TABLE OF CONTENTS

A Decision Tool to Simulate the Concurrent Interdependencies Between Multi-DFX Techniques in Machine Design Conflict Resolution 1
Anas Itani, Rafiq Ahmad and Mohamed Al-Hussein

Robotic Technologies in Concrete Building Construction: A Systematic Review 10
Marwan Gharbia, Alice Yan Chang-Richards and Ray Zhong

The Effectiveness of Virtual Reality in Safety Training: Measurement of Emotional Arousal with Electromyography 20
Sheng Xu, Qingqing Ni and Qiang Du

3D Posture Estimation from 2D Posture Data for Construction Workers 26
Yantao Yu, Heng Li and Xincong Yang

A Low-Cost and Smart IMU Tool for Tracking Construction Activities 35
Xincong Yang, Fenglai Wang, Heng Li, Yantao Yu, Xiaochun Luo and Ximei Zhai

An Investigation into the Effects of Deposition Orientation of Material on the Mechanical Behaviours of the Cementitious Powder and Gypsum Powder in Inkjet 3D Printing 42
Pshtiwan Shakor, Shami Nejadi and Gavin Paul

BIM-based Takt-Time Planning and Takt Control: Requirements for Digital Construction Process Management 50
Juergen Melzner

Automated Unit Price Visualization Using ArcPy Site Package in ArcGIS 57
K. Joseph Shrestha and H. David Jeong

Real-time Tracking for Intelligent Construction Site Platform in Finland and China: Implementation, Data Analysis and Use Cases 62
Jianyu Zhao, Jinyue Zhang and Olli Seppänen

Identifying Moderation Effect between Project Delivery Systems and Cost Performance 69
Hyosoo Moon, Hyun-Soo Lee, Moonseo Park and Bosik Son

Designing a Reliable Fiducial Marker Network for Autonomous Indoor Robot Navigation 74
Bharadwaj Mantha and Borja Garcia de Soto

Designing a Development Board for Research on IoT Applications in Building Automation Systems 82
Markus Hans Schraven, Carlo Guarnieri Calo Carducci, Marc Axel Baranski, Dirk Müller and Antonello Monti

Optimal Laser Scan Planning for As-Built Modeling of Plant Renovations Using Mathematical Programming 91
Eisuke Wakisaka, Satoshi Kanai and Hiroaki Date

Automatic Generation of the Vertical Transportation Demands During the Construction of High-Rise Buildings Using BIM 99
Keyi Wu, Borja Garcia de Soto, Bryan T. Adey and Feilian Zhang

Standard Closed-Circuit Television (CCTV) Collection Time Extraction of Sewer Pipes with Machine Learning Algorithm 107
Xianfei Yin, Yuan Chen, Ahmed Bouferguene, Hamid Zaman, Mohamed Al-Hussein, Randy Russell and Luke Kurach

Implementation Framework for BIM Adoption and Project Management in Public Organizations 114
Giuseppe Miceli Junior, Paulo C. Pellanda and Marcelo de Miranda Reis

Classification and Exemplary BIM Models Development of Design Changes 122
Jia-Rui Lin, Yu-Cheng Zhou, Jian-Ping Zhang and Zhen-Zhong Hu

Multi-objective Optimization Analysis for Selective Disassembly Planning of Buildings 128
Benjamin Sanchez, Christopher Rausch, Carl Haas and Rebecca Saari

Construction and Usage of Three-dimensional Data for Road Structures Using Terrestrial Laser Scanning and UAV with Photogrammetry 136
Satoshi Kubota, Chiyuan Ho and Kotaro Nishi

Cartesian Points Visualization in Game Simulation for Analyzing Geometric Representations of AEC Objects in IFC 144
Jiansong Zhang, Yunfeng Chen, Rui Liu and Luciana Debs

The Benefits of and Barriers to BIM Adoption in Canada 152
Yuan Cao, Li Hao Zhanga, Brenda McCabe and Arash Shahi

On the Estimation of Resonance Frequencies of Hydraulically Actuated Systems 159
Manuel Pencelli, Renzo Villa, Alfredo Argiolas, Marta Niccolini, Matteo Ragaglia, Paolo Rocco and Andrea Maria Zanchettin

Predicting Bridge Conditions in Ontario: A Case Study 166
Maedeh Taghaddos and Yasser Mohamed

Automated Mathematical-Based Design Framework for The Selection of Rigging Configuration 172
Seyed Mohammad Amin Minay Hashemi, Sanghyeok Han, Jacek Olearczyk, Ahmed Bouferguene, Mohamed Al-Hussein and Joe Kosa

An Analysis of the Problems of BIM-Based Drawings and Implementation During the Construction Document Phase 179
Yije Kim and Sangyoon Chin

Identification of the Structural State in Automated Modular Construction 187
Aparna Harichandran, Benny Raphael and Abhijit Mukherjee

A Conversation-based System for School Building Inspections 194
Hao-Yung Chan, Liang-Yuan Liu and Meng-Han Tsai

Enabling BIM for Property Management of Existing Buildings Based on Automated As-is Capturing 201
Ralf Becker, Elisa Lublasser, Jan Martens, Raymond Wollenberg, Haowei Zhang, Sigrid Brell-Cokcan and Jörg Blankenbach

Impact of 5G Technology on IoT Applications in Construction Project Management 209
Varun Kumar Reja and Koshy Varghese

Context-Realistic Virtual Reality-based Training Simulators for Asphalt Operations 218
Faridaddin Vahdatikhaki, Armin Kassemi Langroodi, Denis Makarov and Seirgei Miller

Generating Generic Data Sets for Machine Learning Applications in Building Services Using Standardized Time Series Data 226
Florian Stinner, Yingying Yang, Thomas Schreiber, Gerrit Bode, Marc Baranski and Dirk Müller

Developing Personalized Intelligent Interior Units to Promote Activity and Customized Healthcare for Aging Society 234
Rongbo Hu, Amir Kabouteh, Katja Pawlitza, Jörg Güttler, Thomas Linner and Thomas Bock

A Representative Simulation Model for Benchmarking Building Control Strategies 242
Alexander Kümpel, Florian Stinner, Bastian Gauch, Marc Baranski and Dirk Müller

Accurate Position Control for Hydraulic Servomechanisms 250
Manuel Pencelli, Renzo Villa, Alfredo Argiolas, Gianni Ferretti, Marta Niccolini, Matteo Ragaglia, Paolo Rocco and Andrea Maria Zanchettin

The Automation of the Softer Side of Smart City: a Socio-Semantic Roadmap 258
Tamer El-Diraby, Alain Zarli and Mohamed El-Darieby

Factors Affecting the Performance of 3D Thermal Mapping for Energy Audits in a District by Using Infrared Thermography (IRT) Mounted on Unmanned Aircraft Systems (UAS) 266
Yu Hou, Lucio Soibelman, Rebekka Volk and Meida Chen

Evaluating the Performance of e-Construction Tools in Highway Resurfacing Projects 274
Dhaivat Patel, Roy Sturgill, Gabriel Dadi and Timothy Taylor

Evaluating Risk Response Strategies on Construction Projects Using a Fuzzy Rule-Based System 282
Seyed Hamed Fateminia, Nima Gerami Seresht and Aminah Robinson Fayek

A Review of Data-Driven Accident Prevention Systems: Integrating Real-Time Safety Management in the Civil Infrastructure Context 289
Amin Assadzadeh, Mehrdad Arashpour, Ali Rashidi, Alireza Bab-Hadiashar and Sajad Fayezi

Augmented Reality-Enabled Production Strategy Process 297
Hala Nassereddine, Dharmaraj Veeramani and Awad Hanna

Chatbot System for Data Management: A Case Study of Disaster-related Data 306
James Yichu Chen, Meng-Han Tsai, Cheng-Hsuan Yang, Hao-Yung Chan and Shih-Chung Kang

Integrating Hardware-In-the-Loop Simulation and BIM for Planning UAV-based As-built MEP Inspection with Deep Learning Techniques 310
Kai Wang and Jack C.P. Cheng

A Review of Social, Physiological, and Cognitive Factors Affecting Construction Safety 317
Sahel Eskandar, Jun Wang and Saiedeh Razavi

Automatic Classification of Design Conflicts Using Rule-based Reasoning and Machine Learning—An Example of Structural Clashes Against the MEP Model 324
Ying-Hua Huang and Will Y. Lin

Augmented Reality and Deep Learning towards the Management of Secondary Building Assets 332
Alessandra Corneli, Berardo Naticchia, Alessandro Cabonari and Frédéric Bosché

Assessing Digital Information Management Between Design and Production in Industrialised House-Building – A Case Study 340
Henrik Eriksson, Marcus Sandberg, Jani Mukkavaara, Gustav Jansson and Lars Stehn

Platforms for Enabling Flexibility at Two Construction Companies 348
Henrik Eriksson and Ellinor Emilsson

A Study of Kinetic Façade Modelling Performance Using Virtual Reality 356
David Panyaa, J.H. Seo, H.J. Park, W.J. Lee and Seungyeon Choo

A Basic Study on Methodology of Maintenance Management Using MR 360
T. Kim, J. Jeong, Y. Kim, H. Gu, S. Woo and S. Choo

Process Modelling in Civil Infrastructure Projects: A Review of Construction Simulation Methods 368
Maryam Al-Kaissy, Mehrdad Arashpour, Sajad Fayezi, Ali Akbarnezhad and Baabak Ashuri

Optimizing Site Layout Planning Utilizing Building Information Modelling 376
Abhishek Raj Singh, Yash Patil and Venkata Santosh Kumar Delhi

Hyperspectral Imaging for Autonomous Inspection of Road Pavement Defects 384
Mohamed Abdellatif, Harriet Peel, Anthony G Cohn and Raul Fuentes

Inference of Relevant BIM Objects Using CNN for Visual-input Based Auto-Modeling 393
Jinsung Kim, Jaeyeol Song and Jin-Kook Lee

Predicting Safety Hazards Among Construction Workers and Equipment Using Computer Vision and Deep Learning Techniques 399
Mingzhu Wang, Peter Kok-Yiu Wong, Han Luo, Sudip Kumar, Venkata-Santosh Kumar Delhi and Jack Chin-Pang Cheng

The Design of Building Management Platform Based on Cloud Computing and Low-Cost Devices 407
Li-Te Huang, Yi-Yang Chiu and Ying-Chieh Chan

Spatial Information Enrichment using NLP-based Classification of Space Objects for School Bldgs. in Korea 415
Jaeyeol Song, Jinsung Kim and Jin-Kook Lee

Towards Automated HVAC Controls Commissioning: Mechanisms to Identify Temperature and Flow Related Functions of AHU Components 421
Raghuram Sunnam, Semiha Ergan and Burcu Akinci

A Chatbot System for Construction Daily Report Information Management 429
Jehyun Choa and Ghang Lee

Supporting Deconstruction Waste Management through 3D Imaging: A Case Study 438
Yujie Wei, Akash Pushkar and Burcu Akinci

Text Detection and Classification of Construction Documents 446
Narges Sajadfar, Sina Abdollahnejad, Ulrich Hermann and Yasser Mohamed

Holonic System for Real-Time Emergency Management in Buildings 453
Berardo Naticchia, Leonardo Messi, Massimiliano Pirani, Andrea Bonci, Alessandro Carbonari and Lucia Cristina Tolve

Grasped Element Position Recognition and Robot Pose Adjustment during Assembly 461
Kepa Iturralde, Taku Kinoshita and Thomas Bock

Adaptive Haptically Informed Assembly with Mobile Robots in Unstructured Environments 469
Pradeep Devadass, Sven Stumm and Sigrid Brell-Cokcan

Integrating Earthwork Ontology and Safety Regulations to Enhance Operations Safety 477
Alhusain Taher, Faridaddin Vahdatikhaki and Amin Hammad

Combining Deep Learning and Robotics for Automated Concrete Delamination Assessment 485
Evan McLaughlin, Nicholas Charron and Sriram Narasimhan

Web-Based Job Hazard Assessment for Improved Safety-Knowledge Management in Construction 493
Emad Mohamed, Parinaz Jafari, Estacio Pereira, Stephen Hague, Simaan Abourizk and Rod Wales

Leading Safety Indicators: Application of Machine Learning for Safety Performance Measurement 501
Parinaz Jafari, Emad Mohamed, Estacio Pereira, Shih-Chung Kang and Simaan Abourizk

Towards the Ontology Development for Smart Transportation Infrastructure Planning via Topic Modeling 507
Jin Zhu and Sudipta Chowdhury

Automated Detection of Urban Flooding from News 515
Farzaneh Zarei and Mazdak Nik-Bakht

Adaptive Automation Strategies for Robotic Prefabrication of Parametrized Mass Timber Building Components 521
Oliver David Krieg and Oliver Lang

Semantic Network Analysis as a Knowledge Representation and Retrieval Approach Applied to Unstructured Documents of Construction Projects 529
Rodrigo Rodrigues Aragao and Tamer El-Diraby

Digital Fabrication and Crafting for Flexible Building Wall Components: Design and Development of Prototypes 537
Nzar Naqeshbandi and Paulo Mendonça

As-is Geometric Data Collection and 3D Visualization through the Collaboration between UAV and UGV 544
Pileun Kim, Jisoo Park and Yong Cho

Web-based Deep Segmentation of Indoor Point Clouds 552
Zehuan Chen, Erzhuo Che, Fuxin Li, Michael Olsen and Yelda Turkan

Ontology for Logistics Requirements on a 4D BIM for Semi-Automatic Storage Space Planning 560
Jan Weber, Jana Stolipin, Markus König and Sigrid Wenzel

Integrating Social Sustainability in Value Stream Mapping: Panelized Post-Disaster Temporary Housing Case Study 568
Miguel Mora, Burcu Akinci and Luis Alarcón

An Experimental Investigation of the Integration of Smart Building Components with Building Information Model (BIM) 578
Kereshmeh Afsari, L. Florez, Emily Maneke and Mahdi Afkhamiaghda

Semantic Segmentation of Sewer Pipe Defects Using Deep Dilated Convolutional Neural Network 586
Mingzhu Wang and Jack C.P. Cheng

Information Exchange Process for AR based Smart Facility Maintenance System Using BIM Model 595
Suwan Chung, Soonwook Kwon, Daeyoon Moon, K.H. Lee and J.H. Shin

A Framework Development for Mapping and Detecting Changes in Repeatedly Collected Massive Point Clouds 603
Sanghyun Yoon, Sungha Ju, Sangyoon Park and Joon Heo

Development of the Simulator for Carrying a Lifted Load in Large Plant Construction 610
Yoshihito Mori, Masaomi Wada, Sayuri Maki and Satoshi Tsukahara

Digital Twinning of Existing Bridges from Labelled Point Clusters 616
Ruodan Lu and Ioannis Brilakis

Improved Tag-based Indoor Localization of UAVs Using Extended Kalman Filter 624
Navid Kayhani, Adam Heins, Wenda Zhao, Mohammad Nahangi, Brenda McCabe and Angela Schoellig

Abstract –

The overall performance of a life-cycle phase under investigation can be improved if Multi-Design for X (MDFX) technique's design guidelines are applied concurrently. However, the complexity of selecting MDFX techniques at the conceptual and detailed design stages during machine development can increase by uncertain and imprecise knowledge about the MDFX interdependencies. For many industrial companies, alleviating the design decision complexity at these stages can have a positive impact on the industry's competitive market. Therefore, it becomes crucial to have a robust MDFX tool embedded with conflict resolution in valuing potential applications to justify their cohesion. Some limitations on the compatibility between MDFX remain a challenge. The unresolved challenge is how the information contained within MDFX can be organized such that the implications of design decisions are proactively evaluated and implemented. To address this challenge, an efficient decision tool for applying MDFX in the conceptual and detailed machine design development phases is proposed. In this paper, the relative importance of DFXs guidelines and the essence of the interactions that arise between them are also studied. Also, a matrix model with multi-layers to simulate the interactions between MDFX is suggested to resolve the conflict of experts' opinion and aggregates the decision criteria layers into a single output. The proposed decision tool was applied in a machine design case study and shows its effectiveness in the decision-making process by eliminating MDFX negative interactions and aiding the designer in shaping the optimal machine design with less development cost and time.

Keywords –

Multi-Design for X (MDFX); life-cycle cost; conceptual and detailed design stage; conflict resolution; multi-layers.

1 Introduction

The implementation of MDFX in concurrent engineering machine design can result in contradictory and conflicting conclusions and recommendations for the designer's design-making process. Several independent studies have started to investigate and analyze these contradicting interactions by using various frameworks developed by Watson that can quantify the MDFX usefulness by design phase [9]. They concluded that MDFX, depending on where they are implemented during the machine development process, have a varying impact threshold. Whereas Willcox and Sheldon realized that the implementation of Design for Assembly methodology is most useful at the conceptual stage [10]. Because the tool component analysis is the main part of the methodology, it is preferred during the machine detailed design stage. The DFA analysis tool is an unreliable tool to be utilized during the conceptual machine stage because the design details required to undergo the analysis are not available at this stage. Hence, if the analysis tool is not effective at the conceptual design stage, then the alternative will be the benefits that the design guidelines of a specific DFX provide. So, to minimize the machine redesign possibilities and reduce the cost/time of this activity, the analysis tool should consider the importance of DFX guidelines.

Some research was undertaken to investigate how to tackle the conflicting implementation guidelines of MDFX. Thurston suggests a methodology to model the design decision results on the interval of a machine life-cycle [8]. A framework was developed to facilitate the decision-making process through ranking the design alternatives and calculating design trade-offs. In engineering design, it is a powerful analysis tool for decision making where multiple criteria and objectives exist. Unfortunately, for most applications, this method is very complicated and extensively time-consuming for designers in small to medium-sized organizations. If this ranking method is adopted to classify the design

guidelines, it would be unnecessarily tedious because the model used by Thurston is to some extent more complicated to implement than what is required for this application. A simpler and faster method for trade-off analysis between MDFX is to implement a matrix approach. Meerkamm concludes that if MDFX techniques are to be utilized in a problem context, then their design guidelines will often contradict and constrain the design output [4]. Consequently, as explained by Watson et al., finding an optimal solution is becoming a difficult task for designers [9]. As the design guidelines tend to be the DFX toolbox's most flexible aspect, they accurately indicate the nature of the DFX interactions and links between them and their concurrent interdependencies in ultimately finding an optimal design solution.

It is important to evaluate the application of MDFX in machine design development comprehensively. But due to the absence of information in the conceptual machine stage, problems and conflicts can arise when MDFX techniques are employed. This is because of a lack of information and vague objectives, which interfere with the designer's ability to evaluate design decision alternatives precisely. Decisions that emerge from applying one DFX technique seem to be good for one phase of the machine life cycle but can conflict with other life cycle phases. The designer should oversee the concurrent effects of the decision-making process in machine design. If the previous decisions are based on inaccurate information, the following design stages will be affected significantly. The application of MDFX techniques in machine design development requires effective decision support systems. In view of this, a decision support tool that simulates the concurrent interdependencies between MDFX techniques during the conceptual machine design stage is proposed in this paper.

2 Methodology

The methodology presented in this section is based on Watson et al.'s model that uses a weighted matrix method to exploit the interactions between MDFX [9]. The matrix method is extended to simulate the concurrent interdependencies between MDFX. The model output provides three useful indices. The first one indicates major areas of potential conflict occurring between the compared MDFX. The second illustrates how the value of a specific guideline is modified when interacting with the competing DFX guidelines. And the third is measuring the DFX techniques in terms of time metrics to estimate and reliably verify DFX interactions and design decisions comprehensively.

2.1 Procedure of the matrix

The methodology for assessing and ranking the DFX's competing design guidelines requires six distinct tasks to be undertaken. These tasks are described in the flowchart presented in Figure 1.

2.2 Task 1: Determine DFX overall weight using the analytical hierarchy process (AHP) method

The first task involves selecting and calculating the overall relative importance (weight) of the chosen DFX techniques. This can be achieved by calculating the weight of each DFX technique separately with respect to the design criteria, and then by combining them in an AHP model developed by Saaty to determine their relative importance in machine conceptual and detailed design stages [6]. In general, the relative importance of a DFX technique varies as to where and when it can be applied during the machine development process [1]. He concludes that the area where a DFX technique can be utilized is defined by company and customer requirements, production capabilities, and industry orientations, in addition to other considerations.

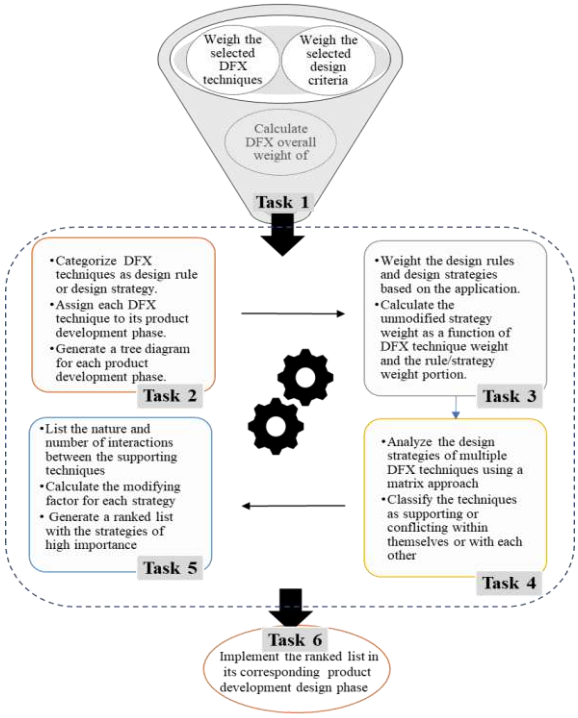

Figure 1. Multi-DFX techniques matrix model flow chart

The product design specification (PDS) must be formulated at the beginning of the project based on the statement of needs prior to any design activity, as shown

in Figure 2. Thus, it acts as the governor for the total design activity model, because it revolves around the boundaries of each design stage for any machine.

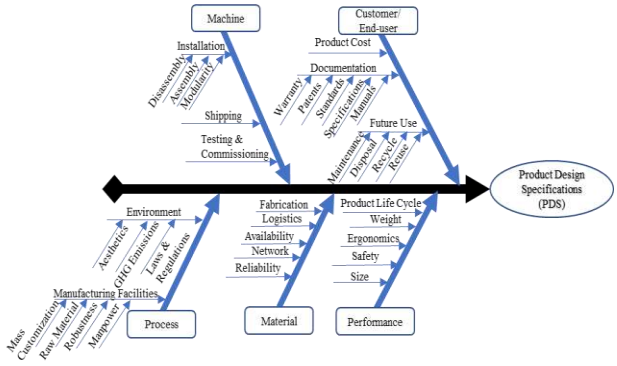

Figure 2. Product design specification (PDS).

The PDS forms a progressive, evolutionary, and extensive written document that evolves in consideration of the final machine characteristics. The PDS is then translated into design criteria that are followed by the design team, and as such, each design criterion will be associated with one or multiple DFX techniques that can satisfy its requirements. By adapting the total life-cycle cost/time method developed by Lukasz and Tomasz, the design team can successfully estimate each DFX technique's effect with respect to the other, and those values will be an indicator as to how much each DFX can reduce the development life-cycle overall cost and time [2].

DFX techniques are weighted with respect to each design criterion to generate an overall general normalized importance weight W_{DFXG} with a total value of 1. From that, the time required for each design activity T_{DFXG} can be derived under a certain DFX. This weighting factor will then be adopted in the general model for conceptual and detailed design stages. The weighting in the AHP model must rely on the designer's experience and intuition. W_{DFXG} and T_{DFXG} are calculated using Equation (1) and (2), respectively, as follows:

$$W_{DFXG} = \frac{Cost\ x}{Cost\ T} \quad (1)$$

Where,
$Cost_x$= The cost of life-cycle area x
$Cost_T$= The combined cost of the life-cycle

$$T_{DFXG} = W_{DFXG}\ x\ T_t \quad (2)$$

Where,
T_{DFXG}= The allocated time for a specific DFX in days

T_t= The total time for the design activity in days

2.3 Task 2: Generate tree diagram to classify DFX design guidelines

In this section, the machine development process is categorized, and the hierarchical level of the DFX technique design guidelines is established. Watson, Radcliffe et al. proved that if DFX decision analysis tools are utilized during conceptual and detailed machine design stages, they could improve the design performance significantly [9]. They also concluded that most DFX techniques fail to give what is expected because they merely provide the designer with directions on how and when the design rules can be implemented.

Pugh's Total Design Activity Model is used to describe the machine development process [5]. The model phases are 1) user need; 2) machine specification; 3) conceptual design; 4) detail design; 5) manufacture; and 6) and sales. Though design activities might not always have to occur concurrently in the sequence outline by Pugh, his machine development model provides a detailed structured procedure of all the stages required. Table 1 contains some design guidelines examples which are the most applicable for machine design development process extracted from the Design for Assembly (DFA) methodology [2].

Table 1. DFA guidelines per design stage

Specification	• Standardize a machine's style. • Establish the machine design specification.
Concept Design	• Reduce the number of parts and components. • Eliminate machine features that do not have any tangible value to the customer. • Standardize a machine's style. • Using new materials and technologies. • Rational machine design by modules and product families.
Detailed Design	• Design multi-functional parts. • Developing the machine features that facilitate the positioning. • Avoid costly clamping systems.
Manufacture	• Simplicity. • Adapted tolerances. • Consideration of process-related design guidelines.

The second task in constructing the model is to organize the DFX technique design guidelines into a decision tree using a hierarchical structure. Each DFX technique consists of primary and secondary design guidelines called design rules and design strategies, respectively. The tree diagram consists of three levels where the first level is associated with the general DFX tool under study, the second level is associated with

DFX design rules, and the third level is associated with DFX design strategies. Table 2 contains an example of the hierarchical tree using the DFA guidelines during the detailed design phase [2].

Table 2. DFA detailed design stage guidelines

Design Rules	Design Strategies
Reduce the number of parts and their types	Reduce unstandardized fasteners. Eliminate parts that function as connectors and conduits. Design multi-function parts. Do not follow piece-part producibility guidelines.
Eliminate physical adjustments	Reduce the number of physical parts between the machine input and output functions. Relocate critically related part surfaces close together. Implement kinematic design procedures and principles.
Ensure adequate clearance and unrestricted vision	Ensure adequate clearance for hands, tools, and subsequent process. Ensure that the vision of the operation is not restricted or compromised.
Minimize re-orientations	Minimize the necessity for reorientations during and after parts installation.

2.4 Task 3: Determining the weightings levels of the guidelines

The third task requires that the DFX technique design rules and strategies be weighted. Regarding the weighting levels, they are determined in each phase, which gives the designer a general design overview of the machine development process. The design rules weighting, W_{TR}, is determined independently, regardless of the design strategies number (on a scale of 1 to 10). While the design strategies weighting, W_{PS}, is determined in proportion to the design rule it corresponds to on a scale of 1 to 10, such that the total weight summation under design rules is equal to 1. The total weight of each design strategy, W_{TS}, is calculated using Equation (3) by multiplying the DFX technique overall weight, the design rule total weight, and the design strategy proportional weight. Thus, the total weight of each design strategy can fluctuate between 0 and 1. While the time required for each design strategy, T_{TS}, is calculated in days using Equation (4) by multiplying the strategy calculated weight from Equation (3) by the allocated time for the selected DFX divided by the summation of strategies weight for the selected design phase.

$$W_{TS} = W_{DFXG} \times W_{TR} \times W_{PS} \quad (3)$$

$$T_{TS} = \frac{T_{DFXG} \, x \, W_{TS}}{\sum_{i=0}^{n} W_{TS}} \quad i=0,1,2\ldots. n \quad (4)$$

2.5 Task 4: Identifying interactions and links between guidelines

The fourth task involves determining the interactions and links between the strategies and reporting them inside the matrix model. The severity of any conflicts can be measured from these interactions. The matrix model can be utilized to compare multiple numbers of strategies from MDFX techniques. However, the process of finding each relationship between strategies can become tedious and time consuming for MDFX guidelines. It is assumed that not more than four DFX tools and a maximum number of ten strategies per phase should be adopted in the model.

Table 3. Strategies comparison values

R Values	Description
+ 1	Two or more strategies interact positively.
+0.5	One strategy supports positively the other in a broader scope.
0	No interaction occurs between the design strategies.
-0.5	One strategy supports negatively the other in a broader scope.
-1	Two or more strategies interact negatively.

From the matrix model, it is possible to pinpoint any conflict between two strategies to alert the designer that special consideration should be in place when dealing with them. This is done using the conflict index, CI, which quantifies the severity of the conflict. When a negative interaction occurs, the equation to calculate the conflict index is employed. The conflict index constant is calculated using Equation (5) as follows:

$$CI = W_{TS} \times W_{TS'} \times R \quad (5)$$

if CI < -10 then conflict must be examined.

Where,

$W_{TS'}$ = Total weight of compared strategy

R = The comparison value for the two design strategies, as shown in Table 3.

2.6 Task 5 & 6: Generating the ranked list of DFX strategies

The fifth task involves calculating the overall value ($\square_{TS}$) of a design strategy considering strategies weight and their interactions with each other. The main process is based on the assumption that each design strategy has a total weighted value (W_{TS}) and interactions with other strategies adjust this. The prime factor is a function of the comparison index and the compared guideline weight. By summing the prime value over all the DFX interactions, a global scaler is determined. Equations (6) & (7) calculate the overall value ($\square_{TS}$) as follows:

$$\square_{TS} = W_{TS} (1 + \delta \square) \quad (6)$$

$$\square_{TS} = W_{TS} \left(1 + \sum \frac{(W_{TS'} \, x \, R \, x \, S)}{100}\right) \quad (7)$$

Where,

$$S=\frac{15}{W_{TS}} \quad \text{if } W_{TS'}>W_{TS} \text{ and } R<0 \qquad (8)$$
$$S=1 \quad \text{else}$$

Where,
δ □ =the total prime factor overall strategies and DFX techniques
S = the scaler
15 = Number of DFX techniques being researched
100 =scaling factor

In Equation (8), the scaler considers the instances when a low weight design strategy conflicts with a high weight one. Having determined the total strategy value, a ranked list can be configured to be implemented in the machine development. Any design strategies that have a negative total value should be ignored because if adopted, then it may lead to a life-cycle performance reduction due to its conflicting correlations with other strategies. After generating the ranked list, the redundant design strategies within the competing DFX will be removed to save time and to eliminate design repetition. However, if both design strategies match each other in the core objective, then the lesser time duration will be selected.

3 Validation Case Study

In this section, the focus of the case study will revolve around a part of the multi-function bridge machine prototype which is the nailing carriage in its conceptual design stage, as shown in Figures 3 and 4.

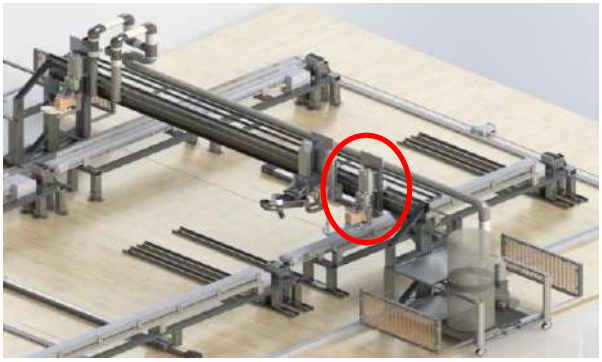

Figure 3. 3D model of multi-function bridge prototype

As the carriage at this stage is primarily a research tool, it is assumed that there would be a maximum amount of flexibility and testability within the variability of the experimental parameters. It also meant that a simple and unique machine would be designed. As the carriage will be operating in a large area with extreme precision at a controlled speed, it is apparent that the geometry and versatility of the carriage are considered as a major design criterion. It is also apparent that because the vertical force loads are so small, any part stresses would be negligible.

Figure 4. Nailer carriage detailed view

From the PDS, the carriage to be designed is to accommodate multiple configurations of interchangeable tools, such as a nailer, stapler, and screwdriver. This operational requirement results in the device being partially disassembled and re-assembled after each operation and for different sheathing configurations. Regarding parts service life, it is expected that no major parts should fail throughout the device's life. The final requirement is that the device is to be designed and manufactured within a very limited budget. The detailed technical information of the machine development is excluded from this paper for patentability and commerciality of the machine. Instead, some of the case study design related issues are discussed in broad terms. The timeline to complete the carriage conceptual design was 60 calendar days. These days are distributed on all 15 DFX techniques in accordance with their global weighting results.

DFA Design rules and strategy weights by product development phase							
Product Development Phase	Design Rules	W_{DFXG}	W_{TR}	Design Strategies	W_{TS}	W_{TS}	T_{TS}

Design for Environment (DFE)	0.024	1.46

In this case, 15 DFX techniques fall under the scope of the conceptual design stage with their global weighting associated with the PDS that was calculated by adopting the AHP model. Table 4 summarizes the results where the total summation of all DFX weighting is equal to 1 and where each DFX has a time allocation associated with it. In this paper, two DFX techniques were selected from the list to demonstrate the model functionality: Design for Assembly (DFA) and Design for Disassembly (DFDA). The DFA technique selected was developed by Boothroyd and Dewhurst [2]. The methodology has been refined and upgraded to provide a realistic and reliable design analysis tool with set of guidelines that are presented in a structured format. The tool follows the same basic procedures to analyze for manual, automatic and robotic assembly with different input data tables for the various processes. For this project, the manual assembly method is adequate. The designed machine would encounter assembly and re-assembly process on a regular basis. This process has a substantial effect on how the design guidelines are interpreted and rated. A team of researchers developed the DFDA technique adopted in this case study at the Manchester Metropolitan University ([7], [11]). The developed technique purpose is focused on the disassembling process to facilitate reconfiguration. Figures 5 and 6 contains the list of design rules and strategies for conceptual design machine development phases for both DFA and DFD techniques. Since two DFX techniques are being investigated, only one decision matrix for the conceptual machine development phase is selected for the demonstration of the comparison and ranking process. Figure 7 shows the conceptual design comparison matrix for DFA versus DFDA highlighting the guidelines interactions.

Conceptual Design	DFDA Strategies	Subdivide the product into manageable subassemblies.	Minimize the number of components and subassemblies.	Standardize the products style.	Avoid long disassembly paths.			
DFA Strategies	W_{TS}	0.25	0.25	0.00	0.10

4 Results and Discussion

As highlighted in the matrix shown above in Figure 7, two design strategies have conflicted, so special consideration must be in place to resolve this conflict before they the ranking procedure starts. However, the conflict occurs, in this case, is when the designer simultaneously attempts to minimize the need for reorientation during assembly while attempting to standardize the machine during disassembly. It is assumed that the arising conflict could be ignored, subject to further investigation, as the conflict index slightly exceeds the threshold value of ten.

Figure 8 summarizes the ranking of the strategies in descending order based on their respective total value. After analyzing the results, the designer can eliminate from the ranked list the strategies that are repeated or have the same core objective, while the strategies with the same ranking order can be implemented concurrently in the design process to emphasize their relatively equal importance.

Figure 9 summarizes the modifications after the designer has conducted the analysis. If both selected DFX techniques were to be applied in standalone mode, then after several design iterations they will conflict, which would lead to a machine redesign. The redesign process is a costly and time-consuming activity, and by applying this methodology, the designer can avoid the pitfall of such activity.

If the designer is to apply DFA with 4.96 days and DFDA with 2.86 days independently then the total time required for both will be 7.82 days. However, if they are applied together, the redundant design strategies between the two and the conflicted area will be removed and adjusted before initiating the design activity. Thus, reducing the total time to 6.63 days with a difference of 1.19 days.

Some observations were concluded after applying the matrix model in the case study mentioned above such as if the value of the conflict index constant exceeds a value of negative ten, then it can be declared that a conflict of substantial consequences has occurred, and some considerations are required to resolve it. This conflict can be resolved and avoided by implementing some tactics as follows:

1. If the conflict index constant is close to ten, then the resulted conflict could be ignored and eliminated on the basis that it will create a down weight effect on the other design strategies in the ranked list.
2. Develop and integrate a design methodology after examining the conflict-specific details to decrease the negative interaction areas between strategies—this is very useful in areas where partial conflict has been spotted ($CI \leq -10$).
3. The matrix model ranking function will eliminate any two design strategies that have a large total value difference, and it will eliminate negative values too.

The weighting procedure of any parameter may sometimes be a subjective process, as two different designers may weigh the same guideline differently. This difference comes from the usage circumstances, the experience, and interpretation of the designers as to what the guideline means. However, these differences will not give the user a misleading result because the guidelines are interpreted according to the designer's understanding.

That said, future work will be required to extend the applicability of the decision tool in the DFX trade-off analysis with respect to cost and quality to provide a better understanding of client needs while controlling the machine lifecycle. Moreover, the future development of this methodology will be required to cover the other phases of the machine lifecycle (e.g., embodiment design, manufacturing, and sales).

DFA and DFDA Strategies in Conceptual Design Stage Ranking List Summary	Ψ_{TS}	Ranked List	T_{TS}

5 CONCLUSION

Engineering design is an iterative process of solution generation and evaluation. It requires a designer to take a forward-thinking and a look ahead approach when finalizing a solution. In a dynamic environment, a concurrent application of MDFX techniques during the design process can be organized into multiple stages in which both evaluation and decision are needed. The main theme of this paper was to present the need for a tool that can reliably estimate and verify the time/benefits of applying MDFX in a harmonized way in machine design. As a result, a decision support tool that can aid the designer in the decision-making process when MDFX are utilized will be required. The main feature of a design decision simulation tool is to enable designers to foresee and explore lifecycle consequences during the machine design. Also, to provide a structured workflow specifying how and when MDFX techniques can be applied with the ability to quantify the arising conflict that may occur between them. The tool's fundamental core is based on the information contained within the DFX guidelines, which may be classified as either a design strategy or rule so their interactions can be examined explicitly. Thus, the generation of a ranked list can be integrated in a time-effective and strategic manner, thereby shrinking the machine design time by at least 15%. As demonstrated, the MDFX decision tool can be implemented to serve as a generative decision system that proactively aids the designer in the decision-making process.

Abstract –

Several researchers have worked in the field of implementing robotics technology in concrete building construction, after the first attempt in the 1980s in Japan. Various motivations such as the shrinking labor population, the aging of skilled workers, and the construction safety issues have promoted the development of such technologies. However, the future visionary on how construction robots can transform the concrete building construction sector is still not solid nor well structured.

What really needs to be changed? What types of construction activities can be taken by automated robotic technologies, as opposed to manpower or skilled worker? To answer these questions, the systematic review reported in this paper seeks to evaluate and synthesize empirical findings on the use of robotic technologies in concrete building construction.

A systematic search of Scopus, Web of Science, IEEE, and Engineering Village databases was conducted, and 48,200 documents were targeted. By applying the inclusion and exclusion criteria, 48,149 records were excluded, and the remaining 51 records were assessed for eligibility and included in the qualitative synthesis. The systematic review shows that researchers in the USA played a leading role on robotics in concrete building construction, followed by Germany and Switzerland. The robotics application and techniques have been largely used on-site and targeted low-rise buildings. The robotic technologies that have been popular in literature included 3D printers, and swarm robotics. Most of the papers have proposed a limited novel structural design, without introducing innovative construction material. Even though the direct and indirect construction activities related to formwork, steel reinforcement, and concreting can be replaced and thus eliminated, the horizontal RC elements still cannot be built on-site without supports. Moreover, rapid prototyping found to be the best robotic design for the purpose of building construction through utilizing manipulator robots.

Keywords –

Concrete buildings; Robotics in construction; Freeform construction; Future of construction.

1 Introduction

The fundamental principles in building construction have not yet substantially changed, since the Romans invented concrete about 100 BC [1]. Later, concrete is still considered globally as the primary material for construction. According to a recent report by the Cement Sustainability Initiative (CSI) [26], concrete is the second most consumed substance after water, with around 10 billion tonnes of concrete are manufactured globally in every year. Consequently, concrete has been the focus in several investigations into robotically fabricated, geometrically complex, non-standard loadbearing constructions [2].

The building construction industry has not been a favourable field for the application of robotic technologies, however, various motivations such as the shrinking labour population, the aging of skilled workers, and the construction safety issues have promoted the development of robotic construction systems [3]. The United Nations world population prospects in 2015 indicated that global population is expected to grow by 34% by 2050 compared to 2014, which will reach 6.5 billion people in 2050 or about two-thirds of the global population [4]. In accordance, the rising in population is expected to growth the necessity for new buildings.

Meanwhile, the building construction process has been characterized as simple and systematic; depending on formwork systems and skilled labour to build any type of concrete structural element [5]. The current construction methodologies used in structural concrete buildings are completely dependent on manual techniques that are slow, expensive, and non-coordinated [27]. Moreover, the main obstacles for the

introduction of robotics within the building construction industry are the variability of the construction processes and the complex conditions of the construction environment [6].

Many building construction activities have the potential to be executed by implementing the robotic technologies techniques [7]. However, adapting new technologies necessitates several special properties of high payload, reliability, and wide workspace to be achieved [8]. In addition, many robots will work in the same task, in which path planning on site would be complicated [9]. As explained by Scott et al. (2011), human construction differs from construction by robots as it involves some sort of pre-defined high-level plan and in some regard is independent from the environment [10].

Several researchers have worked in the field of implementing robotic technologies in building construction, after the first attempt in the 1980s in Japan [2]. While some autonomous construction robots have been developed, they can only be applied to simple tasks to support human workers [9]. An example of such approaches is the Big-Canopy, which is the world's first automated construction system for building a precisely defined concrete structure in Japan [11]. Nevertheless, the degree of intelligence exhibited by commercially-available robots is still deemed very limited, as robots are currently deployed only in a small subset of possible applications with low level of localization accuracy [12, 31].

If robotic technologies could truly be implemented in construction, they would certainly have the potential to improve measures like its speed and efficiency, as well as enabling construction in settings where it is difficult or dangerous for humans to work such as working at heights, in extra-terrestrial environments and disaster areas [13, 32, 33]. In this context, this paper aims to review existing studies in this field, to investigate how the robotic technology can be implemented in the concrete building construction. To overcome the existing constraints and limitations, the ongoing research will examine construction activities with a potential to be executed by robotic technologies, functionality of the robots, and the interaction between humans and robots.

The remainder of the paper is structured as follows. Section 2 introduces the background of the research, followed by the methodology of using a systematic review. Section 4 and 5 detail the results and discussion. Finally, the paper concludes with the guidelines for future research.

2 Background of the study

2.1 Early attempts

Despite the recent advances in adoption of robotic technologies in the construction industry, the architectural processes which demand a high degree of geometric freedom remain largely labour intensive and manual [19]. This is due to the inherent difficulties in robotizing the current implementation of such processes coupled with the lack of alternate technologies [2].

In the last three decades some Japanese construction companies have attempted to remedy the shortage of skilled labour in building construction by resorting to automation [20]. Khoshnevis et al. (2006) categorized the current robotic technologies in concrete building construction in accordance to the Japanese companies. The first one uses single task robots that can replace simple labour activities at the construction sites. The second category consists of fully automated systems that can construct steel reinforced concrete buildings using prefabricated components [11].

So far, the application of robots is feasible only if it generates a value-adding effect. According to Hack et al. 2014, the centralised fully automated Japanese construction systems failed to do so, as they merely tried to automate the existing construction processes. They only focused on the elimination of human labour from the building site, without considering the complexity of the building process. Hence, Hack suggested that some innovated construction processes need to be developed first, to specifically address the strengths of robots to be applied where they actually outperformed humans and conventional construction [14].

2.2 Present attempts

The Chinese Huashang Tengda company in Beijing has recently claimed to 3D print an entire 400 m2 two story villa 'on-site' in 45 days uses a unique process allowing to print an 'entire house' in 'one go'. This is by erecting the frame of the house including steel reinforcements and plumbing pipes conventionally, and then ready-mix concrete extruded over the frame and around the rebars using a novel nozzle design and 3D printer [15].

The WinSun decoration design engineering company worked jointly with architectural and structural design companies such as Gensler, Thornton Tomasetti, and others to build an office building for the Dubai Future Foundation with a technique similar to contour crafting, in which wall elements are manufactured from extruded prismatic bodies [30]. One more technology known as WASP (World's Advanced Saving Project) has focused on using Additive

Manufacturing technologies to build "zero-mile homes" that utilize on-site materials to build houses in places where it is hard to find access to construction materials [16].

In despite of presently attempted, the current construction is in need for large scale 3D printers to build complex geometric shapes on projects where construction time, cost, and quality are the predominant and determining success criteria [17]. In accordance, a novel approach for 3DCP technology for on-site construction, named CONPrint3D, is currently being developed at the TU Dresden, Germany, which intends to bring 3DCP directly into the building sites [15]. In addition, Skanska is a construction company that recently has utilized advancements in the area of additive manufacturing by printing unique cladding for the Bevis Marks building in London [16].

2.3 Future visionary

A comparison by Helm et al. (2012) between the usages of robotic technologies in building site with other industries, revealed that the construction sector has been rather slow to adopt such innovative technologies with most tasks on a building site still carried out using manual methods [18]. As stated by Hwang, et al. (2005), the present state of automation and robotic technologies are not sufficient to economically replace skilled labour, thus suggested that the construction industry needs to think "out of the box" and seek alternatives to existing fabrication and assembly processes [19].

Howe at el. (2000) had a different view, when proposed to study the possible applications of robotic technologies to traditional methods because they are the most familiar to us, while the feasibility of automating the entire construction site would be dependent on need and would occur gradually. At the same time, Howe confirmed that there are many problems need to be overcome first in order to develop usable robotics in the building construction [20].

It has been furtherly explained by Choi et al. (2005) that in a field of construction work, the content of work and working material are frequently changeable, thus construction robot needs several special properties of high payload, safety, reliability, and a wide workspace [21]. Thus, a collaboration between conventional tools, humans and robots, and standard concrete pumps is required to transfer the actual structural mass, while the robot could unlock the inherent potential of concrete to take any desired shape by building complex formwork in high resolution [14].

The new paradigm brings a host of new topics into the forefront of robotics in construction research. These topics have been neglected in the past by researchers inspired by the old paradigm, and therefore there is a backlog of research problems to be solved. This systematic review has been performed to respond to this research gap, and by using its results to develop a comprehensive framework. The methodological approach of the systematic review is outlined in the next section.

3 Research methodology

To provide a robust investigation on the applications of robotic technologies in the concrete building construction, a systematic review approach was adopted. In comparison with a conventional literature review, a systematic review applies an explicit, rigorous, reproducible, and auditable methodology for evaluating and interpreting all available research relating to a particular research question, topic area, or phenomenon of interest [22].

A systematic review originates from the need to overcome the shortcomings of a single facet approach which is often adopted in a literature review, by representing the bigger picture by combining discrete pieces and synthetizing results in an organized way [23]. Additional benefits also include that researchers can summarize existing evidence about a phenomenon, identify gaps in current research, and provide grounds to position or support new ideas and hypotheses [24].

The review has been undertaken in distinct stages as shown in Figure 1, including the development of review protocol, the identification of inclusion and exclusion criteria, searching for relevant studies, critical appraisal, data extraction, and synthesis. In the rest of this section, we describe the detail of these stages and the methods used.

3.1 Protocol development

The protocol for the systematic review has been developed in accordance with the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guidelines [28]. This protocol specified the research questions, search strategy, inclusion, exclusion and quality criteria, data extraction, and methods of synthesis.

3.2 Research question

The aim of the systematic review is to locate relevant existing studies based on the research question of 'What type of robotic technologies have been in use in the concrete building construction industry?', to report the evidence in a way that clear conclusions with regard to further research to be drawn [29]. For the purposes of this paper, the systematic review shall provide a theoretical basis for understanding to what extent the topic of robotic technologies is being

addressed in concrete buildings construction.

3.3 Inclusion and exclusion criteria

Studies were excluded if their focus, or main focus, was not related to robotics in construction or if they did not present empirical data. Furthermore, the research question is concerned with concrete building, therefore, studies that focused on other building construction were excluded. Studies were eligible for inclusion in the review if they presented empirical data on robotics in concrete building construction and passed the minimum quality threshold (see Section 3.5). The systematic review included research studies published up to and including 2018. Only studies written in English, clearly describe its methodology, completed and concluded were included.

3.4 Data sources and search strategy

The search strategy included electronic databases. Of Scopus, Web of Science, IEEE, and Engineering Village. Figure 1 shows the systematic review process and the number of papers identified at each stage.

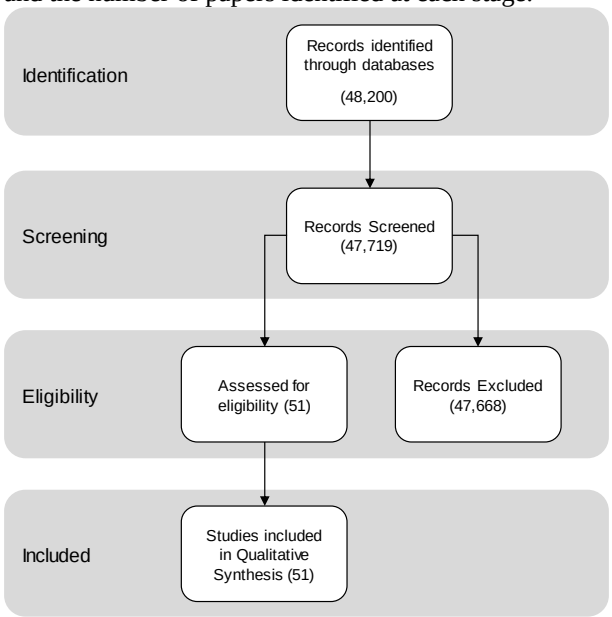

Figure 1. Flowchart of systematic review process. (PRISMA flow diagram [28])

In the identification stage, the titles, abstracts, and keywords of the articles in the included electronic databases and were searched using search term of (robot* AND construction)". These keywords are widely-known for their use in research articles. Excluded from the search were editorials, prefaces, article summaries, interviews, news, reviews, correspondence, discussions, comments, reader's letters and summaries of tutorials, workshops, panels, and poster sessions. This search strategy resulted in a total of 48,200 documents. Of total number of documents (n = 47,719), 1,020 were book sourced, 15,646 journals, and 31,053 were resulted from a conference proceeding source.

At screening stage, duplicates were removed as well as papers from undefined or trade publications resources. At this stage, 481 articles were excluded after removing duplicates as well as papers from undefined or trade publications resources. However, it was not always obvious whether a study was, indeed, an empirical one. Therefore, all studies that indicated some form of experience with robotics in construction were included. At eligibility stage, studies were excluded if their main focus was not robotics in on-site building construction. As a result, 51 primary studies were included for the detailed quality assessment.

3.5 Quality assessment

The methodological quality of the eligible selected studies was critically appraised using a set of screening questions adopted from the Critical Appraisal Skills Programme (CASP) [25]. A summary of the questions used to assess the quality of these studies is presented in Table **1**. The tool provides a guide for appraising qualitative research to consider if the results of the study are valid, what the results are, the benefits of the results, and the tool has been used in a range of reviews. Taken together, these questions provided a measure of the extent to which we could be confident that a particular study's findings could make a valuable contribution to the review. Each of the 9 questions was graded on scale of (YES = 1, NO = 0), and only question 1 was used as the basis for including or excluding a study.

Table 1. Quality appraisal questions

	Screening Questions
Q1	Research: Is the paper based on research
Q2	Aim: Was the aim of the research clear?
Q3	Method: Was the research methodology used appropriate?
Q4	Design: Did the study design address the aims of the research?
Q5	Data analysis: Was the data analysis sufficiently rigorous?
Q6	Findings: Are the findings clearly stated?
Q7	Gaps: Have gaps in the literature been clearly identified?
Q8	Acceptance: Can I accept these findings as true?
Q9	Value: Can I apply these findings to my own work?

The results of the quality assessment are shown in Figure **2**. Because only research papers were included in

this review, all included studies were rated as yes on the first screening question, in addition, they all had a clear statement of the aims of the research as well as appropriate research methodology. While the number of negative answers was three for each criterion of research methodology, study design and findings acceptance. Furthermore, the data analysis did not seem sufficiently rigorous for four of the studies. The highest numbers of negative answers were 17, and 19 as it has been noticed that the findings were not well described, and gaps in the literature were often not identified.

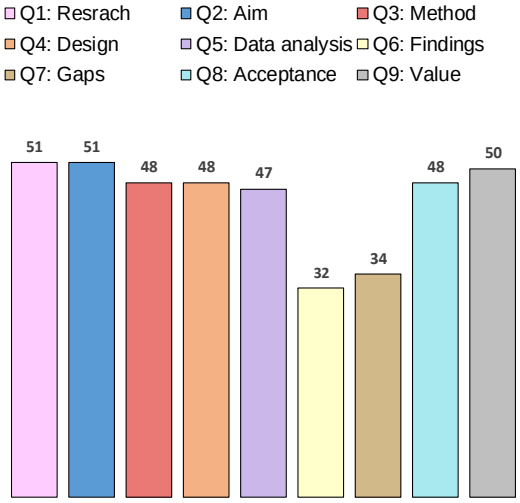

Figure 2. Quality appraisal summary results (out of total number of articles: 51)

3.6 Data extraction

During this stage, data was extracted from each of the 51 primary studies included in this systematic review according to a predefined extraction form (see Figure 3). This form enabled to record full details of the articles under review and to be specific about how each of them addressed the research question. All data from all primary studies were extracted by the authors in consensus meetings. The aims, settings, research methods descriptions, findings, and conclusions, as reported by the authors of the primary studies, were tabulated in Microsoft Excel.

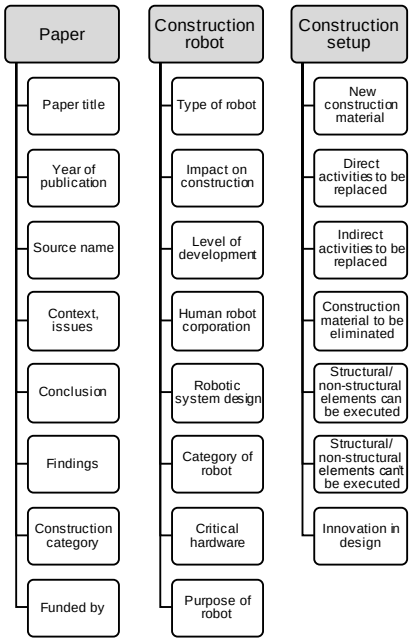

Figure 3. Data extraction

3.7 Peer assessment

The first two authors sat together and went through the titles of all studies that resulted from identification stage, to determine their relevance to the systematic review. At the eligibility stage, the abstracts were divided among the first two authors and the third author in such a way that each abstract was reviewed by two researchers independently of each other. All disagreements were resolved by discussion that included all three researchers, before proceeding to the final stage. Each of the 51 studies that remained was assessed independently by the authors, according to quality assessment procedure.

4 Results

4.1 Publishing framework

The chronological distribution of articles in Figure 4 indicated for a growing interest in performing research related to the subject. 6 papers have been published from 2000 to 2005 and 9 papers from 2006 to 2011. While the period from 2012 to 2018 accounted for the most published papers of 36 number. The analysis results demonstrate that there is a substantial increase in the number of literature during the last 6 years. This would indicate for a promising established research area in concrete building construction.

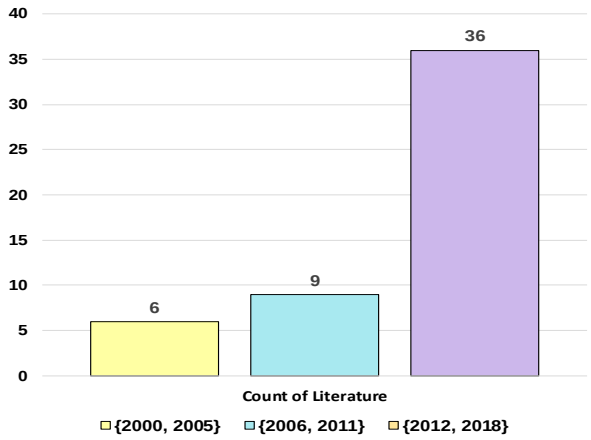

Figure 4. Chronological Distribution of publications (total number of articles: 51)

Furthermore, Figure 5 shows the number of publications according to the different country for each of the authors. When comparing the geographical distribution of the total number of 51 papers, USA and Germany are ahead of all others. However, by filtering out only the 23 articles of highly related studies to the review topic, research on the subject has been dominated by authors from USA, and France. While, focusing on the 4 extremely related studies revealed that authors from Switzerland are leading the topic.

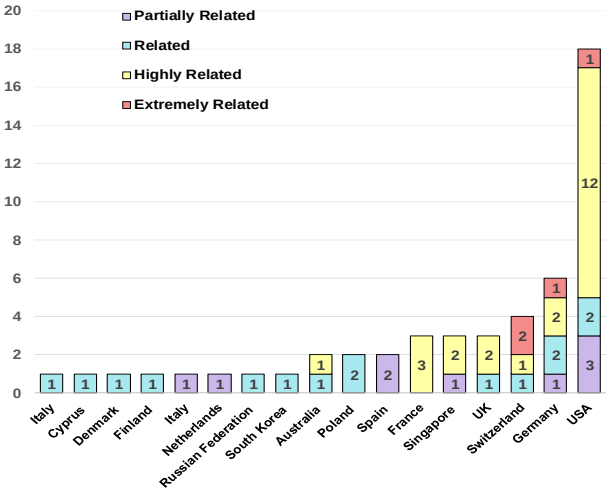

Figure 5. Geographical distribution of publications (total number of articles: 51)

4.2 Implementation on a construction site

The construction applications and techniques for the outcome are mainly on-site and related to the robotic technologies of 3D printers, automated building construction system, and swarm robotics construction system (see Figure 6). In context, 57% from the proposed technologies have targeted low rise building projects and 35% focused on low to medium rise buildings, while only 8% could target the medium to high rise building category. This could indicate that adapting most of the studies for the 3D printing technology, has resulted in a major limitation to target high rise building construction.

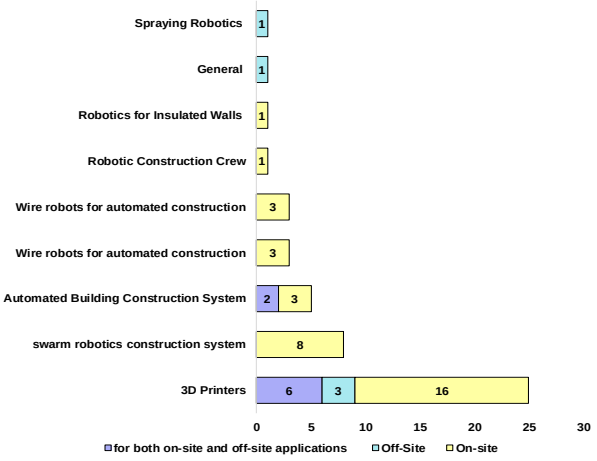

Figure 6. Construction robots' types & application (total number of articles: 51)

In parallel, Figure 7 shows that most of the researched robotic technologies were found to be either under development or conceptual. At the same time, their implementation in concrete building construction is challenging. Only 10% from the proposed topics were classified as developed technologies, and merely 8% could be implemented in a construction site.

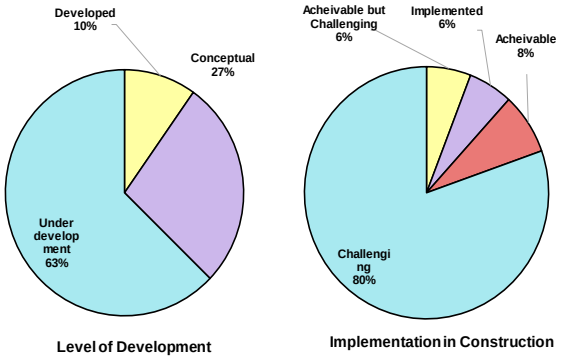

Figure 7. Robotics technologies level of development and implementation in construction

Concerning the reasons behind proposing such technologies, nearly 70% of the papers shared the same goal of enhancing the concrete building construction efficiency. While construction in space, besides proposing new construction technologies have attracted almost 20% from the authors. The remaining papers were interested in the construction in disaster or

hazardous areas, as well as reducing the accident rate. (See Table 2).

