenance tools for failure detection, diagnosis, and prognosis. In the infrastructure sector, Structural Health Monitoring (SHM) plays a similar role and has been following the same path.

There is also an emerging trend to link data-driven predictive maintenance systems to wider facilities maintenance management practices on resource allocation (labor, skills, spare parts, equipment, etc.) and work order management (scheduling, process planning, etc.) Resource allocation aims at optimal alignment of available resources (workers, parts and equipment) to requirements of maintenance activities (Yousefli et al., 2021). These issues and trends are particularly of growing importance due to the dependency on the state of suppliers and supply chain's complexity, for spare parts and equipment, resulting from overseas manufacturing of these requirements, and thus, networked and highly interdependent distribution

channels [29]. In this regard, predictive analytics applications in facilities management shall go beyond failure prediction and diagnosis towards an intelligent and interconnected asset management platform to enhance resilience and efficiency of resource supply chains [30].

These emerging needs call for a paradigm shift towards integrated (IoT-enabled) information systems for value-chain-centric facilities maintenance management. These systems can be used for monitoring, tracing, and analysis of physical assets, resources, and supporting supply chain's data, enabling linking failure predictions to the estimation of resource and supply chain flows. While such data is originally collected for the above-mentioned purposes, it can be extremely valuable in the EoL decision-making and must be stored, processed, and archived properly throughout the life of the built facility.

2.5 Deconstruction and Demolition

Determining the 'residual value' of EoL materials and components is necessary for CRD waste management. The residual value of CRD waste can be affected by various factors, such as material types, physical conditions (which were discussed in the previous sections), and recycled products market. Material type is the key factor to affect the waste residual value. For example, a material like ferrous metal has a high recycling rate due to its relatively high price, while most concrete waste is not. Physical conditions of materials affect the building material and component residual value as well. In addition, the CRD recycling facility specifications and recycled product markets can affect CRD material recycling and reuse decisions. All these factors, not only affect the selection of deconstruction technology but are also affected by the availability of disassembly and dismantling means and methods.

3 EoL Decision Making Requirements

Realistic knowledge of the EoL decisions' nature and expectations will be necessary to best understand the information requirements and plan ahead for the collection and proper aggregation of relevant data. While details in this regard will depend on the type of facility and its upper level (urban/civil) context; generically, three main applications will be of interest: assessing the physical condition of materials and components close to the facility's EoL; planning for CRD waste management; and planning for disassembly and deconstruction.

3.1 Condition Assessment and Recording

There is a wide range of technologies and methods for reality capturing, inspection, and condition assessment of

built facilities. They largely depend on the type of facility (e.g., building, sewer, water distribution, road networks, bridges and overpasses, etc.) and on the materials used in these facilities and their components (e.g., reinforced concrete, asphalt, steel, PVC, etc.). Technologies used for condition assessment and rating can be grouped in two clusters; the first focuses on the diagnosis of defects and their intensity; and the second on identifying locations. Commonly used technologies in the first cluster are those capable of capturing inspection data, such as digital imaging (Adhiraki, et al. 2016), infrared (IR), Ground Penetrating Radar (GPR), 3D laser scanning, acoustic and vibration-based methods as described by Saleh, et al. (2017). The localization technologies of the second cluster include GPS (Global Positioning System), RFID, and UWB (Ultra Wide Band), and one here needs. It is important to note that these technologies can be used individually as well as jointly by making the use of data fusion algorithms (Moselhi et al, 2017). The data captured by inspection-related technologies shall be further processed using AI, machine learning, and deep learning, to assess the residual value of material, components, subsystems, and systems.

3.2 CRD Waste Management

The collection and sorting of recyclable materials are among the most important steps in CRD waste management. On-site sorting requires a viable management system and will be associated with higher labor costs, thus it is still not widely used by contractors [31]. To achieve sustainable CRD waste management, a method called ‘selective demolition’ has been proposed by the European Union [32]. It consists of a series of demolition activities to allow for the separation and sorting of building components and valuable building materials, such as metal, windows, doors, tiles, bricks, etc. [33]. The materials and components of the building must be characterized in advance of the selective demolition to determine their residual values. Materials with a high residual value, such as metal and uncontaminated gypsum boards, could be selectively removed and collected for further recycling and reuse. Yet, the selective demolition may not be able to completely separate all building components from one another (e.g., brick from mortar). The mixed CRD waste needs to be sent to off-site sorting and recycling plants for further processing.

3.3 Deconstruction Management

Finally, awareness is required to recognize that the process of deconstruction must be done with the required quality, within a realistic time frame and cost. As a freshly growing notion, deconstruction encompasses an

exclusive management paradigm and is not only limited to environmental protection. There is also a need to modify the established methodologies in construction management, incorporating the management of deconstruction. The implementation of contents shown in Figure 2 can improve management of deconstruction.