Table 2. Purpose of the robotic technologies (total number of articles: 51)

Purpose of the robotic technology	Number of paper
Construction in disaster areas	1
Reducing high accident rate	2
Construction in a constrained/ hazardous environment	2
New construction technology	5
Construction in space	5
Greater efficiency	36

4.3 Innovation in construction material and structural design

As illustrated in Figure 8, 53 % of the papers proposed a limited novel structural design and 29% projected a complete novel design proposal, while the remaining 18% adopted the conventional structural design for the construction of concrete structures. Concerning the innovation in construction material, the researchers could not introduce novel material to the construction, however they have focused on finding alternatives to replace the conventional ready-mix concrete and steel reinforcement.

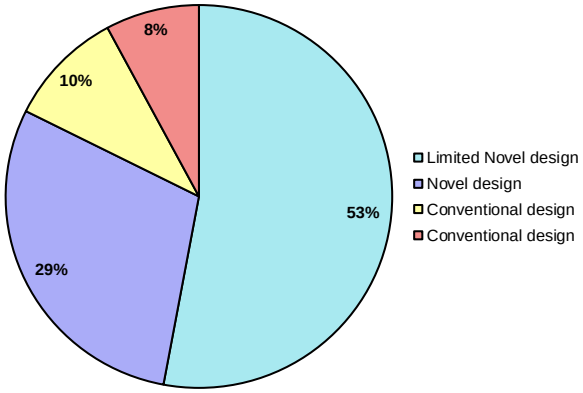

Figure 8. Innovation in structural design

As presented in Figure 9, 45% of the papers considered mesh wire as an alternative to reinforcement rebar, and around 79% from the total literature proposed polymer based material and cementitious material to replace the ordinary cement. While mortar mix, intelligent concrete blocks, and ultra-high-performance concrete found to be the new alternatives to conventional concrete mix.

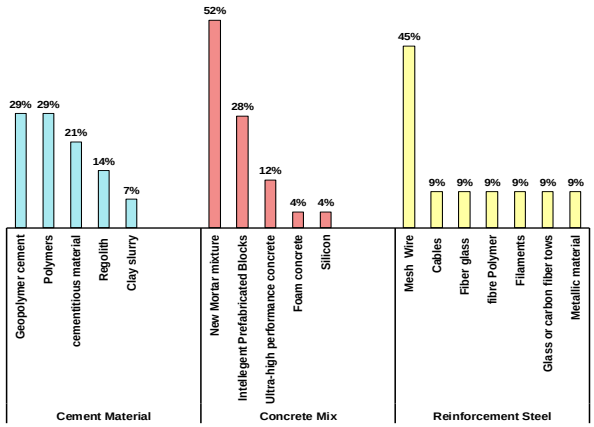

Figure 9. Alternative construction material

4.4 Impact on building construction activities

Formwork fixing and striking, steel rebar fixing, and concrete pouring and curing are the main direct construction activities could be replaced by the proposed robotic technologies. The major indirect construction activities that could be eliminated comprise ready-mix concrete delivery to site, formwork fabrication, steel rebar fabrication, and material handling by cranes and manually (see Figure 10). This would have a huge impact not only on the overall productivity of the construction activities, but also on the entire efficiency of the concrete building construction. The proposed construction technologies will not depend on plywood, formwork systems and scaffolding to build any concrete structural element.

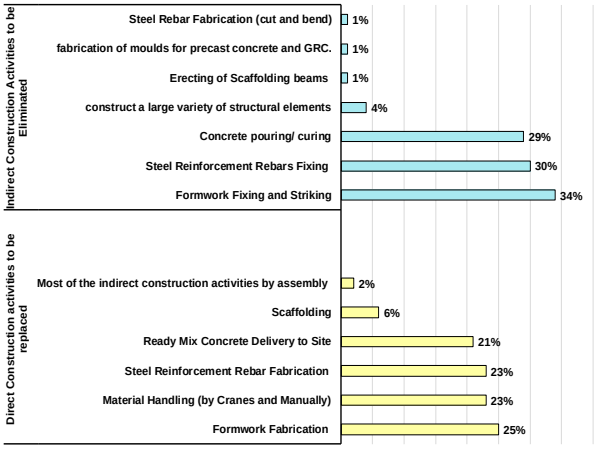

Figure 10. Impact on construction activities

Regarding the applicability of the construction robotics to build all the structural concrete elements, 93% of the literature claimed that their proposed technologies can build vertical RC elements on-site, while 4% suggested pre-casting and assembly, and only 3% proposed a full solution to construct all RC elements on-

site for one story building. The same studies claimed to build vertical RC elements have shown incapability of their proposed technologies regarding the construction of horizontal RC elements on-site, unless they were temporary supported during the construction or pre-casted and assembled by cranes.

4.5 Construction robotic features

Different types of robotic systems have been adopted through the literature, however, rapid prototyping and self-assembly found to be the most appropriate systems for the purpose of concrete building construction (see Table 3). This outcome is in line with the results in 4.2 construction applications and techniques.

Table 3. Robotic system

Robotic system design/ programme	% of literature
VR-assisted virtual prototyping	2%
Multi-robot construction and assembly	2%
Automated assembly systems	2%
Generic, versatile mobile robotics system	4%
Cartesian motions	6%
Self-organized construction	8%
Controlled assembly	8%
Self-assembly	12%
Rapid prototyping	56%

In terms of the construction robotic category, 63% from the studies considered manipulator robots for their proposed technologies, and around 15% adopted the collective construction robot category (see Figure 11). This is in consonance with rapid prototyping and self-assembly systems, in addition to the results in 4.2. Furthermore, nozzle, manipulator arm, and multiple mobile robots were the most critical hardware components for such robotic categories.

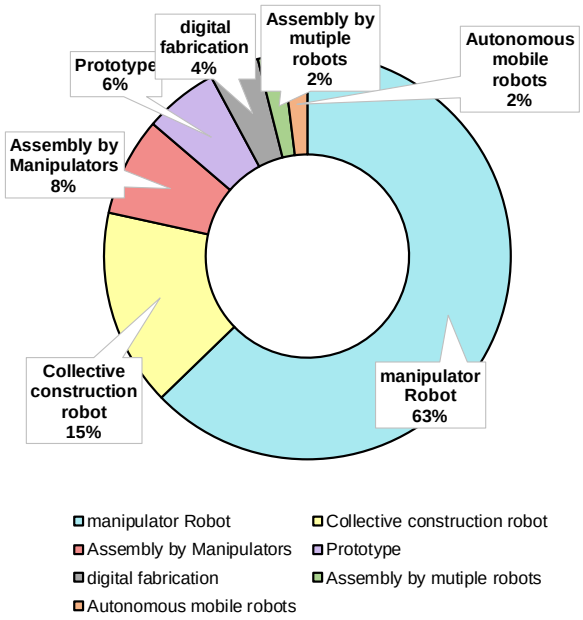

Figure 11. Category of construction robot

5 Discussion

Most of the present attempts to implement robotic technologies in concrete building construction were focusing on freeform construction for vertical RC elements, in the aim of improving the building construction efficiency and reducing the dependency on formwork.

The concrete building industry is currently in need for numerous researches to alter the conventional building process, by thinking out of the box in terms of innovating structural design and construction material. Moreover, lessons should be learned from the past attempts in the last three decades to robotize the building construction sector. Consequently, the future visionary is necessary for a systematic approach to increase efficiency in this type of research. An example for such visionary can be found in few innovative researches adapted the swarm intelligence for building construction by self-assembly.

Despite that the aim of this research is solely for concrete building construction, some other industries have attracted the researchers. Around 40% from the explored papers have been interested in building construction in extra-terrestrial environment. Their researches are mainly funded by the National Aeronautics and Space Administration (NASA), in addition to Kennedy Space Center Swamp Works and the Office of Naval Research in the USA, as well as the European Space Agency (ESA).

In this context, new research questions should concentrate on what could be altered within the

construction process or the robotic technologies, to construct a complete building structure on-site. What type of concrete building structures should be targeted in the future researches, to overcome the present obstructions?

6 Conclusion

The review demonstrates that the research on robotic technologies in concrete building construction is still in its infancy, and thus is characterized to be under development and mostly challenging to be implemented. The literature all points that conventional methods for building construction proved to be inefficient, and the construction industry can innovate towards improved health and safety and time and cost savings.

The systematic review shows that the researchers in the USA played a lead role in researching robotics in concrete building construction, followed by Germany and Switzerland. The robotics application and techniques have been largely used on-site and targeted low-rise buildings. The robotic technologies that have been popular in literature included 3D printers, and swarm robotics. Most of the papers have proposed a limited novel structural design, without introducing novel construction material. Even though the direct and indirect construction activities related to formwork, steel reinforcement, and concreting can be replaced and thus eliminated, the horizontal RC elements still cannot be built on-site unless they were supported. Moreover, rapid prototyping found to be the best robotic design for the purpose of building construction through utilizing manipulator robots.

While the application of robotics in construction has limitations that need to be acknowledged, research for innovative robotic technologies to be adapted in the construction appears as an emergent approach. Collaboration in research across all the segmented disciplines such as architecture, engineering, building, computer science, would be an essential element for developing a related research area and also for deepening and widening research area dimensions and domain. Future research should also focus on the different types of barriers behind implementing the robotic technologies in the construction field.

Acknowledgement

This systematic review was completed as part of the first author's PhD research and is funded by the Dean's Discretionary Doctoral Scholarship, University of Auckland.

Abstract –

The improvement of safety performance of construction workers heavily lies in safety training and great improvement has been achieved in training technology, training materials and training organisation. Currently, the form of training and induction based on traditional lectures and workshop studies has been innovated and enriched by digital and e-learning technologies and applications, such as immersive visualization techniques like Virtual Reality (VR), Augmented Reality (AR) and game engines. The visualization techniques allowed workers to enhance their safety capabilities by playing the safety training game in virtual scenarios. However, the validation of its effectiveness was measured with either self-reported questionnaire or the improvement in safety performance and productivity. This research proposed a framework to directly validate the effectiveness of virtual reality in safety training by measuring the degree of emotional arousal with electromyography (EMG). Specifically, the degree of inducement of fear was measured during safety trainings with pictures, videos and VR. The higher degree of fear was induced, the more effective the safety training was. In this way, this research provided a novel approach to prove the effectiveness of the immersive visualization techniques and a possible framework to further identify important personal and environmental factors of safety training process.

Virtual Reality; Safety Training; Emotional Arousal; Electromyography

1 Introduction

Safety training and education is an important issue in construction safety management. Because of the massive amount of new construction, large groups of new workers come into the construction industry without proper skills or enough experience. Migrant workers are common worldwide. In China, most Chinese on-site workers used to do agricultural jobs, and the number of migrant workers in the construction industry has increased by more than 1 million per year. Less than 7% of them attended vocational training programs. Senior technicians accounted for less than 0.3% of all workers, compared to 20%~40% in developed countries. The US construction sector provided 7% of all employment in the workforce but accounted for 20% of worksite fatalities [1]. According to statistics, there were more than two million Hispanic workers in the construction industry in the U.S., and those Hispanic workers also had the highest injury and fatality rates [2]. Human errors and unsafe behaviours contribute greatly to accidents [3], Garrett and Teizer [4] pointed that previous research showed human factors accounted for 90% of all accidents in complex industries with high risks. Furthermore, inexperienced workers are more likely to perform unsafe behaviour and cause accidents.

Currently, the form of training and induction based on traditional lectures and workshop studies has been innovated and enriched by digital and e-learning technologies and applications, such as accident simulations in Building Information Modelling (BIM) systems, and other immersive visualisation techniques, such as Virtual Reality (VR), Augmented Reality (AR) and game engines [5-7]. The variety of training schemes does not only transfer essential knowledge to workers, it also guarantees the attainment of certain task proficiency that is required to prepare workers for real-work task settings [8], as well as to instil a positive danger/risk-sensitive attitude and safety climate in the workplace [9, 10].

It is well recognised that VR technologies are effective in enhancing construction safety training programs, however, the amount and mechanisms of the improvement brought by VR to safety training have not

been fully explored and measured with objective index other than self-reported questionnaire surveys. Therefore, this research proposed a possible explanation of the enhancement of VR safety training, and an approach to measure the effectiveness of VR safety training.

2 Literature Review

2.1 VR Applications in Construction Safety Training

The literature review identifies a variety of training approaches and techniques for construction safety. There is a long history of using classroom-based studies to upskill the construction workforce. The improvement of knowledge, attitude and self-reported practice followed by a one-hour classroom study, was evidenced by Sokas [11]. Tailored classroom training programs were also applied to 2700 training construction workers working on a railway project, which revealed positive effects, such as that workers were more likely to handle materials safely [12]. The conventional safety training takes the form of classroom teaching, and is tedious, difficult to understand and memorize, and has unsatisfying influence on performance improvement. In recent years, the form of classroom training programs has been enriched. A series of studies have made their efforts to improve safety training, for example, the peer-led training programs, which believed the interventions of co-workers could improve the learning outcomes [13]; the encouragement of verbal communications on safety between supervisors and workers [14]; the localisation of safety training materials for Hispanic workers [15] and narrative simulations, and improved toolbox training programs that are delivered by workmates or trained foremen [16]. Foremen, peers and unions help with safety performance through safety leadership and communication [17], and they improve the safety climate, which has a social influence on construction workers. It has to be noted, however, that classroom-based training was stereotyped, as its form may not be effectively conducive to motivating learners, and the uniform teaching manner may not take the learner disparity into account.

With the emergence of innovative Information Communication and Technology (ICT) applications, construction practitioners and researchers have started to shed light on technology-assisted training paradigms. To gain hands-on skills and practical experience with a shorter training turnaround, it is preferable that traineeships should be more task-oriented and available for both on and off-the-job options. Because it makes more sense to justify workers performance, potential hazards and causation factors in real-time working contexts. To facilitate a more task-oriented, context-aware and customisable training environment, innovative visualisation manners such as Virtual Reality (VR), Augmented Reality (AR), Mixed Reality (MR) and Building Information Modelling (BIM) have been formulated and researched [18]. The rationale of VR, AR, MR and BIM is that these technologies make use of computer graphic representations (e.g., agent-based avatars, virtual/ augmented task instructions and clues, etc.) to create a virtual but immersive space where real-life scenarios can be replicated for trainees to experience and make sense of risks. Traditional safety training with texts and few graphical elements were difficult to be understood, especially by low literacy novice workers. On-the-job training engaging hands-on experience could be more efficient [19] but time-intensive, expensive, and potentially hazardous [20]. To help low-literacy construction workers who may have linguistic and understanding problems at work [14, 21], Lin et al. [19] developed a game-engine based VR serious game which can offer visual representations that remind unsafe conducts; Le et al. [5] proposed an online VR training framework for multiple students to perform role-playing construction safety training with communications within groups and social interactions; Behzadan and Kamat [22] presented an innovative pedagogical tool that adopting remote videotaping, AR, and ultra-wideband (UWB) to better link virtual objects to the real world. One of the advocating evidences is the expedited process of developing complex procedural skills required to operate construction heavy equipment on modern, large scale complex infrastructure projects [7]. Overall, the motivation of safety training can also be intervened by ICT paradigms. For this purpose, one of the proffered research directions is that ICT applications should interface with real-life task scenarios that are often dynamic, complicated and varied.

2.2 Possible Explanations of Effective VR Training

The advantages of using VR in education and training are related to its ability to enable students to interact with each other within virtual three-dimensional (3D) environments. Intuitive sense about the learning subjects can also be developed by interacting with the objects, related messages and signals in the virtual environment. Different from the conventional education and training approaches, such as the utilizations of static pictures or two dimensional (2D) drawings, VR's visual representation allows more degrees of freedom (DoFs) to be integrated. Compared to conventional training methods, ICT innovations for training was reported to be more conducive to development of short-term memory, emotional arousal, attention maintenance,

confidence enhancement [23, 24], information retention, and various essential cognitive mechanisms that underpin workers' kinesthetic and psychomotor abilities [25]. Therefore, it was suggested that the future of construction safety education should incorporate VR/AR technologies into the pedagogy.

Psychologically, a possible explanation of the advantages of VR/AR technologies in safety training might be related to the emotional memory enhancement effect. It was used for the phenomenon that events or materials loaded with emotional information are more likely to be retained in individual memory and have a higher recall accuracy compared with neutral events or materials [26]. This effect can be found no matter whether emotional words, emotional pictures or emotional films are used, or whether they are used in recognition tests, free recall or clue recall [27, 28]. Previous studies have found that the enhancement effect of emotional memory is mainly affected by the arousal level of emotional stimulation, and highly aroused emotional stimulation can get priority attention and thus be processed preferentially [29]. Therefore, no matter emotional pictures or emotional words, highly aroused emotional stimulation has better memory effect. Individuals' fear stimulation is a rapid automatic processing, so as to quickly deal with threats.

In construction safety research, the effects of emotional arousal have been recognised [30, 31]. The assessment of emotions of accidents was included in workers' judgement of construction accidents' likelihood and severity [32], and negative emotions from previous experience could lead to the decision of avoid risky behaviour [33]. Furthermore, while positive emotions in learning could lead to higher levels curiosity, interest, and desire to improve performance, research also showed that negative emotions could arise extrinsic motivation to avoid failure [34], lead to better engagement in learning [35]. Lang [36] proposed limited capacity model of motivated mediated message processing (LC4MP) to explain the relationship between emotion and learning motivation.

Fear is an emotion closely related to evolution. It can stimulate workers' defense mechanism and help human survival and adapt to the environment. The formation and expression of fear is activated by the brain regions including the amygdala, anterior cingulate gyrus and the frontal cortex [37, 38]. The use of event-related potential methods can help the study find the neural basis of emotional infection. It is a research method with high time precision, which can help researchers discover a cognitive processing process and reflect the time course of emotional infection. It can record multiple brain components induced by emotions. The occurrence time, amplitude intensity and brain area of these components will be important indicators reflecting the processing of cognitive emotions. Different components represent different psychological cognitive processes, including P200 and P300. P200 is an early positive component, the peak is located after the stimulus is presented to the left and right, and the scalp is in the forehead or the occipital region [39-41]. P200 peak can be used to reflect the emotional valence (or, pleasure) and arousal of the information (or strength). P300 is related to attention, identification, decision, memory, etc. [42, 43].

However, existing measurement of fear are by means of electroencephalography (EEG), electro-cardio (ECG) and galvanic skin response (GSR), and it was difficult for the portable devices of the measurement of these indicators to be adequately accurate (medical level) and instantaneous enough to capture the spontaneous reaction of fear. On the other hand, electromyography (EMG) signals are perfect to measure real time responses if the responses include muscle motions. Portable devices on the open market to accurately measure EMG are also easily accessible. Therefore, this research used EMG which could be measured accurately with a wristband and be recorded instantaneously.

3 Pilot Study

3.1 Experiment Design

3.1.1 Participants

In the pilot study, university students were recruited as participants, including 9 graduate students in Construction Management major, out of which there were five female students and four male students.

3.1.2 Measuring Devices

An episode of VR safety training material for construction workers on Fall-from-Height was mounted with HTC Vive and displayed to each participant.

Electromyography signals were measured with DTing Gesture Control Wristband, which is in the world's first easy-start gesture-controlled robot series. The wristband is able to detect users' gesture behaviour, including forearm movement, hand gesture and finger force. In this research, put around the wrist, it is able to capture the signals with pollicis. The surface electromyography (sEMG) signal, gyoroscope signal, accelerometer signal and more related signals are fused to recognize gestures in high precision.

Heart rates were measured with Polar H10 heart rate sensor because it monitors heart rate more accurate and adaptable and connect heart rates to cellphones by Bluetooth simultaneously. Pictures of the wristband and heart rate sensor were shown in Figure 1.

Figure 1. DTing Gesture Control Wristband (left) and Polar H10 heart rate sensor (right)

3.1.3 Measurement approach

The purpose of the pilot study was to determine if the EMG devices could reveal the instantaneous muscle tensions caused by fear during VR trainings on the prevention of fall-from-heights and to adjust the experiment design for a larger scale of experiments on diverse students to determine the effect of personal factors on training effects.

The participants wore the HTC VIVE headset and watch a small episode of safety training material on fall from height. Meanwhile, they also wore DTing wristband on their left or right wrist (according to their free will) and Polar H10 heart rate sensor around their chest. The wristband recorded the changes in electromyography on their pollicis instantaneously and the signals were uploaded to an application to process them with an Android device. Then it could be exported to Matlab and be further processed and mapped graphically. Polar H10 heart rate sensor recorded their heart rate changes and could also be exported to Microsoft Excel for further analysis.

Follow up questions for reviewing and sharing feelings during VR training were asked and discussed with every participant. However, those questions and discussion topics were not pre-determined in the pilot study, but along a broad spectrum of their after-test feelings and possible suggestions.

3.2 Results and discussions

The pilot study revealed that the EMG devices had successfully captured muscle tensions in the pollicis, as shown in Fig. 2. A group of peaks could be observed at almost the same time at the moment of falling in the VR training.

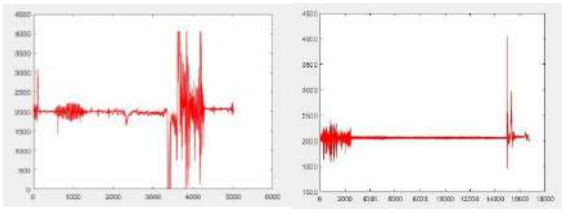

Figure 2. Examples of sudden muscle tensions in pollicis captured by DTing Wristband

However, some participants could be used to the VR trainings after repetitive experiments. Fig. 3 (left) showed that after three trials, the same participants as Fig. 2 (left) showed little tension during the training.

Females and males reacted very different. All female students showed muscle tension to a certain degree at their first trials and reported that VR trainings had raised their fear in the after-test discussions. However, two out of four male students showed little muscle tension and reported “not very scary” in the after-test discussions. Fig. 3 (right) showed a male participant barely tensioned throughout the training, except for the adjustment of his handset at the beginning.

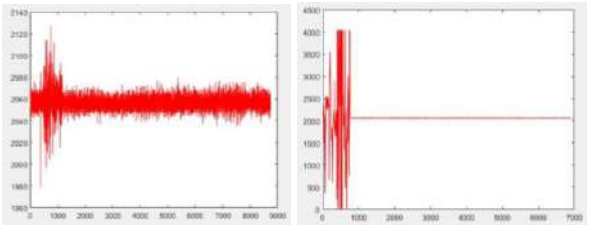

Figure 2. Examples of participants showed little tension during the training after three repetitive trials (left) and from the beginning (right)

The pilot study revealed that several improvements need to be addressed in the experiment design. First of all, the tension of fear could be in different muscles with different participants. Some participants reported tension in the wrist, feeling they “need to grasp something”, and others reported tension in their thighs, feeling that they “could hardly stand straight” and “got cold feet”. Approaches to fix this problem may be providing gesture control bands around the thighs as well as the wrist.

Secondly, the unrelated muscular tensions should be identified and filtered out from tensions caused by fear. Participants could use their pollicis to adjust their HTC VIVE headset and handset, or tensions caused by taking the test, or any other reasons. Fig. 3 shows the signals of a participant feeling tension throughout the training. It would be necessary to filter the actual signals caused by fear of the falling in VR training. Approaches to fix this problem may include developing a filtering algorithm to process the signals, excluding the handset in experiencing the falling to avoid unnecessary muscle tensions and using time stamps to determine the beginning of the signals possibly caused by the falling animation, and so on.

Thirdly, a structured survey should follow up right after the VR training to better review the EMG signals and determine participants’ training effectiveness. As in the pilot study, the follow-up discussion helped the researchers to better understand participants’ reactions to the training materials.

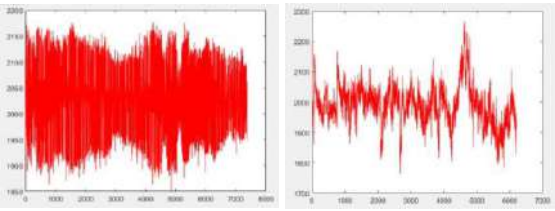

Figure 3. Signals of a participant feeling tension throughout the training.

4 Conclusions

This research tried to validate the effect of VR in construction safety trainings and provide a possible explanation for the advantage of VR training. This research measured the EMG showing muscle tensions of participants watching a piece of VR-based fall-from-height training material with a gesture control wristband. The pilot study confirmed that some participants showed muscle tensions on their pollicis when they experienced falling in the VR training, which indicated that VR-based trainings could raise fear in participants and the fear could improve the effectiveness of training because of the emotional arousal. However, the pilot study also showed that a lot of improvements should be made to the experiment design to provide trustworthy and insightful results.

Abstract –
Construction workers' behaviour is important for safety, health and productivity management. Workers' 3D postures are the data foundation of their behaviours. This paper established a preliminary 3D posture dataset of construction tasks and provided a 3D posture estimation method based on 2D joint locations. The results showed that the method could estimate 3D postures accurately and timely. The mean joint error and estimation time of each frame were 1.10 cm and 0.12 ms respectively. This method makes it possible to estimate construction workers' 3D postures from construction site images and contributes to a data-based construction workers' behaviour management.

Keywords –
Posture estimation; Construction worker; Behavior management

1 Introduction

Construction workers' behavior is an important factor in construction management. Construction workers' behavior is closely related to safety, health and productivities. More than 80% of construction accidents are related to workers' unsafety behaviors [1]. In addition, working behaviors, especially working postures, durations and work-rest schedules, are closely related to musculoskeletal disorders, which are very common in construction workers and have caused extremely negative effects on construction workers' health [2,3]. Finally, construction workers' motions, such as the number of production cycles, can also effect the labor productivity [4]. Therefore, it is important to understand construction workers' behaviors for better performance.

Construction workers' posture data provides a foundation for working behavior analysis. For safety management, working postures could help to identify unsafe behaviors and prevent safety accidents [5,6]. For health and sustainability of construction workers, posture data could help to assess the workloads of different working tasks and mitigate the risk of fatigue and injuries [7,8]. For labor productivity, posture data has been used for working/rest status identification for evaluating work efficiency [9]. The studies have demonstrated the importance of workers' posture data in construction management. However, considering the complexity of construction site environments and the dynamics of construction motions, the posture data collection methods used in previous methodologies cannot support effective behavior-based management due to the inaccurate data, uncomfortableness or limitations on indoor working environments.

This study aims to provide a 3D posture data collection method for construction workers, which (1) could provide 3D joint locations, (2) has no limitation on working environments and (3) doesn't require any wearable sensors and thus will not lead to uncomfortableness of workers. The method could provide the data foundation of posture-based behavior analysis and management for individualized unsafe behavior identification, ergonomic assessments and productivity evaluation.

2 Related work

2.1 Previous posture data collection method in construction industry

There are mainly four categories of objects on construction sites, namely human, materials, machines and environment. For materials and machines, tracking technologies such as radio frequency identification and global positioning system have been widely used [10,11]. For environments, laser scanning techniques were used to collect 3D point data for building construction site model [11]. This section mainly focuses on the approaches for collecting the motion data of construction workers.

Manual observation was commonly-used to collect construction workers' joint angle data for ergonomic assessments [12,13]. Manual observation method usually classifies joint angles in to different categories, such as 0-30 degree, 30-60 degree and 60-90 degree. The results of manual observation depend heavily on the observers' experiences and subjective judgement, thus is not accurate enough. In addition, the manual observation cannot collect data continuously from the whole construction site, thus cannot support timely management [14].

Inertial measurement units (IMUs) have been widely used to collect construction workers' posture data. If attached to the key joints, IMU sensors could provide the three-axis rotation angle of each body segments, which could be used to calculate the 3D joint location if given the length of each body segment [15]. Based on the 3D posture data collected with IMU, previous studies have tried to detect construction workers' unsafe behaviour [16], identify awkward postures [15] and estimate productivity [17]. The main disadvantage of IMU, however, is the requirement of attaching IMU sensors to the human body, which may interfere workers' performance. In addition, such sensors may not be suitable for prolonged usage because they may lead to discomfort [14,18].

Motion capture systems (e.g., the VICON system, OptiTrack and Optotrak) are commonly used in laboratories for 3D motion capture and analysis. To capture motion data, an examiner needs to set up multiple cameras in a laboratory and then put reflective markers on the designated locations of an individual's body. The system estimates the 3D position and movement trajectory of each marker based on the signals of the reflective markers captured by the cameras. The reported accuracy of the VICON system is as high as 2 mm [19]. In construction industry, motion capture systems have been applied to collect 3D joint locations for the detailed biomechanical analysis of working postures. However, since these motion capture systems require the installation of at least 4 cameras within 10 m from the attached reflective markers on the body of target workers in order to capture the whole-body posture, it is impractical to use on construction sites [20].

Depth cameras provides a non-invasive method for 3D posture data collection. Depth camera can provide more information than ordinary 2D cameras [21]. There are mainly two kinds of depth cameras, stereo camera and infrared camera. A stereo camera infers the 3D structure of a scene from tow images from different viewpoints. If applied on construction workers, the method could be used to construction the 3D skeletons with 2D images [22]. Infrared cameras could infer the depth of each RGB pixels and provide 3D skeleton based on machine learning networks [5]. However, as for the application on real construction sites, a search of the relevant products (e.g. ZED, Realsense D435 and Kinect) yielded that depth cameras cannot provide accurate 3D joint locations over a long distance. In addition, the infrared cameras cannot provide accurate depth information in outdoor environments due to the interference of sunlight on infrared signals.

RGB cameras are the most common-seen cameras in daily life. Considering the widely use and low cost of RGB cameras, pervious research has tried to identify construction workers posture motions or cameras based on RGB camera [6,23,24]. The methods successfully recognized construction workers from site pictures and classified postures into squatting, standing or walking. However, these methods could only get 2D joint information from the images, which cannot support 3D posture analysis for accurate behaviour recognition or ergonomic analysis.

In summary, above posture data collection methods have the following limitations if applied on construction sites: (1) intrusiveness: sensor-based methods may make the workers feel uncomfortable and even interfere working performance; (2) possible poor performance on construction sites: depth cameras may not provide accurate 3D pose estimation results over long distances in outdoor environments; (3) the lack of 3D results: 3D poses could provide better support for behaviour-based management. Recent progresses in computer vision provide possible solutions for the above limitations. The following is a review on related computer vision algorithms.

2.2 Pose estimation in computer vision

Pose estimation is a classical problem in computer vision. With the development of deep learning, the performance of pose estimation algorithms has been enhanced a lot [25]. The pose estimation algorithms focus on mainly two tasks: 1) 2D pose estimation, which aims to evaluate 2D joint locations from RGB images, 2) 3D pose estimation, which aims at inferring the depth of each joint based on 2D joint locations. The 2D pose estimation algorithms, open pose [26], has been successfully applied on construction sites to estimate 2D construction postures, which worked well even over long distances or when some parts of the body were obstructed [27]. 3D pose estimation algorithms, however, performed not very well when applied in estimating the postures of construction workers. The gaps are 1) previous 3D pose dataset for training the 3D pose estimation algorithms are mainly

daily life postures, such as sitting, taking and calling, which differ a lot with the postures of the construction workers, and 2) the structures and parameters of the algorithms are not suitable for estimating the 3D postures of construction workers.

3 Research aim and contribution

Considering above research gaps and limitations, this study tries to develop 3D pose estimation algorithm that is suitable for the postures of construction workers. The method could estimate the 3D joint locations based on RGB images in near real time. This method makes it possible to continuously collect 3D pose data from construction site videos and contributes to 3d-pose-data-based behavior management, such as identifying unsafe behavior postures, estimating joint workloads and assessing labor productivity.

4 Methodology

This study aims to train a 3D pose estimation according to 2D pose with transfer learning [25]. To reach the aim, a 3D database of the postures in construction tasks was firstly built, then a deep learning network was trained based on the dataset.

4.1 Establish the training database

The training dataset includes the 3D joint location data of construction tasks and the corresponding 2D joint locations. A laboratory experiment was performed to establish the dataset with an IMU system (3-Space™ Wireless 2.4GHz DSSS, OH, USA).

4.1.1 Collecting 3D posture data

Participants: A healthy male graduate student, aged 27 years, was recruited to perform a simulated plastering task in a laboratory.

Equipment: The participant was required to wear the IMU system to collect 3D posture data. The IMU sensor has an accuracy of 1° and an frequency of 50 Hz [28]. The IMU system includes 13 IMU sensors. They were tightly tied to the head, chest, back, waist, upper arms, forearms, thighs and shanks.

Simulated plastering task: After putting on the IMU sensors, the participant was instructed to perform a simulated plastering task. The participant mimiced the motion of plastering an area of 5 meters width and 2 meters height. To calibrate the IMU system before the task, the paricipant was requried to stand with both feet closed together and both arms stretched out to the sides and held parallel to the ground to form a T shape.

4.1.2 Data processing

The results of the IMU system were 1397 frames of postures. The data was stored in a BVH file, which includesdthe three-axis rotations of each body segments in each frame. The 3D joint locations were calculated based on the three-axis rotations angles and the length of each body segment with Denavit-Hartenberg matrix [29].

Then the 2D joint locations were calculated based on the 3D joint locations with projection matrix. The generated 2D joint locations are related to the location of the camera. In this study, given the hip joint as the origin, the spherical coordinate of the camera is (0°, 75°, 20 m).

4.1.3 Dataset structure

The dataset includes input dataset and target dataset. The input dataset is a matrix with 1397 rows and 48 columns. Each row stores the 3D Cartesian coordinates of 16 joints (head, neck, chest, waist, trunk, central hip, bilateral shoulders/elbows/wrists/hips/knees/ankles). The target dataset is matrix with 1397 rows and 32 columns. Each row stores the 2D Cartesian coordinates of the 16 joints.

For training and testing the algorithms, the dataset was divided into two parts. 1000 rows were randomly selected from the input dataset and target dataset respectively to form the training dataset. The rest rows of the input dataset and target dataset were used for testing the performance of the algorithm.

4.2 Network architecture

The network is composed of several basic network unit. Each unit includes a linear layer and an RELU layers. The linear layer aims to increase the dimensions of the input data to ensure the depth of the networks. The RELU layer next to the linear layer could add non-linearities to the deep neural networks [30]. The residual connections could improve generalization performance and reduce training time [25]. Figure 1 shows the network architecture.

The complexity of the network is decided on the width of linear layers and the numbers of the basic network units. Complex network could increase the accuracy but is prone to overfitting and computationally expensive. In the experiments, various combinations of the width of linear layers and the numbers of the basic network units were tested to decide the proper complexity.

In addition, batch normalization, dropout and max-norm constraints were applied to prevent overfitting and speed up training. Batch normalization allows us to use larger learning rates to accelerate the learning process [31]. Dropout randomly drops components from a layer of neural network, and thus could prevent overfitting and improve the generalization performance [32]. Max-norm constraints enforce an absolute upper bound on the norm of the weight of every neuron, which helps to prevent overfitting.

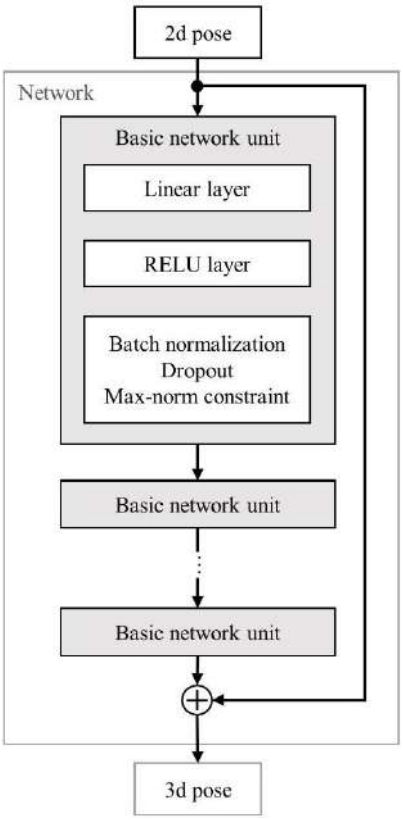

Figure 1. The convergence of training loss (learning rate = 10^{-3}, batch size = 32)

5 Experiment and results

The aim of the experiment is to decide the proper network complexity and the weights of every nodes in the network. In the following training process, the loss function is defined as mean-squared loss and optimized with Adam algorithm [33]. The dropout rate is 0.5. The max-norm constraint is 1.

5.1 Network complexity

As aforementioned, the complexity of the network has a great influence on the network performance. This experiment aims to find the proper network complexity. We change the depth and width of the network through edit the number of basic units (2, 3, 4) and the number of nodes in each linear layer (512, 1024, 2048). As a result, nine different networks were generated. They were trained based on the training dataset, and the accuracy was tested on the testing dataset. In this experiment, the initial learning rate was set as 1e-4, and the batch size was set as 32. Each network was trained for 400 epochs. Table 1 provides the comparison of the performance of the nine networks.

Table 1. The comparison of the performance of different network structures

No. of basic units	No. of layer nodes	Training loss	Test error [cm]	Testing time [ms/frame]
2	512	376.99	24.77	0.09
3	512	78.29	7.76	0.09
4	512	37.67	7.64	0.10
2	1024	29.18	7.16	0.09
3	1024	21.11	5.42	0.09
4	1024	16.09	5.39	0.10
2	2048	13.89	3.46	0.10
3	**2048**	**9.52**	**3.23**	**0.11**
4	2048	8.65	3.42	0.12

Table 1 compares the nine networks according to training loss, testing error and testing time. Training loss represents the final value of loss function. A smaller training loss is preferable. The trained network was then used to estimate the 3D joint locations according to the inputs data in the test database. The estimation results were then compared with the target data. The testing error is defined as the mean of the distances between the estimated 3D location and the target 3D locations of the 16 joints. The last column of Table 1 is the time spent on estimating the 3D joint locations in one frame.

Based on the comparison of the nine networks in Table, it could be found that the increasing the width and depth of the network could significantly decreases the training loss and the testing error. The network with three basic units and 2048 nodes of each layer was selected for the lowest testing error.

5.2 Training the network

Learning rate and batch size decide the step and direction of the training loss decrease, thus are important for the convergence of the loss function. This experiment tried different combinations of learning rate and batch size for training loss convergence and low testing error. Based on the comparison of different network structures in section 5.1, the network with three basic units and 2048-node-layers were used in this

experiment. The combination of different learning rates (1e-3, 1e-4, 1e-5) and different batch sizes (2, 4, 8, 16, 32, 64, 128, 256, 512) were tested. Table 2, Table 3 and Table 4 show the comparison of training loss, testing error and testing time for each

Table 2. The comparison of the training loss with different learning rates and batch sizes

LR* / BS**	10^{-3}	10^{-4}	10^{-5}
2	155.02	2348.89	9583.45

2	0.53*	0.53	0.53
4	0.31	0.31	0.31
8	0.20	0.20	0.20
16	0.14	0.14	0.14
32	0.12	0.11	0.11
64	0.11	0.11	0.11
128	0.10	0.10	0.10
256	0.09	0.09	0.09
512	0.09	0.09	0.09

*The time spent in estimating 3D posture of one frame of 2D posture. The unit is ms.

According to Table 2 and Table 3, both the training loss and testing error reached the minimum when the learning rate was 10^{-3} and the batch size was 32. Table 4 shows that the above combination is also time-saving. In addition, Figure 2 shows the process of training loss convergence under above learn rate and batch size.

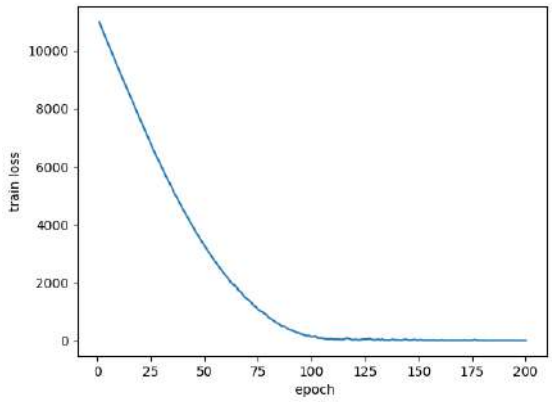

Figure 2. The convergence of training loss (learning rate = 10^{-3}, batch size = 32)

5.3 Testing the results

To this end, the network with 3 basic units, 2048-node-layers, and trained learning rate = 10^{-3}, batch size = 32 was selected. Table 5 shows the mean error of each joints. The mean error of all the joints is 1.10 cm, and the standard deviation is 0.45 cm.

Table 5. The comparison of the performance of different network structures

Joint	Mean error [cm]	Standard deviation [cm]
Waist	0.27	0.28
Right hip	0.46	0.30
Right knee	1.25	1.07
Right ankle	1.51	1.27
Left hip	0.46	0.25
Left knee	1.05	0.99
Left ankle	1.55	1.61
Chest	0.52	0.32
Neck	0.91	0.52
Head	0.94	0.50
Left shoulder	1.08	0.66
Left elbow	1.38	0.78
Left wrist	1.54	0.81
Right shoulder	0.99	0.63
Right elbow	1.60	0.78

Right wrist	2.16	1.08
Mean	1.10	0.45

Figure 3 is the histogram of the mean error of the joints in each frame. The maximum error is about 3.0 cm. Most of the errors are between 0.5 cm and 1.5 cm. The mean error is 1.10 cm, and the standard deviation is 0.45 cm.

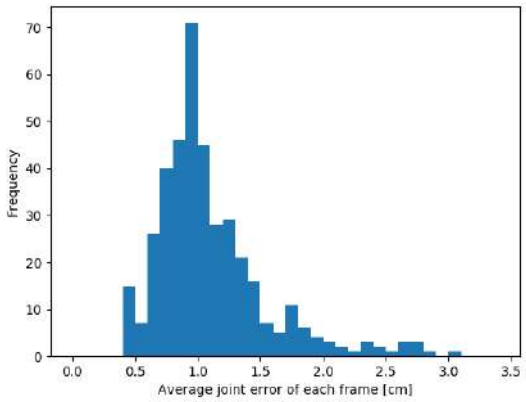

Figure 3. The histogram of the mean error of the joints in each frame

Figure 4 is an intuitive presentation of the estimation results. It could be found that the estimation postures are nearly the same with the ground truth.

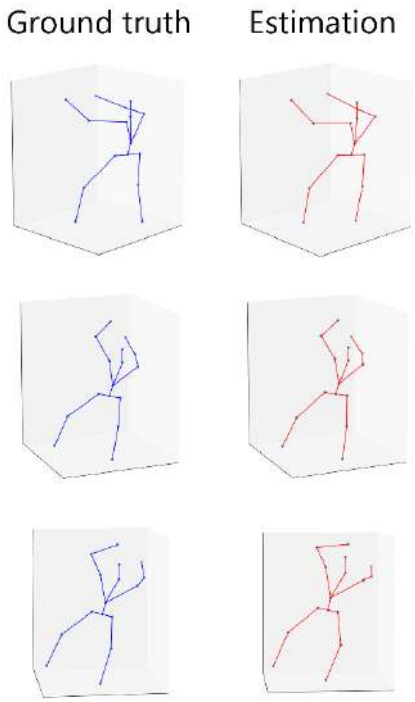

Figure 4. The estimated 3D postures and the ground truth data

6 Discussion

3D postures of construction workers are very important to safety, health and productivity management. This method provides a 3D posture estimator based on workers' 2D postures. The results show that the method could provide accurate 3D posture estimations in nearly real time. The latency time for testing one frame on a GTC 1080Ti GPU was 0.12 ms. The mean error of each joint was 1.10 cm. The accuracy was significantly improved compared with previous computer vision 3D pose estimation methods in construction industry, the mean joint error of which was 3.5 cm [34].

Compared with previous motion capture methods in construction industry, the proposed method was non-intrusive and could work well in outdoor environments. In addition, if combined with 2D posture estimation programs, such as Open Pose [35], the method could make it possible to collect construction workers' 3D postures continuously and timely, providing the data foundation for behavior-based safety, health and production management.

The method has the following limitations and could be improved in the future. First of all, the training dataset is not large enough. The dataset used in this study only includes the postures of one participant during plastering, which may limit the generalization

performance of the method. In future, a more diversified training database should be established, which includes the posture data of different construction tasks collected from participants of different heights, weights and BMIs.

Secondly, the 2D postures were generated from 3D posture based on projection matrix. In the current study, only one projection view was used. In the following studies, the 2D postures generated in different views could be used to train the 3D posture estimation method, so that it could be more applicable on construction sites.

Finally, the current study aims to estimate 3D postures from 2D postures. Future studies could try to combine it with 2D posture estimation method from RGB images, so that the 3D postures could be directly inferred from construction site videos or images.

7 Conclusion

Construction workers' posture data provides the foundation for working behavior analysis, such as unsafe behavior identification, ergonomic assessment and labor production evaluation. This paper established a preliminary 3D posture dataset of construction tasks and provided a 3D posture estimation method based on 2D joint locations. The results showed that the method could estimate 3D postures accurately and timely. The mean joint error and estimation time of each frame were 1.10 cm and 0.12 ms respectively. This method makes it possible to estimate construction workers' 3D postures from the images of construction sites and contributes to a data-based construction workers' behavior management.

Abstract –

Real-time activity monitoring is becoming one of the most significant technologies on construction sites because it can be applied to a variety of management problems, such as productivity formula and safety monitoring. However, current monitoring technologies are limited to recognizing postures in an ideal environment rather than dealing with the ambient occlusion and people-intensive situations on real construction sites. Therefore, this study develops a low-cost, non-intrusion and portable tool system in order to trace and track construction activities on complex and crowed construction sites. This system is composed of wireless sensors and a smart algorithm. Each sensor consists of an inertial measurement unit, a communication sensor (bluetooth low energy sensor) and several environmental sensors, which broadcasts the identification, acceleration, palstance and environmental measurements at a constant frequency. Since the dimension of the sensor is only 20 x 15 x 2 mm, it can be easily attached or screwed on to the hand tools as well as integrated with power tools. When a laptop or cell phone receives from these sensors, the construction activities are derived by the artificial intelligence algorithm in a timely manner, providing an visual posture monitoring as well as an automatic record of project progress. In the end, practical experiments of a concrete vibrator and a hammer prove the feasibility and effectiveness of the proposed IMU-based tool tracing and tracking system.

Inertial measurement unit; Construction tools; Activity recognition; Non-intrusive; Low-cost

1 Introduction

Construction is a typical labor-intensive industry that a variety of construction assignments are accomplished manually, such as wood formwork, bar bending and tying, concrete pouring, etc. Therefore, the on-site construction activity is one of the critical resources contributing to the construction project performance, and its effective control and management is always considered as a key to success [1]. By tracking workers-on-foot and construction heavy equipment, near-misses, collisions and safety risks can be prevented and alleviated [2], dangerous and awkward postures can be detected and alarmed [3], productivity can be measured in a timely and quantitative manner [4-6], etc.

The main obstacle for automated construction activity control and management is the real-time activity tracking. State-of-the-art technologies, including computer vision, wearable sensor, etc., which are available for on-site motion tracking, are emerging; however, the installation or monitoring process is intrusive and the effectiveness is seriously affected by complicated environment, such as none-line-of-sight effect due to ambient occlusions and multipath effect by signal reflection.

The purpose of the present study is to develop a smart and low-cost IMU-based tool system and test the feasibility for on-site activity tracking. The research introduced the novel concept and established the framework of the proposed system at first, developed a general prototype and an effective algorithm for construction works using cyclic patterns, and finally, conducted a pilot study to validate the system [7].

2 Background

The conventional way to monitor construction activities is human inspection, which is still the popular at the present time. An inspector roams around the site at regular intervals, the records the observation and draws a daily or weekly report. Once awkward or dangerous postures are recognized, the inspector send alarms and prevent further damage to the health and safety of workers. This is a commendable achievement, but it requires full time observation, which is impossible

and inefficiency for such a large field as construction site [8].

In the recent times, cutting-edge sensors are introduced to evaluate the spatial-temporal activities in the construction industry by attaching inertial and biomechanical sensors on human body segments [9]. The earliest instruments for linear posture detection are tapes and goniometer, and further progress is the advent of electromyographic devices (EMG) that using the muscle strength to access the movement and rotation. However, these devices are only used in clinical environments as they are tedious and intrusive to deploy [10]. With the emergence and development of micro-electro-mechanical system (MEMS), the device measuring the inertial properties of objects becomes small while the accuracy, robustness and quick response are improved dramatically, which is called inertial measurement unit (IMU). Nowadays, commercial IMU is usually made up of a tri-axis gyroscope and a tri-axis accelerometer (6-axis IMU), and a tri-axis magnetometer (9-axis IMU), enabling the measurement of acceleration, angular velocity, and magnetic field [11]. Scholars have applied this technology to detect awkward postures to prevent musculoskeletal disorders [3, 12, 13], near-misses and hazards are also recognized automatically and analyzed to assess the potential risks [14].

Another popular way to monitor construction activities is by computer vision, which can be briefly categorized into three types according to their instruments: monocular, binocular and depth cameras [1]. Compared with sensor-based activity monitoring, CV-based methods are visual and insightful, enabling to record various information, not only workers but also associated contexts [15]. At the beginning, computer vision is used to localize construction resources, including manpower, excavators, cranes, etc., providing a picture of space use on sites [16], predicting the proximity conflicts [17, 18]. After that, with the advent of deep learning techniques, motion recognition and tracking is available that specific body skeleton can be extracted from images or videos. Scholars then transform the technology into monitoring construction activities [19-21]. Risky and dangerous behaviors, such as falling from heights, not wearing a hat or personal protective equipment, hazardous materials, etc. are identified by cameras.

The pros of sensor-based human posture detection contain direct and simple measuring principle, high accuracy and frequency, as well as low latency and cost. However, the cons of this detection are also distinct that the deployment is tedious and intrusive as people are prone to suffer from discomfort and motion restriction by the attached sensors. What's more, the privacy issue of monitoring the personal data also exacerbates the problem. On the other hand, the considerable advantages CV-based human posture detection consist of non-intrusion into normal construction activities, easy deployment, remote monitoring, tremendous potential for artificial intelligence. Nevertheless, some disadvantages hinder the wide applications in practice. A primary disadvantage of CV-based human posture detection is the legal issue of intrusion of privacy that employees may object to being filmed under constant surveillance. Another disadvantage is the cost. As construction sites are always huge, high-resolution cameras are required, added by the instruments for transmission, compression and storage, it is expensive to purchase and keep the detection algorithms upgraded all the time. The third disadvantage is the non-line-of-sight (NLoS) effect due to ambient occlusions that CV-based detection performs badly without direct observations. What's more, the illumination and transparency of exposed environment also have an adverse impact on the detection. Other disadvantages, such as low accuracy and high latency or frame loss, weaken the applicable ability in construction industry as well.

Either sensor-based or CV-based human posture detection has exposed their weaknesses in literature and practice. This research therefore proposes a novel approach that leveraging the location and posture of a hand tool or power tool to detect the corresponding human postures by a single MEMS-IMU [22, 23]. This creative conceptual approach is not only a positive solution of personnel concerns and privacy that employees are not working under immediate surveillance, but also a non-intrusive and marker-less solution of human posture detection.

3 Framework for tracking construction activities by tools

This is an insightful conception that the way human beings make and use tools is perhaps what sets us apart more than anything else. In turn, tools also have positive impacts on our evolution. Workers in modern industries are always carry out their jobs with the assistance of valuable tools.

Construction is a typical labor-intensive industry that a variety of construction assignments are accomplished manually. To improve the productivity and ensure the safety, diverse tools are designed and adopted on constriction sites, containing hand tools (tape measure, torpedo level, screwdriver, wrench, trowel, hammer, coping saw, etc.), as well as power tools (circular saw, drill. jig saw, orbit sander, angle grinder, etc.) in Figure 1.

Figure 1. Common hand and power tools can be integrated with an IMU sensor

Thus, for these kinds of jobs using various assistant tools, the motions of tools apparently describe the detailed process of construction activities. For example, the trajectory of concrete vibrator suggests the area of concrete consolidation after pouring; the angular rotation of screwdriver indicates the effects of workers on the connection of reinforcement bars. The data of tools therefore not only suggest the status of construction activities, but also work as an event data recorder that record the associated information during specific events. When an accident happens, the information can be collected for analysis, to identify the status before, during and after the accident.

The schematic model for this tool-based construction activity monitoring is illustrated in Figure 2. To monitor the construction activities, manual assignments are transformed into tool motions at first. For example, the acceleration of tools indicates the workload at the construction stage; the velocity and angular velocity (palstance) exposes the mobile characteristics of workers; and position, rotation of tools provides a relative reference of the postures of workers. Then the construction regulations, standards, or codes are represented by tool rules. By comparing the tool data and these rules, it is a quantitative way to determine whether the actual construction activity is in conformity to the existing strict regulations [24].

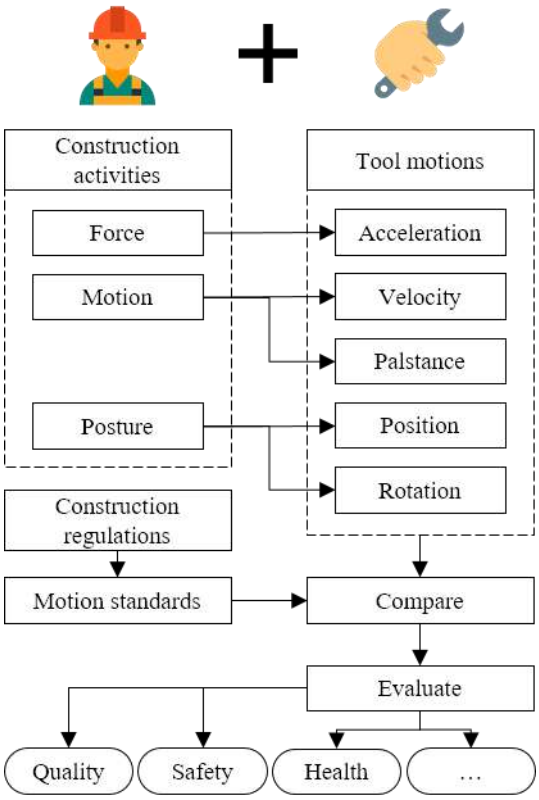

Figure 2. Schematic model for the IMU tool system

4 Data collection method

Various methods can be considered for the implementation of the framework for tracking the construction activities on-site. Among the current cutting-edge technologies, electro-mechanical system inertial measurement units (MEMS-IMUs) are economic and easy-handling.

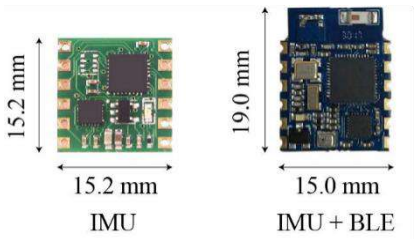

Figure 3. IMU and IMU+BLE sensors to collect tool data

As shown in Figure 3, the sensors are quite small and light, which can be integrated with power tools or installed on hand tools. This simple deployment ensures the non-intrusion during the construction stage.

These sensors are able to collect acceleration and angular velocity as a tri-accelerometer and a tri-gyroscope are imbedded in. Therefore, the task diagram

of IMU sensors is described in Figure 4. The IMU starts with measuring acceleration and angular velocity, and the calibrate each other according to the earth model. The adjusted acceleration is integral to produce velocity, and integral twice to generate displacement. Meanwhile the calibrated angular velocity is then integral to obtain the rotation and orientation at each time interval. By differential operation, the angular velocity can extract the angular acceleration as well. Noted that the magnetometer is more sensitive to tiny changes in direction, 9-axis is more common in applications as the measurement of magnetic field improve the accuracy significantly by calibrating at a high frequency.

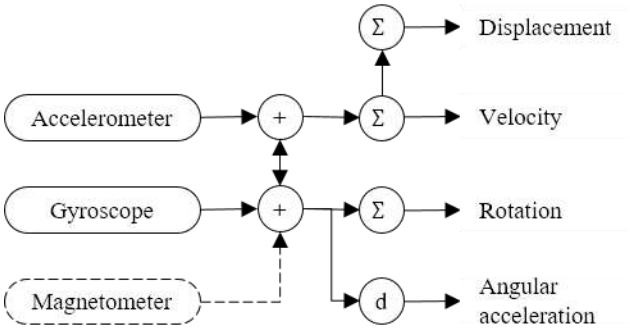

Figure 4. Task diagram of IMUs

The kinematics of a rigid body like a tool is composed of translation and rotation. This research only focuses on the rotation component as it produces considerable impacts on bar connections. Although the initial data collected by MEMS-IMU is in Euler angle form, here the orientation is represented in quaternion form which is simple and efficient in transforming computation. Thus, a rotation around axis $\boldsymbol{n}$ with an angle of θ is represented by

$$\boldsymbol{Q} = \left[\cos\left(\frac{\theta}{2}\right), \sin\left(\frac{\theta}{2}\right)\boldsymbol{n}\right] = [q_0, q_1, q_2, q_3] \tag{1}$$

While the orientation $\boldsymbol{R}$ is denoted by

$$\boldsymbol{R} = [0, \boldsymbol{r}] = [0, r_1, r_2, r_3] \tag{2}$$

The corresponding differential function is written by

$$\frac{\mathrm{d}\boldsymbol{Q}}{\mathrm{d}t} = \frac{1}{2}\boldsymbol{Q} \otimes \boldsymbol{\omega}_{\mathrm{nb}}^{\mathrm{b}} \tag{3}$$

where $\boldsymbol{\omega}_{\mathrm{nb}}^{\mathrm{b}} = [\omega_x \quad \omega_y \quad \omega_z]^{\mathrm{T}}$, refers to the angular velocity of each axis. And the matrix form of formula can be represented by

$$\begin{bmatrix} \dot{q_0} \\ \dot{q_1} \\ \dot{q_2} \\ \dot{q_3} \end{bmatrix} = \begin{bmatrix} 0 & -\omega_x & -\omega_y & -\omega_z \\ \omega_x & 0 & \omega_z & -\omega_y \\ \omega_y & -\omega_z & 0 & \omega_x \\ \omega_z & \omega_y & -\omega_x & 0 \end{bmatrix} \begin{bmatrix} q_0 \\ q_1 \\ q_2 \\ q_3 \end{bmatrix} \tag{4}$$

As the MEMS-IMU measures the angular velocity at a constant frequency, the iteration formulation is

$$\boldsymbol{Q}(t+1) = (\boldsymbol{I}\cos\frac{2\Delta\theta}{2} + \Delta\boldsymbol{\Omega}\frac{\sin\frac{2\Delta\theta}{2}}{\Delta\theta})\boldsymbol{Q}(t) \tag{5}$$

where $\Delta\boldsymbol{\Omega} = \begin{bmatrix} 0 & -\Delta\theta_x & -\Delta\theta_y & -\Delta\theta_z \\ \Delta\theta_x & 0 & \Delta\theta_z & -\Delta\theta_y \\ \Delta\theta_y & -\Delta\theta_z & 0 & \Delta\theta_x \\ \Delta\theta_z & \Delta\theta_y & -\Delta\theta_x & 0 \end{bmatrix}$, refers to the direct output of MEMS-IMU, $\Delta\theta = \sqrt{\Delta\theta_x^2 + \Delta\theta_y^2 + \Delta\theta_z^2}$ is the total changes of angular velocity.

The initial quaternion is determined be the transformation matrix from the earth frame to the sensor body frame, which is represented by

$$\begin{aligned} \boldsymbol{C}_{\mathrm{n}}^{\mathrm{b}} &= [\boldsymbol{c_1}, \boldsymbol{c_2}, \boldsymbol{c_3}] \\ \boldsymbol{c_1} &= \begin{bmatrix} q_0^2 + q_1^2 - q_2^2 - q_3^2 \\ 2(q_1q_2 + q_0q_3) \\ 2(q_1q_3 - q_0q_2) \end{bmatrix} \\ \boldsymbol{c_2} &= \begin{bmatrix} 2(q_1q_2 - q_0q_3) \\ q_0^2 - q_1^2 + q_2^2 - q_3^2 \\ 2(q_2q_3 + q_0q_1) \end{bmatrix} \\ \boldsymbol{c_3} &= \begin{bmatrix} 2(q_1q_3 + q_0) \\ 2(q_2q_3 - q_0q_1) \\ q_0^2 - q_1^2 - q_2^2 + q_3^2 \end{bmatrix} \end{aligned} \tag{6}$$

At the same time, $\|\boldsymbol{Q}\| = 1$ that each quaternion of rotation and orientation is normalized.

Although the integral approach appears to be accurate in theory, random noise, signal bias, etc. accumulates overtime. To improve the robustness and accuracy of rotation measurement, acceleration and magnetic field data collected by accelerometer and magnetometer are fused to orientation estimation by gyroscopes as well. Given a specific construction field, the direction of gravity and magnetic field are known. An orientation of the sensor frame relative to the earth frame is therefore calculated by comparing the measurement by gyroscope and by accelerometer and magnetometer.

If the rotation quaternion relates the earth frame to the sensor body frame is denoted by $\boldsymbol{q}_{\mathrm{e}}^{\mathrm{b}}$, the expected measurement of acceleration and magnetic field in the earth frame is denoted by $\boldsymbol{d}^{\mathrm{e}}$, meanwhile these in the sensor body frame measured in real-time is represented by $\boldsymbol{s}^{\mathrm{b}}$. The fusion of acceleration data and magnetic field data is modeled as an optimization problem. The objective function is

$$f(\boldsymbol{q}_{\mathrm{e}}^{\mathrm{b}}, \boldsymbol{d}^{\mathrm{e}}, \boldsymbol{s}^{\mathrm{e}}) = \boldsymbol{q}_{\mathrm{e}}^{\mathrm{b}*} \otimes \boldsymbol{d}^{\mathrm{e}} \otimes \boldsymbol{q}_{\mathrm{e}}^{\mathrm{b}} - \boldsymbol{s}^{\mathrm{b}} \tag{7}$$

To approximate to the minimum of the objective function, the corresponding gradient of the objective function is written by

$$\nabla f\left(\boldsymbol{q}_{\mathrm{e}}^{\mathrm{b}}, \boldsymbol{d}^{\mathrm{e}}, \boldsymbol{s}^{\mathrm{e}}\right) = \boldsymbol{J}^{\mathrm{T}}\left(\boldsymbol{q}_{\mathrm{e}}^{\mathrm{b}}, \boldsymbol{d}^{\mathrm{e}}\right) f\left(\boldsymbol{q}_{\mathrm{e}}^{\mathrm{b}}, \boldsymbol{d}^{\mathrm{e}}, \boldsymbol{s}^{\mathrm{e}}\right) \quad (8)$$

where $\boldsymbol{J}$ is the Jacobian matrix.

For acceleration data,

$$\boldsymbol{s}^{\mathrm{e}} = [0 \quad 0 \quad 0 \quad 1] \quad (9)$$

$$f\left(\boldsymbol{q}_{\mathrm{e}}^{\mathrm{b}}, \boldsymbol{a}^{\mathrm{e}}, \boldsymbol{s}^{\mathrm{e}}\right) = \begin{bmatrix} 2(q_1 q_3 - q_0 q_2) - a_x \\ 2(q_0 q_1 + q_2 q_3) - a_y \\ (1 - 2q_1^2 - 2q_2^2) - a_z \end{bmatrix} \quad (10)$$

$$\boldsymbol{J}\left(\boldsymbol{q}_{\mathrm{e}}^{\mathrm{b}}, \boldsymbol{a}^{\mathrm{e}}\right) = \begin{bmatrix} -2q_2 & 2q_3 & -2q_0 & 2q_1 \\ 2q_1 & 2q_0 & 2q_3 & 2q_2 \\ 0 & -4q_1 & -4q_2 & 0 \end{bmatrix} \quad (11)$$

For magnetic field,

$$\boldsymbol{s}^{\mathrm{e}} = [0 \quad s_x \quad 0 \quad s_z] \quad (12)$$

$$f\left(\boldsymbol{q}_{\mathrm{e}}^{\mathrm{b}}, \boldsymbol{m}^{\mathrm{e}}, \boldsymbol{s}^{\mathrm{e}}\right) = \begin{bmatrix} 2s_x(0.5 - q_2^2 - q_3^2) + 2s_z(q_1 q_3 - q_0 q_2) - m_x \\ 2s_x(q_1 q_2 - q_0 q_3) + 2s_z(q_0 q_1 + q_2 q_3) - m_y \\ 2s_x(q_0 q_2 + q_1 q_3) + 2s_z(0.5 - q_1^2 - q_2^2) - m_z \end{bmatrix} \quad (13)$$

$$\boldsymbol{J}\left(\boldsymbol{q}_{\mathrm{e}}^{\mathrm{b}}, \boldsymbol{a}^{\mathrm{e}}\right) = [\boldsymbol{J_1}, \boldsymbol{J_2}, \boldsymbol{J_3}, \boldsymbol{J_4}]$$

$$\boldsymbol{J_1} = \begin{bmatrix} -2s_z q_3 \\ -2s_x q_3 + 2s_z q_1 \\ 2s_x q_2 \end{bmatrix}$$

$$\boldsymbol{J_2} = \begin{bmatrix} 2s_z q_3 \\ 2s_x q_2 + 2s_z q_0 \\ 2s_x q_3 - 4s_z q_1 \end{bmatrix} \quad (14)$$

$$\boldsymbol{J_3} = \begin{bmatrix} -4s_x q_2 - 2s_z q_0 \\ 2s_x q_1 + 2s_z q_3 \\ 2s_x q_0 - 4s_z q_2 \end{bmatrix}$$

$$\boldsymbol{J_4} = \begin{bmatrix} -4s_x q_3 + 2s_z q_1 \\ -2s_x q_0 + 2s_z q_2 \\ 2s_x q_1 \end{bmatrix}$$

In this research, acceleration, angular velocity and magnetic field data are available, 9-axis MEMS-IMU algorithms is therefore applied to fuse and combine these data for compensating distortion, filtering erroneous data and smoothing. The fundamental way to accomplish this goal is Kalman filter.

Consider the spatial-temporal characteristics of a construction tool is a state vector that contains a series of variables. The model assumes that the true state at current time t is evolved from the state at the previous time t - 1. This discrete-time linear stationary model without control loop can be represented by

$$\boldsymbol{x}_t = \boldsymbol{\Phi} \boldsymbol{x}_{t-1} + \boldsymbol{\Gamma} \mathbf{w}_{\mathrm{t}-1} \quad (15)$$

where x is the state vector, $\boldsymbol{\Phi}$ refers to the state transition matrix, $\boldsymbol{\Gamma}$ is the control matrix of noises, $\mathbf{w} \sim \boldsymbol{\mathcal{N}}(\mathbf{0}, \mathbf{W}_{\mathrm{t}})$ represents the process noise that is assumed to be generated from a zero mean multivariate normal distribution $\boldsymbol{\mathcal{N}}$ with covariance $\mathbf{W}_{\mathrm{t}}$.

Concurrently, the measurement process is:

$$\boldsymbol{z}_t = \mathbf{H} \boldsymbol{x}_t + \mathbf{v}_{\mathrm{t}} \quad (16)$$

where H is the observation matrix and $\mathbf{v} \sim \boldsymbol{\mathcal{N}}(\mathbf{0}, \mathbf{V}_{\mathrm{t}})$ is the observation noise that drawn from a zero mean Gaussian distribution $\boldsymbol{\mathcal{N}}$ with covariance $\mathbf{V}_{\mathrm{t}}$.

5 Pilot study and results

As shown in Figure 5, IMU sensors can be deployed on the surface of a wrench, a hammer, etc. By tight connection, the data collected is according to the location of sensors, that is to say, the crucial axis for analysis is determined by the position and relation between sensor deployment and the core motion space.

Figure 5. Deployment of IMU sensors

The MEMS-IMU sensor tested here required extra battery support, and the chip is named JY901. The weight is 40 g and the size is less than 2 cm^2, almost non-intrusive when used.

Assume a wrench is adopted to apply torque to turn a screw for connection. Wireless MEMS-IMU is the device collecting the data of the combination wrench, providing a quantitative assessment of turning. In addition, a rubber mallet is also tested to conduct a wood work, requiring a softened strike with a positive drive.

In Figure 6, the curves of raw data revealed the turning process by a wrench rotating around y-axis. It could be seen that the turning job appears to be cyclic in much the same way as a wave with various frequencies. By integral operation, the rotation angle of turning process was shown in Figure 7. The cyclic pattern was more apparent that each cycle ranged from 0 to 90 degree at the begging time for applying torque, and then decreased to the initial position for the next cycle. In this experiment, 22 cycles were counted and the total rotation angle of turning was around 1442 degree, that means the screw has been turned for 4 circles. While the actual rotation was 1620 degree, and the relative measurement error was 10.99%.

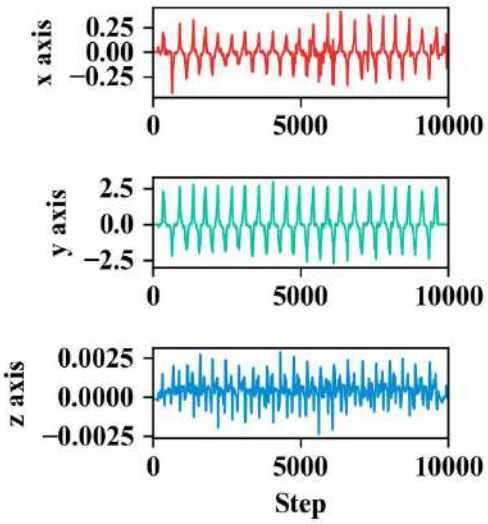

Figure 6. Angular velocity of turning collected by MEMS-IMU

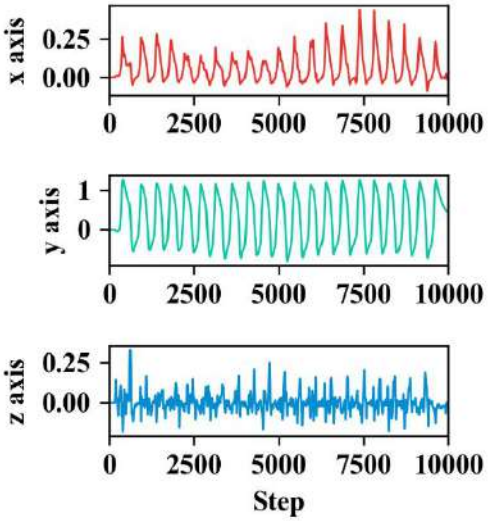

Figure 7. Rotation of turning collected by MEMS-IMU

On the other hand, the angular velocity of hammering process in Figure 8 exposed another kind of cyclic patterns. Here, x-axis was the rotation axis that the rubber mallet was held to hit on the objective panel. The extreme values of palstance were much higher than those of turning process. At the same time, the rotation angle of hammering was also larger as shown in Figure 9. The process begun with hanging on the mallet at the rotation angle of zero, then fell down as the rotation angle raised up to around 90 degrees. However, the measurement of highest rotation angles in each cycle was not accurate that the obtained value was more than 143 degrees. The error was unacceptable at this moment, which required to be improved in the future.

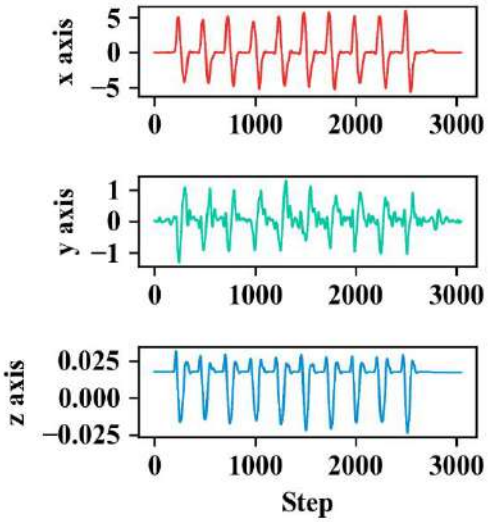

Figure 8. Angular velocity of hammering collected by MEMS-IMU

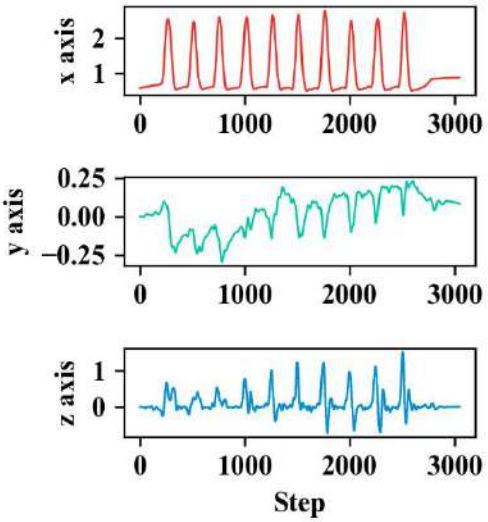

Figure 9. Rotation of hammering collected by MEMS-IMU

By comparing the different cyclic patterns from these two preliminary experiments, the extracted raw data clearly revealed the spatial-temporal characteristics of the different construction activities. Although the data was not so accurate because the current MEMS-IMU algorithm enlarged the cumulative errors over time, these two pilot studies have shown the potential of the proposed IMU-based tool system for monitoring the construction activities in a timely and automated manner.

6 Conclusion

This study proposed a feasible solution to monitor the construction activities without intrusions by collecting and analyzing the IMU data of hand tools used in the construction processes. Two simple experiments validated the novel concept and the preliminary framework. However, further developments were required in the future research, containing the reduction of random errors and cumulative errors and the pattern recognition for various tools and activities.

Abstract –

Three-Dimensional Printing (3DP) is widely used and continues to be rapidly developed and adopted, in several industries, including construction industry. Inkjet 3DP is the approach which offers the most promising and immediate opportunities for integrating the benefits of additive manufacturing technic into the construction field. The ability to readily modify the orientation angle that the printed material is deposited is one of the most advantageous features in a 3DP scaffold compared with conventional methods. The orientation angle has a significant effect on the mechanical behaviours of the printed specimens. Therefore, this paper focuses on printing in different orientations somehow to compare various mechanical properties and to characterise a selection of common construction materials including gypsum (ZP 151) and cement mortar (CP). The optimum strength for the gypsum specimens in compression and flexural strength was observed in the (0° and 90°) and (0°) in the X-Z plane, respectively. According to the experimental results, the compression and flexural strength for ZP 151 are recorded at (11.59±1.18 and 11.78±1.19) MPa and 15.57±0.71 MPa, respectively. Conversely, the highest strength in compression and flexural strength are observed in the (90°) and (0°) degrees in the X-Z plane for the cement mortar, respectively. Moreover, it has been discovered that the compression and flexural strengths for CP are recorded as 19.44±0.11 MPa and 4.06±0.08 MPa, respectively. In addition, the dimensional effect for various *w/c* ratio has been monitored and examined.

1 Introduction

Generally, the most common method in civil engineering is to cast in place or use precast procedures to construct structural members. These structural members are cast using different materials such as concrete, and masonry [10], [12] and [16]. Given the ever-increasing need for speed, quality and tailored design in the construction industry and due to the advances in rapid prototyping, the procedures for constructing structural members need to be rethought and upgraded [18].

Owing to the earlier studies, three main techniques for the 3DP powder-bed process have been recognized [14], i) selective binder (cement) activation, ii) binder jetting and iii) selective paste intrusion, respectively [22] [17]. These process could be monitored via the online vision sensor to control the slurry printing process [26]. The selective binder activation is the process that is used in this paper, which is usually known as powder-bed printing (binder/inkjet printing) [19] [23].

Inkjet printing is a layer-by-layer procedure to complete the entire scaffold using the powder-based materials and an activator such as water, Figure (1).

In inkjet 3DP, there are many limitations while printing the objects. For example, [28] discussed a few limitations in the 3DP such as binder selection, powder reactions, post-processing bed manipulations and de-powdering. One of the major limitations in 3DP is the orientation angle which has been discussed in earlier studies for the plastic and poly-jet materials [25].

In the following subsections, the mechanical strength of the recommended powder (ZP 151) and the modified powder (CP) have been monitored and compared. Moreover, the printed element has been examined within the different inclined rates for different angles. Nevertheless, the maximum compressive strength has been obtained for (CP) and (ZP 151). For the flexural strength, the highest results that have been observed for both (CP) and (ZP 151) are reported. Finally, the conclusions about the experimental study are presented and the future works are discussed.

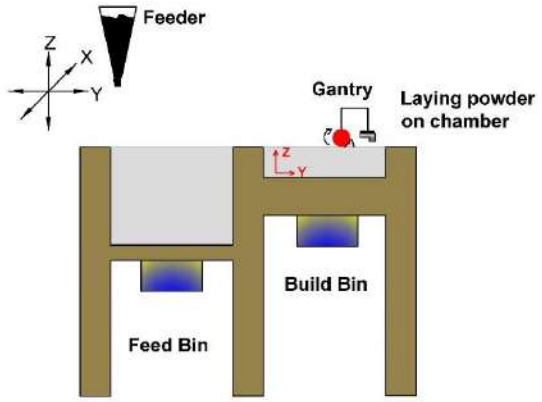

Figure 1. Schematic depiction of the powder-bed printing technique in inkjet 3D printing.

2 Materials and Specimens Preparation

2.1 Materials Composition

According to 3DSystems manual [2], the ZP151 contains (80-90%) of calcium sulphate hemihydrate ($CaSO_4 \cdot 1/2H_2O$). Moreover, Zb 63 is an aqueous solution and known as a binder, which has a high water content and humectant with the density of 1g/cm^3 [1].

In the previous study, [23] it has been found that the water/cement ratio (*w/c)* or (binder/powder) ratio can be determined by using Equation (1). The volume of a drop of binder will be measured according to the enveloped volume of powder in the build chamber of the printer.

$$Sat_{level} = \frac{V_b}{V_{EnvPowder}} \qquad (1)$$

Where Sat_{level} is saturation level (*w/c*), V_b is the volume of the binder, and $V_{envpowder}$ the volume of the enveloped powder on the build chamber (build bin).

The alternative mix that has been used for printing contains as a percentage of total weight are 67.8% of Calcium Aluminate Cement (CAC) ranging sieve (75-150μm), 32.2% of Ordinary Portland Cement (OPC) and 5% of fine sand. Figure (2) shows the histogram and curve of the density distribution of the custom-made and recommended materials versus particle size.

Figure (3) shows the modified mixing powder (cement mortar CP), which replaces the ZP 151. It is noted that the mixing process has been completed using a Hobart mixer at a speed of 1450 RPM.

Moreover, the homogeneity and consistency of the powder materials are crucial factors that must be controlled when in pursuit of superior resolutions and results. Therefore, the speed of the mixer and the time of mixing are considered as a major contributor to the homogeneity of the powder and production of better quality 3DP objects.

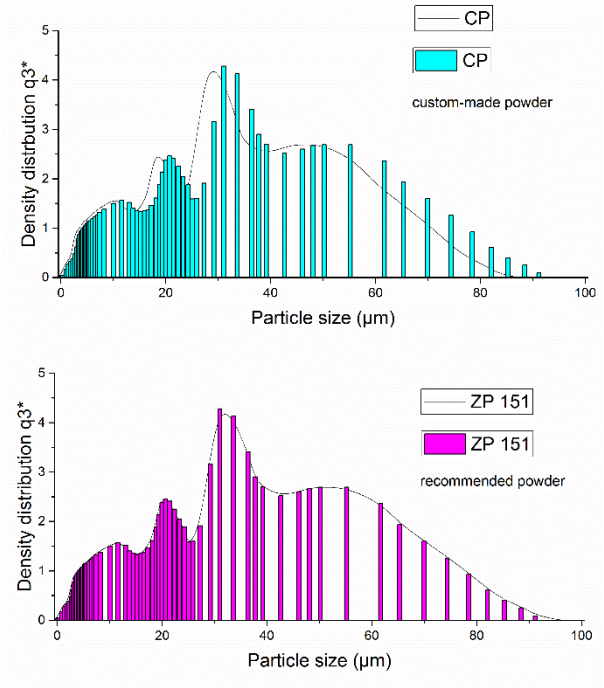

Figure 2. Histogram and curve of particle size distributions of ZP 151 and CP (custom-made) powder. *q3 is the unit standing for the density distribution of the total particles.

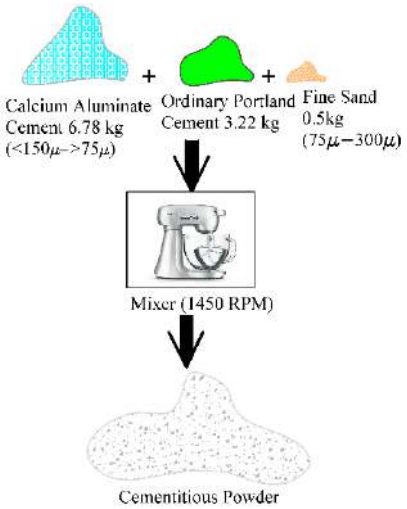

Figure 3. Schematic illustration of the process for preparing cementitious powder.

In addition, the optimum saturation level (*w/c*) of the binder for 3DP specimens has been reported [7]. According to the report, the highest saturation level is (S170C340) (Shell=170, Core=340), determined by Equation (1), which produces the highest result for the mechanical strength in 3DP specimens. The saturation level of the modified powder (S170C340) is equivalent to (*w/c*=0.52) in the manual mixing process for the cement mortar (CP) and (*w/c*=0.46) for the gypsum (ZP 151). The materials' chemical composition have been presented in Table (1).

Table 1. Chemical constituent percentages of the main materials in CP

Chemical Constituent % of Calcium Aluminate Cement			
Al_2O_3	CaO	SiO_2	Fe_2O_3
≥ 37.0	≤ 39.8	≤ 6.0	≤ 18.5
Chemical Constituent % of Ordinary Portland Cement (General Purpose)			
Cement Clinker	$CaCO_3$	$CaSO_4.2H_2O$	Clinker Kiln dust
>92%	0-7.5%	3-8%	0-2.5%

2.2 Specimen Preparation

The (ZP 151) has been directly placed into the 3DP (ProJet 360). However, the modified mix was prepared by a 20L Hobart mixer. The mixing procedure has been conducted in a dry mix state. Then, the prepared mix powder is placed into the inkjet 3D printer to print the mortar specimens. A Shimadzu load cell (AGS-X 50kN, Japan) testing machine was used to perform the mechanical tests at room temperature of (22±2°C) with a humidity level in the range of (60±10) %.

Different orientation angles have been used to print the specimens (0, 30, 37.5, 45, 90)°. These angles have been selected because the halfway point of (0° and 90°), are the angle 45°. Commonly most of the shear rupture happens in concrete were between 0° and 45° [11]. Therefore, this paper focused on these angles between 0° to 45°. Figure (4) schematically shows the specimens with different orientation angles of print. Table (2) presents the name of the tests, numbers of samples, and CAD dimensions for both materials specimens

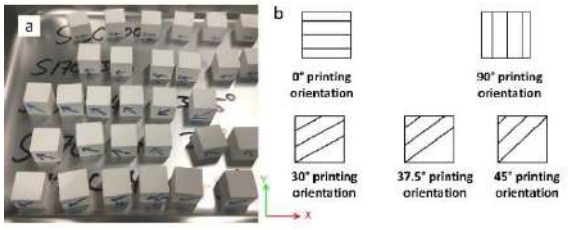

Figure 4. (**a**) Real-world images of the 3DP cubes in (0°,30°,37.7°,45°,90°) orientation (**b**) Drawing of 3DP cubes in (0°,30°,37.7°,45°,90°).

3 Experimental Program

To determine the mechanical properties of the 3DP specimens, all the samples were designed in SolidWorks software as an STL file. Figure (5) shows the cubic samples in different orientation angles, which are printed at (0°, 30°, 37.5°, 45°, 90°). It also shows the orientation angle of prepared specimens with regard to the X, Y, Z plane in the 3DSystems software. A mould (20×20×20), (167×17×7) mm used for casting the comparison, samples. All of the samples for compressive, and flexural strength tests have been prepared in a similar process.

The orientation angles in 3DP can be used in inkjet printing to create different geometries, optimize the mechanical strength of structure parts and optimize the number of layers to print an object.

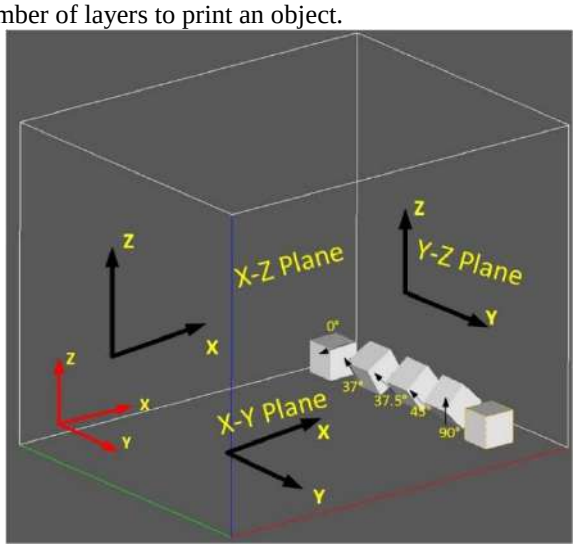

Figure 5. An illustration of the cube to be printed in different orientation angles according to X-Z plane.

Table (2) shows the type of tests, number of samples, and CAD drawing dimensions of the printing parameters.

Table 2. Tests with respect to the numbers and dimensions

Tests	**No. of Samples**	**CAD Dimensions (mm)**
Compression test	36	20×20×20
Three-point bending test	36	167×17×7
Dimensional accuracy	10	20×20×20

3.1 Testing and loading procedures

All the specimens have been tested using the universal testing machine (50 kN) with different rates of speed.

3.1.1 Effect of Dimensional Accuracy

The most vital features that distinguish the powder-based (inkjet) 3DP from the conventional casting method are the accuracy and dimensional precision of 3DP. Figure (6) shows the printed samples (cube and prism), which have been printed by inkjet 3DP: (a) left is mortar (CP) and (a) right is gypsum (ZP 151). Dimensions of the specimens have been measured by digital callipers with an accuracy of 0.01 mm and for the height, it has been used MeasumaX with an accuracy of ±0.04mm. Ten samples were used for the effects of dimensional accuracy test.

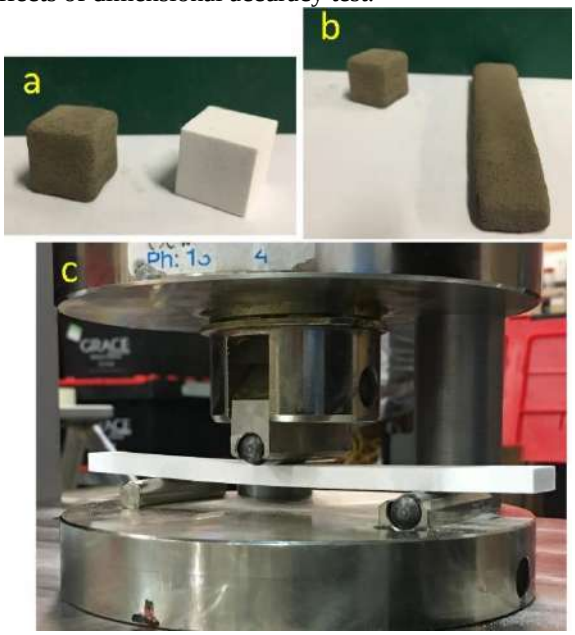

Figure 6. (a) 3DP cubic samples for CP and ZP 151, (b) 3DP cubic and prism CP sample, (c) 3DP prism gypsum while testing for three-point bending test.

3.1.2 Compressive Strength Test

One of the common factors that can be used to assess the durability of the concrete and mortar is its compressive strength [6]. Thus, the compression strength test has been performed for the 3DP samples according to the ASTM standard [6]. A total of 36 samples have been tested including 3 samples for each of orientation angles. The speed rate of the loading in the test was 0.833 kN/sec.

3.1.3 Flexural Strength Test

The specimens for the flexural strength test were prepared according to the ASTM standard [7]. A total of 36 samples have been printed using the manual mix, including 3 samples prepared for each orientation angle. The speed rate of the loading in the test was 426 N/min.

3.1.4 Post-Processing Procedure

The curing and post-processing procedures are crucial to produce robust 3DP elements. After the element is printed, it should be kept for a minimum of 2 hours inside the build chamber of the printer so it can dry. According to the study of Feng et al. [8], specimens should be left for a further three hours to dry in an oven at 60°C after drying inside the build chamber. This leads to accelerating the solidifications and incremental stiffness of the gypsum scaffold (ZP 151). For that reason, the three hours curing in the oven has been implemented for ZP 151.

Curing of CP has been monitored using different trials and tests at the vitro. Accordingly, before and after curing in the water, CP has been drying at 60°C, results in higher compression strength in the CP specimens.

4 Results and Discussion

4.1.1 Effect of Dimensional Accuracy

The major advantage of the inkjet 3DP technique is a fabrication of structural components with complicated geometries without implementing costly formwork. The most vital aspect that distinguishes the inkjet (powder-based) 3DP from conventional casting method is the precision of printing. Figure (7) shows the results of the dimensional accuracy for the green cubic sample (green part) for the CP materials. Note that "green part" means a specimen that has been removed from the build chamber (build bin) prior to any post-processing.

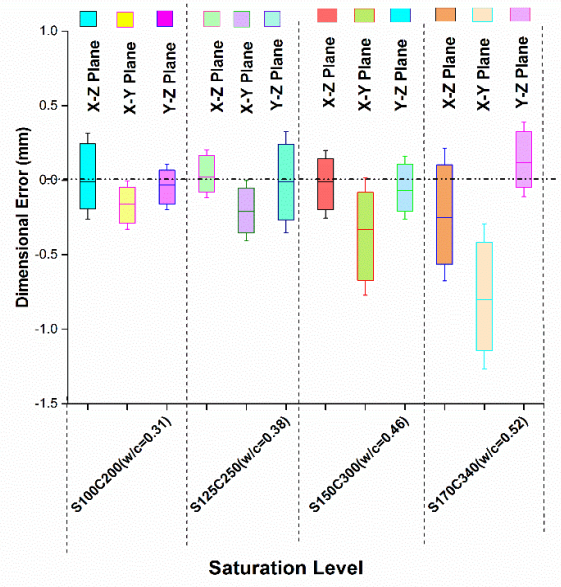

Figure 7. The relationship between dimensional accuracy and saturation level (*w/c*) for printed green cube CP specimens (CAD 20×20×20mm),

printed by ProJet CJP (304 nozzles). (Note: the box is the mean ±standard deviation, and the whisker is ±minimum and maximum).

The dimensional error can be found using Equation (2):

$$D_{error} = D_{printed} - D_{CAD} \quad (2)$$

Where D_{error} is a dimensional error, $D_{printed}$ is an actual printed dimension, and D_{CAD} is a CAD dimension.

Figure (7) also shows that in general the dimensional accuracy increases as the *w/c* is reduced for all planes. However, in the X-Y plane, a significant amount of undesirable deviation in the dimensional precision can be observed. These are lower than the nominal (CAD dimensions) that due to the inaccuracy of the printhead nozzle and closeness of the nozzles. This inaccuracy could lead overlapping and collision of the binder when it drops on the powder. Another reason is the chemical and physical characterization of the powder-to-binder and the ability of the powder for drop penetration. In addition, the printhead located on the fast axis rails which have a high rate movement. This can be counted as another important factor in the contribution of the accuracy of dimensions. The gantry holds all binder supply system, which is located on the fast axis rails in the printer.

4.1.2 Compressive Strength Test

In the previous study conducted by Shakor et al. [19], the porosity and voids in the cubic samples were investigated. The findings and optimum saturation level have been used in this paper to print and prepare all the scaffolds at the same saturation levels.

Figure (8) shows the porosity of the specimens versus the *w/c* ratio, where the highest saturation level (*w/c*) resulted in a reduction of the porosity percentage for both powders (CP) and (ZP 151). According to the study of Popovics et al. [15], the relationship between *w/c* ratio and porosity can be described by Equation (3);

$$p = 0.001a + \frac{w/c}{w/c+1/G} \quad (3)$$

Where p is the total porosity for the fresh cement, a is the air content by volume, G is specific gravity of cement and *w/c* is a water/cement ratio by mass. Consequently, an increase in *w/c* ratio means an increase in porosity of the sample, and resulted in a reduction in strength of the sample. However, this equation cannot be applied to the 3DP cementitious powder (CP) or gypsum (ZP 151). The printing of (CP) and (ZP 151) is completed in a layer-by-layer process. This technique is totally different from the manual mix process, which involves mixing the powder with water within one batch and vibrating it in the casting mould. The process of printing and post-processing applications has various effects on the mechanical properties and durability of the printed object. For example, the hygroscopic of the powder and electrostatic charge on the surface of the powder has a significant influence on the capability of powder to absorb moisture from the air. This leads to an increase in the cohesion and a reduction in the flowability of the powder. Additionally, this property in the powder would affect the size of the specimen and change the mechanical properties of the specimen as well.

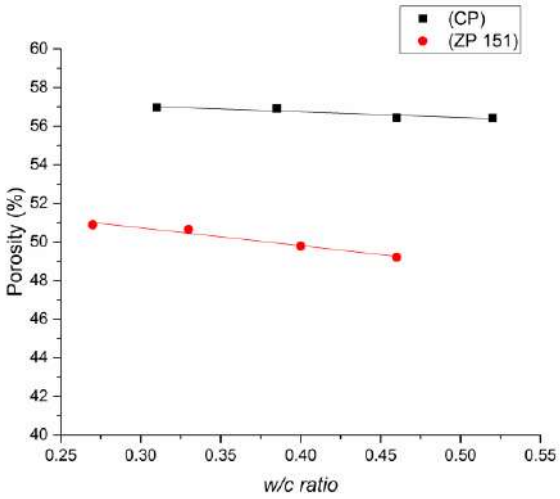

Figure (8) Relationship between porosity and w/c ratio for the mortar and gypsum printed scaffold.

Figure (9) illustrates the compressive strength of the specimen for the saturation level of S170C340. This saturation level is equal to a *w/c* of 0.52 in CP and 0.46 in ZP 151 using for all orientation angle. Accordingly, it shows the orientation angle of (90°) gives the highest value (19.44±0.11 MPa) for CP after curing in an oven for 3 hours before and after wet curing, and a 7-day curing in water. This value is enough to build a structural member, which is cured only for 7-day. According to ACI code, a 7-day cure is counted as a 65% of the strength of mortar or concrete [3], while the compressive strength of mortar or concrete increases to about 99% strength in 28-day.

On the other hand, ZP 151 has recorded the highest result with an orientation angle of (0°) and (90°), i.e. when the printhead is parallel to the *x*-axis the highest result was recorded. This result matches with results reported by Asadi-Eydivand et al. [5]. However, this investigation needs further study to assess specimens in all three planes and axes. In addition, the rotating and changing scale of the specimens also needs further examination.

It is clear from the experimental results that the printing orientation angle has a major impact on the mechanical strength of the specimens, particularly in the cement mortar specimens. As shown in Figure (9) the printing orientation of (90°) has recorded the highest value of compressive strength which means the perpendicular directions has the optimum strength in the X-Z plane for cement mortar. However, the results for gypsum are slightly different since both angles (0° and 90°) could obtain maximum compressive strength. The results of the two angles are very similar to each other with

differences in the decimals range. Thus, it is highly recommended to print in the orientation angle of 90° for CP to achieve the highest compressive strength with concern to the flexural strength, which explaining in the following subsection.

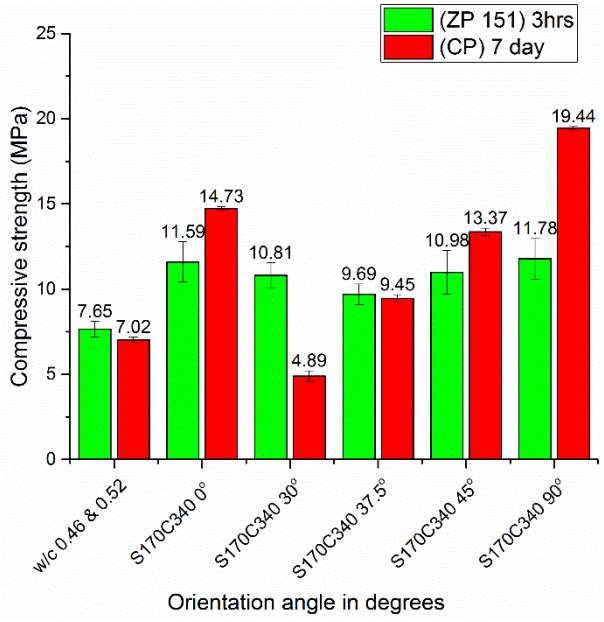

Figure (9) Compressive strength results for the ZP 151 cubes and CP cubes (average ±standard deviation).

The halfway point between 0° and 45° is the angle 22.5° on the plane and is the most critical place for a crack in the concrete sample to begin. In this study, the angle 30° is the closest angle to 22.5° and is the reason for the emergence of a lower mechanical strength specifically in the cement mortar specimens. Further investigations are needed to check the results in different angles, e.g., 22.5° and 67.5°. The procedure used in this study is similar to a study conducted by [27], where tests were performed at a 22.5° angle for concrete blocks with dimensions (454×371)mm. However, the test results are quite different since the samples prepared in [27], were blocks joined by mortar, and not one continuous layer. Another reason is that the size, dimensions and properties of the materials are different which each have a significant impact on the outcomes of "orientational angle" results. Hence, the whole printed specimens are made from mortar and have a continuous longitudinal layer without the interruption of block joints. Therefore, the results would be different from conventional blocks.

4.1.3 Flexural Strength Test

Three-point bending tests have been conducted to evaluate the flexural strength of the printed gypsum and cement mortar specimens. Figure (10) shows that in general, the flexural strength in gypsum is higher than the cement mortar specimens. According to the ACI code [4], the flexural strength of concrete is about 10% to 20% of the compressive strength result. Likewise, the result of CP in flexural strength after 7-day shows that the measured flexural strength is about 14% of compressive strength. Moreover, this could be due to the medium of the specimens, type, sizes, the volume of the particle size and duration of the curing.

Figure (10) shows flexural strength results quite opposite to the compressive strength result of both materials. As shown in Figure (9) the highest result is in CP specimens. However, in Figure (10) the results of the ZP 151 show higher values than the CP specimens. Previous studies have proved that using gypsum leads to an increase in bending and tensile strength [9]. The high percentage of lime content in fly ash with a high ratio of gypsum (1%), leads to a dramatic increase in the tensile strength [9]. Therefore, gypsum is acting as a flexible material and has great flexibility compared to the cement materials. In an earlier study by Lewry et al. [13], it has been proven that the reaction of water to plaster (gypsum), which is similar to the material ZP 151, with a 0.6 *w/c* ratio could gain about 12.2 MPa. This result is quite close to the manual mix of ZP 151 with *w/c* ratio of 0.46 in this study, which is 14.23 MPa. However, post-processing and purity of the materials have a significant effect on the result of the bending strength of gypsum materials.

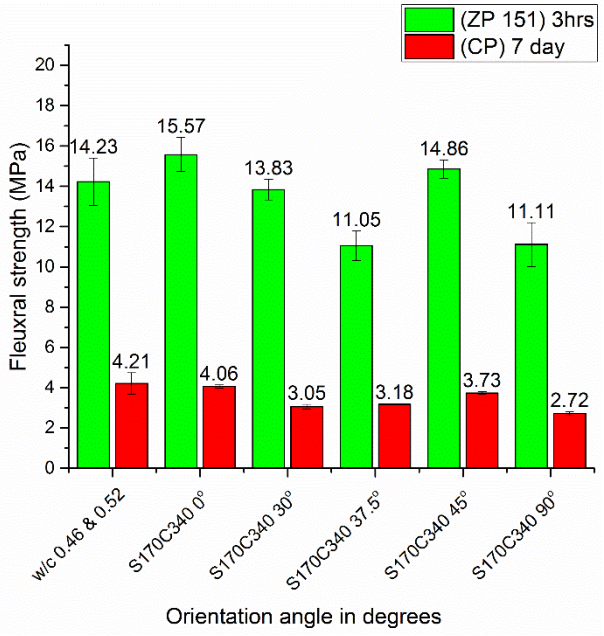

Figure (10) Flexural strength results for the ZP 151 cubes and CP cubes (average ±standard deviation).

Furthermore, the result for the printed ZP 151 and CP samples are important due to the highest bending

strength recorded at the orientation angle of 0°. Meanwhile, the manual mix of CP in bending strength is slightly higher than the printed angle 0°. Therefore, the present study, the printing for the CP in the 0° and 90° are optimum angles to print for construction members because of the highest results achieved for compressive strength at angle 90° and highest results achieved for bending strength at angle 0°. This could be improved by adding reinforcement and later used for façade and cladding of the building [21] [24] [20].

5 Conclusion

3DP cubic and prism specimens have been printed with ZP 151 and CP materials. These specimens have been printed in different orientation angles to obtain better mechanical properties. In this paper, the dimensional accuracy for the CP printed specimens in the various *w/c* ratio (saturation levels) has been scrutinized and discussed. The results show that the *x*-*y* plane always has smaller dimensions than the other planes, this is due to the printhead direction, which is parallel to the *x*-axis and perpendicular to the *y*-axis. The printhead nozzles are too close and adjacent to each other and most probably the liquid binder overlapping and collide when dropping the droplet at high speeds. The other reasons could be due to the high capability of penetration of the water (binder) into the powder. Moreover, the dimensional accuracy is mostly decreased and highly variable while the *w/c* increases as a result of spreading high volumes of the water through the printhead. Particularly, spreading water in the *y*-axis is less than in the *x*-axis, which is perpendicular to the printhead, and vice-versa in the parallel direction (X-axis).

Furthermore, this study has investigated the effect of orientation angle on the printed structural members using CP (mortar) and ZP 151 (gypsum). The results show that this is an important factor that needs to be taken into consideration in the future studies of 3DP. The most appropriate orientations are 90° and 0° degrees for the strongest bending and compression strengths, respectively. In addition, this study is conducted to check the height of the printhead, number of the nozzles and spreading of the water (binder) while the printhead is moving on the powder bed and dripping water droplets at a fast speed. However, the effects of temperature and medium curing needs to be studied in detail for different powder types.

BIM-based Takt-Time Planning and Takt Control: Requirements for Digital Construction Process Management

J. Melzner[a]

[a]W. Markgraf GmbH & Co KG, Germany
E-mail: juergen.melzner@gmx.de

Abstract –

Continuous and robust process planning is contrary to the different goals of project participants in the construction business. The aim of holistic building process management must be to optimize the overall process by streamlining individual processes. Lean management methods are increasingly being used to harmonize building processes. For this purpose, especially the method of takt time planning and takt control is appropriate. Building information modeling (BIM) is another promising way to promote a collaborative planning and construction process. BIM is generally understood as a virtual 3D model of a project with additional information. In order to be able to use the synergies of the two methods, the requirements, framework conditions, and goals of the two methods must be coordinated so that the added value of information for process planning can be used. The parallel application of lean construction methods and BIM can create added value that leads to productivity gains. In established BIM applications, the product (e.g., building) is planned as optimally as possible. However, the production process is not sufficiently considered. This is where lean construction methods are used to optimize the process. This article describes synergies through the combination of both methods and defines the requirements for a new BIM use case, "takt time planning and takt control." The presented concept is prototypically tested on a hotel tower project and the benefits and requirements are discussed.

Lean Construction; Process planning; Construction Management; Building Information Modeling

1 Introduction

A paper of the ISARC 1993 starts with the paragraph "The chronic problems of construction are well-known: low productivity, poor safety, inferior working conditions, and insufficient quality" [1]. Although this statement from more than 25 years ago could describe many of today's construction projects, little seems to have changed since then. Low productivity is one of the biggest challenges facing the construction industry nowadays.

Many studies show that the productivity of the construction industry has not increased in recent years compared to that of other industries. While other manufacturing industries have increased their productivity by more than 20% in the last 20 years, productivity in the construction industry has increased by only about 4%. These considerations raise the question of whether other industries are better at realizing the opportunities of digitization than the construction industry.

The construction industry is facing a change. Digitization is pervading more and more sectors of the industry. The implementation of digitization projects requires a strong standardization for business processes as well as for products and components.

Building Information Modeling is seen as the driver of digitization in construction. All relevant information in a construction project will be mapped into a consistent data model. Thereby an improvement in the achievement of the project goals in the dimensions dates, costs and quality is to be achieved. However, the industry has not been able to increase productivity to nearly the same level as other manufacturing industries. With the aim of increasing productivity, lean management methods are increasingly being adapted in the construction industry. Lean Construction and Building Information Modelling, at first glance, are two independent methods whose evolution has been shaped by different perspectives.

This paper describes two methods currently most promising in construction management to increase productivity, occupational safety and quality. Lean Construction methods and BIM are internationally used methods in construction. However, the combination of both methods lacks framework conditions to enable a digital exchange of building data especially for the takt-

time planning application. Therefore, the minimum requirements will defined in the paper.

2 Problem Description and Objective

Ineffective processes not only lead to a loss of time, but also to wastage of various resources. Not fully used or misdirected resources lead to rising costs during operation, indicating flawed planning and reduced values. Studies in the United States, Great Britain and Scandinavia have shown that wastage in the building construction process is very high:

- 30% of the construction work must be repeated to produce appropriate quality,
- 10% of material assets get lost due to wastage and disorder, and
- only 40–60% of the performance is efficiently used in construction activities [2].

The complex process of construction project planning depends on many parameters and the quality of construction schedules is highly related to the engineers´ knowledge. The initial schedule includes, in most cases, only the basic information about the planned construction. The pieces of basic information are the approximate start and end dates of the different trades. Detailed schedules with linked activities to represent the dependencies between activities are in most cases missing [3].

Software applications relieve users from routine tasks. However, the shortcomings of present software tools, which are currently used for construction process management, include the separate generation of the building information model and the construction process model.

The successful implementation of projects requires a structured and effective communication between all stakeholders. The increasing development of BIM tools has to be evaluated concerning their situational suitability of information exchange in construction projects. Construction projects are generally characterized by a large number of stakeholders such as construction companies, architects, planners, and representatives of regulatory bodies.

In order to gather the relevant information in a BIM process, information pertaining to who, when, how, and which has to be identified and provided. The buildingSMART propagated a method to define such exchange requirements is the Information Delivery Manual (IDM) (ISO 29481). The objectives of IDM are meant to standardize the information needed for specific-use cases in the BIM process. This manual defines the requirements for data exchange for all participants, including software providers.

An IDM targets both BIM users and solution providers and consists of three main parts- process map, exchange requirements, and functional parts. The process map describes the flow of activities for a specific process e.g., cost estimation. It improves the understanding of configuration of activities, the involved actors, the required information, and the consumed and produced information (Figure 1).

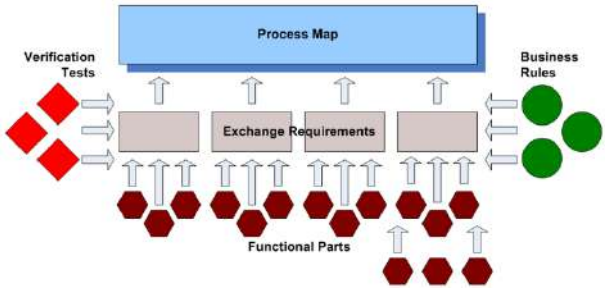

Figure 1. BIM-based lean construction production model [4]

The exchange requirements are a set of information that needs to be exchanged to support a specific business requirement at a particular stage of a project. An exchange requirement represents the connection between process and data. It applies the relevant information defined within an information model to fulfil the requirements of an information exchange. Finally, the functional parts are units of information used by solution providers to support an exchange requirement [4].

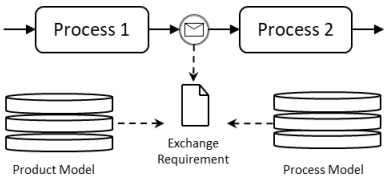

Figure 2. Scheme of Exchange Requirements

This paper describes the requirement of the BIM process to facilitate takt-time planning for a building information model.

3 Background

3.1 Building Information Modeling

The core of BIM-based project management is an integral digital building data model. The aim of the Building Information Model is to combine complex and heterogeneous data from the project participants into a consistent database. The flow of data between project

participants and project phases is best handled digitally in a Common Data Environment (CDE). The current projects are largely concerned with the digital product model and less with the processes surrounding a construction project, even if the BIM vision focuses on process-related project execution.

Digitalization in the construction industry and the application of modern information technologies offer a great potential to improve construction safety and health in the planning phases. According to Eastman et al. [5], "BIM is one of the most promising developments in architecture, engineering, and construction (AEC) industries. With the BIM technology, an accurate virtual model of a building can be digitally constructed." The BIM-based risk management, clash detection, cost estimation, and 4D simulation have now become established features to support construction project management [6]. It supports the design through all its phases until the project is completed, and also allows better analysis and control than existing manual processes [7].

Building Information Modeling (BIM) represents a promising development in the architecture, engineering and construction industries. With this method, accurate building models can be digitally displayed. It supports the design through all its phases till the project is completed and allows better analysis and control than existing manual processes.

3D-model-based clash detection, risk management, cost estimation and 4D animation have become established methods to make construction management more efficient [8]. The use of BIM for construction project planning offers many other advantages [9].

3.2 Lean Construction Management

A production system is based on fundamental principles, standards, methods, and tools. It describes the standardized way of working and organizing companies according to lean principles. The goal of Lean Management in the construction industry is to avoid waste, to focus on the customer, and to increase the added value of its product. So far, the application scenarios used in the construction industry have focused predominantly on analogous processes for planning and controlling construction [10]. The inherent focus of Lean Construction's production system is on the process level, system control, and process-based organizational design.

It is clear from these statements that the two methods have different modes of operation. The Building Information Model represents the product and the Lean Construction Method describes the process

Building Information Modeling (BIM) and Lean Construction are two different methods of improving the construction process originally developed by different stakeholders with different goals. Over the past decade, both methods have begun to spread fast in practice.

Recently, however, it has come to be realized that these two methods have considerable synergy and that it is advantageous to implement them together. In view of this, there is an increasing need to sensitize BIM users to Lean principles and methods as well as Lean users to the BIM project workflows.

3.3 Synergies

A combination of the BIM and Lean methods can generate synergies if the two methods are harmonized. On closer inspection, it can be seen that the two methods are complementary in many target images, but the approaches and modes of action are different. A detailed study examining BIM applications and lean processes was conducted by Sacks et al. a. and showed 56 interactions of both methods [11]. In order to realize the synergies of the two methods, concrete intersections have to be identified.

4 Methodology

This research contributes to the improvement of construction process planning by using the information of a Building Information Model to develop a takt-time plan according to lean construction principles.
In this research, two main data sources are needed for construction process planning. Information about the building including all objects and quantities will be delivered via a Building Information Model (BIM). Second, information about the processes is needed. The process information will be derived from the process model database. The major parts of the proposed framework are shown in Figure 3.

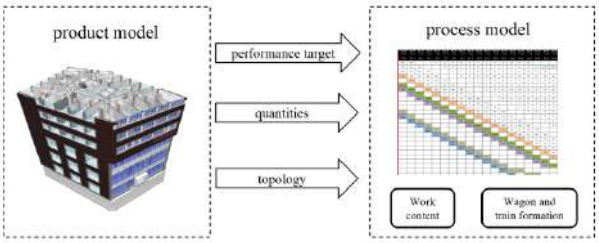

Figure 3. BIM-based lean construction production model

Decision-making in construction management is commonly based on empirical knowledge, because it is not easy to evaluate different execution strategies by using traditional scheduling methods. Although the

number of possible solutions is limited by numerous constraints, the remaining possible execution strategies are almost unlimited. However, they are influenced in terms of production technique and production costs due to different constraints [12].

The objective of this approach is to integrate basic and methodical knowledge of construction management into the model. In order to achieve this objective, four steps need to be defined:

1. Capture the relevant requirement from users point of view,
2. Describe this requirement within a model,
3. Develop abstract solutions by using empirical knowledge and
4. Implement the solutions by adapting them for a specific project.

Building components are represented in an object-oriented context in this work. Accordingly, objects belong to a class with their individual properties. Furthermore, building information models contain geometric data about the material, location, weight and other properties. The building structure is hierarchical. The building is structured in floors, groups of objects (e.g., walls, slabs) and individual objects. Objects must be uniquely identifiable.

5 Use case: Takt-time planning

5.1 BIM-Lean Integration

How can the two methods, Lean Construction and BIM, be combined on a practical level? Lean Construction is operationalized through application-oriented methods. An essential method in construction is the takt-time planning aimed at reducing the size of batches to simplify the control of construction processes. The way to a Lean Construction takt-time planning can be sustainably supported by the consistent and reliable information provided by BIM-based project handling.
The basis of the timing of the construction process is a precise reflection of the performance target. The performance target is guaranteed in the BIM project by a model-based calculation of the construction work. The content of the model-based calculation is the spatially separated quantities and service items and their combination with effort and performance values. Further calculation bases from the product model are - for example, the building topology to derive a zoning for the building. These data can be incorporated directly into the takt-time planning from basic quantities or used as a control entity for plausibility calculations. The link between the production processes and the objects of the building information model enables the simulation of execution strategies and their return to a harmonized production schedule.

5.2 Product Model

The input data for the generation of the schedule are project-specific data generated from the building information model. This model provides the building with specific input data e.g., building objects, hierarchical order, and quantities.

Building components are represented in an object-oriented context in this work. Accordingly, objects belong to a class with their respective properties. Building information models contain the geometric data about the material, location, weight, and other properties. The building structure is hierarchical. The building is structured in floors, groups of objects (e.g., walls, slabs, rooms) and individual objects. Objects must be uniquely identifiable (Figure 4). In the model-based cost calculation phase, every single object will be calculated.

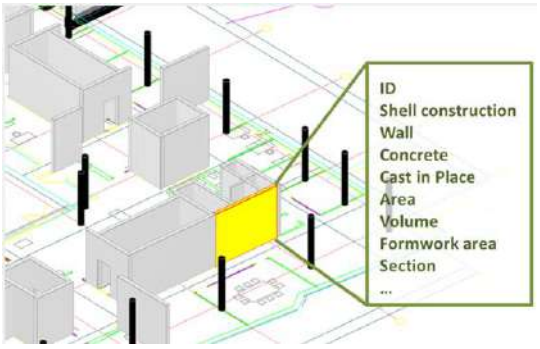

Figure 4. Definition of the building structure

In the cost calculation process, the individual costs of the part services are already determined for every single object. This includes, for example, the costs of wages, materials, and equipment. In the following, this object-oriented cost calculation allows these component and room-specific values to be used as a basis for process planning.

The described preparation process from modelling the building and determining the component-specific costs provides the information needed in the following multi-level process planning.

5.3 Takt-time planning process

Takt-time planning is one of the most used methods in the Lean Construction context. The German word "Takt" means "beat". In this context, it means the processes on the site follow a standardized takt developed in the following eight steps (Figure 5).

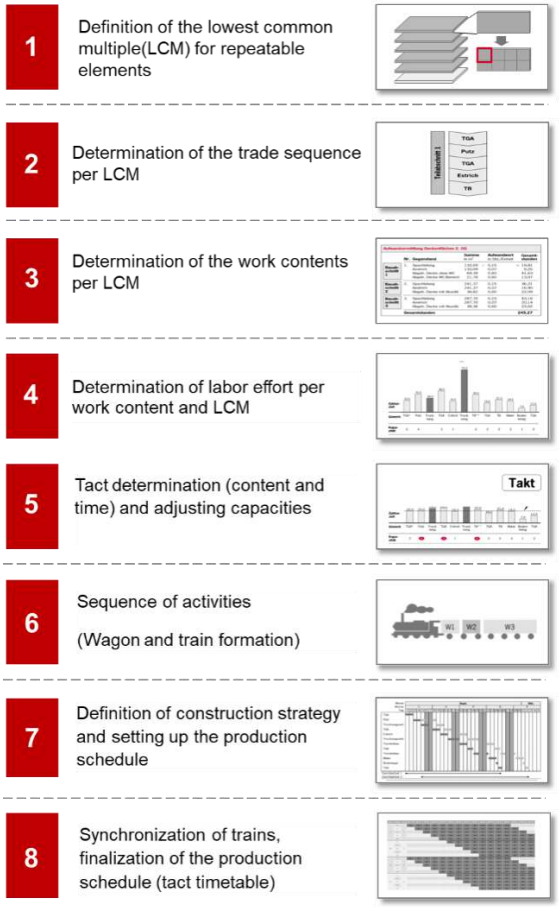

Figure 5.Takt-time planning workflow

In order to determine the exchange requirements with regard to process planning, the eight steps must be examined with regard to the following criteria:

- **Who** is requesting?
- **Why** is this information important to exchange?
- **When** is the information needed?
- **What** information supports the request?
- **To Whom**? Actor that fulfills the information need.

In the first step of the workflow is the analysis of the lowest common multiple (LCM) (Figure 6). Projects with a high repetition factor on similar construction stages are well-suited for takt-time planning. In this case, all services of internal works for a LMC have to be calculated at once and multiplied by the repetition factor.

With the traditional method of process planning, steps 1–4 involve considerable effort. All information must be gathered together from different documents e.g., tender specifications, and expert reports (Figure7).

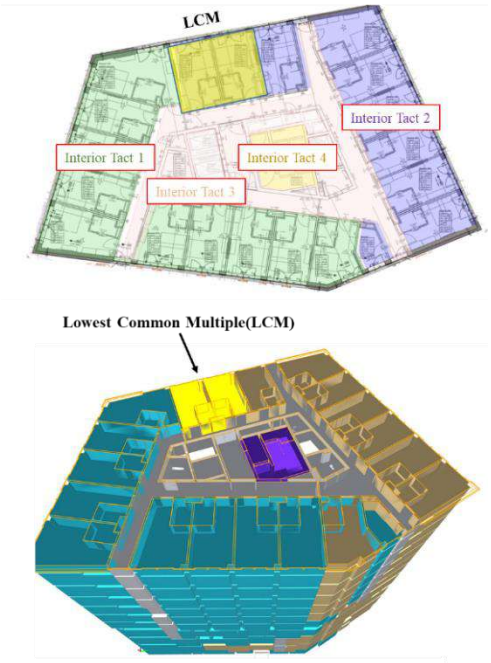

Figure 6.Visualization of interior takt areas on a 2D-plan (on the top) and BIM-Model (below) with the lowest common multiple.

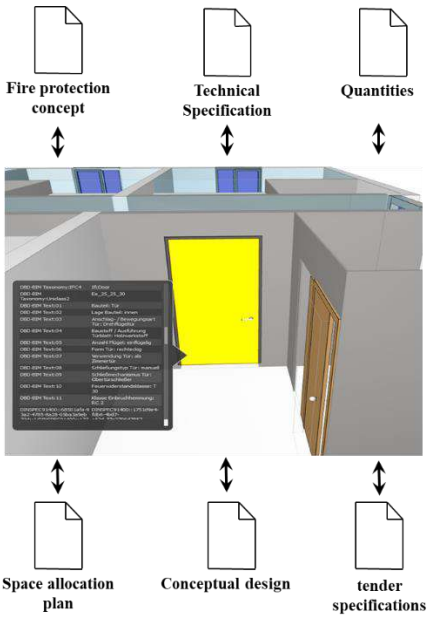

Figure7. Sources of information for building specifications

In BIM-based process planning, the information for steps 1–4 is generated directly from the BIM-model. However, the questions raised before must be addressed.