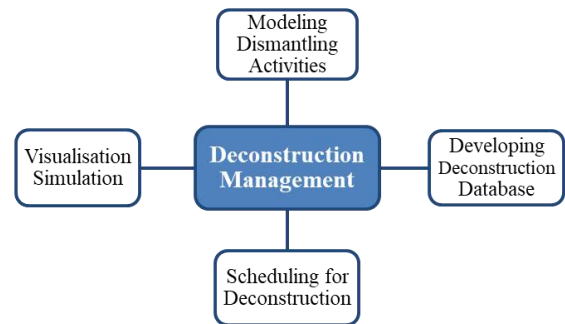

Figure 2. contents of deconstruction managements (based on C. Liu, Pun, and Itoh 2003).

4 Circular Data Stream Proposal

Data-driven EoL decision-making requires collection, compilation, and integration of the data explained in the previous sections. This must, on the one hand, include the lifecycle information of the built facility, which we refer to, as ‘micro-level’; and on the other hand shall support its contextual information in a larger-scale context, i.e., ‘macro-level’ urban model. In this section, we revisit the capacity of existing data models for accommodating such data structure. We focus on open and extendible data standards that are most common in digital twinning of the built environment; since providing meaningful and practical solutions requires a collective effort of multiple researchers and stakeholders, which should be performed in a bottom-up manner.

4.1 Micro-level Digital Twins – BIM

The information about an individual facility’s material, components, subsystems, and systems can be made accessible to all stakeholders through a shared BIM. However, coupling this information with actual development of the project at different phases of its lifecycle requires frequent updates to be done automatically (as well as manually) to track the information of building/infrastructure elements, related to the design, manufacturing, supply chain, construction, maintenance, and decommissioning processes. In addition to the obvious benefits of identifying and locating components using sensors (such as RFID tags and barcodes as discussed in 2.2), having BIM data chunks stored on the tags provides a distributed and dynamic database. The information extracted from

continuously processing such data (ideally through edge computing) shall be stored in a distributed/federated BIM, which allows access to the information for all stakeholders in real-time, without the necessity of having a central database in place [21]. This will be helpful, specifically with the privacy, security, and trust issues that may exist throughout the whole lifecycle supply chain. Modern technologies, e.g., block-chain and federated data mining, details of which are beyond the scope of this paper, can support such dynamic/distributed BIM.

Furthermore, to capture the operation phase information, data exchange between Building Management Systems (BMS) and BIM through open standards such as gbxml, IFC (Industry Foundation Classes), etc., allows for utilizing long term performance of materials and components [35], [36]. In heavy infrastructure, besides the data from operation and service, SHM systems' data reflecting the structural condition of the facility can be linked with the BIM. Using automated monitoring systems can also help to evaluate materials' and components' performance during their second life and beyond. Data collected through such systems, processed, and integrated within the distributed BIM will be essential to support decision-making for selective demolition. Hence, the data standards must be

upgraded and extended to support the storage of such data, in association with the facilities' digital twins.

IFC, as the most comprehensive open BIM data schema, has the capacity to accommodate the majority of inputs required for EoL decisions. Static information regarding the design and construction phases, including geometry, material characteristics, structural attributes, etc., are already fully stored in IFC4. Furthermore, several extensions are offered for accommodating dynamic information, collected through sensors, e.g. [37], [38]; RFID tags, e.g. [39]; and other sensor networks. On the other hand, COBie data model, which is considered a subset of IFC, has been originally developed to support facility management data exchange and can capture most of the information discussed in Section 2.4, including maintenance and repair work orders' information. Nevertheless, as confirmed in other studies, the existing IFC standard lacks all features required to support circular construction [40] and future studies must focus on developing such extensions. For example, while structural properties and construction costs are covered by IFC classes and relationships, attributes, such as deterioration condition and residual value, are not currently supported by the IFC schema. Best practices and guidelines such as 'Materials Passport' developed by TUM (Technical University of Munich) and BAMB