Who is requesting? <<Process planner>> According

to a uniform classification system such as OmniClass.

Why? Process planning according to Lean Construction methods requires detailed information on the performance and structure of the building.

When? The information is transferred after the technical description of the elements before the work preparation.

What information? A set of attributes are the minimum requirement for the process (Table 1).

Table 1. Minimum requirement for process attributes for rooms

Attributes	Attributes
ID	Ceiling surfaces
Component type	Floor area
Classification	Floor
Room number	Construction phase
Length, Width, Height	Takt number
Ceiling height	Process code
Structural height	Costing code
Wall surfaces	

To Whom? <<Architect>> According to a uniform classifications system such as OmniClass.

In step 5, the previously calculated workload must be adjusted to the set takt time (e.g., one week). This happens through the variation of different parameters. This includes the shifting of services within the interior work train, adjusting the number of employees (Figure 8).

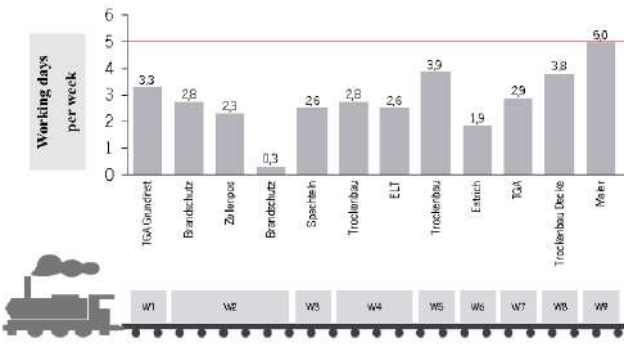

Figure 8. Takt adjustment

Work packages can be grouped together in one wagon if there is a no collision. Such a grouping can be seen in the picture 8 wagon "W2". There, three trades together become a wagon because with simultaneous execution no mutual influence is to be expected.

The first resulting Step 6 is a train of trades to complete the work. Now you can change the construction process by changing the construction strategy. For example, the number of trains and the direction of the construction work flow can be varied. In the proposed framework, the effects can be analysed directly on a 4D model. Figure 9 shows a 4D-takt-time sequence of shell construction work. The wagons "W1"- concrete walls - and "SL1"- concrete slabs - alternate floor by floor between the construction sections. Through this sequencing of work, an optimal use of resources is ensured.

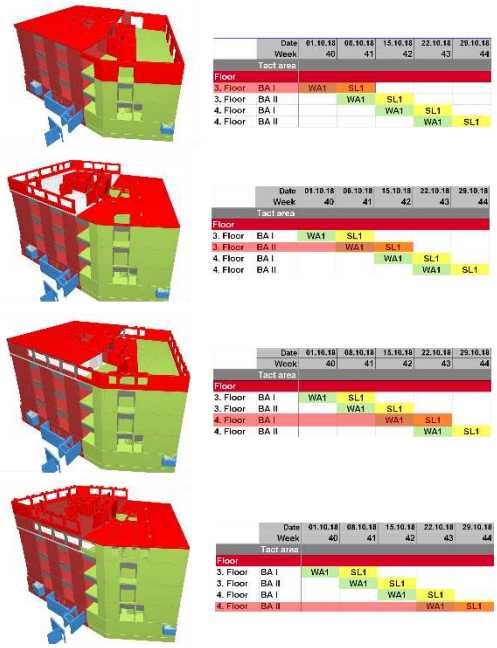

Figure 9. 4D-takt time sequence

6 Results

The following investigations are presented using the example of a real construction project. An object-oriented 3D building information model of a 17-story hotel building was selected for the case study. The hotel building has 220 guest rooms. The 3D model represents all the structural elements of the concrete shell structure such as foundations, beams, walls, columns, and slabs. Furthermore, the model includes all rooms with their specific attributes to determine the interior work processes. The building model contains approximately 55000 objects (Figure 10). The objective of this study was to determine the practical benefits and limitations of the developed system.

The benefit for a process planner is the developed querying function that automatically determines the quantities and labour hours from the model and calculates the duration for each of the planned activities. The developed semi-automated takt-time planning approach has been found to assist the workflow and quality during construction process planning. However, there are some current limitations and challenges. The

framework requires a comprehensive knowledge of the construction processes and its subsequent activities. The gathering of all the necessary input information is a crucial point when generating quality results. While activities related to concreting work were investigated, further investigations have to be done in developing process templates for the major construction works. In order to make use of the full potential of the method, the IDM with all elements must be described in further work.

Figure 10. BIM-Model for evaluations

7 Conclusions

BIM and Lean Construction are promising methods to improve construction processes. Until now, these methods used to be developed and applied separately. Linking the methods may create currently undiscovered benefits. However, finding an effective way to join both methods is difficult. First, this work has determined the minimum information requirements for process-oriented project planning using BIM.

It initially demonstrates the application of an Information Delivery Manual (IDM), specially the exchange requirements to determine the standard attributes that are necessary for takt-time planning.

By using digital building information models, construction processes can be planned in detail. Both the planning and the execution processes are, thus, holistically considered and coordinated. The next development steps are the further expansion of the method for more Lean methods and the integration of the takt control in the framework. Thus, the planned processes with actual site data are evaluated.

Abstract –

State Departments of Transportation (DOTs) in the U.S. have an increasing amount of digital data from various sources. One such set of data is structured unit price data collected from bid lettings. Such data contain unit prices of thousands of bid items from hundreds of projects every year. While state DOTs have such data from over a decade-long period, utilizing such data has been challenging because of the lack of automated analytical and visualization methodologies and tools to generate meaningful and actionable insights. This study develops an automated methodology to quickly and accurately generate color-coded visualization maps representing unit price variation across a geographical region. It uses Inverse Distance Weighted (IDW) technique that is based on the Tobler's First Law of Geography. The law states that points closer together in space are more likely to have a similar value than points that are farther away. The methodology is automated using ArcPy site package in ArcGIS. It imports unit price data from preformatted spreadsheets and boundary maps from existing ArcGIS shape files to generate unit price maps. The tool and the visualizations are expected to aid state DOTs in generating and communicating meaningful insights for making data-driven decisions. It can be used to investigate areas with higher unit prices for various items which can aid state DOTs in identifying potential causes of higher unit prices such as lack of competition and lack of sources of materials (e.g. quarry) in nearby locations.

1 Introduction and Background

Computing accurate cost estimates for highway construction projects is a never ending challenge faced by state Department of Transportation (DOT) engineers. Estimating accurate construction costs is especially challenging in early phases of the project when a limited amount of information is available. Some of the major factors affecting construction costs and its accuracies include project location, project size, project type, and market inflation. State DOTs collect a large amount of data that can be used to improve the construction estimation accuracies. While project size, type, and market inflation can be represented easily using numerical or categorical variables to account for construction cost variations, accounting for the location factor is more challenging. The spatial information collected by state DOTs coupled with computational tools such as ArcGIS can be used to account for the spatial variation of construction costs. A methodology for such process is described in a previous paper by the authors [1]. Although such methodology has been developed, adaptation of such methodology is likely to be hindered by complications in its implementation. Thus, there is a need to develop a tool to automate such spatial analysis to ease its implementation. This paper discusses a tool that is developed to automatically generate and import relevant data and create a unit price map that can be used as a visual communication tool about the construction market across a geographical region and to generate unit price estimates that account for the spatial variation.

2 Prior Studies

The location of a construction project is one of the most important factor affecting the project's productivity, and costs [2,3]. Those effects are a result of the cost for hauling materials, mobilizing equipment, and other site conditions. Other potential reasons that affect the construction costs across a geographical region include the level of competition in the construction market and local regulations such as minimum wage rates. Highway contractors tend to limit their projects in a certain region to remain competitive.

Similarly, the availability of limited space for construction and state DOTs' desire to complete projects faster in populated areas can significantly increase the construction costs in urban areas. Thus, accounting for the spatial factor is a must for accurate cost estimating. However, current practices have been very limited to partial accounting for such spatial effects on construction costs. For example, Iowa DOT uses an average unit prices from across the state to generate estimates for new construction projects [4]. Using the statewide average unit prices basically ignores the effect of spatial variations in the construction costs. In other cases, experienced engineers tend to account for the location factor based on their experience with previous projects. Several organizations have developed location adjustment factors to address this issue. This includes ENR city indexes and RS Means location factors [5,6]. However, those indexes provide data for a limited number of cities and are not necessarily focused on heavy civil construction projects and hence might be of little use for state DOTs' estimation purposes. A previous study by the authors developed a new methodology to account for spatial variation of construction costs across a geographical region by utilizing historical bid data and ArcGIS [1]. Similarly, another study by Zhang [7] also developed GIS based method to adjust construction cost estimates by project location. Another study utilized spatial interpolation method to understand housing and commercial establishment market [8]. However, while the methodologies are powerful, the implementation of such methodologies is challenging for state DOTs' day to day use because of the lack of automation and complexity in manually utilizing such methodologies. Thus, there is a need to develop a tool to automate the methodology to develop unit price maps of bid items which can be used to communicate and account for the spatial variation of the unit prices across a geographical region.

3 Limitations of Prior Studies

While some studies have attempted to solve the issue, the biggest challenge to communicate and account for spatial variation of construction costs in actual practice by state DOT estimators is the lack of automation. While researchers may be able to utilize advanced data analytics to prove the applicability of innovative techniques, such methods are rarely used in actual practice by state DOTs. State DOT employees have limited time and are not necessarily familiar with statistical and visualization theories and computer applications. This study tackles this challenge by developing an automated script that utilizes Python-based ArcPy Site Package developed by Environmental Systems Research Institute (ESRI) for ArcGIS.

4 ArcGIS and ArcPy Site Package

The ArcGIS is a powerful mapping and analytical platform developed by ESRI [9]. While powerful, it can also be complicated and time consuming to manually conduct spatial analysis using ArcGIS – especially when such analysis includes multiple steps and are to be performed by those who are not very familiar with the software. Thus, ESRI has developed an ArcPy Site Package to automate spatial data analysis, data conversion, data management, and map development [10]. The site package is based on Python programing language that is widely used for statistical analysis, text mining, as well as general purpose programming. This study utilizes the ArcPy Site Package to automate the unit price map development.

5 Framework for Automated Unit Price Visualization

The automated unit price visualization framework can be divided into four components (Figure 1): a) database preparation, b) base map preparation, c) unit price map development, and d) unit price estimation.

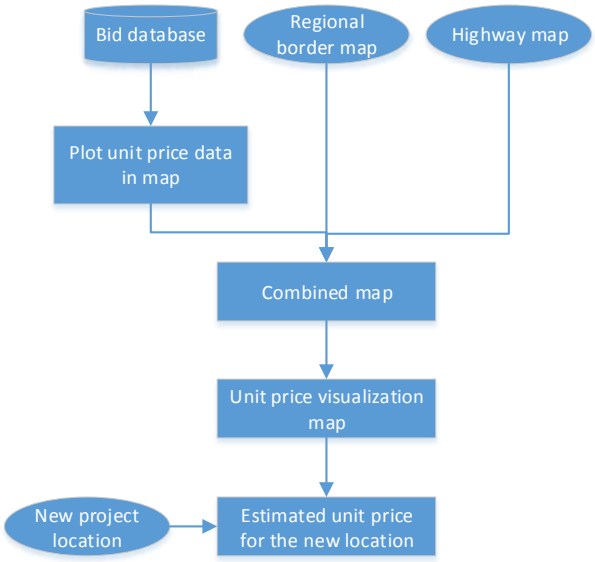

Figure 1. Automated unit price visualization methodology

5.1 Database Preparation

State DOTs have collected digital structured bid data for years. This database consists of historical project information such as the project location and bid data that include the unit prices of various bid items. The project information database can include data such as project ID, contract ID, project description, winning bid

(or contractor), and project location coordinates. The bid database can consist of the project ID that the bid data belongs to, item IDs of all bid items for a given project, and quantities and unit prices of various bid items.

5.2 Base Map Preparation

The geographical maps of the state border lines and highway maps are the two mapping components required for the unit map preparation. The border map becomes a boundary within which the color-coded visualization map will be developed based on the unit prices of items at various locations. The highway maps make it easier to comprehend the visual data points indicating the locations of the projects in respect to the highways.

5.3 Unit Price Map Development

In this step, first, the project data and bid data are combined to generate a list of unit prices of a bid item of interest and coordinates of the project locations where the bid item was used. The data are then plotted in an ArcGIS map to indicate exact project locations and unit prices of the bid item at those locations. Then, the unit price data are interpolated using the Inverse Distance Weighted (IDW) method to generate a map showing the estimated unit prices of the bid item of interest in any location within a boundary map.

5.3.1 Inverse Distance Weighted (IDW) Method

The IDW method is based on the Tobler's First Law of Geography. The law states that points closer together in space are more likely to have a similar value than points that are farther away [11]. Mathematically, the law can be expressed as:

$$p_j = \frac{\sum_{i=o}^{n} \frac{p_i}{d_{ij}}}{\sum_{i=o}^{n} \frac{1}{d_{ij}}} \qquad (1)$$

In this equation (1), p_j is the estimated unit price of the bid item in a new project (j) location, p_i indicates a unit price of the same bid item from a past project (i), and d_{ij} indicates the distance between the past project location and the new project location. Thus, given the locations of the past and new projects and the unit prices of the item of interest in all the past projects, the unit price of the item for the new project location can be estimated.

5.4 Unit Price Estimation

Once the unit price visualization map is developed, estimators can input the location of a new project and obtain an estimated unit price for the location based on the IDW technique.

6 Results

The researchers collected historical bid data from the Montana Department of Transportation (MDT) in Excel format. The most important datasets relevant to this study were the project information and bid item datasets for all the projects awarded from 2010 to 2014. These datasets were imported in MS Access database program to enable generating customized data quickly for only the bid item of interest for select year or range of years by combining the two datasets. The data generated from the query was exported and saved as a comma separated values. Table 1 shows a sample unit price data generated for the bid item 4020368 (emulsified asphalt CRS-2P). This item is one of the largest items in terms of total dollar value accounting for $120,350,573 in the projects included in the database and is also one of the most frequently used items.

This data is read by a python script and a new shape file capable of storing location and unit prices of the bid items is programmatically developed. This shape file is combined with a Montana state boundary map and a highway map obtained from MDT's GIS division. This intermediate map is shown in Figure 2.

Table 1. Sample unit price data for item 4020368 (emulsified asphalt CRS-2P)

Latitude	Longitude	Unit Price	Project ID
48.43666667	-104.4969444	654.26	1196
48.02916667	-115.3302778	658	1257
45.88305556	-111.87	463	791
45.88305556	-111.87	463	790
46.32666667	-112.745	510	834
47.48805556	-111.1813889	925	463
46.36472222	-113.3725	465	845
46.36472222	-113.3725	465	844

47.16111111	-114.86	598	964

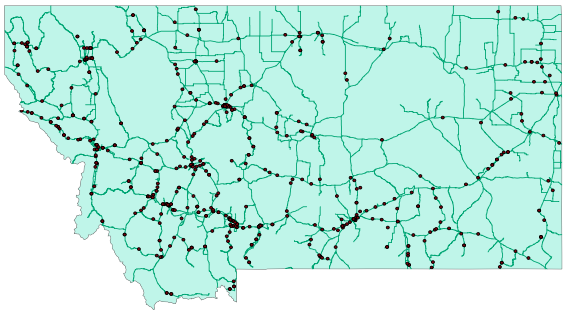

Figure 2. Montana state border map and highway map with project locations.

Finally, a color-coded interpolation map indicating unit prices of the bid items throughout the state is developed as a new shape file and combined with the maps. Figure 3 shows a unit price map generated for the bid item 402020368: emulsified asphalt CRS-2P per ton. The unit prices of the item vary from as low as $125 to as high as $3,500. The red color indicates higher unit prices while the blue color indicates lower unit prices.

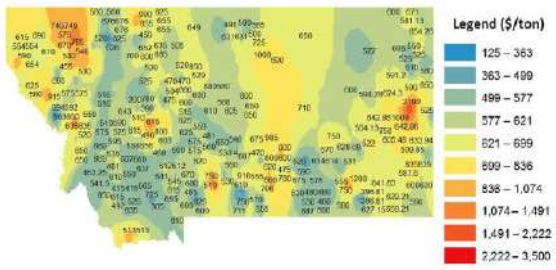

Figure 3. Unit price map for emulsified asphalt CRS-2P per ton

7 Discussion

The automated unit price visualization tool developed in this study enables estimators to easily develop unit price maps of desired bid items. This tool can be used to get insights about the market condition across a geographical region aiding state DOTs to identify areas with higher construction costs. Such insights can direct state DOT estimators to further investigate the reasons behind the higher construction costs and develop strategic plans to potentially reduce construction costs. Further, this highly detailed cost information about the regional construction market enables estimators to determine more accurate construction cost estimates by accounting for the spatial effect that is otherwise challenging to address. This tool also offers a higher granularity than any other location factors that are currently available to state DOT estimators.

8 Future Research

Currently this tool has two separate components: a) generating the required data from the master database containing all the project level and bid level information and b) unit price map generation based on the data generated from the previous component. While both steps are automated, those steps are isolated and hence they need to be executed separately. A future tool should combine those two components into a single coherent system. This can potentially be achieved by using the database such as ArcSDE where the required data are extracted systematically using programmatically generated dynamic Structured Query Language (SQL) queries. Further, the current Python based tool does not have a Graphical User Interface (GUI). Adding a user friendly GUI will make it even easier for the implementation of the tool for unit price map generation as well as estimation purposes.

Current tool is more focused on automating the visual unit map development. Current Python scripts enable estimators to develop a unit price map of one bid item at a time. This function can be further enhanced to develop a more sophisticated tool that possibly takes all bid items of a new project as input to generate unit price maps for all bid items at once. Thus, such tool can be used to effectively generate the total construction cost estimate of a new project.

Finally, the current tool serves as a powerful visualization tool. However, the tool only accounts for the spatial factor and ignores other factors such as project type. Such factors may be incorporated in the future tool by using pre-filtered data only from the projects of the same type to generate a more precise unit price map.

9 Conclusion

This study developed a tool to automate the unit price map generation process using the bid data collected by state DOTs. This tool enables estimators to utilize their own data for construction market analysis, visually communicating the market information, and develop bid item price estimates that can be used to develop construction cost estimates. The automation and ease of utilizing the tool will aid in implementation of the powerful unit price development methodology that might otherwise be a complicated process for DOT estimators.

Abstract –

Production control, especially lean construction approaches, has necessitated the needs of eliminating waste onsite. Though the collaborative methods such as Location-Based Management System (LBMS) and Last Planner System (LPS) have proven the improvement of productivities, the process of data collection has still remained manual, which could result in inaccuracy and incompletion. Automatically locating workers has been proposed to enable a method for production control in construction projects onsite. Thus, a platform is sought where an easy and passive tracking system is designed to enhance the production control processes.

In recent years, Finland is experiencing crucial transition from traditional production to digitalization formation while China has been a model where massive construction takes place as cities are expanding over the economic booming. The extensive building activities require a smooth and automated tracking system that can control and manage resources onsite to monitor in real time and examine the productivities more efficiently. This paper presents case studies in Finnish and Chinese construction sites where the proposed real-time tracking system was implemented, and the tracking data were analyzed for purposes of operations management. The model combines Bluetooth Low Energy (BLE) technology and 3G/4G network as connection methods, and explores the movements and time information of workers onsite, aiming to establish an intelligent construction site platform, which can be used for managing resource flow within lean principles in Finland and China.

1 Introduction

Complexity and hazard in construction sites are not uncommon where coordinating and managing onsite resources such as labor, material and tools with high efficiency is usually challenging [1]. To overcome poor site management performance and improve the workflow in construction, production control has been introduced and developed over years from the perspective of lean construction including Last Planner System (LPS) [2], Location-Based Management System (LBMS) [3] and their integration [4]. The approaches have tested many applications and they are expected to contribute positively to plan and control production scenarios [5] where waste reduction and project duration elimination can be realized through production control and forecasting [6]. However, the data collected onsite depend on manual work of information input, which requires substantial amount of time and resources and could lead to errors and inaccuracy [7]. Thus, it is reasonable to believe that current stages of production control based on manual collection of data have not reached the full potential of site management [8].

In recent years huge amount of construction activities have witnessed the growth of the construction industry in China [9]. However, the risks of project delays, quality defects, low customer satisfaction, etc. have been a series of obstacles that Chinese construction firms have to face [10]. In China, the comprehension and application of lean approaches have still remained in early stages and studies of lean methods in construction are also rare [11]. On the other hand, Finland has been actively piloting lean methods in construction. For example, meetings and data collections were organized by Skanska Finland to execute LPS phase scheduling and define Locations Breakdown structure in addition to tasks and logic in 2010 [3]; I.S Mäkinen Oy as a Finnish turnkey contractor specialized in cruise ship cabin refurbishment

applied Takt Time planning in a project to shorten project duration and improve productivity [12]. Those applications have seen the enhancement of production control in construction, but the difficulties of manual data collection during the process are revealed at the same time [13]. Thus, China and Finland can be good candidates to test the real-time platform under different degrees of lean methods applied and to see if a standardized tracking platform could be developed to unify country-specific requirements (e.g. China and Finland) and enable the potentials of automation of real-time onsite monitoring in construction.

There are many mature tracking methods that have been tested in construction industry with a goal to promote transition from traditional management which is heavily rely on manual work towards more intelligent onsite monitoring system where automation plays an important role of utilizing the input information [14]: (1) Lin et al. suggested a tracking system to support analyzing laborers' behaviors using ZigBee technology[15]; (2) Costin et al. used radio frequency identification (RFID) technology for construction resource filed mobility and status monitoring in a high-rise renovation project [16]; (3) Cheng et al applied Ultra-wideband (UWB) for automated task-level activity analysis [17]. However, among those technologies, Bluetooth-based system are examined to offer high degree of simplicity thanks to its ease of installation [18]. Olivieri et al. (2017) proposed a prototype where Bluetooth Low Energy (BLE) technology was applied to track workers, materials and tools from the perspective of production control [19]. Furthermore, Zhao et al. (2017) implemented the system in a laboratory test and proposed the possible use case scenarios [20]. However, no tracking data have been analyzed for visualization of worker's daily movement or the visualization results from the tracking can be shown to back up the proposed use cases in practice.

Aiming to solve the gaps of lacking data visualization results from the proposed tracking system and visualization-based use cases, we implemented the model on both Finnish and Chinese cases using the standardized procedures; then we gathered, analyzed and visualized the data from a random selected worker to examine his/her daily movement in all cases; at last we proposed the potential use cases based on the visualization results suitable for both Finnish and Chinese scenarios. The paper is focused to answer the following research questions:

1. How to implement the proposed real-time tracking system following standardized procedures in Finland and China?
2. How is the data visualization of randomly selected tracking worker in the case studies based on the proposed system?
3. What are the use cases of this real-time tracking system according to the results of data analysis and visualization?

2 Methods

2.1 Description of the model

Olivieri et al. (2017) have explored the requirements and solutions of the real-time tracking model within the scope of production control using BLE technology [19]. This paper followed the same infrastructure of the system, tried to generate the data visualization and suggest the use case scenarios according to the results.

Figure 1 illustrates how this real-time tracking model works in reality. The model is featured with gateways, beacons and a cloud storage. Gateways are Raspberry pies that are fixed at different places in construction sites, and beacons are portable that can be carried or tagged to track workers, materials and tools. Beacons passively transmit Bluetooth signals to gateways and gateways can determine the relative locations onsite by calculating the signal strength received from the beacons (link 1, 2 and 3). The gateways are connected with WIFI or dongles that uses 3G or 4G mobile network to be able to connect to cloud storage. The cloud processes the incoming data, apply algorithms and logics in production control, visualizes the information, and displays the updates of time and location details of the tracking resources in real time (link 4 and 5). Thus, the data visualization results can serve the purpose of onsite management and monitoring.

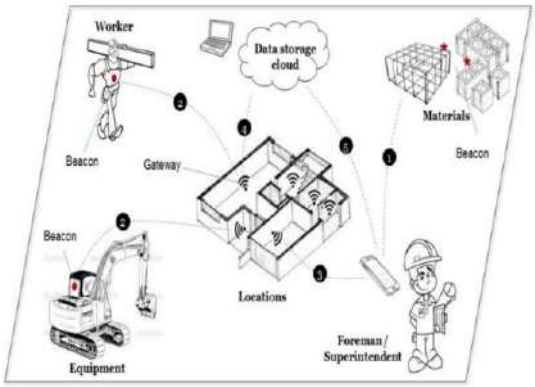

Figure 1. Proposed real time tracking scheme in construction site [19]

2.2 Implementation of the system in Finland and China

Case studies were scheduled one in Finland and one in China. For the Finnish case study, a residential renovation project was selected; for the Chinese case study, the onsite mechanical, electrical and plumbing (MEP) installation project was selected. We aimed to differentiate the project types and countries in our cases so we can test if the model can be applied in different forms and places with a standardized instruction and guidance. In our research, we aim to invest a platform as inexpensive as possible and still obtain holistic visualization information based on our light-weighted and easy implementation onsite. The cost for tracking gateways is 55 euro each and beacons for 4 euro each. Table 1 shows the case study description.

Table 1. Case studies description

Case	*Companies participated*	*Tracked objects and beacon distribution*	*Number of gateways*	*Total cost of the system*
Case 1. Renovation project in Finland	Renovation company	10 beacons to workers and 2 to foremen;	10 gateways onsite;	598 Euro
Case 2. Office building in China	MEP subcontractor	5 beacons to MEP workers; 1 beacons to onsite equipment	5 gateways onsite	299 Euro

2.2.1 Case 1. Residential renovation project in Finland.

The jobsite is located in Helsinki, Finland where we put 10 gateways and the warehouse for material delivery is located in Vantaa, Finland where we put 2 gateways. The renovation building is 3 floors where we put 1 gateway at entry in ground floor, 4 gateways in first floor covering each apartment, and 5 gateways in second floor with 1 additional one in the corridor. Figure 2 shows the simplified jobsite floor with gateways marked. The initial system setup time onsite is 6 hours with a few hours per week for maintenance. However, during the tracking period, the onsite conditions (e.g., gateway connections and locations) did not change, thus making the system maintenance work easy and convenient.

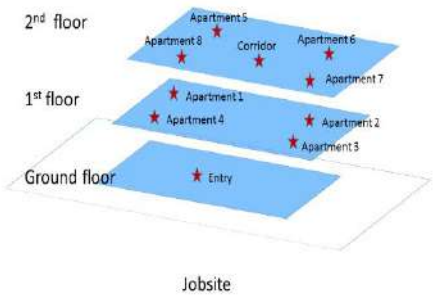

Figure 2. Real time tracking case study floor plan in case 1

2.2.2 Case 2. MEP installation project in China

We selected an entire floor in an office building of around 1500 square meters (open space with length of 50 meters times width 30 meters) to test the same tracking system. The jobsite is located in ShiJiaZhuang, a city that is about 100 kilometers from the capital Beijing. The tracking system monitored the work process of mechanical, electrical and plumbing jobs. Apart from case 1, 4 gateways were placed at each corner of the floor facing northeast, northwest, southeast and southwest. 1 gateway was placed in the middle closed to the entry of that floor. The setup time for the system onsite is 7 hours with approximate 2 hours per week to ensure the gateway connectivity stays valid. Figure 3 lists a floor plan of the jobsite with gateways installed.

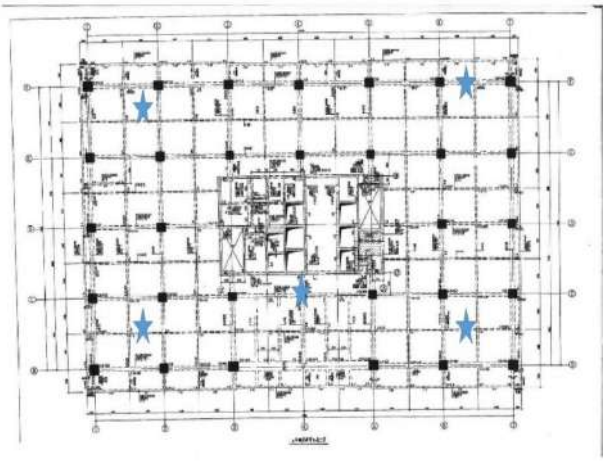

Figure 3. Real time tracking case study floor plan in case 2

2.2.3 Case selection and standardized instruction

We aimed to provide a standardized instruction for installation and implementation of the system onsite so

that we could overcome the country-specific requirement in practice and make the system function well regardless the construction site location. We selected Finland and China as a pilot places for testing because we wanted to see if the real-time tracking system serving the purpose of lean construction can be successfully implemented in these countries where one started to apply lean construction actively for many years [3][12] while the other still remained reluctant to explore the lean approaches [11]. Thus, it would be beneficial to see if the real-time tracking system under the scope of lean construction philosophy, because of its easy installation and automation data collection, can promote the process of applying lean methods in countries that are at the early stage.

We standardized the guidance of installation and instructions of workers in both case studies in order to promote the universal solution of onsite system implementation despite of the location or country selected. The general system implementation processes are: (1) determine the number of gateways and beacons needed; (2) configure file images into each gateway and activate beacons; (3) register beacons with predefined work type (e.g. plumber 1) in the tracking system; (4) onsite gateway installation and mark the gateway location precisely in the floor plan; (5) notify the workers of the tracking process and obtain their consents. (6) Tracking begins.

2.2.4 Data analysis and visualization

The raw data in the cloud storage display thousands of recorded time intervals, which contains information including the tracking carrier (e.g. plumber 1), location, start time, end time and the time duration. Thus, the raw data is very fragmented and hard to comprehend. We filtered out large time intervals such as overnight durations, aggregated them based on site location and visualized the daily movement of tracking workers. The results are especially useful for proposed applications of use cases in different scenarios. To illustrate the movement of workers, the details of random selected workers and time are listed in table 2.

Table *2*. Random selected worker for tracking

Case	*Random selected worker*	*Selected date*
Case 1. Renovation project in Finland	Carpenter 2	June 5th
Case 2. Office building in China	Plumber 4	January 22nd

3 Results

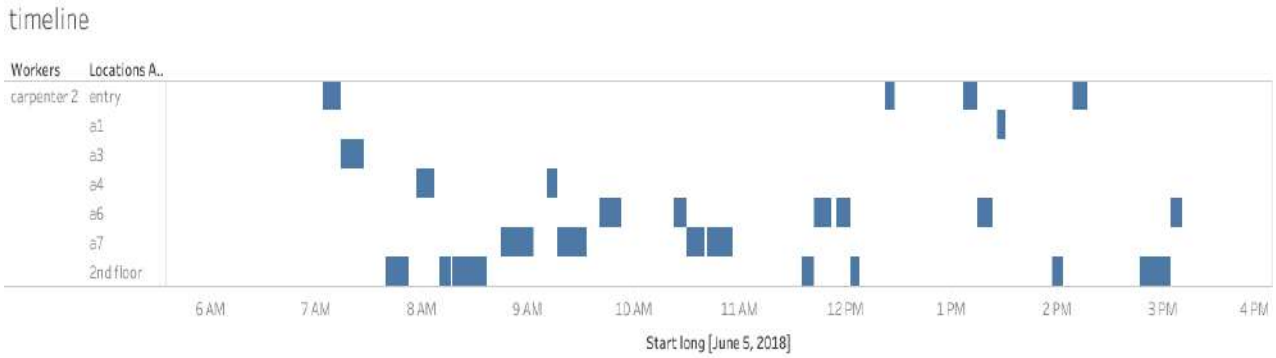

Figure 4. Movement visualization of tracking result for carpenter 2 on June 5th in Finnish case

3.1 Visualization result for the Finnish case

Figure 4 demonstrates the real movement line of the selected worker in Finnish case on June 5th. The horizontal axis indicates the timeline, and the vertical axis shows the location details of the time from 6am to 4pm. In the figure, a1 to a7 are the apartment numbers.

From the figure, we can see that the worker entered jobsite at 7:44 am and left jobsite at 3:05pm. The worker spent his/her first 10 minutes near the entry area and he/she actually first started at the work-related place (e.g. apartment a3) at 7:14am. He/she probably had a lunch break between 11am and 11:30am, and possibly had several coffee breaks between 9:50am to 10:20am and between 12:40 pm and 1:05 pm outside of the jobsite. Since the worker stayed at the second floor the most time during the tracking period, it is reasonable to think that he/she did the most work in the area (especially apartment a6 and a7).

3.2 Visualization result for the Chinese case

We executed the visualization process following the same method and obtained the results for the random selected worker daily movement in Chinese case as in Figure 5.

The horizontal axis indicates the timeline details from 6am to 12pm. The worker did not spent time in northeast area so the system automatically filtered out that location in the figure.

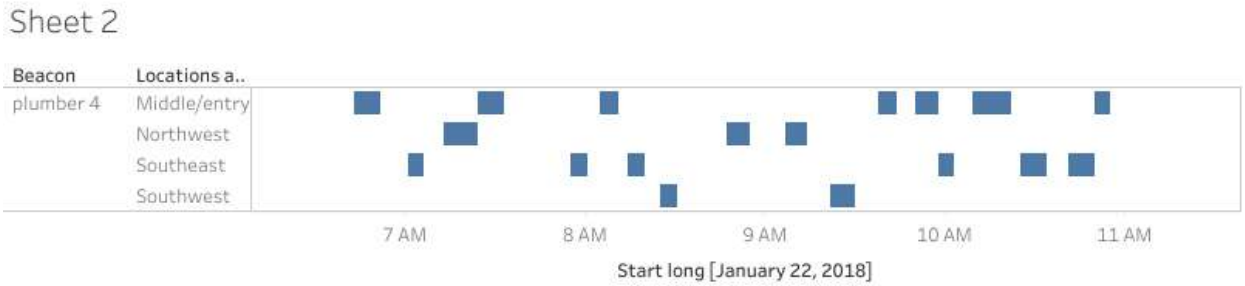

Figure 5. Movement visualization of tracking result for plumber 4 on January 22nd in Chinese case

We can see the plumber entered the jobsite at 6:43am and left the tracking floor at 10:56am. The visualization figure indicates the scattered movement for the worker onsite while in schedules they are typically expected to finish a task in one location before moving to another. This corresponds to our assumption of existence of potential construction waste in jobsite.

3.3 Use case proposal based on visualization

Zhao et al (2018) has suggested several use cases based on real-time tracking system for monitoring the movement of workers in construction sites [21]. However, the paper has not connected the proposed use cases with the actual data visualization results so that no real-life results have yet backed up those use cases. Because of this, we explored the use cases based on the data visualization to promote the underlying tracking system into more practical level.

3.3.1 Waste detection and value-adding activities

Based on the visualization figures, the movement line of a worker can be displayed. It is clear to see how much time the worker has spent in different locations including entry area and offsite. For both cases in Finland and China, workers have spent quite much time in entry area, which would be a notable factor to result in waste on the jobsite. Though it is difficult to judge accurately if a worker has wasted time in the work areas, the waste level in terms of time spent on entry and offsite is obvious and worth noticing for site managers.

Waste level is tied with value-adding activities, which is an important use case for lean construction applications. In figure 4 and 5, the tracking visualization has indicated that the second floor areas in Finnish case and the southeast area in Chinese case are the main workplaces that the laborers performed their jobs. Thus, by aggregating the time durations that workers spent on workplaces to compare with total time of the day spent onsite would be a good use application to explore the value-adding level of the workers.

3.3.2 Safety control

The visualization helps with jobsite safety control in an efficient way. Since the visualization results are classified by location in vertical axis and time in horizontal axis, it is easy to apply safety control in the specified jobsite areas. For example, if southeast area in the Chinese case was alerted as an access-restricted place, it is straightforward for site managers to check whether or not and how many times the workers have entered the area and how much time they spent there. Since the beacons associated with carriers send signals passively to gateways, notifications can be sent to management and worker themselves in real time.

4 Discussion

4.1 Location-based tracking data visualization improvement

Figure 4 and 5 visualized the selected workers' movements in one day based on location and time information from the system. In vertical axis the locations were listed without real-life connections with each other. For instance, in Finnish case, the carpenter first entered the entry then moved to apartment a3 and the movement line connected both ends in the figure. However, it cannot give the information that the workers have necessarily passed through apartment in between. For better visualization experience in future research, 3D approaches are recommended to enable the logics and pathways between tracking locations. BIM applied in construction would be a good candidate to be integrated in the real-time tracking system.

4.2 Value-adding activity determination

Time spent on entry area or outside of jobsite during worktime can be determined as waste or non-value-adding time. However, it is of difficulties to define the amount of value-adding time even if the workers are detected in the workplaces during the worktime. In further studies, the data visualization process can be linked with workers' updated schedule for better recognition of value-adding activities onsite. If a worker is scheduled in a place for his/her work, the time spent in that workplace and captured by the real-time tracking system is more likely to be value-adding activities onsite.

4.3 System limitation and country-specific requirement

To make the tracking system function, gateways need to be connected with internet and power throughout the period. This could be challenging for construction jobsites equipping with all necessary supporting devices. Besides the system limitation, country-specific requirement is also important to observe. For instance, in Finland, it is by law required to get workers' explicit consents of tracking and labor union needs to give a pass too. In China, onsite device safety protection is needed from stealing when the tracking gateways are exposed in the open space. Internet connecting stability is another matter to ensure the usability of the system in China

4.4 Comparison discussion for future studies

The BLE real-time tracking scheme has been successfully implemented in both Finnish and Chinese construction environment and the data results were good for visualization. Compared with the Chinese case, the gateway placement in Finland is denser and in apartment-specific level in contrast of floor level. This provides an interesting perspective when it comes to the optimal gateway tracking placement strategy corresponded to different requirement of detail level of tracking. Furthermore, the visualization analysis can be executed in future study where the workflow and logistic flows can be researched as combination by tracking multiply onsite resources, therefore meaningful metrics such as utilization rate, uninterrupted presence of workers at work location, and material moving times in the building can be calculated and compared in Finland and China for its productivity and waste level of construction projects.

5 Conclusion

The paper has provided a set of standardized guidance and instructions on onsite implementation of BLE technology based real time tracking system. The model follows the principle of production control in construction under the scope of lean approaches, aiming to improve the productivity and decrease the waste onsite.

The case studies were scheduled for actual construction projects in Finland and China, providing time and location information that is recorded in real-time automatically in the system for data analysis. Furthermore, the paper presented the data results by visualizing the movement path of randomly selected workers in both cases. The visualization backs up the two proposed use cases in practice where waste detection can contribute to identifying the value-adding activities onsite and safety control uses can prevent men from entering the restricted areas. The contribution of the research is developing a light-weighted and low-cost tracking system, suitable for multiply construction projects, to seamlessly obtain movement and time information and provide managerial implication to workers and site managers. In future research and the further development of the system, the model is expected to enhance resource flows in construction and automate the management process in a smart and effortless way.

Abstract –

This study was performed to identify the theoretical attribution of project type that moderates the impact of project delivery systems on cost performance. Previous studies have used direct relationship analysis to evaluate the project performance (e.g., the relationship between PDS and its cost performance, or the relationship between project type and cost performance). These analyses can cause inconsistent results and need to be analyzed in a single model. To combine the relationships between influential factors on cost performance, a causal model (i.e., moderation model) was suggested. The objective of this study is to develop a moderation model and test the statistical significance of moderation effect between PDS and cost performance. As a preliminary study, we established a simple moderation model and examine the moderation effect of project type. To test the model, 134 public sector projects completed between 1998 and 2013 in South Korea were utilized. The dataset consists of both Design-Build and Design-Bid-Build projects which are the most prevalent delivery systems. Even though the preliminary test results were not statistically significant, we can suggest the better way to understand the causal relationship moderated by project type between PDSs and their cost performance. This study is expected to provide the theoretical basis of the mechanism by which PDS impact cost performance, help project participants to select PDS by considering moderating effects in specific project types, and evaluate PDS appropriately in terms of cost performance.

Keywords –

Cost management; Project delivery system; Design-build(DB); Design-bid-build(DBB); Cost performance; Change order; Project type; Moderation effect

1 Introduction

Evaluating project delivery system (PDS) in terms of cost performance has been conducted by comparing two prevalent methods: design–build (DB) and design–bid–build (DBB) [1-5]. Until the end of 1990s, most studies had concluded that DB outperforms the traditional DBB delivery systems in all aspects (e.g., cost, time, quality, safety and so on) [1-3]. However, adverse results have emerged in terms of cost performance since the early part of 2000s [4-7]. They found that DB is superior to DBB in terms of project schedule, however, cost performance is uncertain and debatable up to date. According to the previous studies, the reason why the comparison results are inconsistent depends on project type and dataset [7-8]. The explanation about the inconsistent results have been arbitrary without any theoretical basis.

To deal with this problem, causal model that explains the mechanism by which PDS cost effects operate should be needed. In research design, mediators and moderators are necessary to solve complex and unsettled problems in theory development [9]. Identifying and quantifying the mediators and moderators are useful in making contributions to the body of knowledge and both variables are the focus of research design in many situations [10]. Moderation is a causal model that postulates “when” or “for whom” an independent variable most strongly (or weakly) causes a dependent variable, while mediation is explains the process of “why” and “how” a cause-and-effect happens [10-12].

For the first step applying these theoretical basis, we [13] identified and quantified a mediation effect between project delivery systems and cost performance through bidding characteristics (e.g., bid price, the number of bidders). The study suggests that the previous studies of evaluating PDS cost performance could be improved when the bidding characteristics are considered. As a second phase, we explored a moderation effect that affect the causal relationship

between PDSs and their cost performance.

The objective of this study is to develop a moderation model and test the statistical significance of moderation effect. As a preliminary study, we developed a simple moderation model and the test of the significance. The goal of this study is to identify the theoretical attribution of project type that moderates the impact of project delivery systems on cost performance. We use the same dataset as in the previous study [13], also the same cost performance metric (i.e., change order rate) is used. With the results, the current study can provide the theoretical basis on the reason why the cost performance comparison of PDSs is inconsistent.

2 Related Work

This section describes literature reviews related with the moderation effect and the influence of project type on the causal relationship between PDSs and their cost performance. Moderators is defined as a third variable that modifies a causal effect, an association between two variables X and Y is said to be moderated when its size or sign depends on a third variable of set of variables [14-15]. Moderation is also known as interaction. Moderation analysis is typically examined by testing for interaction between moderator and X in a model of Y [15]. In construction management discipline, studies on moderation effects have been rarely conducted [9, 16-17].

Yang et al [17] tested the moderating effect of project type by conducting a two-way ANOVA when examining the relationship between knowledge management and project performance. A number of studies indicate that project type affects cost performance [2, 7, 8, 18-21]. We assume that PDS cost performance varies depending on the project type.

3 Preliminary Moderation Model

As a preliminary model, we postulated a simple moderation model

Models were categorized to conceptual and statistical diagram. Conceptually, the moderation model is depicted in the form of a conceptual diagram in Figure 1. The diagram represents a process in which the effect of PDS on change orders is influenced or dependent on project type, as reflected by the arrow pointing from project type to the line from PDS to change order.

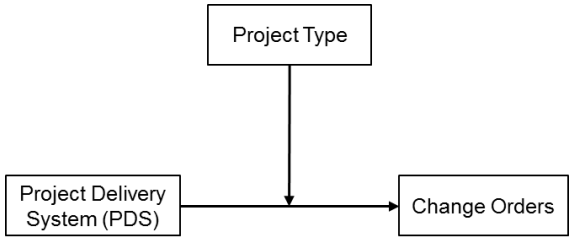

Figure 1. Moderation Model as a Conceptual Diagram

The conceptual diagram is very different in form from its corresponding statistical diagram, which represents how such a model is set up in the form of an equation. As is described in figure 2, the statistical diagram corresponding to this conceptual model requires not two but three antecedent variables, and project type is one of those antecedent.

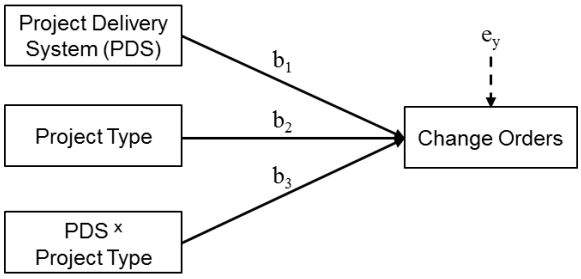

Figure 2. Moderation Model as a Statistical Diagram

Statistically, moderation effect is conducted by testing for interaction between project type(M) and PDS(X) in a model of change orders(Y). With evidence that X's effect on Y is moderated by M, we then quantify and describe the contingent nature of the association or effect by estimating X's effect on Y at various values of the moderator, an exercise known as probing an interaction. Equation (1) shows the standard multiple linear regression model. " b_3 " represents interaction role between PDS and project type.

$$Y = b_{01} + b_1\mathrm{X} + b_2\mathrm{M} + b_3\mathrm{XM} + e_\mathrm{y} \quad (1)$$

The moderation effect is interpreted depending on both the statistical significance and the sign of b_3[22]. If the model result of b_3 is statistically significant. The association between PDS and change orders is various depending on project type (i.e., moderator).

4 Experiment and Results

The developed moderation model is being applied to the construction project of 134 samples from the same dataset of the previous work. Samples are categorized to three project types (i.e., residential building, non-residential building, and road civil work) where the sample sizes are evenly distributed. Table 1 shows the descriptive statistics of change orders according to project types. To examine the effect of moderator, two-way ANOVA was conducted. The results is shown in Table 2.

Table 1. Descriptive statistics of project types

Dependent var.	Project type (M)	N	Mean	S.E.
Change order rate (Y)	Building(residential)	41	13.936	2.753
	Building(non-residential)	49	10.304	2.236
	Civil(road)	44	19.151	2.919

Table 2. Results of two-way ANOVA

Variable	Sum of Squares	df	Mean Square	F	p
PDS (X)	349.185	1	349.185	1.431	.234
Project type (M)	1415.473	2	707.736	2.901	.059
PDS*Project type (XM)	725.054	2	362.527	1.486	.230
Error	31231.363	128	243.995		

According to the test results, the interaction effect (XM) of PDS and project type is not significant (p value > 0.05). Figure 3 shows the moderation effect (i.e., interaction effect) of PDS and project type on change orders.

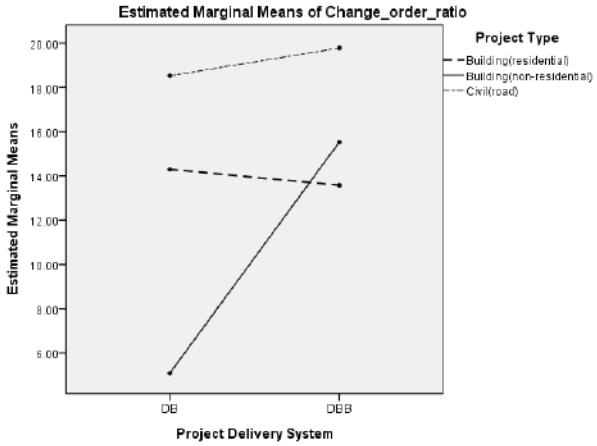

Figure 3. Moderation effect of PDS and project type on change orders

The slopes of non-residential building and civil projects intersect each other in a cross, then the main effect of PDS appears wherever it is, and wherever it is

reversed. That is, the main effect of the independent variable (i.e., PDS) does not consistently appear, and other results appear depending on mutual combinations with other variables. In this case, the model results show the dis-ordinal interaction.

5 Conclusions

A simple moderation model as a preliminary study was proposed to examine that project type moderates the impact of PDSs on their cost performance. This study is expected to provide a better understanding of the mechanism by which PDS impact cost performance, help project participants to select PDS by considering moderating effects in specific project types, and evaluate PDS appropriately in terms of cost performance. The academic contribution of the current study is to theoretically identify project type as a moderator using empirical data.

Regarding the limitations of this study, partial projects were selected from the original database, various combinations of project type should be applied to validate the moderation model. Also, value engineering costs for improvement were not considered because of data limitations.

For the further studies, conditional process model that integrates mediating effect and moderating effect in a single model could be developed. That is, moderated mediation and mediated moderation model considering project characteristics and bidding characteristics simultaneously need to be applied. Those models are to be expected to enhance the explanation the inconsistent evaluating results of PDS performance comparison.

Abstract –

Automation and robotics offer significant potential to address some of the challenges faced by facility managers to efficiently operate and maintain indoor building environments. Previous efforts have focused on deploying mobile service robots for scheduled and periodic tasks such as monitoring, inspecting, and collecting data. Localization and navigation are two of the fundamental capabilities required for any robotic system to accomplish these periodic tasks successfully. Most of the existing approaches for achieving semi/fully autonomous indoor mobile robot navigation either require dense instrumentation of the physical space (e.g., Bluetooth beacons) or are computationally burdensome (e.g., Simultaneous Localization And Mapping). To address these issues, the authors previously developed localization, navigation, and drift correction algorithms based on cost-effective and easily-reconfigurable fiducial markers (e.g., AprilTags). However, these algorithms were based on context-specific assumptions regarding the marker characteristics, sensor capabilities, and environmental conditions. This study comprehensively investigates the design characteristics of a fiducial marker network localization system to achieve autonomous mobile indoor navigation. A generalized framework in the form of a process flow chart is proposed that is agnostic of indoor building environment application, marker category, robot, and facility type. That is, the proposed framework can be used to systematically to design the desired robot, required sensors, and create the optimal marker network map. The feasibility of the proposed approach is explained with the help of a facility management related example. The outcomes of this study can be generally applicable to any mobile robot, building type (e.g., office), and application (e.g., construction progress monitoring).

Autonomous Robot Navigation; Fiducial Markers; Indoor Localization; and Facility Management

1 Introduction

Recent advancements in technology have given rise to the use of intelligent robots for several service applications. Some of the examples of deployed indoor robotic systems for professional and domestic service applications include museum guide robots [1], hotel butler robots [2], vacuum cleaning robots [3], and surveillance robots [4]. As per a report published by the International Federation of Robotics in 2018, the annual growth rate in service robots is about 21% [5]. In addition, Baeg et al. [6] emphasized the significance, usability, and the potential of service robots for everyday activities. It can thus be reasoned that intelligent robots will soon be ubiquitous and there is a strong need to explore the potential of robots to improve autonomy in the operation and utilization of today's buildings.

Two of the fundamental capabilities robots need to possess to enable such autonomy are localization (i.e. identify and orient their location in the physical environment) and navigation (i.e. direct to the respective locations of interest). Previous approaches and methods either require dense instrumentation (e.g., bluetooth beacons) of the physical environment (i.e., significant upfront costs, suffer from low accuracy (e.g., wireless local area network), or made application-specific assumptions (e.g., marker-based systems). To address the limitations of existing studies, the authors propose a general framework for marker-based localization and navigation systems in the form of a process flowchart that is agnostic of the indoor building environment application, marker category, robotic platform, and facility type. The proposed framework is general, not domain specific, and can be used for several single and

swarm indoor robotic system applications. The use and feasibility of the proposed framework are illustrated with the help of several built environment examples.

In the context of this paper, localization is defined as the robot's ability to identify its current location in a given indoor environment setting [7]. For example, a robot being able to recognize that its location is in room 201, or knowing its location and orientation in the global coordinate reference system. The robot's navigation can be briefly defined as the robot's ability to plan a course of action to reach the destination location while accurately localizing itself in its frame of reference at strategic locations [7].

Several indoor localization and navigation techniques have been explored previously. Literature suggests that every method has advantages and limitations. Some of the previous approaches explored for robot localization include Wireless Local Area Network (WLAN), Ultra-Wide Band (UWB), Bluetooth, Cameras, and Lasers. Wi-Fi is an economical solution because most of the existing infrastructure consists of wireless nodes required for localization. However, it suffers from a significant error in localization accuracy [8,9]. Bluetooth based localization tends to be expensive, time-consuming and also have space constraints because of the requirement of wireless infrastructure deployment indoors [8,10]. Similarly, UWB-based systems require a large number of receivers making it inconvenient and infeasible (due to space constraints) indoors [11,12].

Laser scanner based techniques eliminate the need to instrument the physical space but they are highly expensive, sensitive to obstructions and require high computational capabilities [1,13-17]. To summarize, common disadvantages affecting a majority of the reviewed methods include low accuracy, significant upfront investments, high computational requirements and complex instrumentation of the indoor environment.

Vision-based methods using fiducial or natural markers are particularly immune to the disadvantages mentioned above. This is because, markers offer high accuracy in estimating the relative three-dimensional pose in an environment, require relatively less computing capabilities, are cost-effective, and are easy to install [18-20]. In addition, fiducial markers can store virtual information regarding a multitude of things such as information regarding physical location (e.g., room number), emergency evacuation directions, indoor navigational information, and inspection-related data regarding building systems helpful for facility managers [14]. Feng and Kamat [14] demonstrated how markers having virtual information and navigational directions can help humans navigate indoors.

To take this further, Mantha et al. [21] showed that the virtual location information (for localization), navigational direction (for navigation), and 3D pose estimates (for drift correction) can be used to achieve autonomous behavior of the mobile robot. However, this was just a proof of concept which used a specific type of robotic platform, camera, marker type, marker size, and facility type which cannot be generally applicable to other scenarios or built environment applications.

1.1 Importance of the Research

Robots have become increasingly pervasive in our day to day lives, with global experts predicting that intelligent robots will soon be ubiquitous [22]. Baeg et al. [6] emphasized the usability of service robots for everyday activities. Building Service Robots have numerous advantages such as a) high productivity: can perform tasks significantly faster without getting tired (e.g., laying bricks) [23], b) improve safety: can work in harsh and unsafe environments where humans are unwilling or unable to work (e.g., gas pipe inspection) [24], c) reduce cost: cheaper than human counter parts (e.g., it is very cheap to deliver items in hospitals/hotels with robots) [2, 25], d) improve quality: robots can be more precise and accurate than humans (e.g., structural monitoring) [24], e) provide better quality of life: can help the people with restricted mobility or handicaps with several mundane tasks (e.g., help blind people navigate indoors) [26]. The demand for Building Service Robots is also reflected in the exponential increase in the venture capital investment in robotics [27]. More importantly, the world robotics executive summary released in 2016 estimates around 23 billion USD in sales for the professional service robot installations between 2016 and 2019. In addition, a study published by McKinsey shows that the price of these robotics systems continues to drop (almost halved), whereas, the labor costs have consistently increased [28].

Thus, there is a strong need to investigate the potential of these systems, especially for facility management applications. Most of the existing service robotic systems still rely on expensive sensors, computationally intensive methodologies and complex instrumentation for semi and fully autonomous navigation. In addition, these systems are particularly disadvantageous for temporary or one-time applications such as air quality assessment, retrofit decision making, occupant schedule detection, and structural health monitoring [21]. On the contrary, marker-based systems offer significant potential since they are easily reconfigurable, cost-effective (can be printed on paper), and computationally efficient [14].

Different types of markers have been developed and studied in the recent past. For example, Xu and McCloskey [29] developed a 2D barcode-based localization system. Though this is an economical solution when compared to the previous alternatives, 2D systems fail to provide 3D orientation information. This

is particularly important for successful indoor robot navigation. Olson [20] developed AprilTags that can be printed on a regular paper but have the capability to determine 3D relative pose information.

Feng and Kamat [14] used these markers for indoor wayfinding applications. Furthermore, Babinec et al. [19] showed how a mobile robot can be localized using planar markers. Extending this further, Mantha et al. [21] used these markers for mobile robot navigation. However, all these aforementioned methods were just proof of concepts with context-specific assumptions regarding marker size, marker placement, and camera type. On the other hand, several other studies focused on improving individual marker characteristics such as successful detection rate, performance of the detection algorithm, size of the marker, and camera configurations. For example, Romero-Ramirez et al. [18] compared the speed performance of detecting different markers such as ArUco, Chili tags, AprilTags, and ArToolKit+. Lundeen et al. [30] compared the accuracy performance of different marker sizes, relative marker camera distances, and its relevance to the operation of an autonomous robotic excavator. However, none of the aforementioned studies, nor other existing studies, integrate, investigate, and identify the appropriate selection of marker networks for autonomous indoor robot navigation. That is, none of these studies establish a procedure to determine the optimal marker network design characteristics (e.g., marker camera configurations) based on a given set of inputs (e.g., facility type, and application objectives).

Thus, the objective of this research is to develop a general framework that can be used by facility managers or stakeholders to identify optimal camera marker network design characteristics based on different inputs (e.g., application objectives). The proposed framework is applicable to single or multiple robotic systems with and without constraints such as performance speed, occlusions, and lighting conditions. The feasibility of the proposed framework is explained in detail with the help of a facility management related example involving a variety of robotic platforms and marker types.

2 Proposed Framework

The framework is divided based on four main roles namely facility manager, real building, robot, and markers of the whole camera marker network design process for the autonomous robotic navigation. Each of these directly or indirectly influence, possess or are responsible for certain tasks and/or actions. Figure 1 shows the proposed framework including each of the aforementioned roles, their tasks, actions, processes, and sub processes. The different tasks of the proposed framework are illustrated using the example of ambient robotic data collection presented by Mantha et al. [21]. It has to be noted that for simplicity and easier understanding of the reader, tasks are described as sub sections of each role rather than in the chronological order of the process flow shown in Figure 1.

2.1 Facility Manager

One of the important roles of this framework is the facility manager who is responsible to define the objectives pertaining to the application context and the corresponding inputs. The objectives can be derived from the targeted action or intended tasks that need to be performed. In the example considered, the objective is to monitor ambient parameters in buildings. Therefore, the intended action is to gather data regarding ambient parameters such as temperature, relative humidity, and lighting, and compare it with the standard parameter range or the occupant preferences. Other relevant inputs can be the locations in the building and the frequency at which the data needs to be collected.

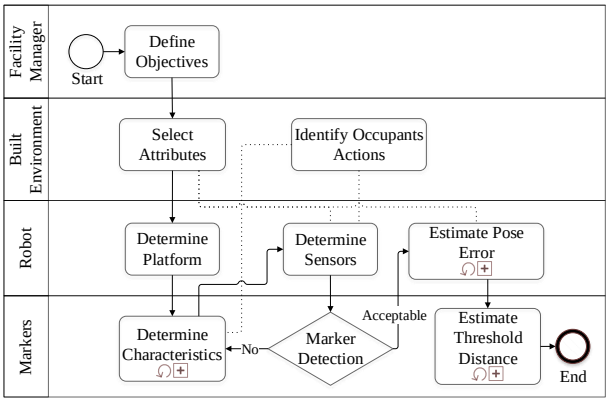

Figure 1. Design of marker network map for autonomous indoor robotic navigation.

2.2 Built Environment

Service robotic systems are designed to navigate in the built environment and perform the assigned tasks. Hence the built environmental attributes along with the users (or occupants) actions will significantly influence the design parameters of the robotic navigation system (marker network system in the context of this paper). Each of these categories is described below in detail.

2.2.1 Select Attributes

Attributes primarily represent the physical properties and characteristics of the built environment such as facility type, floor plans, equipment, surface geometry, flooring type, thermal zones, lighting, acoustics, and other services. In the previous ambient parameter monitoring example discussed at the beginning of section 4, some of the relevant attributes can be indoor temperature, relative humidity, light intensity, sound levels, and indoor air quality.

2.2.2 Identify Occupants Actions

Occupants are users of the built environment who directly or indirectly interact with the robotic systems. Though this task is not part of a technical process flow as can be seen in Figure 1, this can impact the characteristics of the markers (i.e., marker placement in particular) and determination of sensors (e.g., camera in this case) on the robot. Thus, identifying occupant actions is important as they have the potential to impact the successful accomplishment of the goals and objectives. Some examples of the behaviors and actions of the occupants include their movement, schedule, use of the built environment, and routine. In the example case considered, occlusions due to occupant movement and their interaction with these systems to provide feedback in the form of a questionnaire regarding their preferences are some of the most important factors to be considered. Further details regarding the significance of occlusions is described in the marker placement section of this paper.

2.3 Robot

In the context of this paper, three important tasks that encompass the role of an indoor robot are the type of platform, sensors (e.g., camera for detecting markers), and navigation performance (e.g., error accumulation). Though other elements such as task allocation, path planning, and motion planning for task execution are critical, they are not considered in the scope of this study and hence are not elaborated. However, interested readers are referred to [30,31] for further information.

One of the other considerations which did not receive much attention in the past is the cybersecurity implications of these intelligent autonomous agents [32]. This is particularly important in this case because of the potential human-robot collaboration and the accessibility of these robotic systems in these facilities. It has to be noted that the cyber threats are not just limited to data breaches but can cause some serious safety concerns to the infrastructure and the occupants [33,34]. So, with the increasing popularity of artificial intelligence enabled autonomous mobile robots, it is necessary to keep a check on the cybersecurity aspects, safety standards, and risk assessment of the robot chosen.

2.3.1 Determine Platform

As the name suggests, the goal of this step is to determine the ideal robotic platform based on the defined objectives (refer to section 4.1). The classification of robots can be dependent on several things such as the type of work, mechanical structure, or morphology [35]. Here, the goal is to determine the mechanical structure of the robot whether it is a mobile robot with wheels, legs, wings, tracks, or any other existing automated platform. In the example application, since the mobile robot needs to collect data and get occupant feedback, a mobile robot with wheels and a display platform for interaction might be ideal. Though a legged locomotion-based robot might also serve the purpose, a mobile robot with wheels might outpace the legged robots and can be more efficient (faster) in collecting data.

2.3.2 Determine Sensors

Though several sensors will be required on the robot, in the context of this paper, the sensor (camera) for the purpose of localization and pose estimation is discussed. One of the advantages of marker-based pose estimation systems is that they do not require expensive cameras. The type of cameras available on mobile phones these days can be used. Typically, most of the robotic systems come with a built-in camera. These cameras are of sufficient quality to be used for the purpose of marker-based localization and pose estimation [18].

2.3.3 Estimate Pose Error

One of the most important factors that have a direct impact on whether the robot will successfully navigate to desired locations or not, is the relative pose error accumulation of the robot. This is because there is always a difference between the robot's actual and ideal pose. It is important to estimate this at regular intervals and rectify it accordingly. Relative pose between camera and marker can be determined by a total of six components, three of which correspond to translation (e.g., x, y, and z) and three of which correspond to the rotation (e.g., roll, pitch, and yaw angles). This is represented in the form of a homogenous transformation matrix (H) in which R (3*3) denotes a rotation matrix and T (3*1) denotes a translation matrix (Eq. 1). However, depending on the type of application, only some of these six components might be required. For example, in case of ambient data collection, only the lateral distance (distance between the camera and the marker) is extracted and hence the pose error is estimated only using the variance of this parameter with respect to the ground truth values.

$$H = \begin{matrix} R11 & R12 & R13 & Tx \\ R21 & R22 & R23 & Ty \\ R31 & R32 & R33 & Tz \end{matrix} \quad (1)$$

Where,
H is part of the Homogeneous transform matrix
R (3∗3): Rotation matrix
T (3∗1): Translation matrix

A generalized procedure of the sub process for estimating the pose error is shown in Figure 2. First, assume a zero yaw angle (as shown in Figure 3) and determine the camera marker distance range. That is, the minimum and maximum lateral distance between the marker and the camera (i.e., robot) to be able to detect the marker. Then, identify the ideal marker to camera distance to maximize the allowable error accumulation

based on the environmental attributes and robotic platform. Further discussion regarding the reason for maximizing the allowable error is provided in section 4.4.3. If further optimization is required for the pose error, relative camera marker orientation can be varied to achieve the same. Though it might seem counter-intuitive, it is possible that a non-zero yaw angle (e.g. -15 degrees) gives better results than a zero yaw angle [30].

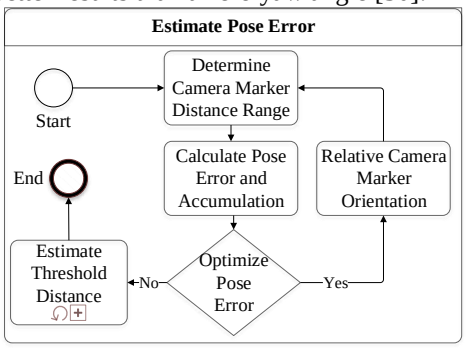

Figure 2. Sub-process to estimate pose error

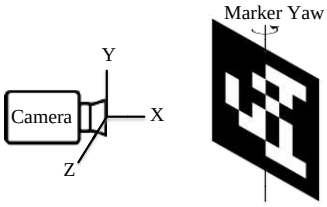

Figure 3. An illustration of marker yaw

For example, in the case of ambient robotic data collection, the robot's ideal path is along the centerline of the corridor to maximize allowable drift as shown in Figure 4. This is because, if the robot's ideal path is closer to the wall, the allowable drift accumulation will be very less (compared to the robot's path being on the centerline of the corridor) to avoid the robot colliding with the wall. The allowable drift accumulation, in this case, will be less than half the width of the corridor considering the width of the robot.

2.4 Markers

A fiducial marker is an artificial landmark with prescribed geometry and features to distinguish itself from the naturally occurring objects and other markers. The detection is usually done by capturing videos of markers using optical cameras and subsequently analyzing the image to determine the relative camera marker pose [30].

Unique fiducial markers are required to be placed at strategic locations along the navigational path of the robot (e.g., corridors, entrances to rooms, etc.) to form a Marker Network Map (MNM). These markers will act as landmarks, and the strategic locations can be the end of the corridors, the intersection of hallways, and entrances to the rooms. A graphical network G = {N, E} can then be generated where N represents nodes representing locations of markers and E represents edge links connecting these nodes (e.g., corridors and stairs). The network formed henceforth can be used to determine the optimal paths in the building and subsequently for the autonomous navigation of the robots. The subsections below provide further discussion regarding different marker characteristics (e.g., type and placement), detection of markers (e.g., placement), and threshold marker distance (i.e., maximum distance between two consecutive markers).

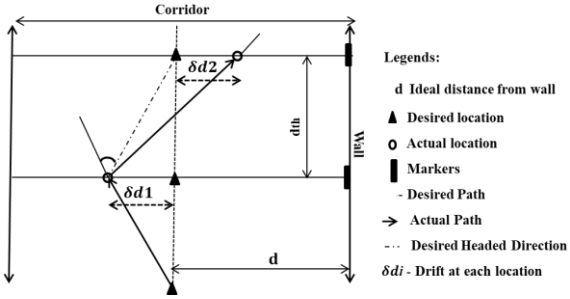

Figure 4. Illustration of drift accumulation and marker to marker distance for an indoor mobile robot (adapted from [21])

2.4.1 Determine Characteristics

At this stage, the building attributes are known and the robotic platform was chosen. This section describes the selection process for different marker characteristics.

Type, Size, and Library Size

One of the significant factors that drive the selection of the marker type and size is the error tolerance range and the type of pose requirements for the intended application based on the identified objectives. Several different types of markers were developed and studied by researchers such as planar markers, 2D bar codes, ARToolKit, BinARyID, AprilTags, ArUco, and ChiliTags [18,20,36,37]. Some of these markers are shown in Figure 5. Based on the accuracy, detection, and library sizes, ArUco and AprilTags are currently the best for marker detection [18,30].

The marker library (or dictionary) size is the number of unique markers available in chosen given marker type. For example, AprilTags have more than 4,000 unique codes, whereas ARTags have about 2,000 [20]. Therefore, it is important to check for the size of the library for the chosen marker to ensure that it meets the corresponding application before proceeding further (Figure 6). That is, estimate the number of unique markers required for the type of application and compare it with the available marker size. For example, in the monitoring example, the number of unique markers is approximately equal to the

number of distinct notable locations (e.g., in front of a room, end of the corridors, and elevators) along with other possible places where data needs to be collected inside the building.

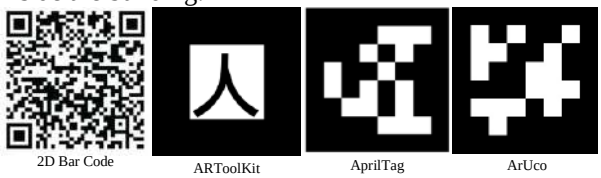

Figure 5. Different types of markers

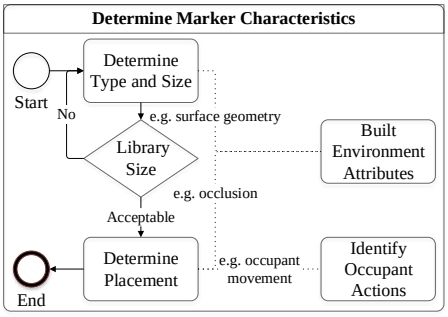

Figure 6. Sub process to determine marker characteristics

In addition, some of the built environment attributes such as surface geometry can influence the marker type and size selection. For example, if the built environment does not have planar surfaces, then larger size planar markers cannot be used because of field-of-view issues in the detection of the markers. In the ambient data collection example, the facility type is buildings with mostly planar surfaces, limited number of locations, and require relative 3D pose requirements. Thus, it is reasonable to assume that AprilTags are suitable because they are planar markers, have a decent library size, and can be used for determining 3D relative pose [20].

Placement

Different marker placement techniques such as wall mounted, ceiling mounted, and floor mounted have been explored for built environment settings [21,38,39]. However, it has to be noted that each of these methods has their own advantages and disadvantages depending on the built environment attributes such as ceiling heights, occlusions, and occupant actions such as occupant movement.

Floor mounted markers have shown promising results in a structured industrial/warehouse setting where Kiva robots manage the entire storage area of the warehouse [39]. Horan et al. [40] used a tape-based path sensing method for mobile indoor robot navigation. A similar study was performed by the National Institute of Standards and Technology (NIST), in which additional boundary markers were introduced along with the tape line [38]. However, the aforementioned floor based marker mounting techniques would suffer from frequent wear and tear in an unstructured building environment with frequent occupant movement. Ceiling mounted marker-based techniques were explored in warehouses as an alternative to the laser triangulation method [38]. However, in the context of ambient data collection, Mantha et al. [21] suggested that the ceiling heights (especially near the atrium areas) might have a significant effect on the pose estimation of the robot. Hence a wall mounted technique is ideal in this scenario or a combination of wall and ceiling mounted if multiple cameras placed on the robot.

2.4.2 Marker Detection

The immediate next step after selecting the marker characteristics is to develop a corresponding marker detection algorithm. In general terms, the marker detection algorithm works as follows. First, images are captured at a very high rate and are analyzed for the presence of a marker. This process is called segmenting. Second, the computer decodes the information from the markers in the form of 1s and 0s and determines the unique identification of the marker by cross-referencing (matching) with the library of markers. Further details regarding the detection algorithm can be found in [14,18].

Two of the important factors to be considered in the marker detection are false positive and false negative rates. False positive rate implies the rate of falsely reporting the existence of a marker in the captured image when there is no marker present in reality. On the contrary, false negative implies that there is a marker present in the image but the algorithm does not detect the maker. It is particularly important to check these rates before finalizing the marker type and size. Though the comparison of rates sometimes depends on the library size, an acceptable rate can be anything less than 0.1% [20,42]. If these rates are not acceptable, it is recommended to alter the aforementioned categories until desired results are obtained.

2.4.3 Estimate Threshold Distance

At this stage, the robot's camera can detect markers (landmarks), localize itself in the built environment, and navigate based on the relative pose. Since there will be errors accumulated along the navigational path as discussed previously (for e.g., as shown in Figure 4), it is necessary to place the markers at strategic locations to rectify the errors and ensure the robot reaches its next intended destination without drifting too much (e.g., colliding with the wall as shown in Figure 4). So, in addition to placing markers at the locations of interest, additional markers need to be placed along the way.

The objective of this specific task is to determine the threshold distance (d_{th}) between any two successive markers. That is, determine the maximum distance

between two consecutive markers along the navigational path of the robot. This is a result of the maximum allowable drift of the robot and hence a direct measure of the camera marker distance and drift accumulation pattern of the robot. To calculate the threshold distance, several robot runs should be performed to estimate the distance the robot will travel with an allowable drift (less than or equal to the maximum possible drift). The threshold distance is the minimum of these distances travelled for that particular case. Figure 7 shows the representative flowchart of the sub-process estimate threshold distance. This is subject to change depending on different factors such as flooring type (e.g. wheeled robot) and payload (e.g. drones). It has to be noted that the density of the markers and threshold marker to marker distance are inversely proportional. The density of the markers is basically the number of markers per area (e..g., m^2) or length (e.g., running meter). So, higher the threshold distance, lesser the density.

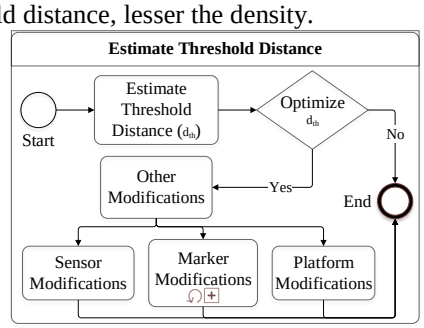

Figure 7. Sub process to estimate threshold distance

If d_{th} needs to be optimized, then the following modifications to the existing system such as a) sensors (on robot), b) markers, and c) platform (robot) can be explored. For example, multiple cameras (e.g. pointing in different directions as shown in [43]) instead of a single camera can be used to overcome occlusions and avoid more frequent placement of markers. 3D markers (i.e., multiple planar markers in the shape of a book used as a benchmark marker in [43]) can also be explored to improve visibility, optimize pose error, and subsequently optimize threshold distance. Further to that, multiple small markers instead of a single big marker can also be used to achieve the same. Finally, platform changes (e.g., other wheel types) can also be explored to optimize the error accumulation and hence d_{th}.

3 Conclusions and Future Work

A generalized framework to design a reliable fiducial marker network for autonomous indoor robotic navigation is proposed. The framework is general and can be applied to different robotic platforms operating in the built environment. Four key roles affecting the design process such as facility manager, built environment, robot, and markers are identified. The corresponding tasks and actions by these key roles that influence the marker network design characteristics such as marker type, size, library size, environmental attributes, occupant actions, robotic platform, camera marker configurations, threshold marker to marker distance are established and described in detail. In addition, four process flow diagrams are proposed that describe a step by step procedure of the proposed theoretical framework. The feasibility of the proposed framework is explained with the help of a real-world built environment example. That is by relating each of the integral task elements in the framework with an autonomous mobile robotic data collection case study. Future work aims to design two different marker network systems using AprilTags and ArUco for autonomous navigation of a specific robotic platform (e.g. Turtlebot3) in a real-world setting. The objective is to compare and analyze different design and performance factors such as threshold distance, marker density, error accumulation, optimal camera and marker configurations. Results of this study are generally applicable to any indoor robot, building type (e.g., office, retail), and application (e.g., environmental data collection). Other potential applications include construction progress monitoring, on-site worker safety identification, and real-time inventory management.

Abstract

Recent advances in the development of Internet-of-Things (IoT) devices have enabled researchers to apply such on building automation systems (BAS). Especially in existing BAS, one big challenge is the diversity of communication methods. In such systems, gateways are required to connect various devices. However, while there are very few IoT-gateways able to interface a wide variety of common sensors and actuators, those often implicate high costs, entailing inacceptable investments for larger field tests.

To overcome this issue, we prototyped a low-cost plug-and-play and freely programmable IoT-gateway, which supports common analog signal interfaces like 0-10 V or 0-20 mA current loop, and digital ones via RS-485 serial communication. The gateway is based on the ESP32-PICO-KIT development board, a fully functional board with a microcontroller and embedded WiFi. Accordingly, we enhanced this board by adding custom-designed peripherals and developing the required firmware for acquiring sensor data and driving actuators.

In order to validate the functionality of the interfaces, we conducted an experimental test series. The experiments comprise measurements of inputs and outputs for either the IoT-gateway or the connected sensors and actuators. The results show an average relative error for analog interfaces of 7 %, hence being sufficient for building automation applications. The RS-485 was successfully tested with a Modbus RTU slave device.

Therefore, the prototyped IoT-gateway is directly applicable to both analog and Modbus-based sensors and actuators, shows acceptable errors in analog readings and can be manufactured at a relatively low price, facilitating test benches containing several plug-and-play gateways.

Keywords –

IoT, Gateway, Building Automation, Wireless Communication, ESP32

1 Introduction

In Germany, potential energy savings due to building automation system (BAS) improvements estimate roughly 20 % [1]. Additionally, in existing non-residential buildings, wireless IoT devices constitute a promising resource to enable BAS without causing high expenses due to elaborate cable installations. However, the beneficial installation of radio-based devices only applies if the configuration effort is not as high as in conventional systems on the other hand. Furthermore, local wired automation systems are well-known and widely adopted due to their reliability. However, there is no comprehensive study on a real BAS yet, which is completely operated via IoT devices. Hence, our research is focussed on the stability and properties of such systems utilizing several IoT devices.

When investigating IoT applications in BAS, the most cost-efficient approach is to use an existing infrastructure. Instead of exchanging sensors and actuators, gateways can be used. With BAS often comprising sensors and actuators with various communication interfaces, there are only few IoT-gateways directly applicable to all these devices. Some of the most popular communication interfaces used are 0-10 V and 0-20 mA analog signal transmission and bus-based communication e.g. via Ethernet, BACnet, LON, KNX and Modbus [2]. Some examples for multi-communication gateways are the BASremote at a price of 350 € [3], the EWIO-9180-M at 425 € [4], the UCM-316 at 325 € [5] and the WISE-4470-S250 at 400 € [6]. All these examples are rather edge controllers than decentral plug-and-play IoT-gateways. These edge controllers imply high costs when used for each sensor and actuator individually or limit one to research activities on decentralized summarized data processing. By contrast, already available open-source platforms like Controllino, PiXtend and UniPi Neuron, just to name a few, prove to be still expensive or not versatile enough for single transducer interfacing.

We thus identified the need to design an IoT-gateway

that features only the necessary characteristics to enable IoT on single devices without causing inacceptable costs.

The rest of this paper is structured as follows: Chapter 2 starts with the deduction of requirements for the IoT-gateway, followed by a detailed description of the electronic design as well as the software implementation. In chapter 3, the conducted test series is described; chapter 4 summarizes the validation results and discusses the purchase cost. Finally, chapter 5 concludes with a summary and future possible improvements.

2 System requirements and design

From our experience with designing and operating BAS, we define the following properties for the IoT-gateway as mandatory requirements to allow for an accurate operation of BAS. These properties were mainly derived by the current technical building equipment, which was planned and used by the Institute for Energy Efficient Buildings and Indoor Climate for their new test hall.

- Timescale – Due to fluid and thermal inertia, but also delay of moving actuators, we suggest a physical and interpretation delay of maximum 1 s.
- Storage – Since the gateway will be connected to a wireless or local area network with constant access to online database storage systems, a limited internal storage capacity is requested for buffering purposes.
- Interfaces – For a start, we focus on analog signals and serial communication and thus omit the Ethernet-based communication. The gateway shall at least support 0-10 V signals, 0-20 mA signals and communication over RS-485.
- Resolution – Actuators such as valve actuators, volumetric flow controllers or pumps commonly receive their values in percent. Therefore, the analog output should at least resolve integer values ranging from 0-100, which represents a resolution of at least 7 bit (2^7 = 128 discrete values). Analog inputs are often used to receive signals from temperature sensors like resistance temperature detectors (RTDs) and negative temperature coefficient (NTC) thermistors. Assuming a range of 140 K, the gateway should at least read for one decimal, resulting in a minimum resolution of 11 bit (2^{11} = 2048 discrete values).
- Network connection – The gateway requires a way to connect to a local area network or the internet, e.g. via WiFi.
- Time tagging – For some control applications, it is necessary to tag each data measurement with a synchronized time. Hence, the IoT-gateway should offer a chronometric and time-reading possibility.
- Software development – In order to test different configuration setups, local or agent-based control strategies, remote service and maintenance concepts as well as different security and encryption functionalities, the gateway needs to be freely programmable. As Python is the most frequently used programming language at our institute, we require Python language support for our gateway.
- Power supply – The gateway should connect to existing sensors and actuators that are often supplied with industrial voltage level of 24 Vdc.

We use the ESP32-PICO-KIT [7] as a base for our IoT-gateway. The ESP32-PICO-KIT is a relatively cheap system on a chip by Espressif, yet providing solutions to several of the defined requirements. A detailed overview is presented in Table 1. ESP32-PICO-KIT properties

Table 1. ESP32-PICO-KIT properties [7]

Feature/requirement	ESP32-PICO-KIT
Timescale (physical, interpretation delay)	0.1 ~ 1 s
Storage	520 KB SRAM
Interfaces/resolution	12 bit ADC (0-1.1 V), 8 bit DAC (0-3.3 V), UART TTL (serial)
Network	WLAN/Bluetooth
Time tagging	RTC (internal real time clock) + NTP (network time protocol)
Software	Micropython support
Power	5 Vdc, 3.3 Vdc

2.1 Electronic Design

From Table 1, we can derive the required adjustments:

- Power supply voltage level,
- 0-10 V reading and writing voltage level,
- 0-20 mA current to voltage and voltage to current conversion and
- UART to RS-485 conversion.

2.1.1 Power Conversions

The IoT-gateway will be connected to 24 Vdc. As the ESP32 runs on a nominal power of 5 Vdc, we use a low dropout voltage regulator (LDO) to provide the requested conversion while being able to supply a current up to 1.5 A. Due to the 5 V operation, the ESP32 cannot provide a voltage output up to 10 V. Therefore, we also use a 10 V voltage reference (VREF), which serves as the upper reference for the 0-10 V output loop. The sensors/actuators and the IoT-gateway share the same ground.

2.1.2 0-10 V Input

As shown in Table 1, the ESP32 has a 12 bit ADC with an input voltage range of 0-1.1 V. This range has to be mapped to a sensor output ranging from 0-10 V.

The easiest and most cost-efficient solution to reduce voltage to a specific range is a voltage divider circuit (see Figure 1). This circuit converts the input signal according to Equation (1). Since the ESP32 ADC input impedance is not provided by the manufacturer, an operational amplifier (OPA) in buffer configuration is used as precaution to decouple the voltage divider from the ADC, thus avoiding measurement errors due to load effects.

$$V_{ADC} = V_{in} \cdot \frac{R_{13}}{R_{14} + R_{13}} \quad (1)$$

As the ESP32 is a low-cost device, its ADC is not of the best quality. It is only assumed to be linear in a range of 100 mV to around 950 mV [8]. Therefore, we selected the resistors so that input voltages of 0-10 V match ADC input voltages of 0-0.91 V. Note, that this reduces the effective resolution of originally 12 bit to about 3400 discrete values, which is still considerably higher than the required 11 bit resolution.

2.1.3 0-20 mA Input

The 0-20 mA input current loop requires a conversion from current to voltage so that the ADC can read its value. The easiest solution is to use a single resistor providing a voltage following Ohm's law (see Equation (2)). Again, we add a buffer to decouple the load resistor R_3 from the ADC and select the resistor so that the ADC input voltages match 0-0.91 V for input currents of 0-20 mA.

$$V_{ADC} = I_{in} \cdot R_3 \quad (2)$$

2.1.4 0-10 V Output

The DAC of the ESP32 has a maximum output voltage of 3.3 V. In order to achieve higher output voltages, this voltage has to be amplified. For this purpose, we use a rail-to-rail OPA in non-inverting amplifier configuration, as shown in Figure 2. By adapting the resistor values, the gain, and hence the output voltage is adjustable, as long as it is below the power supply. The OPA drains a current of just 160 µA, allowing to be powered with a high precision voltage reference (see Section 2.1.1). Whilst the internal voltage supply of the ESP32 is 3.3 V, the DAC may output maximum voltages of 3.2 V. Adopting a conservative approach, we select the resistors to map the DAC output voltage of 0-3.15 V to an output voltage of 0-10.1 V. Because this output is used to control actuators, the output voltage must exceed 10 V, for instance to ensure that the actuator is actually capable of fully closing a valve. The resistor values can be derived by Equation (3). Regarding the effects on the final resolution, the safety margin causes a negligible loss of 12 discrete values.

$$V_{out} = V_{DAC} \cdot \left(1 + \frac{R_{11}}{R_{10}}\right) \quad (3)$$

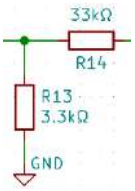

Figure 1. Voltage divider circuit of our IoT-gateway, transfers 0-10 V to 0-0.91 V

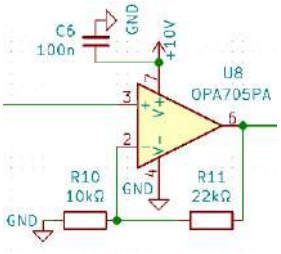

Figure 2. Voltage amplifier circuit of our IoT-gateway, amplifies 0-3.15 V to 0-10.1 V

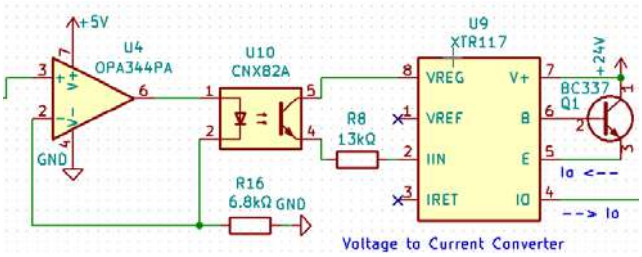

Figure 3. Current loop driver of our IoT-gateway, converts 0-3.15 V to 0-21 mA

2.1.5 0-20 mA Output

We realize voltage to current conversion by resorting to the XTR117 by Texas Instruments, a commercial precision current driver that can be configured both in true and live zero configurations at a very low cost. Since both the DAC and the XTR117 share the same ground, the driving block is isolated from the control block by means of an optocoupler. However, since the relation between the current flowing in the diode and photo-generated current in the bipolar junction transistor is non-linear, the linear control on the former does not result in an equally linear control of the latter. The circuit illustrated in Figure 3 follows the characteristic described in Equation (4), which we derived by measuring the driver current for different values of control voltage.

$$I_{out} = \mathrm{a} \cdot {V_{DAC}}^{b} \quad (4)$$

2.1.6 UART TTL to RS-485 Conversion

The Universal Asynchronous Receiver Transmitter (UART) interface is an interface used to transfer serial data asynchronously. The asynchronous communication does not require a clock signal but rather expects a start and an end of a transferred message [9]. On the ESP32, the UART runs on 5 V. A further difference is the line driver, which converts single ended UART signal to a bi-directional differential signal resulting in two data lines, Data A and Data B. The signals for RS-485 usually range between +/- 1.5 V [9]. For the signal conversion, we use a commercially available UART to RS-485 converter, which also features automatic flow control. Without automatic flow control, a digital control signal is required, in order to assign one line the for communication, as it is not possible to transfer data over both reading and transmitting line at the same time. This, in particular, complicates timing the communication, hence we decided to use a module with automatic flow control.

2.1.7 Reference Voltage Calibration

The ADC and DAC lack quality in terms of linearity that are mainly due to noise and varying reference voltages between different microcontrollers. Hence, we perform an automatic ADC and DAC calibration by calculating two points used for linear interpolation.

A reference voltage for the ESP32 is set, emitted and redirected to two ADC pins, after the voltage is reduced to 1/3 and 2/3 of the reference voltage, respectively. With this construction, the ADC is calibrated. Afterwards, the DAC redirects its output to an ADC pin, reading the provided voltage from the DAC.

2.1.8 Low-Pass Filter

Input and output stages are low pass filtered using first order RC filters to reduce the noise. The adopted bandwidth of 15 Hz is selected to allow all signals in timescales down to 1 s without significant delays and attenuations.

2.1.9 Summary

The ESP32-PICO-KIT is expanded by adding a 24 Vdc power conversion, 5 circuits for each of the individual communication interfaces and a calibration circuit. Figure 4 depicts a view of our finished prototype. The schematic and Printed Circuit Board (PCB) layout can be examined on the publicly available GitHub repository [10].

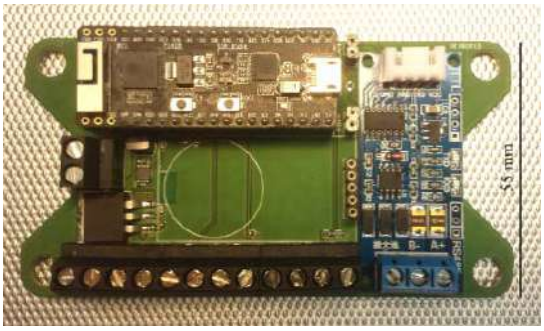

Figure 4. Assembled IoT-gateway PCB prototype from our defined requirements

2.2 Software Design

We programmed the firmware in Python code. However, the microcontroller could also be programmed with other languages like Arduino or C++. The storage space on the ESP32 is limited, therefore we use Micropython, which is a lean Python implementation and was especially developed for microcontrollers [11]. Because the basic Micropython firmware does not allow for setting a reference voltage, we used the LoBo Micropython implementation, that is freely available on GitHub [12]. The GitHub page also contains some instructions on how to flash the firmware onto the ESP32 (we use the esptool for flashing the firmware and ampy to transfer files over serial connection). Following the instructions, the ESP32 accommodates a file system, so the software can be written with any Python programming environment or plain text editor and be transferred onto the ESP32.

When booting the ESP32 with Micropython firmware, two files, boot.py and main.py, are always executed one after the other. The following sections explain the individual parts of the software in more detail.

2.2.1 Main.py

In this file, an instance of the board class is created. All functions, which are used for addressing the analog signal transmissions and Modbus communication, are implemented within the board class. The functions may be called from the instance within a Python shell that is available on the ESP32 when e.g. connecting via serial connection.

2.2.2 Board.py

The board.py is the main file for interfacing the different communication interfaces and provides the corresponding functions. In this file, a class “board” is defined. All parameters are stored within the class object. The following methods are available:

- __init__(self): This function is called when creating an instance of the board class. Parameters are

fetched from the parameters.py and assigned to the attributes. In addition, the ADC and DAC pins for 0-10 V input and output as well as 0-20 mA input and output are assigned. After this, a Modbus instance is created. Finally, the methods for setting a reference voltage and executing the calibration are called.

- set_ESP_referenceVoltage(self): This function sets the reference voltage to the predefined pin (in our case IO27, see schematic [10]).
- calibrate(self): This function calls the ADC and DAC calibration.
- calibrate_adc(self): In this function, the ADC regression parameters are calculated and slope and intercept are returned.
- calibrate_dac(self): In this function, the ADC regression parameters are calculated and slope and intercept are returned.
- Four methods for either ADC or DAC conversions between digital and voltage values: This allows an incremental and consistent calculation for the reading and writing functionalities, but also requires to define the ADC and DAC characteristic at least once.
- Four methods for either reading or writing analog voltages and currents: The reading and writing methods contain the relations described in chapter 2.1.
- Modbus-related functions are callable by the Modbus instance.

2.2.3 Parameters.py

This file contains all predefined parameters. E.g.:

- Pin numbers
- Predefined digital and voltage values for calibration
- Parameters of the relations described in chapter 2.1.
- Modbus-related parameters: Definition of the physical serial port and other specific parameters like the baudrate of the connected device, the Modbus slave address and register lengths.

2.2.4 Modbus

For Modbus, the modules uModbusSerial.py, uModbusFunctions.py and uModbusConst.py are available. These files are slightly adjusted versions of the uModbus package for Micropython [13]. The uModbusSerial.py being the main file provides a class with standard reading and writing functionalities for registers and coils. Our changes mostly concern reading the UART interface.

2.2.5 Summary

The software implementation features a board class that provides the interfacing methods for reading and writing analog voltages and currents as well as receiving and sending Modbus signals. At current state, no automatic sensing or control and logging routines are implemented. When booting the ESP32, a “board” instance is created. This board instance is used via console from serial connection. Modbus-specific functions were taken from the Micropython uModbus module. Parameters may be accessed and changed in the parameters.py module. The complete software implementation is available in the GitHub repository [10].

3 Test series

In order to validate the functionality of the interfaces, a test series is conducted. For the validation of analog reading and writing, we use a test setup consisting of a Programmable Logic Controller (PLC) and terminals for 0-10 V input and output as well as 0-20 mA input and output. With these terminals, it is possible to provide constant voltages and currents or read those generated by the IoT-gateway. We validate the RS-485 interface with a Modbus RTU slave device – an electric valve actuator [14]. The Modbus protocol works with digital values stored in registers and coils; a description of the Modbus registers is provided by the manufacturer [15]. Table 2 provides an overview of the used testing hardware components.

Table 2. Test series hardware

Tested gateway interface	Testing device
-	CX5130 (PLC)
0-10 V input	EL4008
0-10 V output	EL3008
0-20 mA input	EL4018
0-20 mA output	EL3048
RS-485	LM24A-MOD

3.1 Setup

We investigate the analog reading and writing functionality by providing predefined voltages and currents with either the PLC terminal or the IoT-gateway and measuring the corresponding value on the other side. For 0-10 V, we therefore varied the voltage with a step width of 0.5 V, for 0-20 mA we used 1.0 mA steps. Accordingly, we compared the IoT-gateway’s signal to the terminal’s signal. Because of noise, the signal may vary at equal conditions. Therefore, we read 1000 samples and calculate the average value.

The Modbus communication is validated by simply writing a set point to a register, waiting for the actuator to move and reading its corresponding actual value afterwards. We wrote on register 1 a value of 2500 and 7500 and read the related value on register 5. Register 1

is related to the positional set point, which ranges from 0-10000, where 10000 corresponds to 100 %. Register 5 reads the actual position, again ranging from 0-10000.

3.2 Calibration issues

With the proposed calibration method, the ADC and DAC results show severe deviations from expected. However, the problems with noise and accuracy due to different reference voltages are known issues to the manufacturer of the ESP32, Espressif, that provide in their own software development kit and programming guide some useful calibration functions that depend on the internal reference voltage.

For chips produced after the beginning of 2018, the internal reference voltage is measured and directly fused to each chip and hence the calibration can be automated easily. Since the chips of our ESP32-PICO-KITs were produced in 2017, their reference voltage cannot be read directly from the chip. Therefore, in order to use the calibration functions provided by Espressif, we measured the reference voltage and calculated slope and intercept for the linear regression. The calibration functions by Espressif lead to results that are more accurate; consequently, we use their calibration method over our two-point regression. The next section gives an overview of the validation results with this calibration applied.

4 Results and Discussion

The validation results for 0-10 V input and output are summarized in Figure 5, Figure 6 illustrates the corresponding results for 0-20 mA input and output. Table 3 summarizes the maximum and average deviations for the analog communication.

Even with the calibration functions given by Espressif, the results show significant errors for both small voltage and current values. On the one hand, the internal ADC characteristic typically exhibits a negative offset of almost 75 mV that results in the impossibility of reading any value below that threshold, i.e. approximately 750 mV and 1.5 mA for the voltage input interface and the current one respectively. On the other hand, the DAC characteristic shows an offset of almost 300 mV, thus resulting also in this case in a reduced effective range.

With regard to control purposes, the DAC should always be able to apply a zero voltage; besides that, the DAC deviations are probably negligible, since, in many applications, control algorithms rather rely on differences between set and actual values to produce a specific output for an actuator, for instance in case of simple proportional–integral–derivative (PID) control. On the contrary, the ADC readings should be accurate and hence improved on the whole range. This, for instance, applies in case of cascaded PID control where different single sensor errors could add up to significant gain errors. However, the minimum range limitation rather affects actuator position feedback, as e.g. temperature or humidity sensors normally operate far from the minimum of the range. Besides that, following the example of simple PID control, the sensor data acquisition inaccuracy would lead to a different gain, but would not change the general behavior. In order to fully evaluate the limitations for BAS operation, a detailed study is required addressing specific criteria like cyclic communication times, packet size, delays et cetera to guarantee the system's controllability.

At this stage, excluding the error below the 20 % of the input/output range, maximum absolute errors are 0.08 V and 0.16 mA, respectively, which shows that the device is usable for operating with standard voltages 2-10 V and standard currents 4-20 mA for control purposes.

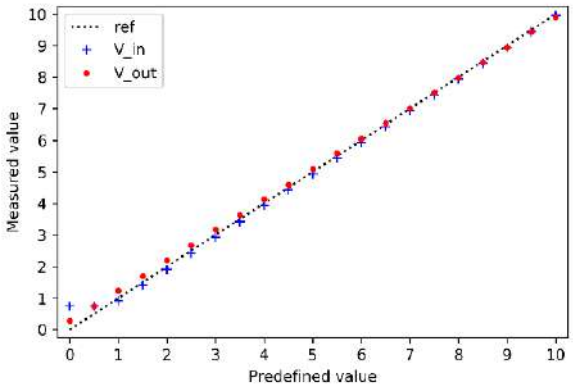

Figure 5. Validation of 0-10 V input and output

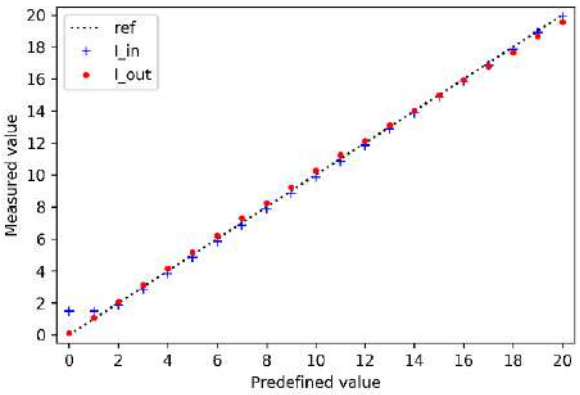

Figure 6. Validation of 0-20 mA input and output

Table 3. Analog relative (e_r) and absolute (e_a) maximum, minimum and average errors

Interface	0-10|2-10 V in	0-10|2-10 V out	0-20|4-20 mA in	0-20|4-20 mA out
	[%]	[%]	[%]	[%]

For the Modbus device set point of 2500, we read a value of 2501, for 7500 we read 7502 on register 5. Modbus is a digital communication, hence not causing any deviations. The very small deviations may occur due to the accuracy of the actuator position.

From the validation results, we conclude following assertions:

- Due to varying internal voltages between different ESP32 modules, the proposed calibration method did not show the desired improvement on the ADC and DAC accuracy. A different method should be proposed in the future to calibrate the conversions between analog and digital values automatically.
- Within the range of 2-10 V and 4-20 mA, the IoT-gateway was able to read analog voltages and currents at an average error of 1.45 % and 1.44 %, respectively. The maximum deviation amounted to 4.19 %. In the same range, writing of analog voltages and currents accounted for average errors of 2.43 % and 2.32 %, respectively. The maximum deviations for writing amounted to 10.1 %. For smaller voltages and currents, the ADC is not able to dissolve them. This issue should be addressed in the future, since reading the actual value accurately is important when calculating a specific output. The writing functionality yielded an acceptable accuracy.
- The PLC terminal EL3048 has an input impedance of about 85 Ω. The current output loop was tested with different loads and showed that a maximum load of 250 Ω can be handled. Further research on input impedances of BAS devices is necessary to assure a general suitability for BAS applications.
- Communication via RS-485 was tested with a Modbus device. The set point register was written and the actual value register read with success. Very small deviations occurred, probably due to the electric motor accuracy.
- The IoT-gateway transmitted signals within 1 s for all tested interfaces.

The technical requirements are met. However, one question remains: How much does this multi-gateway cost compared to the commercially available devices?

4.1 Prices

With the assumption, that a larger field test would require around 50-100 IoT-gateways, we examine the prices for all used components. Figure 7 shows the cost distribution: except for the RS-485 converter, all component prices are fetched from www.mouser.de [16].

This diagram shows that the ESP32-PICO-KIT costing 8.73 € accounts for almost half of the total costs. The circuits for 0-10 V in- and output as well as 0-20 mA input are equally distributed with costs of about 1 € each, the RS-485 module falling little behind with 1.18 €. Because of the high precision reference voltage for the OPA705, the power supply costs 4.34 € and thus causes the second highest costs in total. Since the OPA705 is the only part in need of 10 V, this design should be revised in order to further reduce the costs. However, this component could also help utilizing and improving an automated ADC calibration. The current output loop yields the fourth highest costs and should be revised as well, in order to allow for devices with higher input impedances. The total component price is 23.57 €.

In addition to the components, the PCBs have to be produced and all parts have to be assembled. The costs for 100 PCBs including assembly and shipping account for roughly 400 € corresponding to 4 € per piece. In total, the purchasing costs for one IoT-gateway at quantities of 100 amount to about 28 €. From a vendor's perspective, this price could obviously be reduced by purchasing the components in larger amounts or entering special contracts with manufacturers. However, aside from researching aspects, a single-gateway would probably be more suitable for industrial BAS applications.

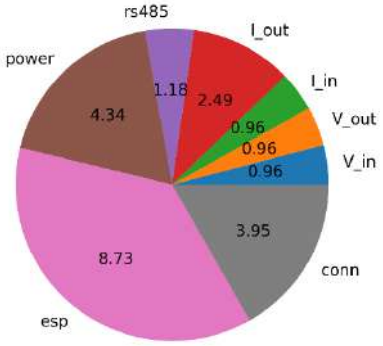

Figure 7. Cost distribution of the IoT-gateway; costs per gateway in € for 100 pieces ordered

5 Summary and Conclusion

In this paper, we designed an IoT-gateway for research on applications in BAS. From our experience, we derived technical requirements for an IoT-gateway in BAS applications. More specifically, we defined:

- Timescales for physical and interpretation delay
- Storage and resolution requirements
- Commonly used signal transmission interfaces
- Software requirements
- Network and time-tagging requirements

- Common industrial power supply in BAS

Utilizing the ESP32-PICO-KIT as a base module satisfies several of the defined requirements such as network connection and time-tagging abilities, ADC and DAC functionalities with appropriate resolution or enough storage capacity for buffering purposes. In order to provide the required interfaces, we designed the additionally necessary peripheral circuits accordingly to allow for analog as well as bus-based communication via RS-485. The ESP32 is a freely programmable WiFi controller; the software addressing all interfaces was written in Micropython, however, it could be programmed with different languages either.

To validate the designed circuits for the different communication interfaces, a test series was conducted comparing target values to measured values. In the validation, analog readings showed severe issues when reading very small values. The average relative errors were around 4.3 %. The analog writing functionality resulted in deviations that were higher than the deviations in reading. In BAS, control algorithms often use differences between set and actual values to calculate an output, hence we conclude that the reading functionality requires improvement. However, further investigations should aim for specifying the exact limitations for BAS operation. Besides that, the analog writing functionalities require small changes in order to at least ensure reaching both upper and lower limit. Additionally, the current output loop is only able to produce a current for devices with resistances up to 250 Ω. For RS-485, we successfully tested a Modbus device. This interface could also be utilized to realize BACnet communication. Further development should focus on extending the firmware and testing BACnet support. In general, the technical requirements could be met showing some restrictions.

Additional improvements include logging routines and streaming of measurement results over WiFi as well as the implementation of control loops.

As regards purchase costs, the total costs amount to roughly 28 €, hence being far below comparable IoT-gateways like a shielded Raspberry Pi with a retail price of 100 €, a Controllino at 200 € or edge controllers at 300-400 €.

Abstract –

In recent years, terrestrial laser scanners have been introduced to enable efficient as-built modeling. Since heating, ventilating, and air conditioning facilities often include many pipes and ducts packed into small spaces, it is difficult to manually determine optimal scanner placements that can capture their surfaces with high accuracy and quality and with few occlusions.

To solve this problem, we propose an optimal scan planning method based on mathematical programming that uses a coarse 3D model obtained from structure-from-motion as prior knowledge of the objects to be scanned. Integer programming enables us to identify optimal scanner locations that maximize scan coverage while satisfying general scan constraints. The proposed method can outperform experienced operators in terms of scan coverage and modeling accuracy. In addition, we extend our original method to address additional objectives and constraints encountered in practice, such as ensuring full scan coverage, minimizing travel time, and guaranteeing point cloud registration. We also confirm our methods' effectiveness via computer simulations.

1 Introduction

Recently, increasing numbers of building facility renovations are being conducted in the heating, ventilating, and air conditioning (HVAC) industry. Laser scanning with terrestrial laser scanners (TLSs) is being used to reconstruct as-built three-dimensional (3D) models of these facilities, enabling shorter survey periods and in-depth construction planning. To reconstruct such 3D models to the precision required for renovation, the TLSs must be positioned appropriately and the scanning process must consider several different objectives and constraints. First, with a TLS, the scanning error depends on the scanning range and the incidence angle between the scanning beam and the surface to be scanned [1]. Second, the acceptable level of scanning error can vary for different parts of the facility depending on the scan's purpose. Finally, the aim is to maximize the scan coverage, with as few occlusions as possible, while respecting the first and second constraints.

Currently, however, the TLS positions are generally determined manually by experienced operators, so there is no guarantee that the scanner placements will satisfy the above scanning objectives and conditions.

To deal with these issues, in this paper, we propose a new optimal laser scan planning method for TLSs that utilizes a coarse 3D model reconstructed via a structure-from-motion (SfM) technique as prior knowledge. It uses integer programming to find optimal scanner placements that maximize scan coverage while satisfying the beam incidence angle and scanning range constraints. We also propose ways to address three further objectives and constraints encountered in practice: providing full scan coverage, minimizing travel time to increase scanning efficiency, and guaranteeing point cloud registration. To achieve this, we develop three extensions to the original method. Finally, we evaluate our methods' effectiveness via experiments and computer simulations.

2 Related Work

In the reverse engineering and robotics fields, the problem of automatically determining optimal sensor placements and measurement sequences is known as the *next-best-view* (NBV) problem [2]. NBV problems can be divided into two types: ones with prior knowledge about the objects to be scanned and ones without. It is known that better sensor placements can be found in the former case [3] than in the latter.

Several NBV problem studies have considered optimal laser scan planning problems involving prior knowledge. Soudarissanane et al. [4] and Ahn et al. [5]

proposed scanner placement estimation methods that maximize the building's measurable wall length using greedy methods, based on 2D drawings of the building's interior and exterior. However, since their methods treat scanner placement as a simple two-dimensional (2D) optimization problem, it is difficult to ensure the scanner placements provide sufficient scan coverage, minimizing occlusions, when applied to scanning plant facilities involving complex, 3D structures with TLS.

Turning now to 3D optimization approaches, Kitada et al. [6] and Zhang et al. [7] proposed methods for deriving optimal scanner placements that maximize scanned surface coverage. These apply integer programming [6] or full search [7] to a 3D model of the building's exterior, but they do not consider the beam incidence angle and scanning range constraints. In addition, these studies did not compare the optimal scanner placements found by their algorithms with those determined by experienced operators in terms of scanning efficiency and quality for as-built modeling.

In our previous study [8], we also proposed a method of solving the optimal TLS planning problem that uses the mesh model representation of an SfM model as prior knowledge. Our method formulates the problem of maximizing the number of measurable surfaces while satisfying the incidence angle and scanning range constraints as a 0–1 integer programming problem, deriving the optimal scanner placements from its solution. However, this method cannot provide full scan coverage, minimize travel time, or guarantee point cloud registration.

To address these issues, in this paper, we extend our previous approach [8] so as to derive the additional scan positions needed for full scan coverage, optimize the scan sequence to minimize travel time, and generate scanner placements that guarantee point cloud registration.

3 Planning Optimal Scans Using Mesh Models And Integer Programming

3.1 Algorithm Overview

In this section, we provide a brief overview of our previous planning algorithm [8]. As shown in Figure 1, the first step is to generate a coarse 3D SfM model from photos of the facility to be modeled. Next, since the required scan quality can differ substantially depending on the area and construction type, we assign a "scan significance level" to each region to specify the quality needed, which is later used to determine the constraint level. Each of the SfM model's surfaces is assigned one of three scan significance levels: *high*, *medium*, or *low*.

During the second step (Figure 2) the space enclosing the SfM model is decomposed into a set of

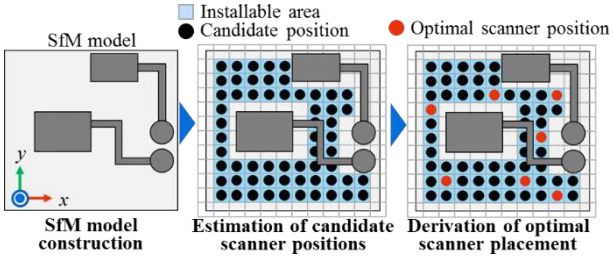

Figure 1. Outline of our optimal scan planning algorithm based on mesh-based integer programming

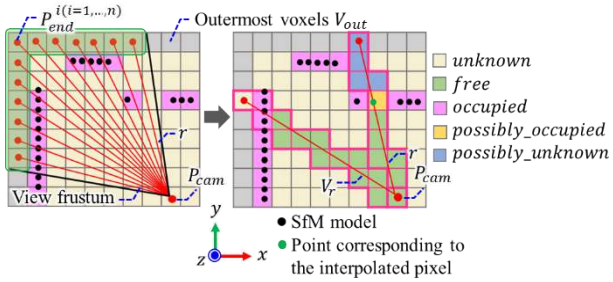

Figure 2. Spatial occupancy classification

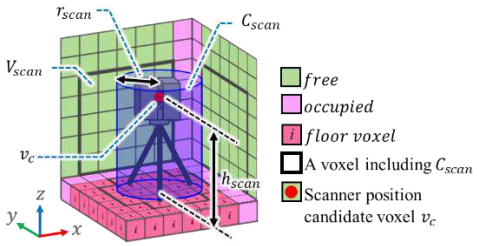

Figure 3. Candidate scanner positions

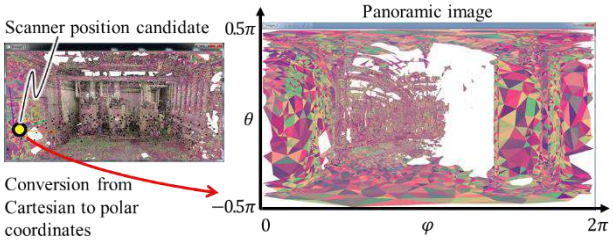

Figure 4. Rendering of an SfM model's surfaces as a panoramic image

voxels with a spatial resolution of l_v, and any voxels that include one of the SfM model's surfaces have their space occupancy attributes set to *occupied*. Next, rays are cast from each camera position toward the centroid of the outermost voxel P_{end} included in that camera's view frustum. Based on these results, the space occupancies of the remaining voxels are set to one of the remaining three types: *free*, *possibly_occupied*, and *possibly_unknown*. Then, as shown in Figure 3, based

on the voxels' space occupancy classifications, a set of candidate scanner positions v_c is extracted from the voxel space enclosing the SfM model.

The final step is to reduce the optimal scan planning problem to a 0–1 integer programming problem. First, we calculate the observation matrix $A = \{a_{v_c,f}\}$, where $a_{v_c,f}$ indicates whether surface f of the SfM model is visible from scanning position v_c. To efficiently determine the visibility, we render the sections of each surface of the SfM model in different colors on a spherical image generated from v_c (Figure 4). Then, surface f is visible if the color used to render it remains in the image produced by the graphics processing unit (GPU). If f also satisfies the incidence angle and scanning range conditions, it is labeled as *observable* $(a_{v_c,f} = 1)$. By repeating this process for all $v_c \in V_c$, we can generate the observation matrix A.

Finally, we derive the optimal scanner placements by integer programming, where the indicator variables represent whether or not a scanner should be placed at v_c. Here we use the Numerical Optimizer [9] package, with the branch and bound algorithm.

3.2 Performance

We compared the performance of our original method with that of experienced operators for a room containing a machine acting as a heat source (12.1 × 14.1 × 4.6 m^3) in terms of the number of scans, scan coverage ratio, modeling accuracy, and processing time. The scanning conditions and threshold constraint values were as shown in Tables 1 and 2, respectively. The optimal laser scanner positions found by both methods are shown in Figure 5.

These results confirm that the proposed method yielded higher scan coverage than the human operator could achieve. The geometric errors in the point cloud-based model captured with the optimal scanner positions were less than 5 mm, sufficient for practical use, while those in the model captured using the operator's placements were more than 7 mm and it is too high for the model to be useful. Furthermore, our method was able to generate optimal scanner positions in only a few minutes, giving it a significant advantage for use in practical scanning tasks.

4 Addressing Practical Constraints

4.1 Issues and Resolutions

Unfortunately, several issues still remain when applying the original optimal scan planning algorithm (Section 3) in practice, namely the following.

- When scanning complex facilities, the use of 2D candidate scanner positions, with the scanner placed at a constant height on a tripod, means that un-scanned SfM model surfaces often remain near ceilings, regardless of the scanner positions used.
- Since the sequence in which the scans are performed does not affect the coverage or scan quality, the sequence used is left to the operator's judgment. However, when scanning large-scale facilities, it is difficult for unskilled operators to move from one position to the next efficiently without getting lost.
- Since no constraints are imposed on the overlaps between point clouds from different scans, the scanner positions generated do not necessarily ensure point cloud registration.

Table 1. Scanning parameters

Parameter	Value
Scanner height (h_{scan})	1.4 m
Scanner base radius (r_{scan})	0.3 m
Vertical field of view	320°
Horizontal field of view	360°
Vertical and horizontal scan pitch	0.072°

Table 2. Scanning constraints

Constraint	Scanning significance level		
	High	Medium	Low
Max. incidence angle	45°	90°	90°
Min. scan range	0.3 m	0.3 m	0.3 m
Max. scan range	5.0 m	8.0 m	20.0 m

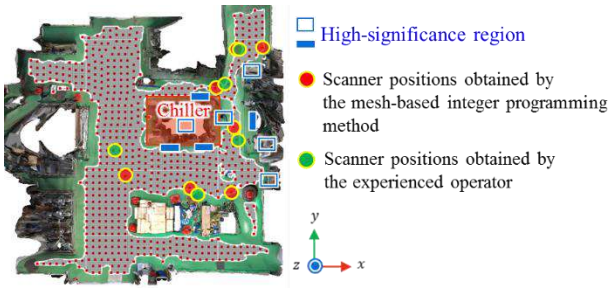

Figure 5. Scanner positions in a room with a machine-based heat source

To address these issues, in this study, we extend our original method in the following ways, then evaluate the effectiveness of these extensions in computer simulations.

1. We formulate an additional planning problem using integer programming to derive additional and optimal 3D scanner placements that can achieve full scan coverage with the minimum number of scans.

2. We formulate an optimal scan ordering problem, deriving the shortest distance needed to travel among the scanner positions from an instance of the *traveling salesman problem*.
3. We formulate scan planning as a constraint satisfaction problem to derive optimal scanner placements that guarantee point cloud registration.

4.2 Full-Coverage Scan Planning Algorithm

4.2.1 Generating Additional Scanner Positions

First, based on the constraints given in Table 2, we define a view frustum (Figure 6) such that the viewpoint is located at the centroid f_u of the unmeasured surface, with the view direction directed toward the surface's normal vector n_i, the vertical and horizontal fields of view being $2\theta_\alpha$, and the *near* and *far* planes being d_{min} and d_{max}, respectively. Then, *free* or *possibly_occupied* voxels whose centroids are included in the view frustum are extracted as additional candidate scanner positions $v_s \in V_{scanner}$.

4.2.2 Checking Visibility and Generating the Observation Matrix

As with the original method [8], we formulate the problem of planning additional scans as a 0–1 integer programming problem. Therefore, we again need to generate an observation matrix $B = \{b_{f_u,v_s}\}$, where b_{f_u,v_s} indicates whether or not the un-scanned surface f_u is observable from scanning position v_s.

To efficiently evaluate these element values, we generate spherical images of the SfM model's surfaces as seen from each position v_s as before, labeling each surface as *observable* $(b_{f_u,v_s} = 1)$ or *unobservable* $(b_{f_u,v_s} = 0)$ using pixel-wise visibility checks and scan quality checks that consider the beam incidence angle and scan range. By repeating this process for all $v_s \in V_{scanner}$, we can generate the observation matrix B.

4.2.3 Generating Additional Scanning Positions

Using the observation matrix B (Section 4.2.2), we formulate the additional scanner placement problem as the following 0–1 integer programming problem.

$$\left|\begin{array}{ll} \underset{z_{v_s}}{\text{minimize}} & \sum_{v_s \in V_s} z_{v_s}(1 + \alpha h_{v_s}) \quad (1)\text{-}1 \\ \text{subject to} & \sum_{v_s \in V_{scanner}} b_{f_u,v_s} z_{v_s} \geq 1 \ (f_u \in F_u) \quad (1)\text{-}2 \\ & z_{v_s} \in \{0,1\} \ (v_s \in V_s) \quad (1)\text{-}3 \end{array}\right.$$

Here, the terms are defined as follows:
$v_s \in V_s$: a candidate additional scanning position,
$f_u \in F_u$:an unmeasured triangular SfM model surface,

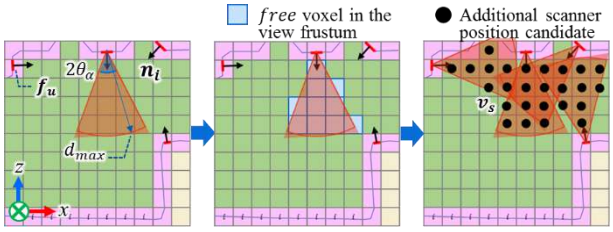

Figure 6. Generating additional scanner position candidates

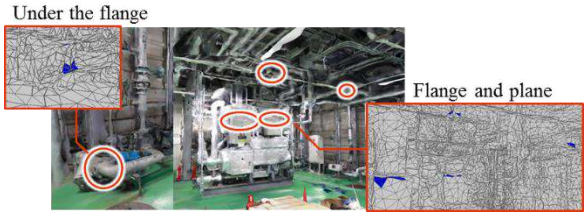

Figure 7. Distribution of the unmeasured high-significance surfaces

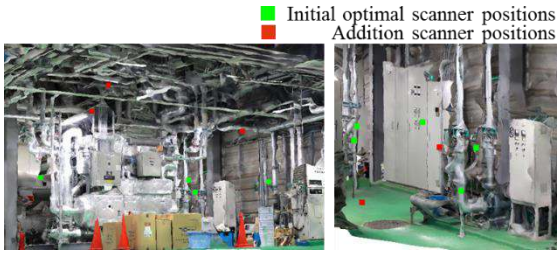

Figure 8. Distribution of additional scanner positions

$$z_{v_s} = \begin{cases} 1 & \text{if } v_s \text{ is used as a scanning position,} \\ 0 & \text{if } v_s \text{ is not used as a scanning position,} \end{cases}$$

$$x_f = \begin{cases} 1 & \text{if } f \text{ is measured,} \\ 0 & \text{if } f \text{ is not measured,} \end{cases}$$

and

h_{v_s}: z coordinate of v_s.

Here, the objective function (Equation (1)) aims to minimize both the number of additional scan positions and their z-coordinates, so lower v_s positions will tend to be selected as additional scan locations.

Finally, we derive the solution to this optimization problem by integer programming. The centroids of the voxels v_s for which $z_{v_s} = 1$ are adopted as additional scanning positions, and added to the set of scanner positions Z_{opt} derived in Section 3.