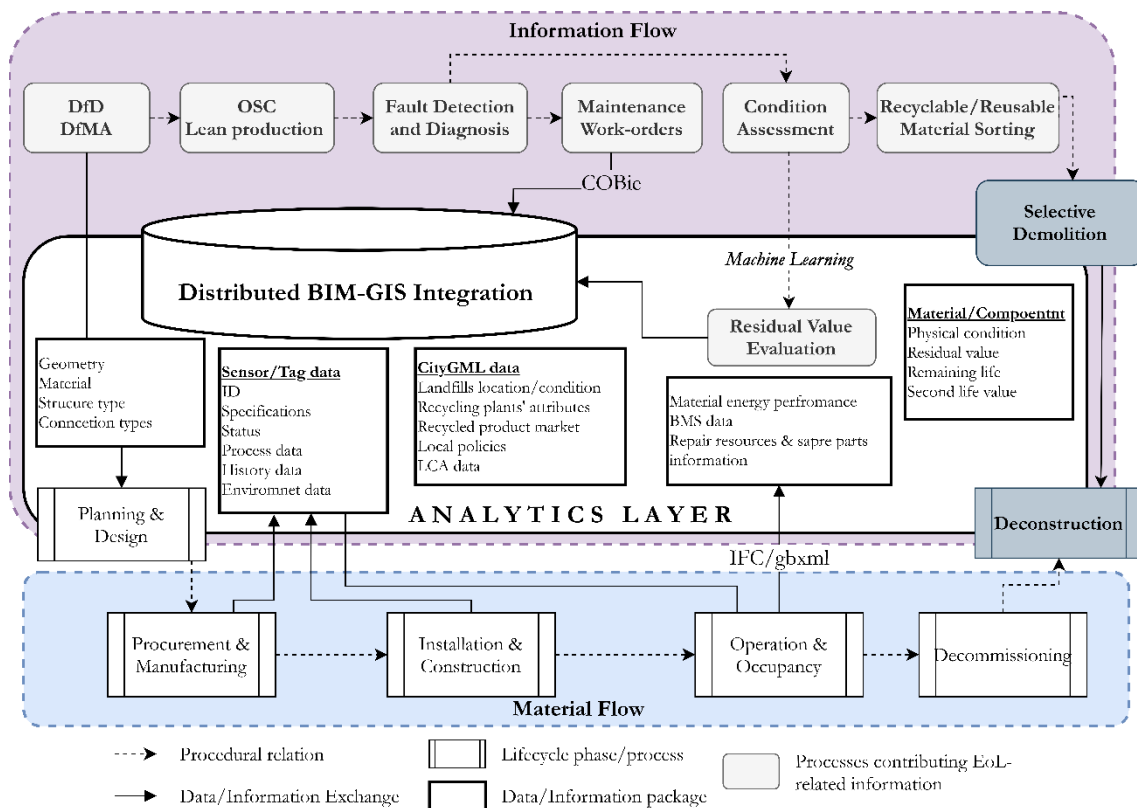

Figure 3. Proposed value stream map for critical lifecycle data to support EoL decision-making

(Buildings As Material Banks) [41] provide a good taxonomy for mapping the required (and enhancing the existing) classes, subclasses, and attributes.

4.2 Urban-scale Digital Twins

The abovementioned distributed BIM can help to support data-driven EoL decision-making for an individual facility. However, as discussed earlier, information will also be required at a macro-level, for integrated decision-making regarding deconstruction, reuse, and recycling of materials and components. Such information includes, but is not limited to, (i) typical GIS data, such as the location and attributes of landfills, recycling plants, etc.; (ii) local policies concerning recycling and reuse of CRD waste; and (iii) data required for a full lifecycle assessment (LCA). Data schema to support such information is required to be open, extendible, and integrable with BIM data standards. CityGML is an XML-based open data model that can store and exchange virtual 3D city models at various levels of detail, and has these characteristics. The data schema organizes basic entities, attributes, and relations of a 3D city model in a semantic format; but is also extensible through its Application Domain Extensions (ADEs). This capacity can be used to accommodate the macro-level information required to support EoL decision-making, taking the bigger picture of the urban context into consideration.

The closest ADE to such a macro-level LCA is Energy-ADE (briefly introduced in Figure 4), which extends CityGML by characteristics and properties essential to perform urban energy simulation and store the corresponding results [42]. To date, for most of the cities around the world, LCA data requirements have not been adequately integrated into the CityGML format, nor its ADEs [43]. The most relevant module for LCA in the Energy ADE's is the 'Material and Construction' module. In it, building construction parts and components are physically characterized with details of their structure as well as their thermal and optical properties. For a comprehensive deconstruction plan, information related to the four following categories are needed: (i) Embodied carbon and embodied energy of utilized raw or reused/recycled materials in the construction phase; (ii) Types and amounts of materials needed for refurbishment and renewal of internal and external finishes; (iii) Disposal of the materials that are not reusable or recyclable; and (iv) Discount of CO₂ equivalent emissions attributed to the reuse and recycling of components.