4.2.4 Results

We applied the above algorithm for planning additional scans to the room used for the previous evaluation (Section 3.2). Figure 7 shows the high-significance surfaces that could not be measured using only the previous scanner positions. The parameters and

constraints were as before (Tables 1 and 2, respectively).

Here, 2,258 additional candidate scanner positions v_s were considered, from which the proposed algorithm extracted the five positions shown in Figure 8. These included several high locations, needed to scan several pipes installed near the ceiling. We were able to confirm that the scan coverage reached 100% with these additional scanner positions added. The time required to solve the optimization problem was 9.6 min, which is reasonable for on-site planning.

The TLS unit used for these experiments weighed 9.8 kg, and its body was 170 mm wide, 286 mm deep, and 286 mm high. This made it difficult to position at the heights required on a tripod due to instability. Therefore, for these additional scans, another laser scanner would be needed that is smaller, lighter, and has a tripod capable of greater extension.

4.3 Optimal Scan Ordering Algorithm

4.3.1 Estimating the Passable Areas

First, the areas of the SfM model through which the operator can travel are extracted using the voxels' space occupancy attributes (Section 3.1).

This is achieved by approximating the shape of a human body as a closed cylinder C_{human} with a radius of r_{human} (Figure 9), and determining the minimum connected voxel set V_{human} that can include C_{human}. As shown in Figure 9, if the ratio of the area of the projected floor voxels (M) to that of V_{human} projected along the z-axis (N) is greater than the threshold value τ_{place}, the floor voxel is classified as *passable*. This condition can be represented as

$$M/N \geq \tau_{place}, \tag{2}$$

where we set $\tau_{place} = 0.80$ in this paper.

4.3.2 Constructing the Path Graph

Generating the optimal scan ordering that achieves the shortest possible travel distance among the given scanner positions can be formulated as an instance of the traveling salesman problem. In this problem, the costs, namely the distances $dist_{i,j}$ between pairs of scanner positions i, j, have to be evaluated and assigned. With this in mind, we construct candidate operator routes as path graphs.

First, as shown in Figure 10, the passable voxels are projected onto a horizontal plane and the centroids of passable voxels are designated as nodes, with pairs of adjacent nodes connected by edges. Then, the set of optimal scanner positions Z_{opt} is projected onto this horizontal plane and the closest nodes are regarded as the scanner nodes. Finally, the shortest path between each pair of scanner nodes, i.e., the path that minimizes

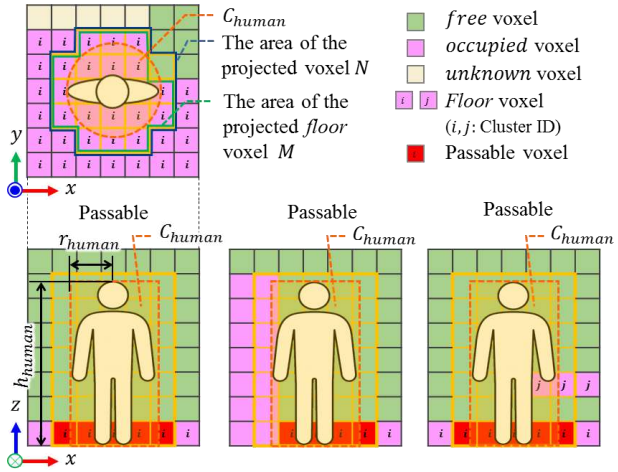

Figure 9. Estimating passable area

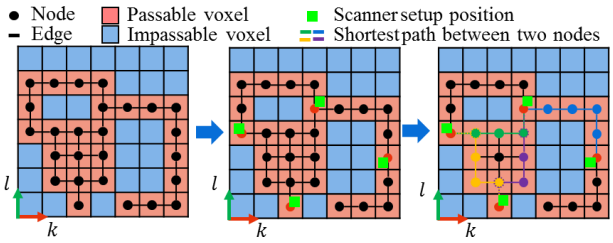

Figure 10. Constructing path graph

the distance between them, is evaluated using Dijkstra's algorithm. Here, the distances between scanner nodes are calculated in terms of the Manhattan distance. This enables us to define all the distances $dist_{i,j}$ between pairs of scanner nodes.

4.3.3 Calculating the Shortest Path and Optimal Scanning Order

The optimal scan ordering problem can be formulated as the following traveling salesman problem.

$$\text{minimize}_{x_{i,j}} \quad \sum_{i \in V_{opt}} \sum_{j \in V_{opt}} dist_{i,j}\, x_{i,j} \tag{3}\text{-1}$$

$$\text{subject to} \quad \sum_{j \in V_{opt}} x_{i,j} = 1 \left(\forall i \in V_{opt}\right) \tag{3}\text{-2}$$

$$\sum_{i \in V_{opt}} x_{i,j} = 1 \left(\forall j \in V_{opt}\right) \tag{3}\text{-3}$$

$$y_i - y_j + (n-1)x_{i,j} \leq n-2 \quad \left(\forall i, j \in V_{opt} \setminus \{1\}, i \neq j\right) \tag{3}\text{-4}$$

$$x_{i,j} \in \{0,1\} \left(\forall i, j \in V_{opt}\right) \tag{3}\text{-5}$$

Here, the terms are defined as follows:
$i \in V_{opt}$: a scanner node,
$x_{i,j} = \begin{cases} 1 & \text{if the path traverses from nodes } i \text{ to } j, \\ 0 & \text{otherwise,} \end{cases}$

$dist_{i,j}$: the distance from nodes i to j,
and
y_i: a dummy variable.

Finally, we can solve this optimization problem using integer programming.

4.3.4 Results

We used the above scan ordering optimization algorithm to plan the scanning sequence for the machine room example considered in Sections 3.2 and 4.2.4. The eight scanner nodes shown in Figure 11 had previously been derived using the original method [8]. Here, the numbers indicate scanner position IDs. In this case, since the entrance and exit were located at the lower left of the room, this was selected as the start point S, and a route derived that started and ended at *S*. For this experiment, we used $r_{human} = 0.3$ m and $h_{human} = 1.6$ m.

The optimal route is shown in Figure 11. Conducting the scans in the order $S \rightarrow 1 \rightarrow 5 \rightarrow 7 \rightarrow 6 \rightarrow 4 \rightarrow 3 \rightarrow 2 \rightarrow S$ gave us a minimum travel distance of 35.1 m. Constructing path graph process (Section 4.3.2) took 309 s, and the optimization process (Section 4.3.3) took 0.4 s, meaning this approach could also be used for on-site scan planning.

Being able to calculate such optimal routes could be very helpful in practice, as it could enable unskilled operators to complete scans efficiently without getting lost.

4.4 Planning Optimal Scans that Guarantee Point Cloud Registration

4.4.1 Problem Setting

Point cloud registration is the process of aligning overlapping scanned points or point clouds with common target markers. It is essential to ensure point cloud registration in laser scanning to create as-built models, so we must generate scanning plans that guarantee point cloud registration. In this paper, we simplify this problem by using target markers to assist with point cloud registration when planning the scans.

In particular, we enforce the following two constraints to enable point cloud registration.

1. As shown in Figure 12, at least two common target markers must be visible from any two different scanner positions.
2. The registration graph must be fully connected. This graph defines the scanning positions as nodes, and has edges between positions that satisfy Condition 1.

Here, the proposed scanner placement method only attempts to satisfy Condition 1 because it is almost satisfied during the scanning of an open room with plenty of planes. Conversely, when aligning plurality of rooms, second Condition 2 must be satisfied. Therefore, we plan to deal with Condition 2 in the future.

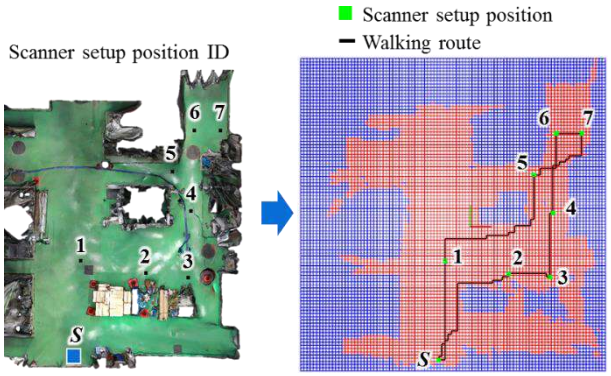

Figure 11. Shortest route and scanning order

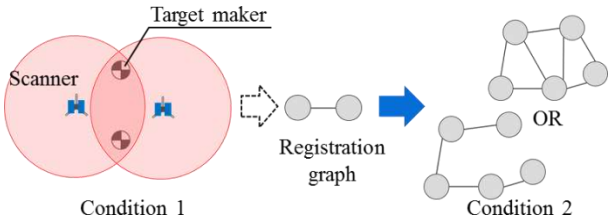

Figure 12. Conditions required to create a point cloud registration graph

4.4.2 Selecting Planar Regions

First, the operator interactively designates planar areas in the SfM model as target markers, and assigns each one a marker ID.

4.4.3 Checking Visibility and Generating the Registration Matrix

Again, our approach is similar to that used for the original method [8]. First, we construct an observation matrix $A = \{a_{i,f}\}$ describing whether or not the surface f can be observed from the candidate scanner position i, in the same way as in Section 3.1.

In addition, we also calculate the registration matrix $G = \{g_{i,j}\}$ describing whether or not given pairs of scanner positions i, j enable registration between their point clouds. Here, we first calculate the marker observation matrix $E = \{e_{i,m}\}$ describing whether or not marker m can be observed from scanner position i. Next, as shown in Figure 13, if the marker plane f_m passes the pixel-wise visibility check (Section 4.2.2) then it is labeled as *visible*. If f_m also satisfies the incidence angle and scanning range conditions given in Equations (4) and (5), it is labeled as *observable*.

$$ang\{l(f_m, i), \boldsymbol{n_f}(f_m)\} < \theta_m \quad (4)$$

$$d_{mmin} < dist(f_m, i) \leq d_{mmax} \quad (5)$$

$$f_m / F_M \geq \tau_m \quad (6)$$

Then, as described in Equation (6), if the ratio of observable plane elements f_m to the complete set of plane elements F_M constituting the marker is larger than τ_m, we set $e_{i,m}$ to 1, i.e., observable.

Next, we calculate the inner product of the row vectors $\boldsymbol{e_i}$ and $\boldsymbol{e_{i'}}$ in the marker observation matrix E, which correspond to the i-th and i'-th scanner positions. When $\boldsymbol{e_i} \cdot \boldsymbol{e_{i'}} \geq 2$, the point clouds scanned at these two positions have at least two markers in common, so point cloud registration is possible and we set $g_{i,i'} = 1$:

$$g_{i,i'} = \begin{cases} 1 \text{ if } & \boldsymbol{e_i} \cdot \boldsymbol{e_{i'}} \geq 2, \\ 0 \text{ if } & \boldsymbol{e_i} \cdot \boldsymbol{e_{i'}} < 2. \end{cases} \quad (7)$$

4.4.4 Generating Optimal Scanner Placements that Allow for Registration

Using the registration matrix G (Section 4.4.3), we can generate optimal scanner placements that ensure point cloud registration as follows.

$$\begin{aligned}
&\underset{x_f, z_i}{\text{maximize}} && \sum_{f \in F} x_f && (8)\text{-}1 \\
&\text{subject to} && \sum_{i \in V_c} z_i \leq T && (8)\text{-}2 \\
& && \sum_{i \in V_c} a_{i,f} z_i \geq x_f \ (\forall f \in F) && (8)\text{-}3 \\
& && \sum_{i \in V_c} z_i z_{i'} g_{i,i'} \geq 1 \ (\forall i' \in V_c) && (8)\text{-}4 \\
& && z_i \in \{0,1\} \ (\forall i \in V_c) && (8)\text{-}5 \\
& && x_f \in \{0,1\} \ (\forall f \in F) && (8)\text{-}6
\end{aligned}$$

Here, the terms are defined as follows:
$i \in V_c$: a candidate scanning position,
$f \in F$: a triangular surface with high significance in the SfM model,
T: the upper limit on the number of scans,

$$z_i = \begin{cases} 1 & \text{if position i is adopted,} \\ 0 & \text{if position } i \text{ is not adopted,} \end{cases}$$

$$x_f = \begin{cases} 1 & \text{if } f \text{ is measured,} \\ 0 & \text{if } f \text{ is not measured,} \end{cases}$$

$$a_{i,f} = \begin{cases} 1 & \text{if } f \text{ is observable from } i, \\ 0 & \text{if } f \text{ is not observable from } i, \end{cases}$$

and

$$g_{i,i'} = \begin{cases} 1 & \text{if positions } i \text{ and } i' \text{are aligned,} \\ 0 & \text{if positions } i \text{ and } i' \text{ are not aligned.} \end{cases}$$

In the formulation of 4.2 and 4.3, as the objective function and constraints can be expressed as linear functions, 4.2 and 4.3 can be handled as an integer programming problem. Therefore, an optimal solution can be derived through the simplex method. In contrast,

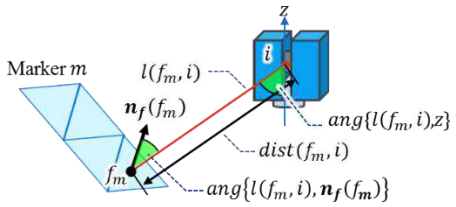

Figure 13. Checking the visibility of the surface f_m containing the marker

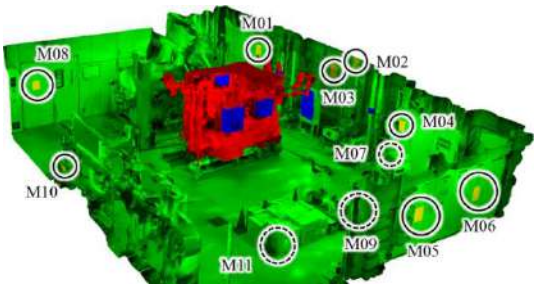

Figure 14. Planes selected as target markers

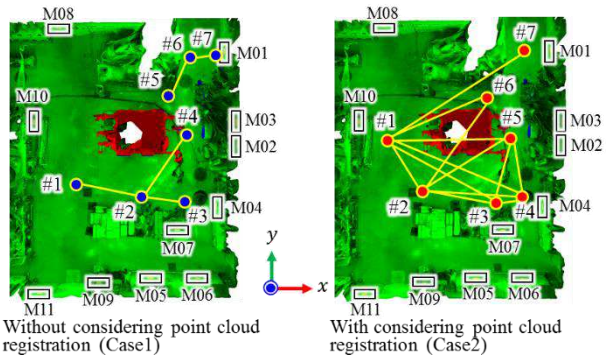

Figure 15. Scanner position pairs that enable point cloud registration

as the registration constraint in the formulation of 4.4 needs to be expressed by a quadric function, it cannot be handled as an integer programming problem. Therefore, we treat it as a constraint satisfaction problem, and derive a solution using tabu search, which is a metaheuristic [10], [11]. This algorithm solves the problem of minimizing total penalty for the violation of each constraint. Because this algorithm is an approximate solver, even if there is no solution that satisfies all constraints, we can derive a solution that satisfies the constraint to the maximum possible extent.

Finally, the scanner positions i for which $z_i = 1$ were added to the set of optimal scanning positions Z_{opt}.

4.4.5 Results

We again applied the algorithm to the machine room used in our previous evaluations (Sections 3.2, 4.2.4, and 4.3.4). As shown in Figure 14, eleven planes were

chosen as being representative of the given area, excluding the floor, and were selected as target markers. The same parameters and conditions were used as before (Tables 1 and 2). In addition, since the target markers had to be scanned with high precision, the conditions for Equations (4) and (5) were taken to be $\theta_m = 45°, d_{mmin} = 0.3\ m, d_{mmax} = 10.0\ m,$ and $\tau_m = 0.8$.

We compared the scanner placements obtained by the proposed method (Case 2) with those obtained via the original integer programming method (Section 3) that does not consider registration, with $T = 7$ (Case 1).

The resulting scanner placements are shown in Figure 15. The scan coverage of the high-significance areas was 85.0% in Case 2, which was 3.2% lower than in Case 1 (88.2%). We also confirmed that the proposed scanner setup (Case 2) yielded a fully-connected registration graph, with every point cloud pair including at least two markers that were visible from both clouds and it being possible to connect all the point clouds to each other by a sequence of registrations. By contrast, in Case 1, the registration graph was not fully connected and the scanner positions were divided into two connected components, making it impossible to register point clouds in different components.

5 Conclusions

In this paper, to ensure that the laser scans used for as-built modeling are sufficiently complete, efficient, and reliable for use in plant renovation, we have proposed three optimal scan planning methods that extend our original method.

First, we confirmed that we could achieve 100% scan coverage using the additional scanner positions generated by our extended planning method. Next, we confirmed that we could derive the scan order that minimized the total travel distance using our scan ordering method. Finally, we confirmed that the scanner positions generated by our registration-aware method ensured that every pair of point clouds included at least two markers that were visible from both clouds and that all the point clouds could be connected via a sequence of registrations.

In future work, we plan to introduce conditions on the scan overlap to ensure global registration in the optimal scan planning problem, and also to develop a navigation system that can present the scanner setup positions without requiring any survey instruments.

Abstract –

The explosion of high-rise building projects has increased the awareness on the importance of the planning and management of vertical transportation systems (i.e., tower cranes, construction elevators and concrete pumps). Although researchers have made beneficial efforts in several aspects of vertical transportation systems (e.g., optimal design capacities and layouts), the estimation of demands on vertical transportation systems (i.e., the quantity of construction resources associated with location, trip date and vertical transportation mode) has not been fully integrated. Currently, this process is still done manually. Building information modeling (BIM) provides the possibility to automate this process, decreasing the time it takes to gather that information and reducing errors associated with manual collection and quantification. This paper proposes a BIM-based framework to generate the vertical transportation demands during the construction of high-rise buildings. It consists of six parts: (1) determine the vertical transportation information of building materials, (2) generate the vertical transportation information of temporary construction materials, (3) link the project schedule with construction materials, (4) generate the vertical transportation information of construction workers, (5) determine the vertical transportation mode for construction materials, and (6) generate the vertical transportation demands. A prototype tool, in the form of an add-in using Revit API, has been developed to demonstrate the functionality of the proposed framework through testing the BIM model of a 36-story high-rise building. The findings show that the framework allows to exploit BIM to generate the information needed to determine the vertical transportation demands quickly and effortlessly.

Keywords –

BIM; Vertical transportation demands; Vertical transportation systems; High-rise buildings

1 Introduction

In recent years, the number and height of high-rise buildings have increased significantly [1]. According to the Council on Tall Buildings and Urban Habitat (CTBUH) [2], the total number of 200-meter-plus buildings in the world was 263 in 2000. This number increased to 1,319 in 2017, a 402% increase from 2000. The average height of the world's 100 tallest buildings increased from 285 meters in 2000 to 372 meters in 2017, a 31% increase.

The vertical transportation of resources required in construction projects is becoming increasingly important, especially in the case of high-rise buildings [3]. During the construction of high-rise buildings, there are not only more resources to be transported, but also transportation distances are longer, making the vertical transportation efficiency an important factor when considering the progress of construction projects [1]. For this reason, vertical transportation systems, including tower cranes, construction elevators and concrete pumps (Figure 1), are attracting more and more attention from both academia and industry.

Figure 1. Tower cranes and concrete pumps used in the early stages of the construction of a high-rise building (source: the authors)

Some researchers have made beneficial efforts in several aspects of vertical transportation systems, such as optimal design capacities [1] [3] [4] and layouts [6] [7] [8]. These studies require vertical transportation demands (i.e., the quantity of construction resources (e.g., weight and volume of materials, number of workers) associated with location, trip date and vertical transportation mode) as the basis for analysis and calculation. However, a main challenge is to obtain the required information because the current estimation process is still being done manually, making this process time consuming, tedious, and prone to errors [1] [9].

As a rapidly developing digital technology in the AEC industry, building information modelling (BIM), has made it possible to solve some of the above problems due to its rich information stored (e.g., quantity and location of building elements), with the potential of automating the estimation process [10] [11]. Some researchers have made beneficial attempts to estimate the vertical transportation demands using BIM. In their research, the quantity, weight, dimension, coordinate and level of building elements in the BIM model were extracted to determine the load and destination of each transportation for tower cranes [4] [9] [12]. Each building element was categorized according to its material under the same family name and associated with schedule information [4] [9]. In order to estimate the vertical transportation demands of temporary construction materials, formwork and scaffolding were created in the BIM model [9]. However, these studies still have some application limitations. First, manually creating temporary construction materials is inefficient, it has been showed that the total modelling time doubles or more according to previous project experience [14]. Second, the researchers have not yet developed a method to link the objects explicitly according to their characteristics due to the discrepancy between the model break down structure in the BIM model and the work break down structure in the project schedule [13]. Although some BIM tools, such as Autodesk Navisworks, can link project schedule information with building elements semi-automatically [5], they are still inconvenient due to the need to create the corresponding collection of building elements in the BIM model according to tasks in the project schedule. Third, construction workers have a greater impact on the transportation performance of construction elevators than construction materials [1], nevertheless, construction workers are difficult to capture in the BIM model, and have not been included yet in the previous studies. Fourth, there is a variety of vertical transportation modes (e.g., tower crane, construction elevator, and concrete pump) to be used in high-rise building construction, the researchers have not yet allocated transportation resources to different vertical transportation modes available.

In order to address these limitations, this paper proposes a BIM-based framework to generate the vertical transportation demands during the construction of high-rise buildings. The remainder of the paper is organized as follows. First, each part of the framework is explained in detail. Subsequently, an example is tested using a prototype tool to validate this framework. Furthermore, the benefits and limitations of the framework are discussed. Finally, conclusions and ongoing work are provided.

2 Proposed Framework

Based on the use of BIM authoring tools (e.g., Autodesk Revit), a framework to generate the vertical transportation demands is proposed (Figure 2). It consists of the following six parts: (1) determine the vertical transportation information of building materials, (2) generate the vertical transportation information of temporary construction materials, (3) link the project schedule with construction materials, (4) generate the vertical transportation information of construction workers, (5) determine the vertical transportation mode for construction materials, and (6) generate the vertical transportation demands. These six parts are explained in the following subsections.

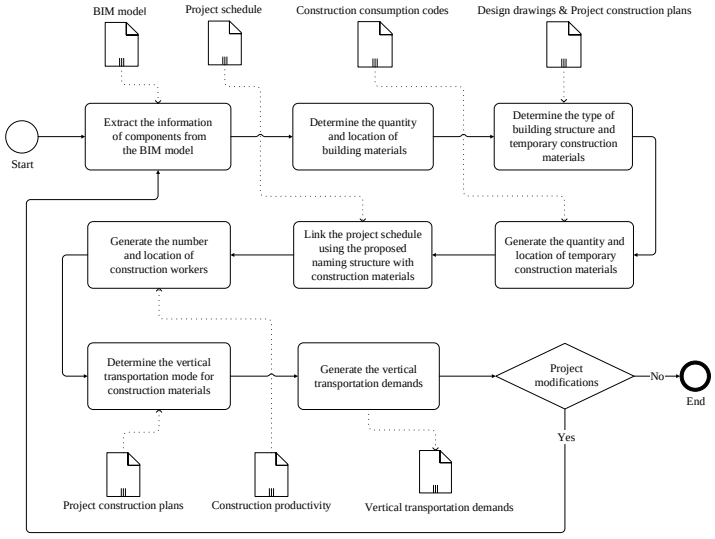

Figure 2. A BIM-based framework to generate the vertical transportation demands

2.1 Part 1: Determine the vertical transportation information of building materials

In Part 1, the information of components is extracted from the BIM model, including building elements (ID number, category (e.g., columns, walls, beams, slabs, stairs), type (e.g., rectangular beam, special-shaped beam), floor, material property (e.g., material quality, density) and dimension (e.g., height, length, width)), building areas (ID number, floor and area), and building levels (ID number, level and elevation). This information is used to determine the quantity (i.e., weight and volume) and location of building materials, and to gather the information required to generate the vertical transportation information of temporary construction materials in the next part.

2.2 Part 2: Generate the vertical transportation information of temporary construction materials

During the construction of high-rise buildings, the quantity of temporary construction materials (i.e., formwork and scaffolding) to be transported is large. It becomes critical when deciding vertical transportation cycle-time [15]. Part 2 is to generate the vertical transportation information of temporary construction materials, including quantity and location.

In the construction industry, there are existing construction consumption codes to estimate the quantity of temporary construction materials. For example, according to the consumption code [16], the quantity of formwork is based on the type (e.g., rectangular beam, special-shaped beam, lintel) and dimension (e.g., height, length, width) of building elements to be constructed, as well as the type of formwork to be used (e.g., bamboo plywood formwork with steel shoring). Similarly, the quantity of scaffolding is based on the building structure type (e.g., frame structure, shear wall structure), building height and area, as well as the type of scaffolding to be used (e.g., steel pipe scaffolding). In this part, the construction consumption codes are used. Figure 3 shows the process to estimate the quantity of temporary construction materials using the consumption codes. It consists of three steps. First, obtain the information required by the consumption codes from the BIM model and project construction documents (i.e., design drawings and project construction plans). Then, determine the unit quantity of the corresponding items in the consumption codes according to the information obtained, including the unit quantities of formwork for different building elements and the unit quantities of scaffolding for different building areas. Finally, calculate the quantity of temporary construction materials. Meanwhile, the location of temporary construction materials is determined from that of corresponding building elements (in the case of formwork) and building areas (in the case of scaffolding). Through using the BIM model and applicable consumption codes, the vertical transportation information of temporary construction materials is generated without creating them directly in the BIM model.

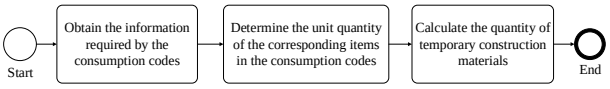

Figure 3. Process to estimate the quantity of temporary construction materials

2.3 Part 3: Link the project schedule with construction materials

Part 3 is to link the information from the project schedule (i.e., start and finish dates) with construction materials. This information will be used to quantify the number of construction workers and determine the trip date of construction materials and workers in the subsequent parts (Part 4 and Part 6).

The work break down structure of the project schedule typically has four levels (Figure 4 (a)), including sub-projects (e.g., foundation, main structure,

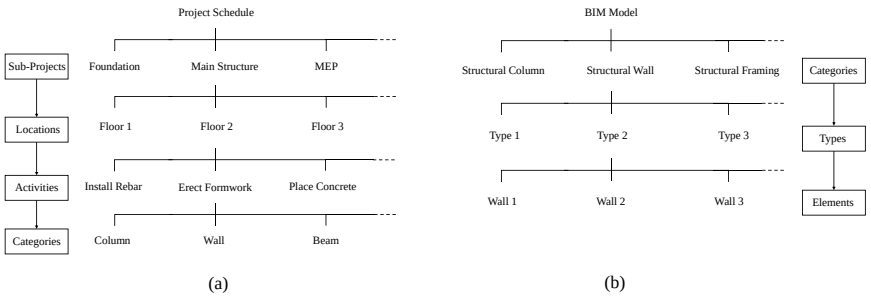

Figure 4. Work break down structure of the project schedule (a) and model break down structure of the BIM model (b)

MEP), locations (e.g., floors), activities (e.g., install rebar, erect formwork, place concrete), and categories (e.g., column, wall, beam). While the BIM model is generally broken into three levels (Figure 4 (b)), with categories, types, and elements. The discrepancy between the work break down structure in the project schedule and the model break down structure in the BIM model, leads to considerable time and efforts spend in matching and linking construction tasks and building elements [13]. To address that, a naming structure for tasks of the project schedule is proposed, as shown in Figure 5.

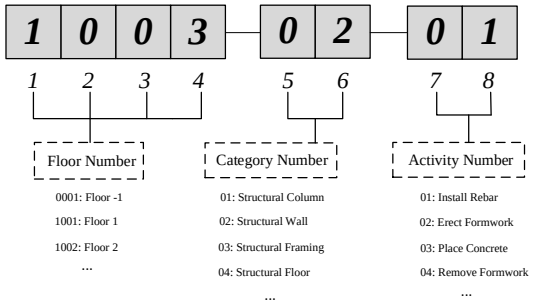

Figure 5. Proposed naming structure for tasks of the project schedule

The naming structure consists of three parts, namely (1) floor number, (2) category number, and (3) activity number. The floor number indicates the location of tasks. The category number is defined based on building element categories in the BIM model. The activity number represents the work scope of tasks. For example, a task with a "1003-02-01" name, as shown in Figure 5, means (read backwards) installing rebar for the structural walls in floor 3. According to this information, the task links all the structural wall rebar located on floor 3, meanwhile, the construction workers installing the structural wall rebar will also be connected in Part 4.

2.4 Part 4: Generate the vertical transportation information of construction workers

Ensuring that construction workers can be transported to destination floors on time, has a great influence on the construction progress, in some cases, it is more critical than transporting construction materials [1] [17]. Therefore, having a good understanding on the vertical transportation demands of construction workers is very important. In Part 4, the number and location of construction workers are generated.

The number of construction workers are calculated based on the quantity of construction materials, the duration of tasks (i.e., start and finish dates), and the construction productivity (Equation (1)).

$$N = \frac{Q}{(F - S + 1) \times P} \quad (1)$$

Where, N represents the number of construction workers per day for a given task; Q indicates the quantity of construction materials, with units depending on the type of materials (e.g., rebar (kg), formwork (m^2), concrete (m^3)); S and F are the start and finish dates, respectively, of the task evaluated; and P, namely the construction productivity, refers to the construction quantity per worker per day (e.g., for concrete: m^3/worker/day). For example, if the concrete volume of a structural column is 17.5 m^3, the start and finish dates of placing concrete are the same day, and the construction productivity is 35 m^3/worker/day, the construction worker number, using Equation (1), is 0.5. Meanwhile, the construction worker location is determined based on that of the column. The total number of construction workers required at a given date and location will be aggregated in Part 6.

2.5 Part 5: Determine the vertical transportation mode for construction materials

In the construction of high-rise buildings, different types of construction materials are usually transported through specific vertical transportation modes, for example, rebar is generally transported using tower cranes. But in some cases, some types of construction materials may also use different vertical transportation modes, for instance, concrete is usually transported by concrete pumps, but sometimes tower cranes are also used to lift it using concrete buckets. Therefore, Part 5 is to determine the vertical transportation modes for all construction materials taking into account actual planning defined by the project team.

Figure 6 shows the process to specify the vertical transportation modes to be used for different construction materials. It consists of the following three steps: (1) select the material to be transported (e.g., rebar, formwork, concrete); (2) choose the location to which the material will be transported (e.g., floor 1, floor 2, floor3); and (3) specify the vertical transportation mode to be used (e.g., tower crane, construction elevator, concrete pump).

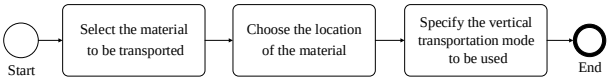

Figure 6. Process to specify the vertical transportation modes to be used for different construction materials

Table 1. Quantity output of construction resources using different vertical transportation modes

Vertical transportation mode	Quantity output		
	Material weight	Material volume	Worker number
Tower crane	✓		
Construction elevator	✓	✓	✓
Concrete pump		✓	

2.6 Part 6: Generate the vertical transportation demands

After the implementation of Part 1 through Part 5, the quantity, location, trip date, and vertical transportation mode of different construction resources have been determined. In Part 6, this information is compiled to display the vertical transportation demands for each type of vertical transportation systems. If there are any modifications to the project, the vertical transportation demands will be regenerated according to the updated BIM model and construction documents.

In general, the transportation volume of vertical transportation systems is limited by their loading capacities and space constraints. For tower cranes, the loading capacity is the main limiting factor. With respect to construction elevators, cages impose constraints on the dimensions of the object being transported, hence, construction elevators are limited by both the loading capacity and space constraint simultaneously. Concrete pumps are different from the above two types of vertical transportation systems since their transportation volume is based on the volume of concrete transported per hour. Thus, the quantity output of materials to be transported by tower cranes is weight, that of materials to be transported by construction elevators is weight and volume, that of materials to be transported by concrete pump is volume, and workers are output by number (Table 1).

3 Example

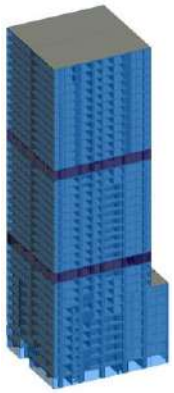

Figure 7. 3D view of the BIM model used in the example

A BIM model developed using Autodesk Revit 2017 [18] was used to test the proposed framework. The BIM model consists of a 36-story high-rise building with a height of 149.6 meters (Figure 7), which contains columns, walls, beams, slabs, stairs, wall finishes, doors, windows and glass curtain walls. For simplicity, the MEP system was excluded. The rebar information was generated using the Glodon software (GGJ 2013) [19]. Based on the framework, a prototype tool was developed in C# by using Revit API [20]. A database containing 14 tables was created using MySQL [21] (Figure 9), it can be divided into 4 parts, the blue table information (i.e., “Building Element”, “Building Area”, and “Building Level”) was from the BIM model, the green table information (i.e., “Consumption Code”, “Construction Productivity”, and “Formwork Content) was from the construction codes, the yellow table information (i.e., “Project Schedule”, “Vertical Transportation Mode”, “Formwork Type”, “Scaffolding Type”, and “Building Characteristic”) was from the project construction documents, and the red table information (i.e., “Formwork”, “Scaffolding”, and “Construction Worker”) was from the generated information. A use interface (Figure 8) was developed to determine the formwork type (i.e., bamboo plywood formwork with steel shoring), building structure type (i.e., frame-shear wall structure), scaffolding type (i.e., steel pipe scaffolding) and vertical transportation mode (e.g., tower crane, construction elevator, concrete pump) used for construction materials. Microsoft Project was used to develop the project schedule. The vertical transportation demands were generated as the Microsoft Excel files (Figure 10 to Figure 14).

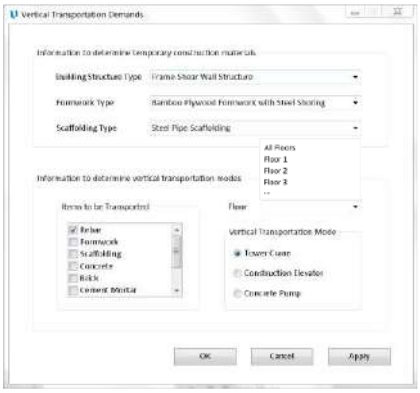

Figure 8. Developed user interface

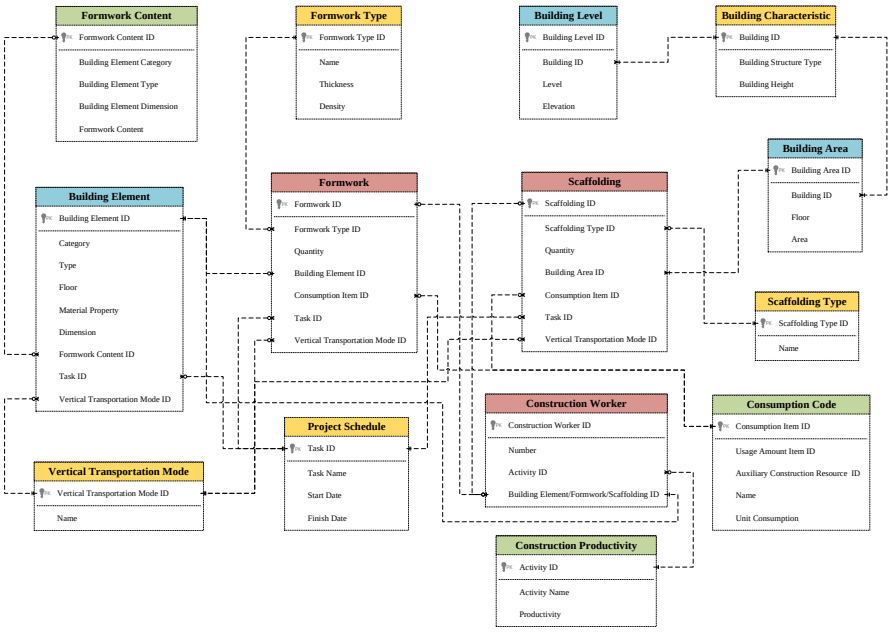

Figure 9. Database model diagram of the prototype tool

Figure 10 through Figure 14 show the vertical transportation demands for different types of vertical transportation systems. The horizontal, longitudinal and vertical axes represent the trip date, location and transportation volume, respectively. They provide valuable information for the project team. For example, this information shows that the maximum transportation weight of 765,871.43 kg for tower cranes occurs on May 24, 2015 and it is transported to floor 1 (Figure 10); the maximum transportation weight for construction elevators is 411,943.68 kg (139,232 kg to floor 4 and 272,711.68 kg to floor 19) on October 18, 2015 (Figure 11); the maximum transportation volume for construction elevators is 385.61 m³ to floor 8 on August 22, 2015 (Figure 12); the maximum transportation volume to be transported using concrete pumps is 615.57 m³ to floor 24 on October 22, 2015 (Figure 13); 238 construction workers (the maximum number) take construction elevators to floor 2, 3, 8, 16 and 21 on October 5, 2015 (Figure 14). With the information generated, the maximum transportation demands for different types of materials can also be obtained. For example, the maximum transportation weight for rebar is 142,613.59 kg (May 24, 2015/floor 1) and the maximum transportation weight of formwork is 176,658.9 kg (August 2, 2015/floor 10).

In addition to the obvious maximum transportation demands, the different trends can also be analyzed from the results. For example, different phases can be defined by the project manager based on the requirements for different transportation modes. When looking at the number of construction workers using construction elevators per day (Figure 15), from May 24 to August 20, 2015, the number of construction workers gradually rises to 149, this period could be defined as Phase 1. From August 21 to December 28, 2015, the number of construction workers starts to exceed 150, with the peaks over 200, this period could be defined as Phase 2. From December 29, 2015, the number quickly drops below 100, after that, the utilization remains stable, this period could be defined as Phase 3. The number and type of construction elevators to be used can be adjusted for each phase.

4 Discussion

This study is beneficial to the information collection of vertical transportation resources, and it makes three main improvements to the existing literature. First, the information of temporary construction materials is automatically generated without creating them directly in the BIM model (i.e., the design information model), as well as that of construction workers, which greatly enhance the efficiency of the collection process. Second, the proposal of the naming structure for tasks in the project schedule breaks the information barriers between BIM model and project schedule, making no additional manual operation is required for their interoperability so that reducing the unnecessary duplication of work and the loss of information. Third, the demands on multiple vertical transportation modes (i.e., tower crane, construction elevator and concrete pump) are generated simultaneously, not just one mode, allowing the project team to easily plan and manage the overall vertical transportation systems for achieving the global optimal solution. At the same time, the framework provides a dynamic aspect, generated results can be easily adjusted to account for changes.

This framework provides a promising solution to automate the generation process of vertical transportation demands during the construction of high-rise buildings, however, there are limitations yet to be addressed. First, it is common to use some floors as temporary storage spaces in the construction of high-rise buildings, hence, it is necessary to account for the transportation of resources between floors. Second, the framework does not consider the issue of transporting construction waste produced during construction down due to the amount of construction waste is not negligible in high-rise building construction. Third, it is normal to use permanent elevators when construction elevators have to be removed before finishing building enclosure work, which would reduce the demands on construction elevators, so the permanent elevator should be included as a vertical transportation mode. Ongoing research is carried out by the authors for addressing these limitations to make the framework more practical and valuable.

5 Conclusion

The boom in the construction of high-rise buildings creates some new challenges, such as the planning and management of vertical transportation systems. It also indirectly puts forward new requirements for the speed and accuracy of the vertical transportation demand collection. This paper proposes a BIM-based framework to automatically generate the vertical transportation demands, integrating the construction codes and project construction documents. The framework has been validated through an example project consisting of a 36-story high-rise building using a developed prototype tool. From the application of the proposed framework, the construction materials and workers needed by different types of vertical transportation systems were obtained quickly and effortlessly, greatly reducing the collection time. The generated three-dimensional graphs clearly show the quantity, location, and date of different vertical transportation demands, they can be utilized by the project team during the planning and management of

vertical transportation systems (e.g., determine vertical transportation period time). The current framework is at an early stage, it is expected to make the estimation on vertical transportation demands faster and more accurate by expanding and extending this basic framework. Ongoing work is conducted to address the limitations mentioned above.

Abstract –
Closed circuit television (CCTV) is probably one of the most important technologies that is used by municipalities in order to monitor the structural and operational condition of sewer pipes. To be useful, CCTV video footage needs to be collected according to standards, which make such an operation, time consuming especially when pipes have operational issues like debris or tree roots. In this respect, developing benchmarks for data collection can be an important source of information that can improve the efficiency of future surveying campaigns. Computer simulation is an effective method for improving the efficiency of maintenance work schedules. However, CCTV collection data consists of abundant noise (waiting time or defect inspection time) due to the characteristics of pipes in different structural or operational conditions. For example, crawlers equipped with CCTV cameras could be blocked by deposits or serious structural issues in the pipe, which would cost some waiting time for the crawler to proceed with the inspection. In order to extract the standard CCTV collection time, excluding waiting time and defect inspection time a machine learning based approach is proposed in this work in the form of an algorithm commonly known as the Random Sample Consensus (RANSAC). This algorithm is developed to clean the data automatically, arriving at a function of CCTV collection time with two variables (i.e., length of pipe segment and number of taps in the pipe). The results can be fed into a simulation model to imitate the CCTV collection work in future research.

Keywords –
CCTV; Sewer pipes; Time extraction; RANSAC

1 Introduction

The sewer system plays an important role as a type of municipal infrastructure that has a significant influence on the efficiency and quality of our lives. However, the pipes that make up a sewer system undergo deterioration due to aging, external force, excessive demand, and other factors. [1]. This deterioration poses a great challenge for municipal maintenance departments since the maintenance is time-consuming and heavily dependent on capital investment and operating costs. To perform an efficient and quality sewer maintenance job, closed-circuit television (CCTV) is commonly adopted as the pipe condition inspection technique [2–4]. The wide usage of CCTV for pipe inspection has been driven by many practical reasons the most important of which being safety since this monitoring procedure does not require man entry [2]. Furthermore, since the videos are stored on appropriate media, they not only can be visualized for the purpose of inspection or comparison with other techniques (e.g., laser-based system, ultrasonic-based sensors and ground penetrating radar [5]) but more importantly they can serve as accurate historical data.

The CCTV collection process will be discussed in the next section. For this research, it should be noted, we only consider the time period that starting at the beginning of the video to the end. The objective of this research is to extract the standard CCTV collection time, excluding all waiting time, idle time, and other time delays in the collection process. The results can be fed into a simulation model to perform schedule optimization, which is the next stage of our research. In addition, the extracted standard CCTV collection time can be viewed as a benchmark for the CCTV collection process. Management decision can be derived for each

of the CCTV collection job in the perspective of time efficiency. For example, CCTV collection time within in new developed neighborhood should be align to the standard CCTV collection time; while it could be slower in older neighborhood theoretically considering the deterioration of the pipe, since more defects may cause more waiting time.

2 CCTV Collection Process

CCTV operators travel to inspect sewer pipes at the assigned locations as per the schedule set up by the municipal maintenance department. In general, before beginning the video collection phase, the pipes to be inspected are cleaned in advance by means of flushing equipment, in order to eliminate deposits and obstacles in the pipes which in turn ensures that the conditions for data collection are acceptable [6,7]. Following flushing activities, operators begin set-up work for CCTV data collection on the ground. The setup includes adjustment of a remotely controlled robot equipped with a specialized television camera. Next the camera begins to record a video for the observed pipe from the start point. In the process, the operators need to adhere to standards such as those described in National Association of Sewer Service Company (NASSCO) in order to obtain quality information that can be accurately analyzed later in the process. For instance, four primary categories of pipe defects are listed based on the pipeline assessment and certification program (PACP) [8]: that is, (i) structural defects, (ii) operation and maintenance defects, (iii) construction defects, and (iv) miscellaneous defects. While collecting the video, the technologist controlling data acquisition can decide to spend more time on serious defect such as those referred to as pipe broken or substantial deposits. The total CCTV collection time can be derived by means of Equation (1),

$$Time_n = a \bullet L_n + b \bullet T_n + W_n + C + \varepsilon_n \quad (1)$$

where $Time_n$ represents the total CCTV collection time for pipe segment, n; L_n is the length of the pipe segment; T_n is the number of taps of this pipe segment; W_n is the total waiting time, which may include the time for inspection of severe defects, adjustment of camera, etc.; C is the fixed time for the CCTV collection process, which may include time for equipment setup and other routine processes; and ε_n is an error representing the uncertainties regarding this process.

From a theoretical viewpoint, if there are no serious defects or other accidents that hinder the CCTV collection process observed in one pipe, a CCTV collection time can be generally described in Equation (2),

$$Time_n = a \bullet L_n + b \bullet T_n + C + \varepsilon_n \quad (2)$$

The waiting time is eliminated in this equation. $Time_n$ is denoted as standard CCTV collection time. The data points that contain waiting time are the noisy points that we want to exclude. The standard CCTV collection time extraction is conducted by the RANSAC algorithm, which will be described in the next section.

3 RANSAC Model

In order to extract the standard CCTV collection time, this research applies the Random Sample Consensus (RANSAC) algorithm to clean the raw data automatically. RANSAC, proposed by Fischler & Robert in 1981, is a non-deterministic approach to use the smallest initial dataset to determine the parameters of a model, then repeat the process until it reaches the predefined criterion [9]. Unlike linear regression using least-squares estimation, which seeks to minimize the distance from all the data points to the fitted function, RANSAC model searches for the best fitted function without considering the outliers (see Figure 1). From Figure 1. we can see that the solid line constructed by the RANSAC algorithm is better at describing the trend for all five points than the dotted line developed by least-square estimation. The outlier is called a noise point in this scenario, and it is these noise points that are supposed to be eliminated in constructing this regression model.

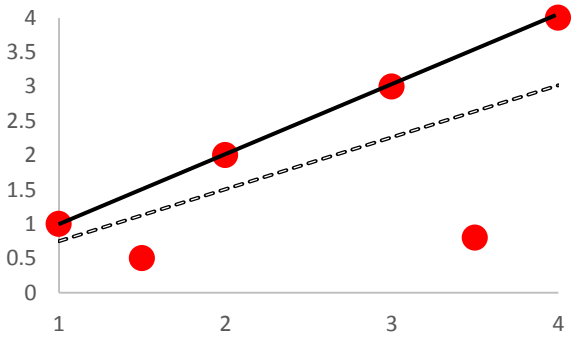

Figure 1. Comparison of least-square estimation and RANSAC.

The mechanism of the RANSAC algorithm is presented in Figure 2. The algorithm starts with selecting X points (where X = number of independent variables + 1). For instance, two points are needed to fit a line (2-dimensional problem) while three points are needed to fit a panel (3-dimensional problem). From Equation (2), we know that the extraction of the standard CCTV collection time is a problem with two independent variables, namely, the length of the pipe segment associated with video (L), and the number of taps within the pipe segment (T). Therefore, three points

need to be selected for each iteration. An objective function (Y_i) can be formed based on the selected points. Then, the Euclidean distance of each point to the objective function is calculated. A threshold (t) should be selected in order to decide whether the point is an inlier or an outlier. If the distance is within the threshold, it is an inlier; otherwise, it is an outlier. The number of inliers (N_i) should be counted and compared with the N_{i-1} (i.e., the greatest number of inliers among all the historical iterations). If the N_{i-1} is bigger, we save the N_{i-1} as N_i, and Y_{i-1} as Y_i. Otherwise, we update the N_i and Y_i accordingly. The process is repeated until the predetermined number of iterations (N) is reached. As for the number of iterations (N), it can be calculated by means of Equation (3) [10].

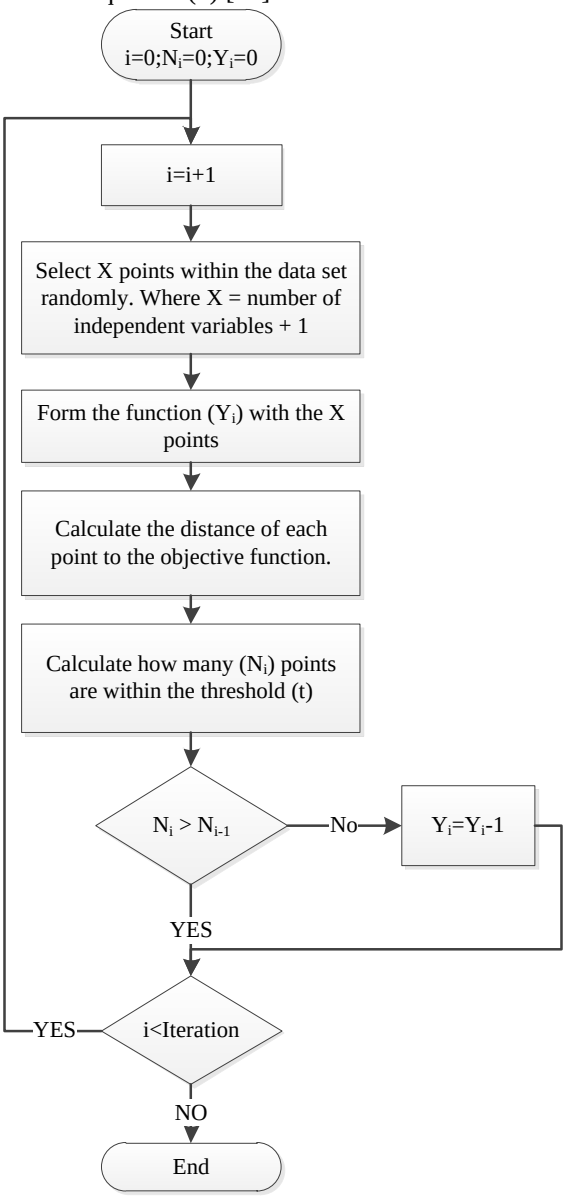

Figure 2. Flow chart of RANSAC algorithm.

$$1-p=(1-\lambda^X)^N \Rightarrow N \geq \frac{\log(1-P)}{\log(1-\lambda^X)} \quad (3)$$

where X is the number of points needed to construct the objective function; N is the number of iterations; P is the probability that at least one of the objective functions built in all N iterations is constructed by X inliers; and λ is the inlier ratio, which can be calculated using Equation (4). Although a priori it is an unknown ratio, it can be updated during the algorithm progress [11].

$$\lambda = \frac{Inliers}{Inliers + Outliers} \quad (4)$$

Considering the probabilistic nature of the RANSAC algorithm, the parameters (e.g., a and b) of the objective function will vary from one time to another if the algorithm runs multiple times. Therefore, the mathematical expectation of each parameter can be calculated from a large number of run-times of the algorithm. The mathematical expectation of the parameters will be used to form the objective function for the convenience of constructing the simulation model in the future research.

4 Case study

4.1 Data description

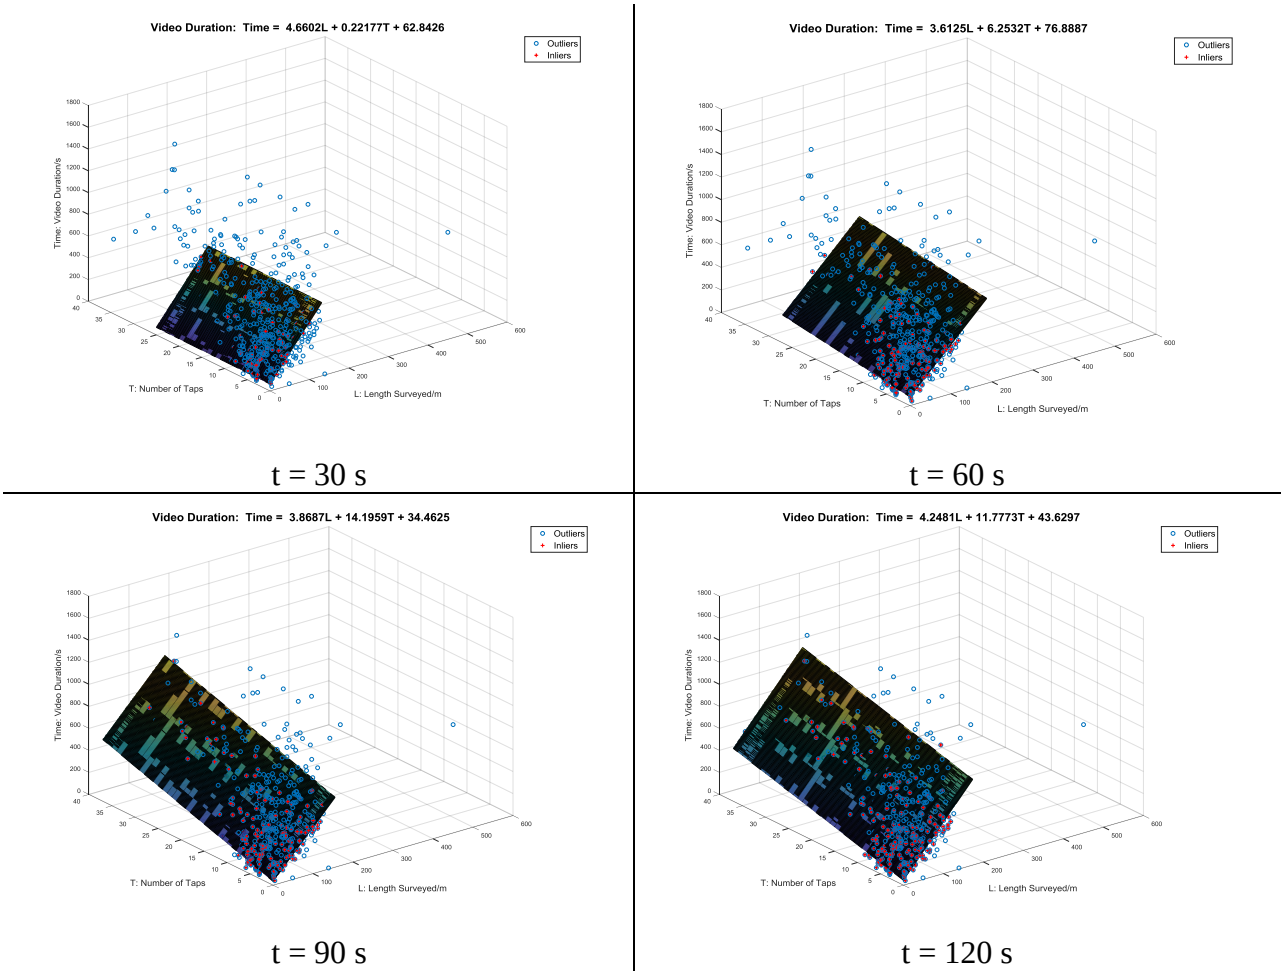
The data used in this research was collected by EPCOR Drainage Services, which is responsible for the operation and maintenance of the sewer infrastructure in Edmonton, Canada. For each pipe segment, the data is provided in two formats (two types of files), namely, Microsoft Access (.mdb), and video file (.mp4). The video duration (in seconds) and length of pipe segment surveyed (in meters) can be retrieved from the Access database directly. The number of taps is counted by a count query (combining all kinds of code associate with taps, such as Breaking-In/Hammer, Factory-made, Saddle, etc.) in the database in order to derive the total number of taps in a given pipe segment. Other attributes associated with the pipe segment can be derived from the Access database as well, such as the number of defects, location, and material type. The CCTV video serves as the validation function; that is to say, it is used to check the validity of the data recorded in the Access database either through manual viewing and analysis of the CCTV footage or by means of algorithms. In this research, we consider three attributes— video duration (s), length of pipe segment (m), and number of taps. 540 data records are fed into the RANSAC model to capture the relationship described in Equation (2) by excluding

any data records that contain forms of waiting time as described above.

4.2 Results and findings

As discussed in section 3, three parameters need to be determined for the RANSAC model: the number of points needed to form the candidate objective function (X), the number of iterations (N), and the threshold (t). In this case, X = 3 since there are two independent variables in this model, as per Equation (2). The lower boundary of the number of iterations, meanwhile, can be calculated from Equation (3). Considering the positive correlation between the number of iterations and the probability of obtaining the optimal results, along with the size of the dataset and CPU processing time, an iteration number of 100,000 was selected. As for the threshold, several experiments were conducted with different values of t (see Fig 3).

From Figure 3, we can see that the objective function can be plotted as a plane in a 3D space. The video duration (time) increases with an increase in the length of pipe segment (L), and number of taps (T), a finding which aligns with reality, since an increase in either the length of pipe segment or the number of taps will increase the CCTV collection time. The red dots represent the pipe segments classified as inliers; that is to say, these pipes are in good condition since there are no severe defects or other accidents that would lead to significant waiting time during the inspection process. Similarly, the blue dots represent the pipe segments that are classified as outliers, which means that these inspections must have been delayed by some extenuating circumstances (either sever defects within the pipe or other accidents such as equipment failure). The inliers and outliers are tabulated in Table 1.



**Note that the red dots are the inliers (within the threshold) and the blue dots are outliers (outside of the threshold).*

Figure 3. Results of RANSAC model with different values of threshold (t)

Table 1. Number of inliers and outliers at different thresholds.

Threshold	30 s	60 s	90 s	120 s
Inliers	130	217	285	335
Outliers	410	323	255	205

Comparing the results in Figure 3 and Table 1, we can see that, as the value of the threshold grows, the number of inliers shows an increasing trend. The information in Figure 3 and Table 1 can be interpreted as follows: with the relaxation of the conditions, the number of pipe segments classified as being in good condition increases. A box-plot can be plotted based on the inliers at the four threshold values, along with the original video duration in the original 540 data (see Fig 4). Obviously, the original dataset has the highest median video duration, while the dataset has the lowest video duration when the threshold is set at the lowest value (30 s). The medians of the last three scenarios (t = 60 s, t = 90 s, and t = 120 s) do not vary significantly compared with the variation between the first two scenarios (t = 30 s and t = 60 s). Similar relationships for the 75th quantile of the video duration in the box-plot can be observed. The threshold selection is subjective due to the nature of this algorithm. Although a smaller threshold ensures that all the inliers are classified correctly, it may lead to the loss of points that should have been classified as inliers in reality. On the contrary, if the threshold is greater, it may include points that should have been classified as outliers in reality. Identifying the optimal tradeoff between accuracy and completeness in this threshold selection process requires several experiments and statistical analysis at the same time. Ultimately the threshold of 60 s was selected, as it contains the inliers that take part in around 40% of the total data points, which is aligned with the empirical judgment from the dataset.

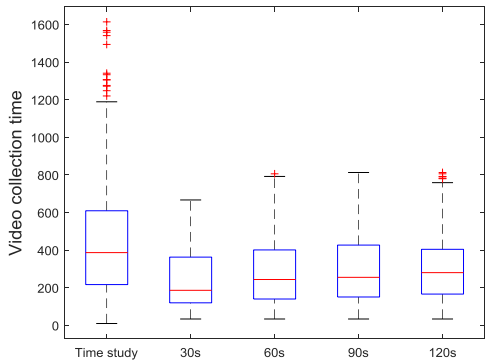


Figure 4. Box-plot of video durations of inliers in four scenarios, along with original dataset.

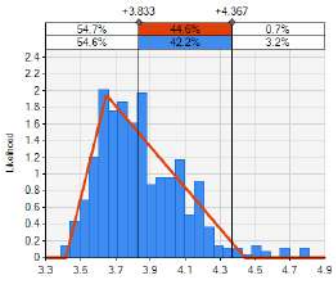
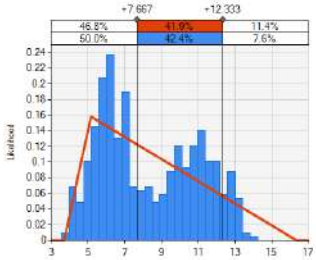
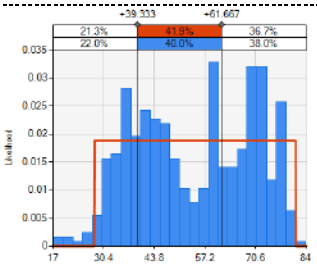
As discussed in Section 3, due to the probabilistic nature of the RANSAC algorithm, multiple runs are needed to capture the distribution of the three parameters (a, b and C) in Equation (2). Figure 5. shows the results of 500 runs of the RANSAC algorithm with the threshold of 60 s. Parameters a and b are both fitted with triangular distribution, with the mathematical expectation of 3.84 and 8.34 separately. Parameter C conforms to the uniform distribution with an expectation of 54.56. Therefore, the objective function can be summarized as $Time_n = 3.84 \bullet L_n + 8.43 \bullet T_n + 54.56$. The statistical analysis can be interpreted as follows: for one meter of pipe segment in good condition, it takes 3.84 s to finish the CCTV collection process; if there is one tap present within the pipe segment, it takes 8.43 s to finish the inspection; the fixed duration for the CCTV collection process is 54.56, which may include equipment setup time, camera adjustment time, and other routine processes. With the function derived from the RANSAC model, theoretical video collection time can be calculated with the two inputs (L and T). A histogram (see Figure 6.) can be constructed to show the performance of the RANSAC model by comparing the distribution of video collection time of the original data (inliers) and the theoretical results calculated from the RANSAC model. We can see from Figure 6 that the two histograms are largely co-terminous, which means that the results from the model are quite close to reality.



Parameter a: Triangular distribution; Expectation (a) = 3.84



Parameter b: Triangular distribution; Expectation (a) = 8.34



Parameter c: Uniform distribution; Expectation (a) = 54.56.

Figure 5. Results of the parameters in RANSAC model.

This function can be fed into a simulation model to model the CCTV collection process. In addition, it can be used as a classifier to distinguish whether or not a given pipe segment being inspected by CTTV is in good condition.

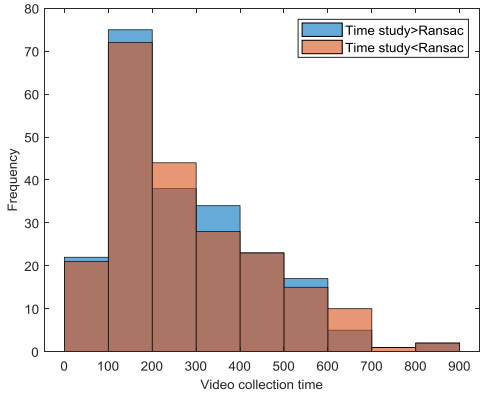


Figure 6. Histogram of RANSAC model and original time study.

5 Conclusion

Exclusion of noisy data is the objective of this research, so the RANSAC algorithm is utilized to exclude all data points that contain noise of any form. The CCTV collection process is summarized as a background of this study. Followed by the interpretation of the RANSAC model, focusing on the mechanism of the algorithm and the implementation process. Three key parameters need to be determined based on the nature of the problem and the authors' subjective judgment, namely, the number of points needed in order to form the candidate objective function (X), the number of iterations (N), and the threshold (t). A case study was performed to show the application of the RANSAC algorithm. Five hundred-forty data records collected by EPCOR Drainage Services were utilized to build the model, leading to a linear function that describes the relationship among CCTV collection time (Time), length of pipe segment (L), and number of taps (T). The results can be used in a simulation model to simulate the CCTV collection process in future research.

Abstract –

The arrival of Building Information Modelling (BIM) platforms to the Architecture, Engineering and Construction (AEC) markets and companies has led to a significant increase in efficiency in this economy sector. However, many AEC companies try to implement BIM as a normal or incremental change or improvement in technology rather than as a technological paradigm shift that radically affects most organizational processes, which may hinder a successful adoption of BIM with a deployment of its full potential. This paper aims to present a basic BIM framework amenable to ensure a successful BIM adoption in public organizations, particularly adapted to the Brazilian federal government. Based on a literature review, we propose to split the factors into three main groups: project development procedures, model development procedures and public governance policies. Some processes were studied in order to infer which of them is necessary for a successful BIM adoption. A BIM implementation is expected to be a success only if all main groups of factors are well defined and the established goals for each of them are reached. We also describe results of two concept proofs related to actual cases of BIM processes implementation, with extensive changes in product and governance management processes. Main results show that any BIM adoption should consider the close relation among model management, product management and governance management groups. All these groups should be contextualized in the environment of any public organization.

Keywords – BIM adoption; Collaborative Design; Building Information Modelling; Public Works.

1 Introduction

The current main paradigm for project process managing is the Building Information Modelling (BIM). It can be defined as a set of associated technologies, processes and policies to produce, communicate and analyse constructive models, enabling the stakeholders to collaboratively design, build and operate a facility [1-2]. It has been successfully implemented around the world, becoming a common practice in many countries and internal markets, whether public or private.

However, while the adoption of BIM is commonly related to significant increases in efficiency, many public organizations are unaware that BIM is primarily a process change that depends on a well-defined action plan to be successfully implemented.

This work aims to develop a management framework for BIM adoption in Brazilian public organizations, which encompasses all main factors that could guarantee an optimized implementation process.

This paper is organized in five sections besides this introduction: Section 2, with a literature review on BIM adoption and all factors related to a successful BIM implementation; Section 3 with the management framework enunciation; Section 4 with the description of two concept proofs in two different public organizations in Brazil; and a conclusion with the main remarks about results.

2 Literature review

2.1 BIM adoption in public organizations

Many countries around the world have adopted BIM. The United States is believed to be one of the pioneering countries for BIM adoption, and several of USA public-sector organizations in different government levels have established BIM programs, set up BIM goals, begun implementation roadmaps and created BIM standards [3].

Apart the USA, many European and Asian countries have been implementing BIM successfully. Noteworthy is the United Kingdom, which published its family of PAS 1192 standards - in revision and transformation processes to international standard ISO 19650 [4;5]. Studies on BIM adoption in public environments can also be highlighted, for example, in Sweden, Finland, Norway and Singapore [6].

BIM has been implemented in Brazilian public

organizations since 2010, when the first state action with public results took place with the development of an initial version of a BIM component library for state program "Minha Casa Minha Vida" [7;9]. Several public and state organizations have been implementing BIM in their project processes; most adopted use cases have been quantification take-off, 4D planning and geometric modeling of civil engineering projects.

Experiences in contracting BIM projects have been developed in southern Brazilian states, with accurate BIM mandates with guidelines for projects to be contracted by the state government. The technical evaluation of the companies' proficiency and the level of development of their projects have been carried out with the analysis of IFC models with automated routines of code checking [7].

In an operational point of view, Brazilian Army has improved real estate management quality by using the Unified System of Works Process (from the Portuguese expression "Sistema Unificado do Processo de Obras", whose acronym is OPUS), a technology information and communication system developed by its Directorate of Civil Works. OPUS is described as an integration of specialized Enterprise Resource Planning (ERP) software with construction building information models, created for supporting built environment lifecycle management including buildings and assets related to AEC [8-9].

2.2 Management factors

One can try to figure out the factors that influence a good BIM adoption in public environments. In this work, these factors will be classified into three groups of actions, described below and illustrated in Figure 1.

- Model management actions, referring to building information models utilization in process management and all related specifications, including the BIM adoption effort in organizations;
- Product management actions, referring to product adequacy to client technical specifications and its compliance with deadlines and costs; design and construction methodologies conducted by related teams are also included in this group;
- Public governance management actions, which submits any and all project effort to auditing rules and all necessary and legal internal and external governance and auditing rules.

2.3 Model management

All tasks on this group refer to the growing influence and impact of BIM in project process, from its implementation in company to supervision of all day-to-day procedures. Building information model (BIModel) turns into the principal database of any architecture or engineering project:

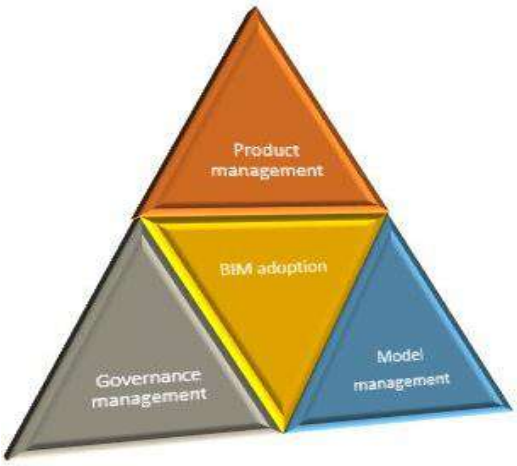

Figure 1. Management groups in BIM adoption

- Employer Information Requirements (EIR), sometimes called "BIM mandate" or "BIM manual": document where the contractor declares what they are after when they ask for BIM [5].
- A BIM Execution Plan (BEP), with an identification of the objectives and the goals of the implementation process in answer to the EIR desired by the organization, as well of the definition of all supporting infrastructure needed. This phase can be split in two parts: one pre-contractual BEP before procurement, containing the project implementation plan, its schedule, all information modelling and collaboration goals, as well the main milestones of the project information design creation; and a post-contractual BEP, beyond pre-contractual BEP, it still encompasses all project management processes description and to all methods and procedures that will be followed, as well as all solutions to be employed in implementation, including software, hardware, cloud and network solutions [5;11].
- A Project Execution Plan (PEP), with all necessary guidelines for good work of professionals. It encompasses all guidelines that make BIM workflow possible: modelling, file linking, work sharing, work sets, interoperability between programs and collaboration among professionals, information exchange. It also regulates all deliverables that would be produced (e.g. quantity take-offs, model templates, model views, annotations, sheets and model standards) [11-12].
- The modelling process itself, that is always related to a cyclic design process with high BIM tool interoperability and broad collaboration among professionals. It encompasses all development process with intense BIModel creation under BEP

and the PEP directives.

Generally, the three first steps described above are developed by consulting companies specialized in BIM implementation. It involves generally a knowledge transfer agreement contract, which may or may not cover the sale of software licenses, modelling software training or in-company support.

The modelling process of all disciplines and the related federated BIModel is always developed by the project team, along with product management and great participation and aid of the team of BIM champions.

2.4 Product management

Product management is related to project development and all stages that form part of it. Under this group task, client's technical demands and needs must be considered for the development of the project. It also includes all the documents that regulate them, such as sustainability analyses, budgeting and scheduling rules, works supervision standards and its compliance with performance, operation and quality organizational standards.

Although there are different definitions and standards for which project phases exist, the phases generally follow a sequence. In England, for example, there are six design phases: brief, concept, definition, design, build and commission, handover and closeout, followed by maintenance and proper use [5].

On the other hand, Brazilian standards divides project effort in a design preparation phase, including feasibility studies, preliminary and specific data collection and location definition; and a technical design development phase, including draft development and construction design itself.

2.5 Governance management

In general, a public organization must always be accountable for its actions and expenditures, so BIM adoption processes must take it into account. In this group are included all effort of the public organization for public hiring processes, personnel admission and accountability principles, guaranteeing compliance to public administration principles.

Unlike the other two groups, governance management activities are not sequential, but all of them interfere the entire project process. A summary of some important governance tasks that ensure a good project development and BIM deployment in given in the following:

- Demand of the organization direction for starting a new project;
- Requirements definition for project development, cost and schedule management;
- Provision of all conditions for project team to develop the project (budget prediction and authorization for bidding);
- Definition of bidding processes for services and public process to select professionals necessary to enable the satisfactory development of the product;
- Monitoring and supervision of project development and the construction model;
- Definition of bidding process for contract award;
- Bidding process itself and contract award;
- Construction contract inspection and follow up;
- Commissioning;
- Handover and close.

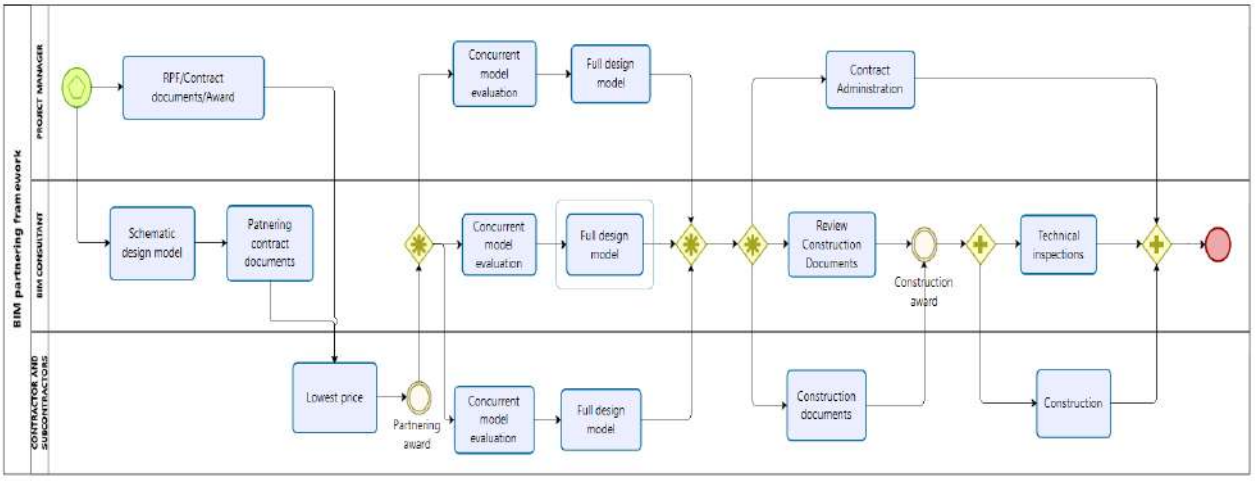

Figure 2. Partnering framework for public construction projects (adapted from [6])

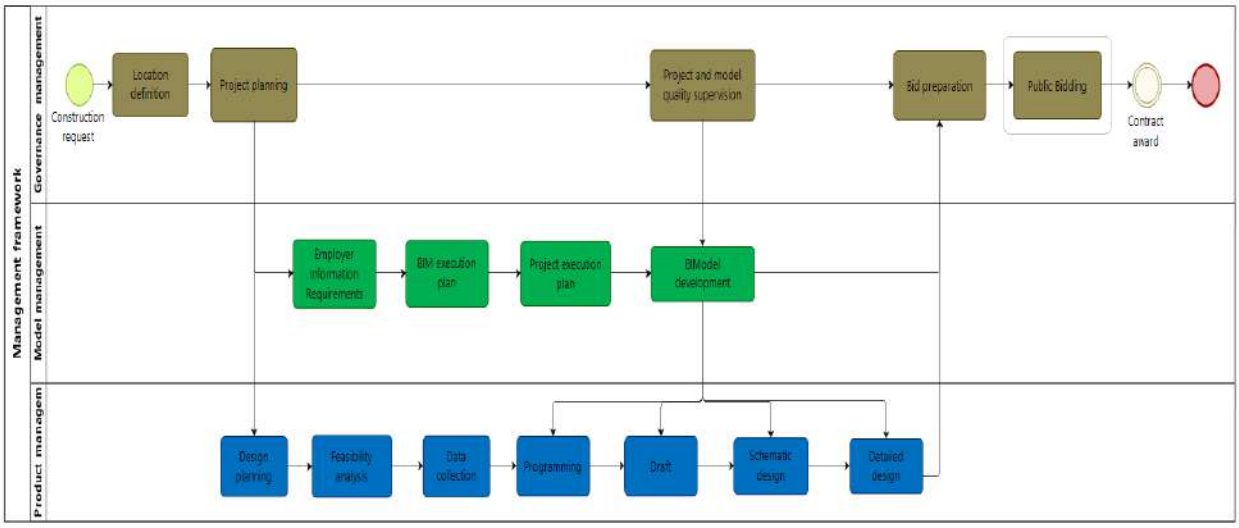

Figure 3. Framework proposition, with all three management groups.

With respect to BIM implementation in public environments, Porwal and Hewage [4] define a BIM partnering framework for public construction projects, in opposition to traditional methods of procurement where design and construction processes are separated.

A broad integration between product management and model management activities is suggested from Figure 2. Unfortunately, in some countries, Brazil included, there is little legal support for non-Design-Bid-Build (DBB) bidding and procurement process, so most BIM public projects, if not all of them, follow DBB pattern.

3 Framework map process

Once all management groups have been described, one must organize them in order to reflect an acceptable sequence for the framework. In its representation in Figure 3, it is assumed that the public institution has not yet implemented BIM or that an unsuccessful implementation has been initiated.

First action was the decision of the authority responsible for construction of the work, followed by site location definition according to feasibility studies of the project.

Next phase, within the governance axis, represented in brown boxes, is project planning. This is an important phase because it directs all of project's upcoming planning efforts. It must provide all conditions for both BIM deployment and project development to occur with minimal disruption, avoiding design rework.

In this way, all efforts to acquire the necessary resources - hardware, software, new network solutions, CDE, contract auxiliary services - topographic and geotechnical surveys, demolition teams, and hire professional and technical personnel must be initiated. All processes must be conducted according to well-defined bidding documents that have undergone prior legal analysis.

Only from this moment, after all contract awards, model and product management have their main actions. Any unplanned service may put design and project development in risk.

Model management efforts, represented in green boxes in Figure 3, are initially defined by the client in the EIR. They are then best developed in the BEP, which describes all implementation efforts and procedures of all work processes, and in the PEP, which encompasses all information regarding to day-to-day work conducted by the professionals since the very beginning of design development.

Product management phases, represented in blue boxes in Figure 3, however, are directly linked to project development, beginning with its planning, following the feasibility analysis, data collection and design programming.

At all stages of model and product management, there must be supervision of engineers, architects, and managers who are able to oversee the developed products - designs, models and their deliverables -, as well as to manage all contracts related to project.

A careful preparation of all tender documentations, where all bid conditions are given, is mandatory for a good public bidding. Any lack of data could make the bidders request for further information, and then, causing delays in tender documentation openings.

At the end of tender preparation, bidding process should be launched, usually on an on-line platform for government acquisitions. Tender process continues until contract award.

4 Concept proofs

Two concept proofs are presented, each one in a distinct public organization responsible for military work projects. Both projects have a profile of defense and public safety, which began to be developed within the framework of two recent BIM deployments.

Each experiment refers to public works projects focused on strategic and control areas that are currently being developed. Organizations are expected to tender both construction by DBB contracting process.

4.1 Concept proof 1 (CP1)

The first experiment is a project that will be built in an area of about 20,000 m^2 with a constructed area on a plot of about 28,000 m^2, from a demand of Organization A, currently considered one of the references in BIM adoption in Brazilian public service. Due to project order of magnitude, a specific BIM adoption became necessary.

Since project beginning, there was a rigid delivery schedule that was accompanied by the project management team and the client, with strict delivery deadlines. Thus, construction is formed by a building with five floors, being them underground, ground and three floors.

Programming studies and draft development were then developed over several meeting cycles, considering all necessary terrain and geotechnical surveys, predicted area for each office based on their organizational requirements and all expected mechanical and electrical equipment needed for the involved complex operation.

Since project initiation, a room was separated for the team, which worked collaboratively on a shared network even with development of the initial drafts in Autodesk AutoCAD.

BIM implementation in project office started to be conceived from this moment to optimize collaborative work within the project process, obtaining all necessary means - personnel and technologies - to guarantee its success, by bidding processes and professional selection processes, always with legal approval of a federal attorney:

- Personnel: personnel selection process were initiated, in which civil engineers, electricians and mechanics as well as architects were hired. A good knowledge in BIM software was mandatory, though most of them had only some prior knowledge;
- Hardware: fixed workstations were acquired in three different biddings, with necessary configuration for collaborative work and the building information model's development.
- Software: through a specific bidding process, new software licenses were acquired to enable model development by all professionals;
- Computer networks: there was no assembly of a new network with support to the high flow of information, dedicated to the project; new computers were connected to the existing administrative network;
- BIM Consultancy: through a bidding process, a BIM consultancy was also contracted, whose mission was the technology transfer as a progressive process of BIM implementation, involving development of a BEP, component library development and all necessary software training and support for adequate design development.

After consultancy contract award, diagnostic meetings between the consultant and office representatives were then held for the development of a BEP. The target was set so that, at the end of the project, the management procedures and all project professionals would evolve from the "pre-BIM" stage to stage 2, when BIM collaboration procedures is totally based in BIModels [1].

BEP contained general guidelines for template and file development, file naming, component material creation, as well as shared parameters creation. Components were then developed at the same time the design was being developed, according to the professionals – engineers and architects – needs.

The first implementation activities had as first case uses to be developed the design authoring, 3D coordination, cost estimation and phase planning, 4 out of the 25 BIM uses described by [12], so that the technical requirements, budget development and schedule planning were directly linked from beginning of the design.

It was from the preliminary phase that the concepts of construction information modeling developed a greater synergy with project management, where a maximum of 14 professionals were involved in model and design development.

Based in BEP, a Common Data Environment (CDE) was created within existing organization network, where all professionals developed their model designs, obeying a previous norm of file and model naming. Because of the organizational security requirements, the use of cloud-based CDE, as well as any cloud communication platforms, has been strictly banned.

Geometric coordinates were shared from the design beginning, either through work sets or through model links to a federated model. For each main discipline in the first-level partition around federated model, a discipline model was created; second-level subdivisions were then linked to each discipline model, as shown in the scheme of Figure 4.

IFC (Industry Foundation Classes) was interoperability standard for communication between suite software and interference detections. However, in cases where software offered few interoperability resources or did not have versions that could be IFC-compatible, DXF file format was then used: DXF drawings were created from design models and then they were read by the applications. BEP predicted these interoperability guidelines.

The collaboration and interoperability procedures made clash detection much easier and more efficient. Compatibilization routines were realized in a daily basis, and clashes were solved as soon as they were discovered. Team communication was done personally in the team room in short reunions all the time or through a message platform where all design decisions and interference resolutions were recorded.

In general, design development expanded from design programming (still with CAD files) to schematic and detailed design completely developed using BIM software. Once design had a minimum maturity, 4D planning and cost estimation, based in Brazilian cost databases, evolved quantity take-offs and specific budgets provided by qualified suppliers.

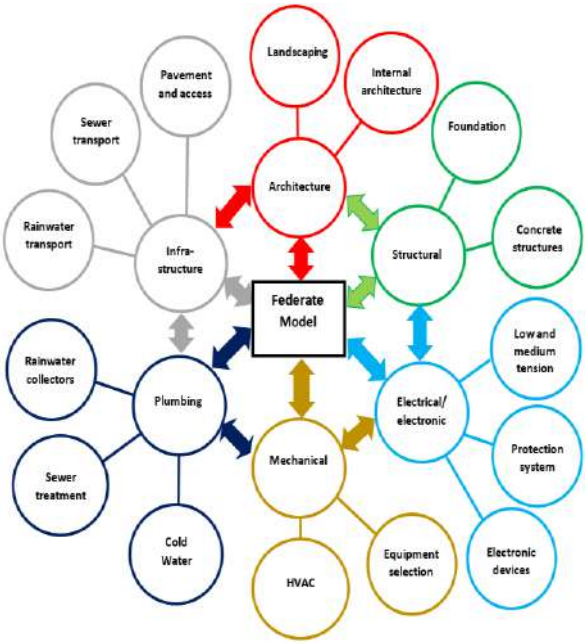

Figure 4. Coordination scheme for CP1

4D planning was carried out initially in MS Project, following a defined process. As quantity take-offs were extracted from all discipline models, predecessors and successors were defined for all tasks for project Gantt chart, for future work progress visualization using Autodesk Navisworks.

Budget development was based in take-offs extracted from discipline models and calculation reports extracted from engineering software. There was no direct interface of BIM authoring tools and the budget development software adopted by the organization. Although budget process was constantly error-prone, an experienced planner revised project budget and schedule all the time.

Currently, detailed design is near to completion. Client seeks from federal agencies the money needed to bid and contract the project.

4.2 Concept proof 2

The second experiment describes BIM implementation in organization B, conducted differently from the first experiment.

In 2016, BIM usage became mandatory for all professionals. Before that, only some professionals have had an interest in applying BIM in their workflow, with initial training in geometrical modelling and information management. These pioneer professionals, called internally “BIM team”, have already used some BIM processes in their workflow in the development of three simple proofs of concepts.

It was then necessary to contract an outsourced consultancy through a specific bidding and procurement process, in order to gain knowledge on BIM processes.

Implementation had as main aim technology the transfer of technology from outsourced consultants to BIM team. At the end of 24 months and three proofs of concept, which involves design, construction and operation of a building, the team would be responsible for disseminating knowledge obtained to all other design teams and professionals in other sections.

The consultants also had another aim: meet all information requirements for a new CDE that would provide interoperability between BIM models, data and related databases. It would play a similar role to construction and operational management that OPUS already plays in Brazilian Army.

Hardware in organization B – workstations in general – is at least three years aged. The last software acquisition was four years ago, when 2015 Autodesk Building Design Suite was installed in all computers.

Professionals working at organization B are generally high skilled, partially because of specific scope of all projects which are developed there. They have been working in organization at least for 10 years.

To meet organization demands, a broader BEP was developed by the consultants, encompassing several use cases related to design, construction and operation. BIM implementation would then last two years from contract award but would also include future tasks for the next eight years.

First concept proof conducted by organization B is currently in progress – an operational update of a 1000 m2 and four floors design, aiming to improve

operational project in order to allow the installation of other specific electronic equipment. At that time, it became necessary to update terrain and geotechnical survey of the construction area; based on new organization needs, new architectural and operational requirements were developed.

Until beginning of BIM implementation, there has not much difference between product development flow from organizations A and B, beginning with programming based in strict organizational needs, preliminary studies, work planning, design and project development, scheduling and budget development in order to start future procurement process.

With BIM implementation, design development has shifted from a sequential process to a matrix collaborative process in which all professionals started to participate. BIM team itself has been developing construction components and architectural and engineering templates for their own use, following BEP with the consultants aid and supervision.

Design process became then under a "development-analysis-discussion meeting-design" revision cycle. Coordination meeting were held at the end of each design phase with participation of the BIM team, their managers and their clients by videoconference. The meetings have been used for solving design decisions, for deciding about project cost estimate (based in preliminary BIM models) and discussing the next steps of the project.

Until now, lack of modern engineering software imposes DXF and proprietary file formats as preferred interoperability standard. On the other hand, all files and models follow a strict organization in network, separated by design phase and design discipline. All models also follow a collaboration scheme, where each team professional is responsible for only one design model, as showed in Figure 5.

Nowadays, although project is still in draft phase, with development of the first discipline models following Figure 5 scheme, information regarding to 4D planning, quantity take-off and operation have been added to federate model. Budget planner has got access to all design models since programming phase, with which he already develops construction site simulations, budget estimates and the first schedule forecasts.

Expectation in the future is to use acquired software suite at full potential, including Dynamo procedures for enhancing it in structural and MEP designs. Only after reaching this milestone, acquisition of more modern architecture and engineering BIM tools would happen, considering in-depth study of consultants team.

What one must have in mind is that the presented framework contains only general procedures. All its procedures must be detailed in depth, considering all organizational culture and public environment constraints involved.

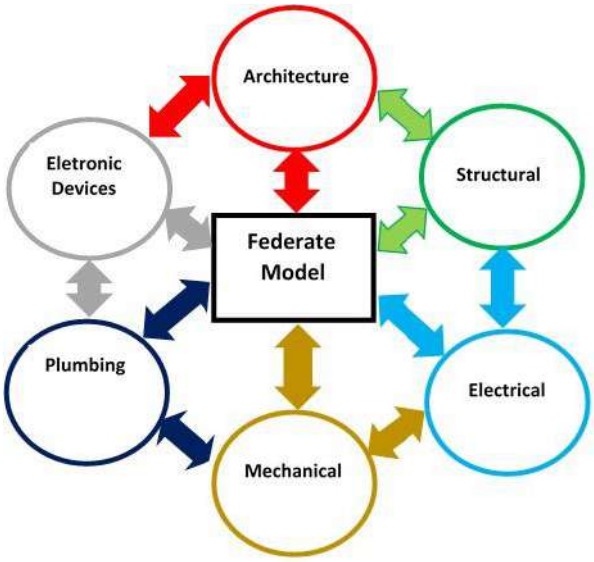

Figure 5. Coordination scheme for CP2

5 Conclusions

The aim of this article was to develop a conceptual structure that would contain all main factors that would guarantee an optimized development of a construction project with the use of BIM.

Conceptual structure can be divided into three groups: model management, product management, and governance management. Each group has a defined sequence: while model and product management follow a strict sequence of processes, governance management includes all public administration processes, without which other two groups cannot be developed.

In general, BIM implementations described in both CP followed the framework described in Figure 3. Public administration processes permeate all product and model processes.

In summary, three described groups constitute parts of a suggested tri-axial conceptual structure where each axis has a deep relationship with each other, so that a harm of one of the axes compromises project management in some way.

One can remark that BIM has already been adopted in both organizations A and B. However, it was totally based in software acquisition and basic training, not considering characteristics of product and management organization processes.

Any BIM implementation should then consider the "tri-axial relationship" among model management group, product management group and governance management group, so that each group procedure be contextualized to the public and organizational

environment.

Abstract –

Detection of design changes is essential for collaboration and version management in the design process of buildings. However, current detection methods based on Building Information Modeling (BIM) usually cause unreliable or meaningless results. This is because most of the current researches look at the question from a data change view, which sometimes is meaningless from a designer's view. To overcome this problem, this paper first classifies and identifies meaningful design changes from a designer's view, and develops exemplary BIM models of typical design changes. In this paper, categories of data changes are divided into property data, appearance data and relationship data, and design changes are classified into instance level, type level and model level from a designer's view. The test of two BIM tools (Autodesk BIM360 and IFCdiff) with developed BIM models shows that the detection results for changes at instance level are perfect while detection results for type and model level still need to be further improved. This work contributes a new view and classification method of design changes, and also sets up a baseline model database for further development and validation of relevant methods and tools.

Design Changes; Classification; Building Information Modeling (BIM); Exemplary Model Database; Validation

1 Introduction

The design process of Architecture, Engineering and Construction (AEC) is complex. It includes a lot of iterative work and involves multidisciplinary design work that can be done sequentially, concurrently or in parallel [1] .Changes of a project are inevitable, which can occur from multi-source in any time, and have extensive impact [2]. Accordingly, ensuring the accuracy and consistency of data after sharing and emerging is significant, which raises the requirement of detection of design changes. Building Information Modeling (BIM) is widely used for building lifecycle management. However, current methods for design change detection of BIM models are still not perfect.

Generally, current methods are mainly based on comparing all properties of each instance in BIM models one by one, which is not always meaningful for designers. For example, exchanging the location of two columns that have the same properties should not be detected as a design change in spite of changes of location. To contribute to the development and validation of detection, this paper classifies and identifies meaningful design changes from a designer's view, and develops exemplary BIM models of typical design changes.

This paper is structured as follows. Section 2 reviews the related works and analyses some existing detection methods. Section 3 lists all possible design changes by classifying it by different categories and levels. Section 4 uses exemplary BIM models developed to test some BIM tools and summarizes their results. Finally, section 5 concludes this paper's contribution.

2 Literature Review

Design changes in the BIM model has been extensively studied by researchers. These research works included the management of design changes by versioning Industry Foundation Classes (IFC) models [3] or IFC extension [4], improving design coordination [5], quantifying the design change time ripple effect [6], and assessing impacts of construction change orders [7]. Even though these researches made design changes to be managed and evaluated more effectively, few works focused on the definition and classification of meaningful design changes from a designer's view.

The most common method used for detecting design changes between two BIM models is based on the ID (e.g. GlobalId in IFC file or ElementId in Autodesk Revit) and comparing all properties between two instances, which is adopted in the above references and most commercial BIM platforms such as Autodesk Revit, Navisworks, etc..

However, ID is unstable sometimes, which will lead to wrong and unnecessary detection results. Meanwhile, its detection results are not always meaningful. For example, exchanging the location of two same columns will be detected as a change by this method, but that is a meaningless change for designers actually.

Daum, S. and A. Borrmann [8] proposed an approach for detecting equivalences in datasets of the Industry Foundation Classes (IFC), which based on a geometrical matching and semantic comparison method. This approach is independent of ID, which means the detection can be completed even IDs are not reliable. Nevertheless, meaningless results will still be detected by this method.

Shi, X., et al. [9] proposed a content-based automatic comparison approach for IFC files. This approach will construct a hierarchical structure for both files and then use an iterative bottom-up procedure to compare them. However, the test results of detecting changes in some cases such as exchanging location of two same columns and deleting and recreating a same beam are still not perfect.

In summary, most of the current methods only look at the problem from a data change view, while ignore the designers' view. To overcome this problem, the design changes should be carefully reviewed and classified.

3 Classification of Design Changes

As an open BIM model data representation standard, IFC defines an express based entity-relationship model consisting of several hundred entities organized into an object-based inheritance hierarchy [10]. And in Autodesk Revit, the data in a document consists primarily of a collection of elements [11], where each element has many properties. It can be seen that BIM models can be described by instances (objects), which consist of many properties.

Design change detection is usually between an old and a new files (documents). Previously, design changes can be divided into 3 change types from a data change view as follows.

- Added. An instance is created in the new file.
- Deleted. An instance is deleted in the old file.
- Modified. An instance exists in both old and new file but its properties has been changed.

However, it is not enough to simply classify design changes as the above three types. Because that may lead to meaningless results and the results can be further optimized. To address this issue while ensuring all the changes can be properly identified from a data change view, this paper firstly divides data changes of BIM into three categories, namely, property data, appearance data and relationship data. Then, all possible design changes are classified into three levels, instance level, type level, and model level respectively from a designer's view.

3.1 Categories of Data Changes

The data changes of BIM can be divided into three categories as follows.

- Property data: represents instances' properties, such as parameters or other user specified attributes.
- Appearance data: represents instances' 3D appearance, such as the geometry and location.
- Relationship data: represents the relationship between two instances, such as the relationship that a wall hosts a door.

As for property data, the possible changes are:

1. Added. Add a new property of an instance.
2. Deleted. Delete an existing property of an instance.
3. Value Modified. Modify a property's value.
4. Name Modified. Modify a property's name.
5. Order Changed. Change the order of some properties of an instance.

As for appearance data, the possible changes are:

1. Added. Add a new geometry of an instance.
2. Deleted. Delete an existing geometry of an instance.
3. Geometry Modified. Modify a geometric shape of an instance.
4. Transformation Modified. Modify a transformation property of an instance. Such as scaling, translation and rotation.
5. Representation Method Modified. Change the way of representation of a geometry. Such as converting a solid model to a surface model.

As for the relationship data (assuming that the order of relationships is meaningless), the possible changes are:

1. Added. Add a new relationship between two instances.
2. Deleted. Delete an existing relationship between two instances.
3. Instance Modified. Modify property data of a relationship instance.
4. Relationship Modified. Modify a relationship between two instances, e.g. change the relationship between A and B to A and C.

3.2 Levels of Design Changes

The possible data changes given above should be identified as least at the instance level. Thus, adding and deleting properties of an instance should be identified as changing an instance, so as modifying some properties of an instance (Left part of Figure 1). However, for meaningful and optimal identification results, the

perspectives of type level and model level are required.

From the perspective of type level, the changing of instances may be caused by changing of a type (or family type in Revit) of the instances. For example, the geometric changes of multiple instances caused by changing the geometry of the type that all the instances inherit from should be correctly detected (Middle part of Figure 1), which can reduce the detection results and make the results more meaningful.

From the perspective of model level, data changes or modification of instances may be meaningless sometimes. For example, exchanging the location of two same columns should not be identified as a change, so as deleting a beam and recreating a same one (Right part of Figure 1). Besides, modification of the elevation of a Level may result in a large number of changes in related instances. So identifying the source of the change is better than just detecting the changed related instances, and that will contribute to more meaningful results. Changes from the perspective of these three levels are illustrated in Figure 1.

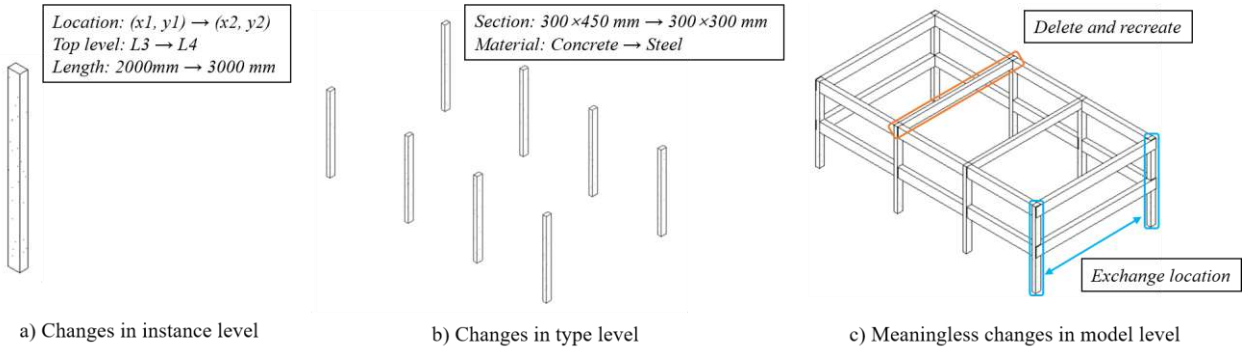

Figure 1. Design changes from perspective of instance level, type level and model level

4 Exemplary Models and Case Study

4.1 Exemplary BIM Models

Since there is no public available database for testing and verifying current design change detection methods, this research develops 11 simple BIM models according to the changes described in section 3. In these changes, added or deleted in all types of data are combined to facilitate test. And the order change of property data and representation method change of appearance data are ignored in this paper. Meanwhile, type level design changes and meaningless design changes at model level are also embedded in the developed BIM models. Detailed information of these models are shown in Table 1, and their screenshots are shown in Figure 2.

Table 1. The detailed information of exemplary BIM models

Model Name	Category of Data change [a]	Level of Design Change	Description of Changes	Meaningful [b]
M1	-	-	The origin model	-
M1_All-A	Added in P, A and R	Instance	Add 2 beams and 2 columns (new category)	O
M1_All-D	Deleted in P, A and R	Instance	Delete 2 beams and 4 columns	O
M1_All-DA(M)	Deleted and then added in P, A and R	Model	Delete 2 beams and 4 columns and recreate them	X
M1_A-MG	Geometry modified in A	Instance	Modify the sectional dimensions of 2 beams	O
M1_A-MG(T)	Geometry modified in A	Type	Modify the section of family of a beam from 400×800 to 800×400	O
M1_A-ML	Location modified in A	Instance	Modify the location of 4 columns and 2 beams	O
M1_A-ML(M)	Location modified in A	Model	Exchange the location of 2 pairs of columns and 1 pair of beams	X
M1_P-MV	Value modified in P	Instance	Modify a parameter (COMMENTS) in a beam	O
M1_R-MI(M)	Instance modified in R	Model	Modify the elevation of a level (Level3)	O
M1_R-MR	Relationship modified in R	Instance	Modify the top level of 4 columns	O

[a] P, A, R means property data, appearance data, relationship data respectively.
[b] O and X means the change is meaningful and meaningless respectively.

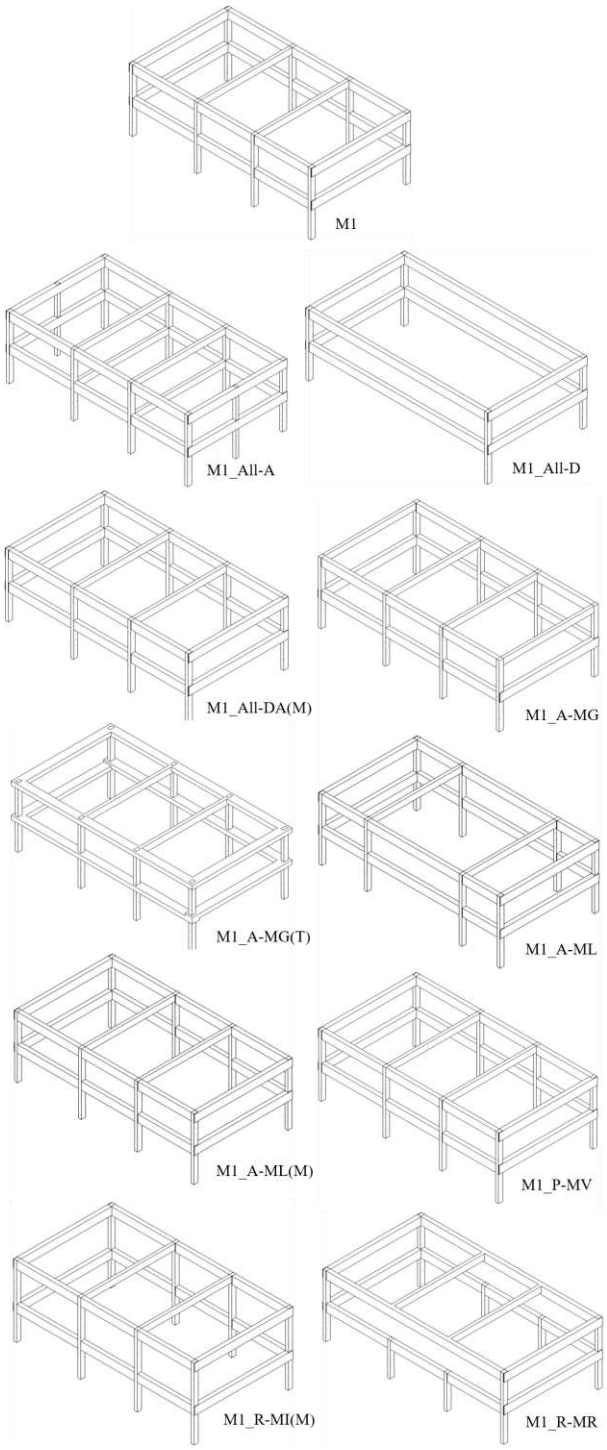

Figure 2. Exemplary BIM models

It is apparently that the model named M1 has 8 columns and 10 beams, and the changes from M1 to any other model can be used as a test case for design change detection methods. A repository contains these exemplary BIM models and their detailed description are established on GitHub. Each model has a .rvt and .ifc file (the contents of the files in these two different formats are the same). The link address is: https://github.com/smartaec/Design-Change-BIM-Models.

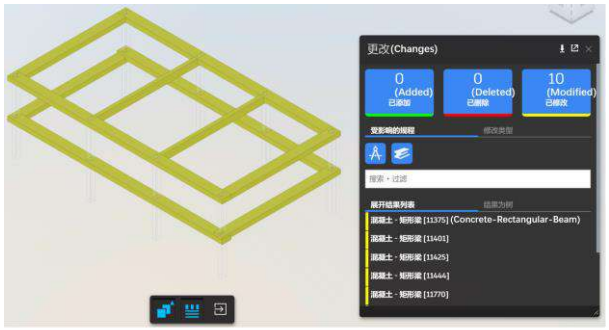
4.2 Test of Related Systems

This paper selects Autodesk BIM360 and the IFCdiff [9] to verify their accuracy of detection (according to the file format they support, BIM360 uses the .rvt files while the IFCdiff uses the corresponding .ifc files).

The ideal test results are all changes at instance level are detected. Meanwhile, for changes at type level, the source of changes should be detected instead of the direct results. And for changes at model level, the results should be that nothing has changed because changes in these cases are meaningless.

4.2.1 Test Result of Autodesk BIM360

BIM360 has the correct results for all test cases of changes at instance level, but its results for type and model level are incorrect. The screenshots of detection results in M1_A-MG(T) and M1_All-DA(M) using BIM360 are shown in Figure 3.



a) M1_A-MG(T)

b) M1_All-DA(M)

Figure 3. The detection result of M1_A-MG(T) and M1_All-DA(M) by BIM360.

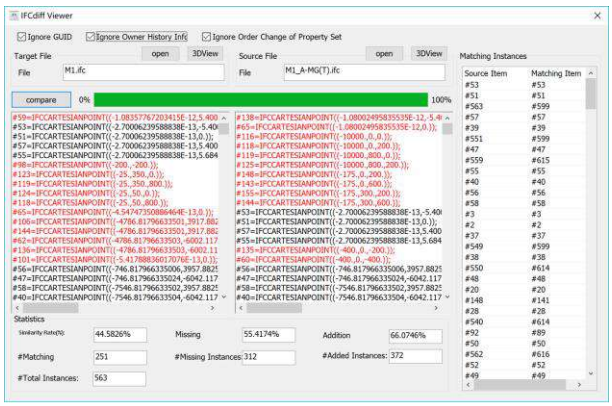
In Figure 3 a), 10 modified changes are detected. 8 beams of them are changed in section size while other 2

beams are changed in volume because of the affect in geometry of joint. Actually, the only change is the change of the section dimension of a family of beam from 400×800 to 800×400 mm, which is a change at type level. However, BIM360 detected the changes of the affected 8 beams but doesn't identified that the family of these beams has changed. So, BIM360 is not as good as we expected.

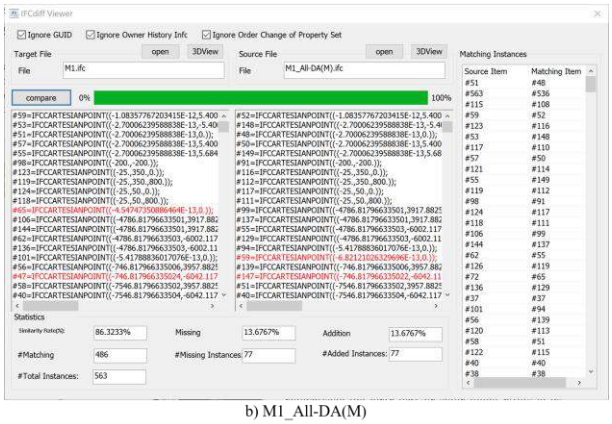
In Figure 3 b), 6 added and 6 deleted changes are detected. The actual operations in this model are delete 6 components and recreate 6 same one. And the ground truth from a designer's view is that nothing has changed since these changes are meaningless. So, BIM360 cannot handle the model level changes properly now.

4.2.2 Test Result of IFCdiff

Similar to BIM360, IFCdiff has correct results for all test cases of changes at instance level and incorrect results for type level. But for changes at model level, its results are better than BIM360. The screenshots of detection results in M1_A-MG(T) and M1_All-DA(M) using IFCdiff are shown in Figure 4 (the output of IFCdiff is text).



a) M1_A-MG(T)



b) M1_All-DA(M)

Figure 4. The detection result of M1_A-MG(T) and M1_All-DA(M) by IFCdiff.

In IFCdiff, the similarity rate (%) is defined as the rate of the number of identical instances between File A (the target file) and File B (the source file) divided by the total number of instances in File A (both files have been removed redundant instances), i.e.

$$\text{Similarity}(A,B)(\%) = \frac{|A \cap B|}{|A|}.$$

In Figure 4 a), File A (i.e. M1) has 563 instances and File B (i.e. M1_A-MG(T)) has 623 (251+372) instances. The number of matching, missing and addition are 251, 312 and 372 respectively. From the result of BIM360, 10 of 18 components have been changed, about 44.44% (8/18) of the components have not changed. So, the similarity rate 44.58% given by IFCdiff is reasonable. But it also cannot identified that the family of these beams has changed from the perspective of the type level. Therefore, IFCdiff cannot handle type level changes properly.

In Figure 4 b), the similarity rate is 86.3% and the added and deleted rates are both 13.6%. In contrast, the test result of BIM360 is 6 added and 6 deleted. It can be inferred that the added or deleted rate is about 33.3% (6/18) detected by BIM360. Thus, the result of IFCdiff is a bit better than BIM360 but still not perfect.

In the authors' opinion, the reason why test result of IFCdiff is better than BIM360 in the latter case is IFCdiff can ignore changes of GlobalId, Owner History, etc. when comparing two instances. In the latter case, the deleting and recreating same instances are equivalent to updating their ID, so IFCdiff will detect less changes. But for the former test case, there is no essential difference between IFCdiff and BIM360 when detecting changes at type level, so neither can give a perfect result.

4.3 Summary of Test Results

According to the results of the case study and analysis, Table 2 summarizes the correctness of the two tools.

Table 2. The detection results of BIM360 and IFCdiff using developed exemplary models

Model Name	BIM360	IFCdiff
M1_All-A	O	O
M1_All-D	O	O
M1_All-DA(M)	X	*
M1_A-MG	O	O
M1_A-MG(T)	X	X
M1_A-ML	O	O
M1_A-ML(M)	X	*
M1_P-MV	O	O
M1_R-MI(M)	X	X
M1_R-MR	O	O

○ means the result is correct (only this means passed the test).
X means the result is not completely correct.
⋆ means the result is not completely correct but better than X.

It can be seen from the Table 2 that both BIM360 and IFCdiff can passed tests when detecting changes at instance level but cannot deal with type and model level changes now. Meanwhile, the detection results of IFCdiff for changes at model level are better than BIM360, since IFCdiff will get fewer changed results when detecting meaningless changes.

5 Conclusion

This paper proposes a new view and classification method of design changes, and also sets up a baseline model database for further development and validation of relevant methods and tools. Three categories of data changes (property data, appearance data and relationship data) and 3 levels of design changes (instance level, type level and model level) are considered, and corresponding exemplary BIM models are developed. Then, this paper selects Autodesk BIM360 and IFCdiff to verify their accuracy of design change detection. The results show that both BIM360 and IFCdiff can detect changes at instance level well but cannot handle type and model level changes properly.

This work reveals current problems in design change detection and introduces new method on classification of design changes. Meanwhile, this paper first sets up an exemplary BIM model database of design changes, which can be used as baseline data for the validation of future methods and tools for design change detection.

Abstract –

Adaptive reuse has the potential to maximize the residual utility and value of existing assets through green design methods such as selective disassembly planning. Studies in the field of selective disassembly for adaptive reuse of buildings are scarce and there is no evidence of established methodologies and/or analysis for the optimization of the environmental and financial benefits. In this paper we provide a framework for the multi-objective analysis to obtain several effective selective disassembly plans through the combination of different deconstruction methods. The analysis is delineated in terms of the physical, environmental, and economic constraints of the deconstruction methods per building component. Then, a weighted multi-objective optimization analysis is incorporated to generate the set of noninferior solutions that minimizes environmental impacts and building cost. For adaptive reuse of buildings, the methods described in this study can be used to improve the project outcomes according to specific goals and constraints (e.g. environmental, economic, technical).

Keywords –

multi-objective optimization, selective disassembly, adaptive reuse, Circular Economy, green design.

1 Introduction

Adaptive reuse of buildings plays a key role in the transition from a resource-based economy and towards a Circular Economy (CE) in the construction industry. Adaptive reuse has the potential to maximize the residual utility and value of existing assets by "giving them new life" through green design methods, such as selective disassembly planning. Adaptive reuse is considered a disruptive practice in the current capital project delivery model for the renewal of today's built environment [1,2]. Therefore, the field of green design methods for buildings is still underdeveloped in comparison to other industries such as automotive, textile, and manufacturing. In particular, the studies in the field of selective disassembly for adaptive reuse of buildings are scarce and, to the knowledge of the authors, there is no evidence of established methodologies and/or analyses for the optimization of environmental and financial benefits. The aim of this study is to develop the framework for a multi-objective optimization analysis for the selective disassembly planning of an existing asset through the combination of different deconstruction methods. The analysis is carried out in terms of the physical, environmental, and economic constraints of the deconstruction methods per building component. The Sequential Disassembly Planning for Buildings (SDPB) method, presented in previous studies [3,4], is used in order to generate the optimized disassembly plans for retrieving single or multiple targeted components. The SDPB method is extended with the purpose of including more than one deconstruction method per component. Finally, a weighted multi-objective optimization analysis is incorporated to generate the set of noninferior solutions that minimizes environmental impacts and building costs.

The study shows that different complete disassembly plans exist for all the possible combinations. The possible combinations are driven by the deconstruction methods per component, as well as the dismantling interdependence. For adaptive reuse of buildings, the proposed study can be used to improve the project outcomes according to specific goals and constraints (e.g. environmental, economic, technical). The implementation of this approach could improve the decision-making process for adaptive reuse building projects by adding comprehensive quantitative analysis towards resource optimization. This study provides a better understanding of the management of the multiple variables involved in the process of selective disassembly for adaptive reuse in order to improve the project performance.

2 Background

Over the last two decades, environmental concerns have driven the research of construction projects' life cycle performance towards a holistic approach to

sustainability [5-8]. In this matter, several studies have recognized the importance of the End of Life (EoL) stage in existing buildings, and the opportunity of their adaptive reuse as a superior alternative in terms of CE [3,9,10]. However, for the capital project delivery in a CE framework, there is a lack of science-based, user-friendly, and generic methods to: 1) improve adaptive reuse project outcomes, 2) develop appropriate planning for closed-loop cycle construction, and 3) plan for the optimization of the benefits of adaptive reuse.

2.1 Green Design Methods for Adaptive Reuse of Buildings

In previous work, the important role of green design methods and deconstruction planning methods in the adaptive reuse process of buildings has been discussed [3]. Green design methods are intended to reduce environmental cost and increase economic benefits over the entire product or service lifecycle [11]. Examples of green design methods are design for assembly, supply chain management, Product Recovery Management (PRM), Life Cycle Assessment (LCA), design for disassembly, design for remanufacture, and disassembly sequence planning.

In the field of design for disassembly and deconstruction for buildings, improvements can be achieved by considering future disassembly of building elements at the planning stage of new buildings [12]. Studies have investigated the optimization of the economic performance of the deconstruction and recovery processes of EoL buildings by using mixed-integer and binary linear programming [13,14]. Despite the advances in the area of building deconstruction planning, only a few studies have developed deconstruction planning methods for the adaptive reuse of existing assets. Sanchez and Haas [3] developed the first-in-its-class selective disassembly sequence planning method for adaptive reuse of buildings. The method seeks to minimize environmental impact and cost of the selective disassembly of building components to retrieve, based upon physical, environmental, and economic constraints. As an extension of this work, Sanchez, Rausch, and Haas [4] developed a multiple-target sequential disassembly planning model for buildings, as well as a novel approach for deconstruction programming for adaptive reuse of buildings.

2.2 Multi-objective Optimization Analysis for Selective Disassembly

According to Revelle & Whitlach [15], the goal of multi-objective optimization analysis is to quantify the degree of conflict among objectives. The conflict between objectives originates when a strategy that is optimal with respect to one objective may be nonoptimal for another. Therefore, the concept of optimality may be inappropriate for a multi-objective analysis. Instead of searching for an optimal or the best overall solution, the goal of a multi-objective analysis is to define the set of solutions for which no other better solutions exist for the objectives of interest. This set of solutions is well known with the name of noninferior solutions or Pareto frontier. An important characteristic when dealing with a multi-objective analysis is that each objective is measured in different units. In other words, the units are incommensurable. At the end of the analysis, the decision makers have the responsibility of choosing the appropriate solution from the set of noninferior solutions.

The multi-objective optimization analysis for this study deals with managing environmental and economic resources in the process of selective dismantling of an existing asset. We might seek to evaluate environmental quality and economic efficiency trade-offs along the deconstruction process. For this study, one of the objective functions seeks to minimize the amount of environmental impacts due to the discarded parts during the selective dismantling process of a building, that might involve the total or partial disassembly of multiple buildings' subsystems. Depending on the approach of the overall analysis, the user can select a specific environmental impact of interest, such as Global Warming Potential (GWP), Primary Energy Demand (PED), and Water Consumption (WC). The second objective function seeks to minimize the overall cost of deconstruction works. The conflict or trade-off between the mentioned objectives is found in the incommensurable differences between the environmental value and removal cost of different selective disassembly plans for components.

2.3 The Knowledge Gap

The field for improving the inefficiencies inside the process of adaptive reuse of buildings through the implementation of green design methods, such as selective disassembly planning and PRM, is still underdeveloped in comparison to other industries (e.g. automotive, textile, and manufacturing). The purpose of this study is to describe a methodology for optimizing the environmental and financial performance of the selective disassembly planning process for adaptive reuse of buildings. A multi-objective optimization analysis is key to finding several effective selective disassembly plans for the adaptive reuse of an existing asset through the combination of different deconstruction methods.

3 Methodology

The proposed methodology for a multiple objective optimization analysis is incorporated into the framework of selective deconstruction project planning by using

BIM-based phase planning presented in a previous work [4]. First, the Sequential Disassembly Planning for Buildings (SDPB) method is used to generate the optimized disassembly plans for retrieving single or multiple target components from a given building's assembly, and according to the adaptive reuse design. The SDPB method optimizes disassembly plans in terms of the physical, environmental, and economic constraints per building component and by using just one deconstruction method per building component, which is "selective disassembly". Once the disassembly plans are ready, more deconstruction methods per component are included in the next stage of the analysis. The other deconstruction methods included are "selective demolition" and "perfect disassembly". At the end, a weighted multi-objective optimization analysis is implemented to generate the set of noninferior solutions that minimizes a specific environmental impact and the building cost (see Figure 1). After finding the set of noninferior solutions for a given disassembly plan, the decision makers can select the alternative that is more aligned to the objectives of the overall project and they can continue with the next stages of the deconstruction planning, in order to estimate the final cost and total duration. As shown on Figure 1, this becomes an iterative process whereby if the project needs are not fulfilled, the adaptive reuse design should be changed by the designers.

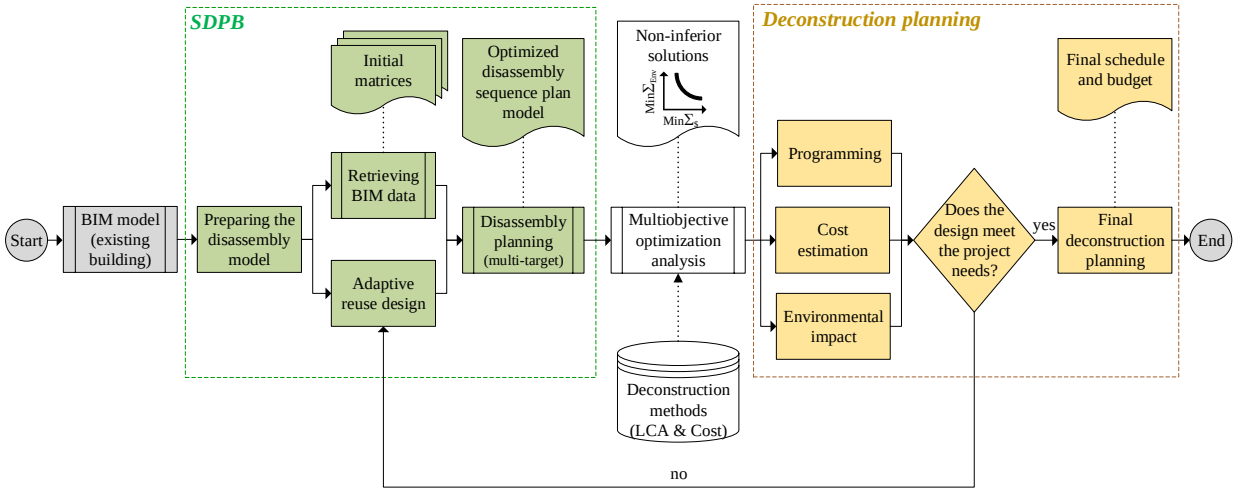

Figure 1. Multiple objective optimization analysis for selective deconstruction project planning

3.1 The Disassembly Sequence Plan Model for Adaptive Reuse of Buildings

This study is built on previous works related to selective disassembly planning for adaptive reuse [3,4]. First, the authors developed the SDPB single-target disassembly sequence plan model which is an inverted tree that contains a minimum set of parts that must be removed before retrieving a target component. A part *p*, in this case, can be a component *c* (building component) or a fastener *f* (building connection). Root nodes in the inverted tree represent target components, leaf nodes represent parts that constrain the target components, and the links between them represent constraints. A constraint can be physical, or functional. The SDPB method for creating a single-target selective disassembly model for buildings gets parts from the Disassembly Graph (DG) model, arranges and orders the parts in levels, and adds the parts to the inverted tree [3,16]. Finally, the approach uses expert rules to improve solution quality, minimize graph complexity, and reduce searching time for finding optimized disassembly sequence plans [3,11,16]. In a subsequent study, the authors extended the SDPB method to multiple-target selective disassembly of building components, and also provide the programming of deconstruction works.