In the Energy ADE, data specifications are available related to the embodied energy and embodied carbon of materials used in the production phase. This data allows doing a cradle to grave LCA. However, the data related to the other three phases (refurbishment, disposal, and

recycling) are still not being supported and must be added, perhaps through new ADEs. In addition, transport related carbon should be included in each of the phases, separately, for a comprehensive LCA. To provide a comprehensive data model, the new ADEs must also cover soft aspects such as policies and regulations regarding emission, recycling, and reuse.

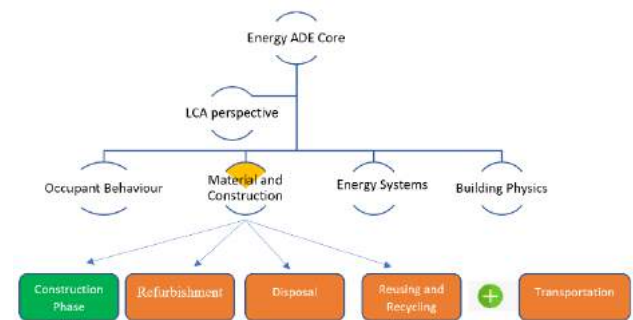

Figure 4. Energy Application Domain Extension in the CityGML standard and life cycle related missing features.

4.3 Integrated Data Model

While a large amount of data is being generated and can be virtually collected throughout the comparatively long lifecycle of built facilities, it would be the processed information, rather than the raw data, which should be stored and documented for EoL decision-making. Machine learning and data mining techniques are to be used for processing data into actionable information. For example, 3D laser scanning and digital imaging used in the assessment of structural defects in sewer mains are jointly used with artificial neural networks (ANN) for diagnostic of a set of functional defects in the sewer networks such as tree-routes penetration, joint misalignments, and debris blockages (Reference?). Similarly, IR and GPR data is used in condition assessment and rating of reinforced concrete bridge decks and overpasses (Moselhi et al, 2017). These technologies jointly with AI are used for identification, classification and severity assessment of different types of defects such as cracking, rusting of reinforced bars, spalling of concrete, etc.

Aside from inspection and condition assessment data capturing utilizing the technologies and methods highlighted earlier, maintenance records are useful in the condition assessment of near EoL built facilities and in projecting their condition in targeted time horizons to support optimized intervention plans and related budget allocations. Accordingly, the information flow tier of the circular construction VSM should include an analytics layer to process data into the actionable information and integrate the two sources of macro- and micro-level

information within digital twin models of the built environment.

Figure 3 provides a schematic view of the proposed VSM, structured around the distributed (and federated) BIM/GIS-based digital twins. This figure is not meant to document every single data exchange and/or procedural relationship throughout the whole lifecycle. Rather, it highlights the flow of major events during the lifecycle of the built facility, metaphorically called the flow of material, that leads to the CRD waste at the EoL; together with general activities that provide critical information for the EoL decisions. As suggested by the figure, a data/analytics layer is required around the centrality of BIM/GIS for managing information and supporting data-driven EoL decision making. The main requirements for the analytics layer include (i) upgrading and extending open BIM/GIS data schemata and enriching them with EoL-related attributes, with emphasis on selective demolition, recycling, and reuse of the built facilities; (ii) enhancing distributed processing methods for data collection and analysis (including edge computing and federated machine learning) and information recording (such as block-chain) to manage the distributed information model; and (iii) developing AI-based models for processing lifecycle data collected through IoT and other sensory networks into actionable information, to support EoL decision-making. Future studies are expected to focus further on these requirements, as well as the development of quantitative decision analysis models and tools to use the collected information/analytics for selection of the most suitable deconstruction alternatives.

5 Conclusion

Shifting from a linear to circular flow for materials and components in the construction industry will be a long endeavor, and requires effective contributions from various levels of stakeholders. While in this paper we solely took the perspective of information requirements for making better decisions at EoL under the criteria of circularity, a large gap still exists in current practices for collecting data; processing/reprocessing it to actionable information; and continuously recording up-to-date information for making such decisions. Bridging this gap requires approaching the problem (i) from three angles (i.e. collecting, processing, and recording); (ii) at various levels of micro (i.e. individual facility) and macro (i.e. urban) contexts; and (iii) throughout various phases of the facility's lifecycle (i.e. from design and procurement to construction, operation, repair/rehabilitation, and finally, deconstruction). IoT and other digital data acquisition tools; open standards for building and urban information modeling; and distributed and federative data processing offer promising tools to tackle this

problem. Nevertheless, it should be emphasized that the technological aspect of the problem is less challenging than other 'soft' aspects such as the high-level regulation and de-regulation strategies, industry-wide culture, market value of material and components at their second lives, etc. Any future research agenda in the area of circular construction must adhere to these constraints and their dynamism.