Figure 2 shows as an example the multi-target SDPB for a building assembly subset which was part of an adaptive reuse project of the "Engineering 2" (E2) building at the University of Waterloo campus. Figure 2 shows the 57-part assembly model under study. The SDPB method creates optimized single-target disassembly sequences for the targeted components c_7 and c_{13}. For Figure 2, the best direction for removing components c_7 and c_{13} is $+x$ direction. Figure 2 also shows a multiple-target disassembly plan (inverted tree) for components c_7 and c_{13}. For the disassembly plan in Figure 2, n_t are the number of targeted components; and n_c, n_f, and n_p are the number of components, fasteners, and parts in the disassembly plan, respectively.

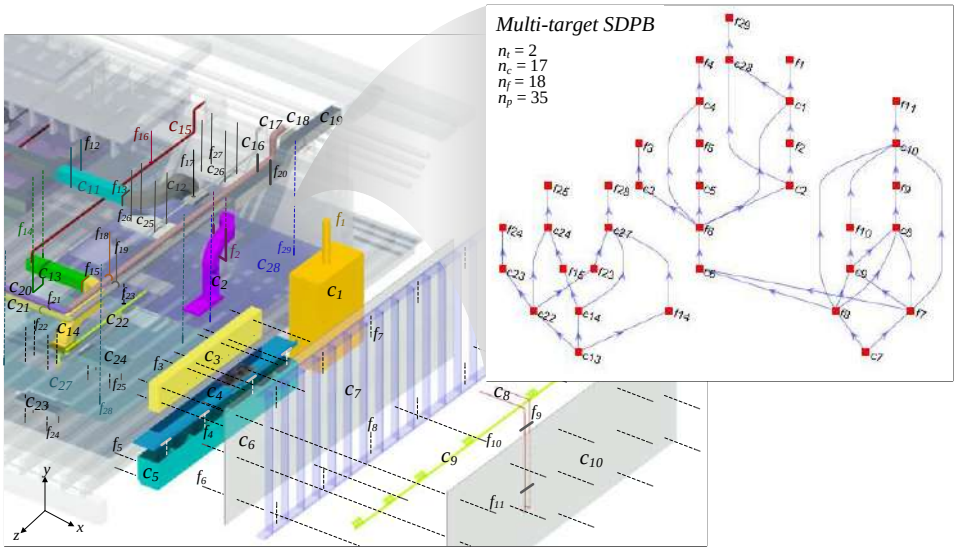

Figure 2. Automated generation of the multiple-target SDPB for components c_7 and c_{13}

3.2 Deconstruction Methods per Building Component

For the proposed approach in this study, it was necessary to estimate the environmental and economic information related to the deconstruction methods included for the multi-objective optimization analysis. The environmental data for building components includes the LCA of selected environmental impacts for each component j ($j=1,\ldots,J$) meant to be part of the same assembly. The LCA system boundaries and limitations were determined according to the most common current practices for buildings and in accordance with a full cradle-to-grave life cycle analysis as in previous studies [3]. The Environmental Impacts EI^a, *where* $a \in A$, were: 1) Global Warming Potential (GWP) in kilograms of carbon dioxide equivalent (kg CO_2 eq) and 2) Primary Energy Demand (PED) in Mega Joules (MJ). The phases included in the LCA were production stage, construction stage, and End-of-Life (EoL). According to Schultmann & Sunke [17] the operational stage of an LCA cannot be assigned to a building component or material separately. Fortunately, the sustainability of disassembly plans should theoretically not differ based on the building use phase, assuming they support the same functions. Three different deconstruction methods m ($m=1,\ldots,M_j$) were analysed for the EoL stage per building component: 1) selective demolition, 2) destructive disassembly, and 3) perfect disassembly. Therefore, the LCA, LCA_{jm}^{a}, of a specified environmental impact a of a building component j in deconstruction method m is calculated according to Equations (1)-(3).

$$LCA_{jm}^{a} = EI_{jm}^{a,production} + EI_{j}^{a,construction} + EI_{jm}^{a,EoL} \quad (1)$$

$$EI_{jm}^{a,production} = EI_{jm}^{a,raw\ materials\ supply} + EI_{j}^{a,transport} + EI_{jm}^{a,manufacturing} \quad (2)$$

$$EI_{j}^{a,construction} = EI_{j}^{a,transport} + EI_{j}^{a,installation\ process} \quad (3)$$

Selective demolition is defined in this methodology as being synonymous with the destruction of components and connections. The EoL treatment for selective demolition is based on average US construction and demolition waste treatment methods and rates, including an avoided burden approach for recycling processes, credit for average energy recovery rates on materials' incineration, and impacts associated with landfilling of materials [18]. The LCA for selective demolition was calculated per component using the commercial 6D BIM software Revit® and Tally®.

Destructive disassembly is defined in this methodology as the disassembly of components and connections in a manner which preserves their physical integrity. As a simplification for the LCA of destructive disassembly, the results of selective demolition were used with a reduction of 80% of the production stage for raw materials supply and manufacturing, assuming that disassembled components could be reused with only minor refurbishments being made [19].

For estimating the LCA for destructive disassembly, the avoided environmental burden of the recycling processing was neglected from the selective demolition LCA calculations since destructive disassembly does not presume the recycling of the recovered components. Perfect disassembly in this approach is defined as the disassembly of building parts with extreme care in order to warrant their direct reuse (i.e., complete physical and

functional utility). The LCA for perfect disassembly assumes 100% reduction of the production stage for raw materials supply and manufacturing from the selective demolition LCA. These simplifications were made to accelerate the process of calculating LCA per building component and also due to technical limitations of the LCA software Tally® employed in this research. Further investigations are required in order to make these calculations more accurate and representative. Therefore, the environmental impact EI^a of the LCA production stage for a building component j with an associated deconstruction method m (m=*selective demolition*, *destructive disassembly*, *perfect disassembly*) is calculated according to Equations (4)-(6):

$$EI_{j,sel.demolition}^{a,production} = EI_{j,sel.demolition}^{a,raw\ materials\ supply} + EI_{j}^{a,transport} + EI_{j,sel.demolition}^{a,manufacturing} \quad (4)$$

$$EI_{j,destruct.disassembly}^{a,production} = EI_{j,destruct.disassembly}^{a,raw\ materials\ supply} + EI_{j}^{a,transport} + EI_{j,destruct.disassembly}^{a,manufacturing} \quad (5)$$

$$EI_{j,perfect\ disassembly}^{a,production} = EI_{j}^{a,transport} \quad (6)$$

Where:

$$EI_{j,destruct.disassembly}^{a,raw\ materials\ supply} = \left(EI_{j,sel.demolition}^{a,raw\ materials\ supply}\right)0.2 \quad (7)$$

$$EI_{j,destruct.disassembly}^{a,manufacturing} = \left(EI_{j,sel.demolition}^{a,manufacturing}\right)0.2 \quad (8)$$

Similarly, the environmental impact EI^a of the LCA EoL stage is calculated according to Equations (9)-(11):

$$EI_{sel.demolition}^{a,EoL} = EI^{a,demolition} + EI^{a,transport} + EI^{a,waste\ processing} + EI^{a,disposal} + EI^{a,recovery\ \&\ recycling\ potential} \quad (9)$$

$$EI_{destruct.dissasembly}^{a,EoL} = EI^{a,deconstruction} + EI^{a,transport} \quad (10)$$

$$EI_{perfect\ \ dissasembly}^{a,EoL} = EI^{a,deconstruction} + EI^{a,transport} \quad (11)$$

The economic data for building components j' includes the information related to the budgeting (bare cost) C associated with the three deconstruction methods m described above. The cost information for destructive disassembly was retrieved from the national database RSMeans®. The data recovered from this database is considered representative for the scope of this study (i.e., the building market in North America). Nevertheless, further investigations should be done in order to adjust the fluctuations of the suggested prices due to particularities of the local economies of the building location. Even though RSMeans® contains the prices for a wide variety of construction activities, in the matter of deconstruction activities such as selective deconstruction, selective demolition, and building refurbishment, the estimations are limited to only a few options according to the most common trends in the construction industry. RSMeans® was therefore used for estimating the building cost for the destructive disassembly per building component, and adjustment factors of 0.65 and 1.35 for estimating the selective demolition and the perfect disassembly costs, were used respectively. This is just a rough approximation of the cost variation between conventional demolition and deconstruction/disassembly of building components [20]. The cost estimations in this study do not include salvaged material resale value for simplification purposes. As part of future research, the assumptions used for estimating the LCA and deconstruction cost should be refined. Therefore, the cost C associated with each deconstruction method m for a building component j is defined as:

$$C_{j,m} = c_{j,m}^{materials} + c_{j,m}^{labor} + c_{j,m}^{equipment} \quad (12)$$

The developed form of Equation (12) for the deconstruction methods m are:

$$C_{j,destruct.disassembly} = c_{j,destruct.disassembly}^{materials} + c_{j,destruct.disassembly}^{labor} + c_{j,destruct.disassembly}^{equipment} \quad (13)$$

$$C_{j,sel.demolition} = \left(C_{j,destruct.disassembly}\right)0.65 \quad (14)$$

$$C_{j,perfect\ disassembly} = \left(C_{j,destruct.disassembly}\right)1.35 \quad (15)$$

3.3 Multi-objective Optimization Analysis for Selective Disassembly

Several methodologies have been devised to portray a multi-objective optimization analysis. For the purposes of this study, we used the weighted method of multi-objective optimization that boasts widespread use among engineers and is acknowledged as the oldest multi-objective solution technique [15]. The multi-objective optimization problem in this study is to minimize the environmental impact LCA^a, as well as the total cost C for the selective deconstruction of a building assembly. Depending on the approach of the overall analysis, the user can select a specific environmental impact of interest. For each building component j (j=*1,…,J*) that is part of the final disassembly sequence plan calculated by the SDPB, one of the three different deconstruction methods m (m=*1,…,*M_j) established in the previous section could be applied. Each deconstruction method has an associated environmental impact EI^a and building cost C. Therefore, the two objective functions have been formulated as follows.

$$Minimize\ Z_1 = \sum_{j=1}^{J}\sum_{m=1}^{M_j} LCA_{jm}^{a} \quad (16)$$

$$Minimize\ Z_2 = \sum_{j=1}^{J}\sum_{m=1}^{M_j} C_{jm} \quad (17)$$

According to the multi-objective weighted method, the objective functions must be combined into a single-objective function, or grand objective function, by multiplying each objective function by a weight w_n and adding them together. For minimization objectives the grand objective function is multiplied by -1 to change its sense to a maximization. The weight is a variable whose value will change systematically during the solution process. The resulting grand objective function is:

$$Maximize\ Z^G = -w_1 \sum_{j=1}^{J} \sum_{m=1}^{M_j} LCA_{jm}^a - w_2 \sum_{j=1}^{J} \sum_{m=1}^{M_j} C_{jm} \quad (18)$$

Subject to:

$$\sum_{j=1}^{J} \sum_{m=1}^{M_j} x_{jm} = 1 \qquad j = 1, \dots, J \quad (19)$$

$$\sum_{k=1}^{K} w_k = 1 \qquad k = 1, \dots, K \quad (20)$$

$$x_{jm} \in (0,1) \qquad j = 1, \dots, J; m = 1, \dots, M_j \quad (21)$$

Where:

- j building component of a building assembly, $j=1,\dots,J$,
- m deconstruction method for a building component, $m=1,\dots,M_j$,
- a type of environmental impact, $a=1,\dots,A_{jm}$,
- k associated weighting factor, $k=1,\dots,K$,
- LCA_{jm}^a LCA for an environmental impact a of a building component j in deconstruction method m
- C_{jm} total cost for deconstruction of a building component j in deconstruction method m
- w_k value of the associated weighting factor k
- x_{jm} decision variable

$$x_{jm} = \begin{cases} 1, & \text{if comp. } j \text{ ends in deconstr. } m \\ 0, & else \end{cases}$$

The grand objective function (18) will generate the set of noninferior solutions for the multi-objective optimization problem. Constraints (19) ensure that every deconstruction method is processed once. Constraints (20) ensure that every weighting factor is processed once. Constraints (21) define the decision variable $x_{jm} \in \{0,1\}$ as binary.

4 Preliminary Experiments

For the process described in Figure 1, BIM was used as the main digital platform for the preliminary experiments. The E2 assembly building example in Figure 2 is used to demonstrate our approach for a multi-objective optimization analysis for selective disassembly planning for buildings. The software used for this purpose was Matlab®. Once the disassembly plan DSPB is ready, the weighted multi-objective optimization analysis for deconstruction methods is implemented to generate the set of noninferior solutions that minimizes a specific environmental impact (GWP) and the building cost. Table 1 summarizes the result of the calculations, and Figures 3 and 4 displays in a graphical way the noninferior solutions founded with the proposed approach.

Table 1. Set of noninferior solutions for the SDPB of components c_7 and c_{13}

k	w_1	w_2	Solution	GWP (Kg CO_2 eq)	Deconstr. Cost ($USD 2018)
1	1.0	0.0	A	120	$2,955
2	0.9	0.1	B	121	$2,930
3	0.8	0.2	C	135	$2,856
4	0.7	0.3	D	144	$2,833
5	0.6	0.4	E	330	$2,507
6	0.5	0.5	F	640	$2,117
7	0.4	0.6	G	844	$1,900
8	0.3	0.7	H	981	$1,876
9	0.2	0.8	I	1,930	$1,462
10	0.1	0.9	J	2,080	$1,430
11	0.0	1.0	K	2,199	$1,423

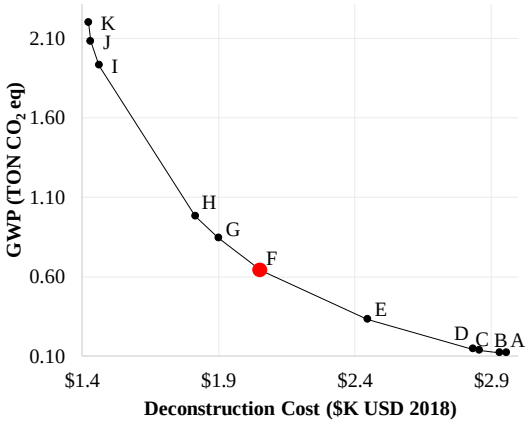

Figure 3. Pareto frontier for minimizing the Global Warming Potential and deconstruction cost of the SDPB for components c_7 and c_{13} by using different deconstruction methods

The result of the case study shows that the different deconstruction methods per building component influence the environmental and economic cost of the selective deconstruction process. The solution A represents the eco-friendlier option because it is the one which reduces its negative environmental loads as represented by GWP. In contrast, the solution K represents the most cost-effective option because it minimizes the cost for the deconstruction of the building

assembly. The points in between are intermediate points that balance the negative environmental load and building cost according to the weighting factors defined by the user. Potential weighting factors determine solutions that are part of the Pareto frontier. This method is thus an effective approach to generate a set of non-inferior solutions for multiple objectives in the selective deconstruction planning of buildings. In the end, the decision makers have the responsibility of choosing the most appropriate solution from the set of non-inferior solutions, according to the specific adaptive reuse building project goals. The methodology described in this study is an effective and user-friendly tool for practitioners and decision makers to perform a multi-objective analysis based on scientific and holistic life-cycle techniques.

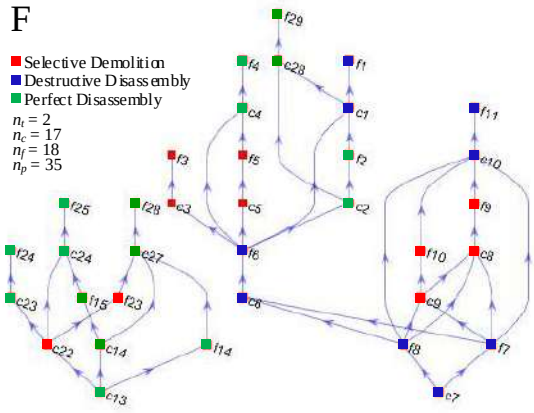

Figure 4. Graphic representation of the noninferior solution "F" for the SDPB of components c_7 and c_{13}

5 Conclusions

Adaptive reuse has the potential to maximize the residual utility and value of existing assets through green design methods, such as selective disassembly planning. Green design methods are used to reduce environmental impacts and to increase economic benefits over the entire product or service lifecycle. However, the field of green design methods for buildings is still underdeveloped in comparison to other industries such as automotive, textile, and manufacturing. Attending the aforementioned need, the aim of this study is to develop a multi-objective optimization analysis framework for the selective disassembly planning of an existing asset through the combination of different deconstruction methods. The analysis is carried out in terms of the physical, environmental, and economic constraints of the deconstruction methods per building component. The SDPB method presented in previous studies is used in order to generate the optimized disassembly plans for retrieving target components. The SDPB method was extended with the purpose of including more than one deconstruction method per component. At the end, a weighted multi-objective optimization analysis is incorporated to generate the set of noninferior solutions that minimizes environmental impacts and building cost.

This study demonstrates that there is a considerable environmental and economic savings potential along the selective deconstruction planning for adaptive reuse of existing assets. During the process of selective deconstruction planning the designers have to wisely evaluate the environmental and economic cost of the building components to deconstruct and the deconstruction methods to apply. In this way, it is possible to maximize the net benefits of the selective deconstruction of a building. Even though the main objective of this study is focus in the optimization of selective disassembly planning for adaptive reuse of buildings, emphasis is placed on the potential for reusing the recovered building components through the proposed selective disassembly methods. It is well known that reuse of components is the best EoL alternative in terms of sustainability due to the amount of environmental benefits embedded. As demonstrated in the case study, the recovery of building components through selective disassembly increases the building cost but it decreases considerably the negative net environmental loads (emissions to the atmosphere, energy demand, water depletion, etc.). Other potential environmental benefits of deconstruction are: decreased disturbance to the site (its soil, ground cover, and vegetation), conserved landfill space, reduction in material mass sent to landfill, conservation of natural resources by reused materials replacing new building materials (this allows the regeneration rate of natural resources to be faster than the depletion rate), and decreased air-borne lead, asbestos, and nuisance dust at and around the job site [20].

The major contribution of this work is the development of an integrated decision-making methodological framework for the adaptive reuse design process, encompassing the optimization of the environmental impacts as well as the building cost through the deconstruction processes. In contrast, the past research efforts focused mainly on suggesting qualitative and quantitative approaches for the entire deconstruction of a building asset with a fixed deconstruction programming of activities that do not capture the issues of customized selective deconstruction processes.

A number of methodologies have been devised to portray the noninferior set among conflicting objectives in engineering problems. For the purposes of this study, we use the weighted method of multi-objective optimization that has widespread use among engineers.

The final goal is to generate the set of noninferior solutions by the appropriate technique. Based in previous studies in the field of selective disassembly planning for buildings, the proposed approach has been demonstrated to be a strong and efficient way to generate comprehensive information about the best available choices for the selective deconstruction of a building asset. This method represents an affordable tool for the decision makers along the deconstruction process for the adaptive reuse of an existing building.

This study has demonstrated the technical affordability of applying the proposed methodology with a reasonably level of complexity and accuracy. The tools and methods that are part of the workflow in the proposed approach, such as the SDPB method, 6D BIM modeling, RSMeans® databases, and Tally® LCA analysis, are available in the market and they are specialized tools for buildings with simplified procedures in order to keep the overall analysis in a reasonable range of complexity. The evidence suggests that in the future all these tools and methods will be continuously developed in order to make them more efficient, simple, and reliable. The proposed study represents an advance on the integration of diverse technologies in the fields of deconstruction building planning, virtual building modelling, environmental assessment, and cost performance of adaptive reuse building projects.

Abstract –

In road maintenance, it is necessary to construct an environment that manages three-dimensional data and maintenance information for its effectivity and efficiency. The primary objective of this research is to support road maintenance work using three-dimensional data by combining point cloud data of terrestrial laser scanning and unmanned aerial vehicles (UAV) with photogrammetry. For on-site surveying, the limitations have been clarified. The first limitation is based on site circumstances. Passengers and cars use the road being surveyed during measurements. There are few berms and little space for setting a terrestrial laser scanning. In addition, locations where instruments can be placed are limited. It is difficult to perform the number of measurements necessary for acquiring point cloud data. The second limitation is the measurement range, given the specifications of the instrument functionality for pavement surveys. The experimental results indicate that the high-density measurement range is restricted to within an approximately 10-m radius.

Based on these limitations, the upside of a slope or a landform is surveyed using a camera mounted on a UAV. Point cloud data for these objects are constructed using photographs with SfM technology. SfM data and terrestrial laser scanning data are combined because three-dimensional data for bridge sides and lower works cannot be constructed. To evaluate the accuracy of three-dimensional data, we compare the three-dimensional data with its design conditions. The inaccuracy for the bridge is an effective length of 12 mm and an effective width of 19 mm and the three-dimensional data describes the structure of the bridge with high accuracy.

The three-dimensional data for the road structures could be used to develop a road maintenance management system that accumulates data and refers to the inspection results and repair information in three dimensions.

1 Introduction

Roads must be safe and maintained in good condition. Maintenance management is an essential operation that must be carried out effectively for maintaining, repairing, and rehabilitating roads. If large-scale damage occurs to a road in an urban area and it cannot be used, many aspects of life may be affected. Thus, it is important to protect roads from large-scale damage and to carry out road maintenance in order to maintain services for the public. In addition, it is necessary to accumulate information produced during the entire life cycle of a road in order to analyze problems and solutions within a temporal sequence and to maintain roads strategically and effectively. In Japan, much road infrastructure was built over fifty years ago. Due to progressive deterioration in road infrastructure, ensuring proper maintenance of overall facilities to avoid potential problems is currently an important issue. In particular, in order to avoid or reduce substantial loss, deal with an emergency, prevent damage, perform emergency disaster control, and carry out disaster recovery, road administrators must maintain roads more efficiently. In current maintenance work, road administration facilities are represented on a two-dimensional map, which is not suitable for pothole repair, inspection, or annual overhaul. Locating and analyzing a position can be difficult when using such a map.

In road maintenance, it is necessary to construct an environment that manages three-dimensional data and maintenance information. A road management system comprises functions for planning, design, construction, maintenance, and rehabilitation of roads. A fundamental requirement of such a system is the ability to support the modeling and management of design and construction

information, and to enable the exchange of such information among different project disciplines in an effective and efficient manner.

Engineers should be able to use three-dimensional data not only for virtually reviewing the design of a facility, but also for analyzing building operations and performance. Three-dimensional data tend to be applied to a particular phase of a construction project. Using three-dimensional data will thus improve the efficiency of operations and maintenance.

Dense point cloud data were generated using three and over pictures which taken same points [1], [2]. Agarwal et al. and Frahm et al. were constructed three-dimensional city by automated reconstruction [3], [4]. The three-dimensional point cloud data are constructed on the basis of the Structure from Motion (SfM) range-imaging technique of photogrammetry using video camera data. The accuracy of three-dimensional model by SfM were evaluated by several researches [5]. And, the generated point cloud data which measured the objects from several measurement points are integrated for representing the accurate objects. The integration method of point cloud data is iterative closest point method (ICP) [6], globally consistent registration method of terrestrial laser scan data using graph optimization [7], curve matching [8], [9], and automated registration using points curve [10].

The primary objective of this research project is to propose a road maintenance framework using three-dimensional point cloud data. A point cloud is a collection of data points defined by a given coordinate system. In a three-dimensional coordinate system, for example, a point cloud may define the shape of some real or created physical system. Terrestrial laser scanning [1], [2], and [3] and photogrammetry technologies are used to survey road structures. In road maintenance work, a mobile mapping system (MMS) is used, which generates point cloud data. In this research project, terrestrial laser scanning and photogrammetry by an unmanned aerial vehicle (UAV) are used. Three-dimensional data for the Shiraito Highland Way in Japan are constructed using point cloud data generated by terrestrial laser scanning. Shiraito Highland Way is approximately 10 km in length, and its elevation varies between 1000 m and 1400 m. The measuring range of terrestrial laser scanning on a road varies from approximately 10 m to 100 m. Point cloud data are combined using coordinate points. In addition, the data are used for road maintenance, taking into consideration data size and accuracy. Road maintenance information can be referenced at any three-dimensional point in the point cloud data. PhotoScan Professional (Agisoft) is used for SfM. This paper evaluates the accuracy of the usage of point cloud data by laser scanning and photogrammetry for road maintenance. For example, this method can be used to check potholes and surface irregularities on pavement that can be easily and quickly confirmed by management.

2 Usage of Terrestrial Laser Scanner and Photogrammetry of UAV Camera

There are a number of survey methods for constructing three-dimensional data using laser imaging detection and ranging (Lidar; laser profiler), laser-based photogrammetry, mobile mapping system, terrestrial laser scanning, and photogrammetry using a camera by UAV. Combining these survey methods according to site situations and structures enables surveys of civil infrastructure and construction of three-dimensional point cloud data. It is necessary to understand the characteristics and specifications of the specific measurement instruments and choose suitable point cloud data for a use case for a road maintenance site. In this research project, terrestrial laser scanning and UAV-based photogrammetry are used for usage scenes as shown in Figure 1.

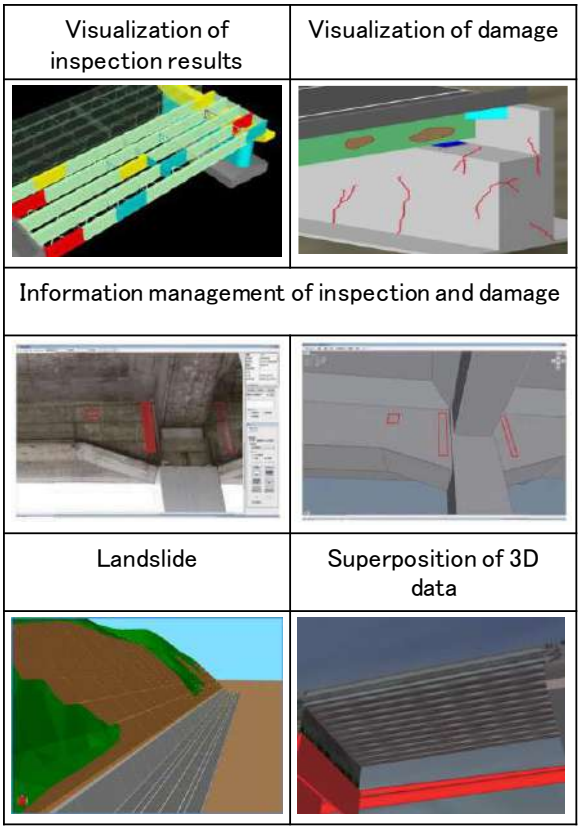

Figure 1. Usage scenes of three-dimensional data

2.1 Usage of Terrestrial Laser Scanner

A terrestrial laser scanner is set on a ground surface,

and the laser component illuminates objects. A laser beam is reflected, and a return-beam detection device records two-way travel time, calculating the distance between the scanner and the object. As a result, point cloud data for an observed object are generated. When using terrestrial laser scanning, it is important to choose a location where the instrument can be set up easily. It is usually advantageous to overlook and survey the location when setting up the instrument.

Table 1 Characteristics of point cloud data by TLS and UAV photogrammetry

	Terrestrial Laser Scanner	UAV photogrammetry
Survey cost (time)	Expensive, but portable	Less expensive and small size
Measurement range	Narrow area	Wide area
Visible area	Visible area from point of terrestrial laser scanning	UAV flight area
Invisible area	Superior surface cannot be measured	Overhang area cannot be measured
Accuracy	A few millimeter	Depends on SfM software
Density of points	Extremely high	High
Distribution	Non-uniform	Depends on SfM software
Angle	10 to 90 degrees	Approximately 90 degrees
Measurement of edge	Exactly	Potentially inaccurate
Measurement of surface	Including noise	Including noise
Measurement of structure	Side surface can be measured	All surfaces can be measured
Noise	Including noise	Including noise
Reflected data	*xyz* coordinates value of local coordinate	*xyz* coordinates value of plane rectangular coordinate system

2.2 UAV Platform Camera

Point cloud data are generated by aerial photogrammetry using photographs or a video-output camera on a UAV. The data are generated using a SfM process [4], [5], and [6]. The characteristics of terrestrial laser scanning and UAV photogrammetry are represented in Table 1. They are analyzed with respect to time cost, measurement range, visible area, invisible area, accuracy, density, distribution, angle, measurement of edge, ground, and structure, noise, and enabled data.

3 Survey and Construction of Three-dimensional Data

Terrestrial laser scanning and UAV photogrammetry technologies are used to survey and generate road structures. Three-dimensional point cloud data for the Shiraito Highland Way in Karuizawa Village, Kitasaku County, Nagano Prefecture, Japan, are used.

In this paper, usage of point cloud data for road maintenance is proposed. If a road administrator possesses point cloud data for a MMS, the data are used for road maintenance. Usage of terrestrial laser scanning is more efficient for surveying narrow areas to check for cracks and holes in the pavement of a road. In the case of a landslide on the side of a road, using terrestrial laser scanning to survey the upside of a slope can be difficult. The reason is that terrestrial laser scanning has limitations for measuring the upside of a landform or slope occluded by such objects as trees or other vegetation and by the angle of incidence of the scanner.

3.1 Construction of Landform Data

Therefore, the upside of a slope or a landform is surveyed using a camera mounted on a UAV. Point cloud data for such objects are constructed using photographs employing SfM technology. Figure 2 depicts SfM data and laser scanning data for a slope. The point cloud data are constructed by combining SfM data with laser scanning data corresponding to 5000 random points between those data, as depicted in Figure 2. The constructed three-dimensional data were superposed for grasping the difference in temporal sequences. The data of 2017 and 2018 were used. The difference was calculated and represented using difference analysis function of Cloud Compare software as shown in Figure3. The lack of soil in slope was represented using blue color and was used for understanding the shape of cross section.

A terrestrial laser scanner is set on a ground surface, and the laser component illuminates objects. A laser beam is reflected, and a return-beam detection device records two-way travel time, calculating the distance between the scanner and the object. As a result, point cloud data for an observed object are generated. When

using terrestrial laser scanning, it is important to choose a location where the instrument can be set up easily. It is usually advantageous to overlook and survey the location when setting up the instrument.

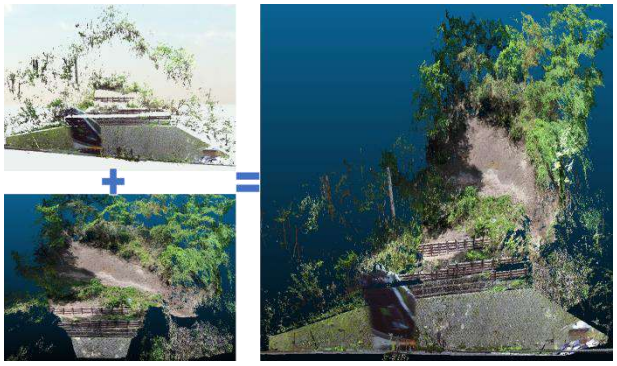

Figure 2. Fusion of three-dimensional point cloud data acquired by terrestrial laser scanning and UAV photogrammetry on slope

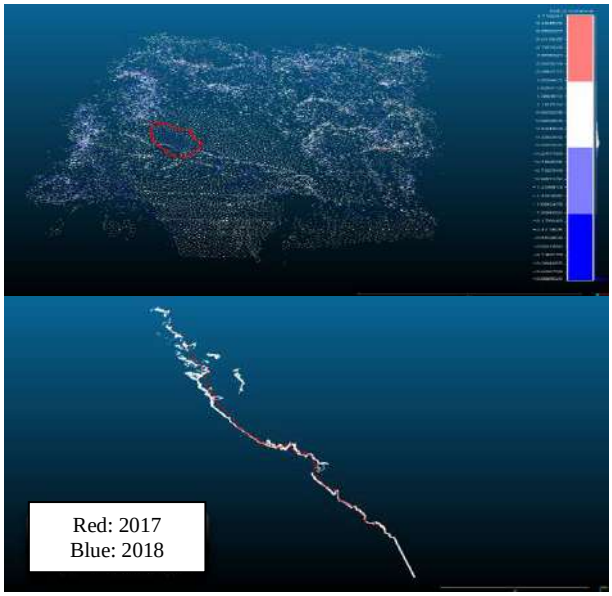

Figure 3. Difference of cross section in temporal sequences

3.2 Limitations for On-site Survey

According to the results of an on-site survey, limitations have been discovered. The first limitation is based on site circumstances. Passengers and cars pass by on the road being surveyed during measurement. There are few berms and little space for setting a terrestrial laser scanning, given the high slope on the Shiraito Highland Way. In addition, locations where instruments can be set are limited. Therefore, it is difficult to perform a number of measurements for acquiring point cloud data. It is necessary to pay attention to surveyors and instruments, and to determine measurement range and accuracy for the set of circumstances.

The second limitation is measurement range, given the specifications of instrument functionality for pavement surveys. According to experimental results, high-density measurement range is restricted to within an approximately 10-m radius, as depicted in Figure 4. It is necessary to perform a number of plural measurements for surveying wide-range pavement data. Figure 5 shows the three-dimensional data of road surface connected the thirteen laser scanning data of 10 m radius. The reference points such as trees and guard rails were set for data fusion. The data have about 300 m length and 208,375,900 points.

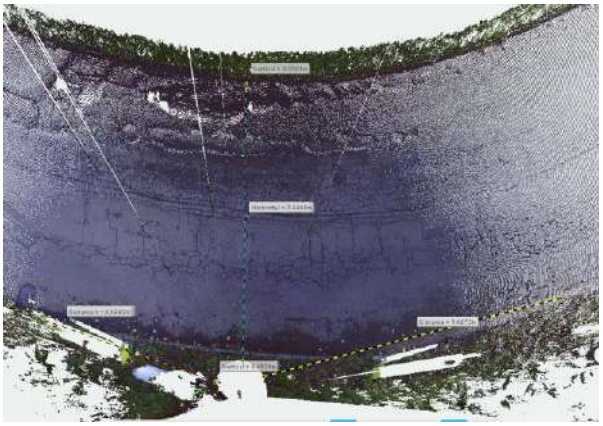

Figure 4. Point cloud data on road surface

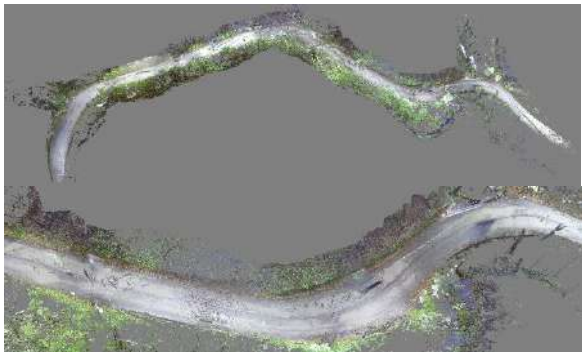

Figure 5. Three-dimensional data of road surface

3.3 Construction of Bridges

To construct the three-dimensional data for the upper and lower part of bridges, UAV aerial photogrammetry and terrestrial laser scanning measurements were performed for the Kashii River (Izumisano City) and Kimyuji River (Sennan City) in the south of Osaka Prefecture in November 2017. During the UAV aerial photogrammetry, the UAV flew at an altitude of 30 m, the movie was converted into pictures, and SfM processing was performed with PhotoScan to construct the three-dimensional data.

Figures. 6 and 7 depict examples of data fusion of terrestrial laser scanning and SfM data acquired by a UAV using the same method as described above.

Figure 6. Data fusion of terrestrial laser scanning and UAV in road and bridge

Figure 7. Data fusion of terrestrial laser scanning and UAV on a bridge

4 Accuracy Evaluation of Three-dimensional Data

4.1 Accuracy of UAV Photogrammetry Data

The accuracy of UAV photogrammetry data and constructed three-dimensional data were evaluated by assigning absolute coordinates from the global navigation satellite system survey to the three target points as reference points, and four verification points were used as shown in Figure 8. The accuracy is validated using root mean squared error with *xy* plane and altitude of *z* coordinate. RMSE is calculated using the true coordinate measured by GNSS (Pentax G3100-R2B) and point clouds. The root mean square error was 0.272 m in the *xy* direction and 0.261 m in the *z* direction (Table 2). Because the wind was strong at the time of the measurements, the fact that the aircraft and the camera were not stable affected the accuracy. For the terrestrial laser scanning, we targeted the Megata Bridge in Kashigawa River and the Warazuhata Bridge in Kinyuji River, the feature points of multiple-point group data measured from six places bridges from five places were matched, and thinning processing was applied to obtain one data point.

Figure 8. Target setting points

Table 2. Accuracy verification results for SfM data

Inaccuracy (m)	*xy* direction	*z* direction
Point A	0.199	0.349
Point B	0.232	0.082
Point C	0.414	0.211
Point D	0.185	0.120
Average	0.258	0.191
Root mean squared error	0.272	0.216

Table 3. Accuracy verification results for fusion data

Inaccuracy (m)	*xy* direction	*z* direction
Point A	0.035	0.033
Point B	0.011	0.009
Point C	0.010	0.008
Point D	0.043	0.047
Average	0.025	0.024
Root mean squared error	0.029	0.029

4.2 Accuracy of Fusion Data

The three-dimensional point cloud data obtained by SfM are measured from the air, and SfM data and terrestrial laser scanning data are combined because three-dimensional data for bridge sides and lower works cannot be constructed. The accuracy of terrestrial laser scanning data is higher than that of SfM data, and therefore duplicate SfM data are deleted before combining. According to Cloud Compare, we can combine 50,000 characteristic points for each type of data with reference to each other type of data and describe the side and bottom works of bridges that could not be acquired by UAV aerial photogrammetry as three-dimensional data. The fusion data of Warazuhata Bridge were evaluated by root mean squared error in Table 3. The root mean squared error was 0.029 m in the *xy* direction and 0.029 m in the *z* direction. It

represents high accuracy of the three-dimensional data combined by terrestrial laser scanning data and UAV photogrammetry data. To evaluate the accuracy of three-dimensional data, we compare the point cloud data of the Warazuhata Bridge with its design conditions. The bridge length is 22.20 m and its width is 4.00 m, whereas the bridge length from the point cloud data is 22.212 m and its width is 4.019 m. Therefore, the inaccuracy for the bridge is an effective length of 12 mm and an effective width of 19 mm (Figure 9) and the three-dimensional point cloud data describes the structure of the bridge with high accuracy.

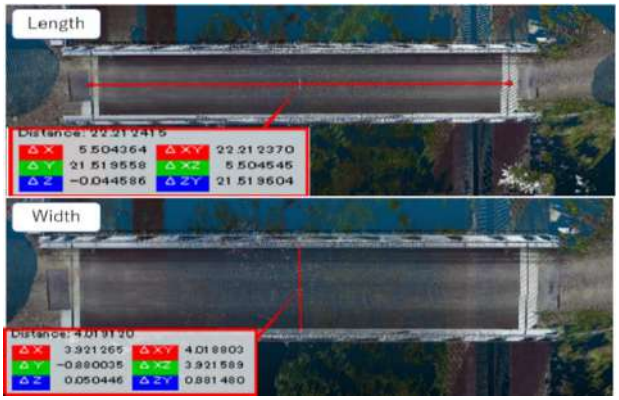

Figure 9. Length and width based on the combined point cloud data for Warazuhata Bridge

5 Proposal of Road Maintenance Information System Using Three-dimensional Data

The three-dimensional point cloud data for the road pavement surface and the bridge could be used to develop a road maintenance management system that accumulates data and refers to the inspection results and repair information in three dimensions.

An information system for road maintenance is proposed in this research project. This chapter discusses the information system, which uses point cloud data based on the definition of an information system.

By definition, an information system collects, processes, transfers, and utilizes information in its own domain. Figure 10 depicts the definition of a road maintenance information system using point cloud data.

A road maintenance system was considered based on the definitions within an information system. The road maintenance system can link inspection results and recondition information with the point cloud data for display, storage, and reference, facilitating the management of road cracks and areas for repair. In future work, point cloud data will be used to identify changes in the shape and condition of damage through spatial and temporal management.

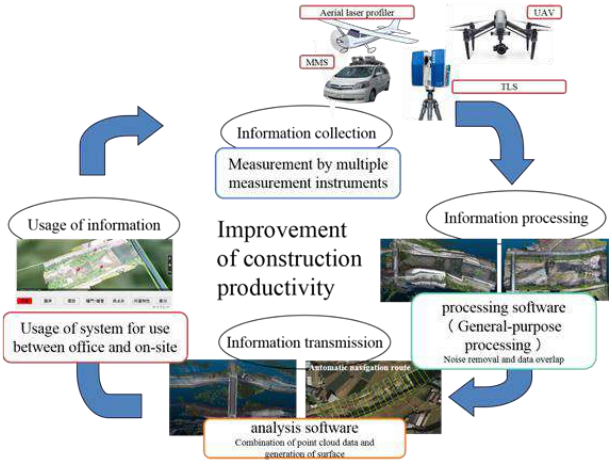

Figure 10. Definition of road maintenance system

5.1 Information Collection

Point cloud data for road infrastructure are collected using terrestrial laser scanning and UAV-based photogrammetry. In addition, maintenance and operation data, such as for inspection, rehabilitation, and repair, are collected on-site for the system.

5.2 Information Processing

Point cloud data generated by terrestrial laser scanning contain noise data concerning trees and vegetation on a road. In information processing, such objects should be removed in order to represent road structures accurately. terrestrial laser scanning's survey range is confined to the visible range and the scan range of the scanner; therefore, it contains blind spots that are not represented by the point cloud data cloud. Accordingly, surveyors need to move the scanner to multiple locations across a number of points in time. UAVs can acquire photographs or videos in-flight. Such visual records are used for SfM software and translated point cloud data. In addition, the point cloud data are colorized for visualization.

5.3 Information Transmission

Terrestrial laser scanning and UAV-based photogrammetry each have distinct characteristics with respect to survey time cost, scan range, and accuracy. Wide area and high precision point cloud data are generated by combining each set of data units. In addition, in this process, structural members and surface data, such as a triangulated irregular network, are extracted and generated in accordance with the purpose of usage. Furthermore, it is also possible to compare

two different temporal data units for analysis.

5.4 Usage of Information

In this research project, instead of a surface model, point cloud data are used for road maintenance. A road maintenance information system is proposed, which has functions for detecting cracks and superimposing photographs based on point cloud data. In addition, a function is needed for reflecting inspection and repair events that have been represented on a two-dimensional map displayed on a smart device onto three-dimensional point cloud data on-site.

In the road maintenance system, the inspection result and repair information can be linked with three-dimensional point cloud data and displayed, stored, and referenced. It is easy to detect road cracks and spots in need of repair, as depicted in Figure 10. In addition, it is possible to determine changes in shape and damage using temporal management of point cloud data.

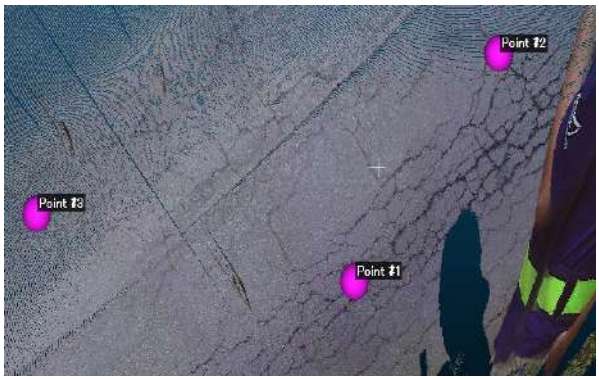

Figure 11. Repair information linked with three-dimensional point cloud data

6 Conclusion

In this research project, point cloud data for road infrastructure have been surveyed using terrestrial laser scanning and UAV photogrammetry for road maintenance. For on-site surveying, the limitations of these methods have been clarified. The first limitation is based on site circumstances. Passengers and cars use the road being surveyed during measurements. There are few berms and little space for setting a terrestrial laser scanning, given the high slope on the road. In addition, locations where instruments can be placed are limited. Therefore, it is difficult to perform the number of measurements necessary for acquiring point cloud data. The surveyors, instruments, and measurement range and accuracy of the conditions should be considered. The second limitation is the measurement range, given the specifications of the instrument functionality for pavement surveys. The experimental results indicate that the high-density measurement range is restricted to within an approximately 10-m radius. Thus, multiple measurements must be taken for surveying wide-range pavement data. Based on these limitations, in this work, the upside of a slope or a landform is surveyed using a camera mounted on a UAV. Point cloud data for these objects are constructed using photographs with SfM technology. SfM data and laser scanning data are used for slopes. The point cloud data are constructed by combining SfM data with laser scanning data corresponding to 5000 random points between these data.

Abstract –

Industry foundation classes (IFC) is widely accepted as a promising standard for building information modeling (BIM). IFC data can be processed with many open toolkits such as IfcOpenShell and java standard data access interface (JSDAI), which greatly supports BIM research and technology development. However, IFC data is not intuitive and requires training to understand it fully. As the core of almost any IFC data, understanding geometric representation is critical in most BIM research and technology development. The official IFC schema specifications provide detailed explanations of entities and attributes in IFC, which are helpful for gaining such understanding. However, understanding the explanations in the specifications requires certain knowledge and background. To facilitate an easier understanding of IFC data and to promote a wider adoption of IFC-based BIM, in this paper, an interactive visualization of the formation of fundamental 3D representations of a selected architecture, engineering, and construction (AEC) object was created in game simulation in a first-person view. The interactive simulation can help people gain understanding of 3D geometric formation and representation in IFC in an intuitive and speedy manner, which is expected to achieve retention of such knowledge comparable to or better than the conventional way of reading the specifications. The visualization was tested by 14 volunteers in comparison to reading the IFC schema specifications. A survey based on the experiment showed that the game simulation-based visualization was significantly easier to understand and took significantly less time to understand comparing to reading the specifications.

1 Introduction

Building information modeling (BIM) is a "data rich digital representation cataloging the physical and functional characteristics of design and construction" [1]. It is expected to serve as "a shared knowledge resource for information about a facility forming a reliable basis for decisions during its life-cycle from inception onward" [2]. Since its inception BIM has been used for various purposes such as 3D coordination, 4D modeling, design reviews, as-built conditions modeling, structural analysis, energy analysis, cost estimation, sustainability evaluation, lighting analysis, and asset management [3]. For each of these purposes there are multiple (if not many) software applications to use, which benefited project stakeholders by reducing errors, time, and cost, improving quality, safety, profitability, and facilitating collaborations [4]. BIM applications are intended to be interoperable by definition, meaning that these applications should be able to "exchange information and to use the information that has been exchanged" [5]. However, a seamless interoperability between BIM applications is far from reality. Information missing and information inconsistency is not uncommon when BIM is exported from one application and imported into another. Even BIM applications from the same software provider may not have fully seamless interoperability [6] [7]. Such a lack of BIM interoperability costed the architecture, engineering, and construction (AEC) industry $15.8 billion annually [8].

In North America, the adoption of BIM in the AEC industry increased from 28% in 2007 to 71% in 2012 and is continuing to increase [4]. With the increased adoption of BIM, the lack of interoperability between BIM applications is only becoming a bigger problem, as was evidenced by a survey of contractors which showed that almost half (46%) of contractors with heavy software use considered the need of improving BIM interoperability to be of high/very high importance [4].

Standardization is one potential solution for BIM interoperability. Two main standardization efforts are industry foundation classes (IFC) and the CIMSteel Integration Standards Version 2 (CIS/2) [9]. While CIS/2 focuses on exchangeable data representation and information modeling for structural steel type of projects [10], the IFC standard is designed to be able to represent any type of building construction projects. IFC is an open and neutral data standard that is registered as an international standard ISO 16739 [11]. IFC has been widely accepted as the most promising data standard to solve BIM interoperability. IFC is dominating BIM research in academia and almost all main BIM software applications claimed to be compatible with IFC (i.e., through exportation and/or importation). Since its inception in 1997, IFC has been going through eight main release versions (IFC1.0, IFC1.5, IFC2.0, IFC2x, IFC2x2, IFC2x3, IFC2x3_TC1, IFC4) and is still under development towards IFC5, which is planned to extend to represent not only building projects but also infrastructure projects such as roadways and bridges. It stimulated a national trend in the U.S. towards civil integrated management (CIM) which is about implementing the same life cycle information management idea of BIM from vertical building projects to horizontal infrastructure projects [12]. Therefore IFC is attracting great attention in all sectors from academia, industry, and government. Some familiarity and understanding of IFC data is gradually becoming necessary for practitioners in the AEC industry, therefore IFC contents are entering the curriculum of construction education and training.

In spite of the openness of IFC standard, data instance files using IFC schema are not directly understandable like a bar chart. As of the current version IFC4, the IFC schema includes more than 750 entities and more than 350 types [13]. Each entity has its own specifications that define its attributes and allowed value assignments to the attributes. In an effort to limit the size of IFC instance files, cross referencing is used ubiquitously where one entity instance can refer to another entity instance as the value of one of its attribute. It takes a certain level of training to understand IFC data, and the learning curve is not steep. For example, in a graduate level class taught by the first author, it took a significant portion of a lecture's time to explain the intricacies of the IFC data.

Geometric information is an essential part of any BIM data, and it is a critical part of any IFC data files. Entity instances that represent geometric information can take a significant portion of an IFC instance file. For example, "in the 'Duplex Apartment' IFC data published by buildingSMARTalliance of the National Institute of Building Sciences [14], more than 71.6% (27,866 out of 38,898) of the entities were directly used for representing geometric information." [15]. Therefore, IFC data cannot be fully understood without understanding its geometric information representations.

Cartesian points are the most fundamental elements for representing geometric information in IFC data, they play critical roles in the interchange of information between as-built model and as-design model, and from as-design model to advanced visualization platforms such as game simulation and virtual reality platforms. To help understand geometric representations using Cartesian points in IFC data, the authors proposed the use of a new game simulation-based interactive visualization. The remaining sections of this paper describe the background of this visualization technique, the details of an example using this visualization and its testing results and analysis.

2 Background

This background section introduces background knowledge in game simulation, industry foundation classes (IFC), and Cartesian points in IFC.

2.1 Game Simulation

The concept of game simulation is a combination of the concept of game and the concept of simulation. The key elements of a game are rules and goals, interaction and feedback, challenge and strategies, and motivation and fun [16] [17]. The key elements of a simulation are model of reality, abstract concepts, interaction, experiment, decisions from a specific angle of view, and purposeful testing [17]. Therefore interactions from a specific role or angle of view is an essential element of a game simulation. Game simulation has been shown to be an effective teaching tool, based on the two assumptions that "practice improves one's ability to perform" and "simulations provide students with opportunities to practice making management decisions in a safe environment" [18].

Game simulation has been widely used in AEC research to help with construction engineering and management education [17][19], architectural design review [20] [21] [22], mechanical, electrical, and plumbing (MEP) design and analysis [23], facility management [24] [25], constructability and productivity analysis [26], and construction operation/safety training [27] [28].

There are multiple game engines available off-the-shelf such as Unity3D, Unreal Engine, and CryENGINE. Game simulations using these game engines may well use information from BIM especially geometric information, through intermediate format transfers such as FBX and OBJ files. Cartesian points lay the foundation of geometric information representation in these formats. For example, Figure 1 shows the starting section of an OBJ file that represents the geometry of a bent wood

plank. While the lines starting with # indicate comments, each line that starts with a "v" is representing the x,y,z coordinates of one Cartesian point.

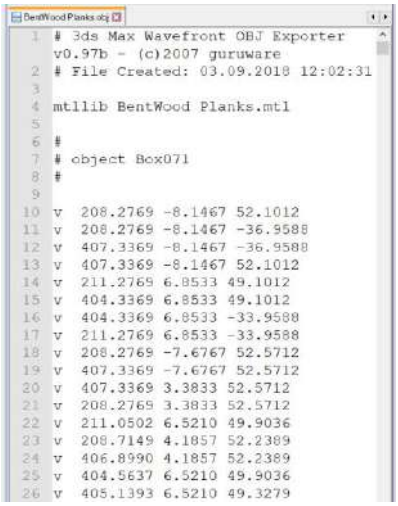

Figure 1. Starting section of an OBJ file

2.2 Industry Foundation Classes

Industry foundation classes (IFC) is an open and neutral data standard for building and construction industry data, and it is registered as ISO 16739 since the IFC4 version [29]. IFC data files can be using one of three main formats - .ifc, .ifcXML, and .ifcZIP, which are the default, XML represented, and compressed formats, respectively. The default and XML represented formats are mainly used in BIM research, especially the default .ifc format. Because it is based on the STEP physical file structure which is according to another international standard ISO10303-21. There are many open sourced utilities that can be used to directly read/write .ifc files, such as IfcOpenShell, java standard data access interface (JSDAI), and IFC++.

In the IFC schema, entities and attributes of the entities are used to represent concepts and relations between or properties of concepts, respectively. For example, *IfcWallStandardCase* is an entity to represent a standard wall concept. The second attribute of *IfcWallStandardCase*, *OwnerHistory* is used to represent the relation between the standard wall and an owner history entity that is used to represent all history and identification related information of the standard wall. The third attribute of *IfcWallStandardCase*, *Name* is used to represent the name property of the standard wall. In the instantiated data files using the IFC schema, cross referencing is used between one entity instance and another to represent the relations between entity instances. For example, Figure 2 shows the partial view of an IFC instance file where six cross references were highlighted.

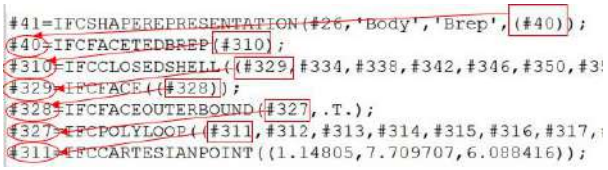

Figure 2. An example partial IFC instance file

Geometric information is an important part of an IFC model. The mechanism for representing geometric information in IFC is based on an international standard ISO 10303-42 [11]. In spite of the standardization of the geometric representation, the geometric data in an IFC file is not intuitively understandable. One reason is the varieties of geometric representations in IFC, such as "Body" and "Axis" [30]. Another reason is the complexities within each type of geometric representation. For example, the solid model of a "Body" can be represented by "Swept Solids" "Boolean Results" or "Brep Bodies." [31]. "Swept Solids" use the solid sweeping technic to form a 3D representation, i.e., planar bounded surfaces swept along a defined direction. "Boolean Results" take the union or intersection between two solids to define a new solid. "Brep Bodies" use boundary representations to represent a 3D shape where each boundary representation is a surface element. The IFC data in Figure 2 was using the "Brep Bodies" 3D geometric representation, which can be seen from the use of the entity *IfcFacetedBrep*. The *IfcClosedShell* is an entity to represent the 3D shape. Figure 3 summarizes the path from the *IfcClosedShell* to the lowest-level element *IfcCartesianPoint*. The boundaries of this *IfcClosedShell* are represented by multiple occurrences of *IfcFace*. The boundaries of the *IfcFace* are defined by *IfcFaceOuterBound*, whose boundaries, in turn, are defined by *IfcPolyLoop*. Finally, the definition of the *IfcPolyLoop* is achieved by using multiple occurrences of *IfcCartesianPoint*.

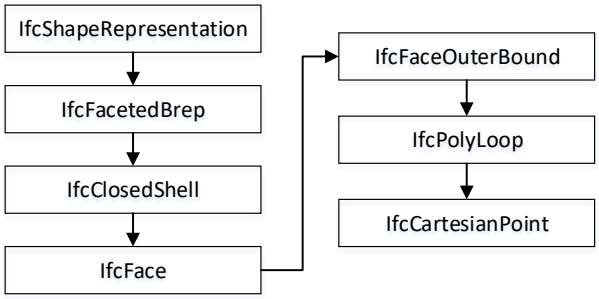

Figure 3. Summary of the pathway of a Brep geometric representation in IFC

2.3 Cartesian Points in IFC

In spite of the variety of ways of representing geometric information in IFC, they all reduce to Cartesian points in the end. Therefore the understanding of Cartesian points is the key to the understanding of geometric information in IFC. Such an understanding is also important to the collective use of IFC model with other models such as as-built models [32], which can be collected using various sensing technologies such as laser scanning [33] and image sensing [34]. One classic use of as-built models together with as-designed models in IFC is to monitor the progress of construction, where matching Cartesian points from as-built point clouds and IFC data need to be performed manually and/or algorithmically [34] [35].

In the future use of robotics both in a built environment and in the construction of a built environment, the geometric information carried by an IFC model could foreseeably play critical roles. For example, IFC models have already been used in researching and developing indoor robotic navigation algorithms [36] [37]. IFC models have also been proposed to guide the use of robotic systems to automatically construct different types of structures such as concrete structure [38], masonry structure and prefabricated steel structure [39].

Due to the importance of geometric information representation in IFC, it is desirable to incorporate its introduction to modern AEC curriculum. In fact, in the first author's graduate level class titled "automation in construction management," a 3-hour lecture is designated to the introduction of BIM with a focus on IFC. There are also homework assignments, quizzes, and exams to enforce students' learning. However, such a devotion of time and efforts is not practical for all learners, especially for casual learners who just need to grasp a basic understanding of IFC data without too much detail. Unfortunately, IFC data was not designed this way. For example, Figure 4 shows partial data instances of an IFC file that represents a cone frustum-shaped bridge pier. All entity instances in Figure 4 except for the last one are representing Cartesian points, and the last entity instance is representing a poly loop that is defined using all the shown Cartesian points that are above it. It is not intuitively clear how these Cartesian points form the poly loop and it is not clear either where the poly loop fits in the cone frustum shape, even if a visualization of the cone frustum shape is given (Figure 5).

3 Proposed Method

To help casual learners grasp how Cartesian points were used to form and represent a 3D shape in IFC data, the authors propose a new interactive visualization method based on game simulation. Such method is also useful for serious learners to quickly grasp the idea before they go deeper in learning the details.

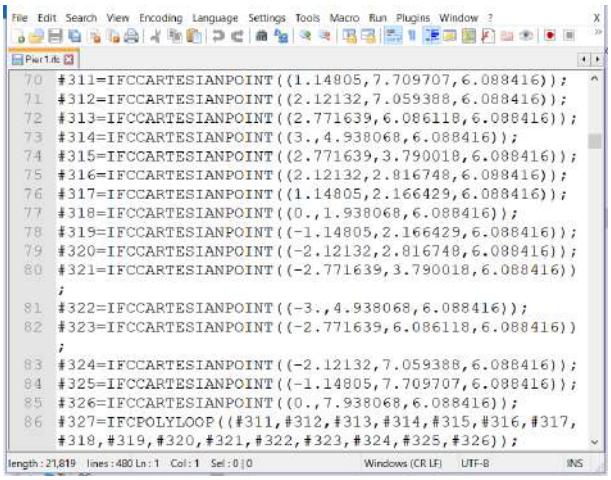

Figure 4. Cartesian points data from the geometric representation of a cone frustum shape in IFC

Figure 5. Visualization of a cone frustum shape

As shown in Figure 6, the proposed method uses an elemental cube to represent a Cartesian point and a colored line to represent a relation between one Cartesian point and another. In the time dimension, the Cartesian points and their connected relations are visualized one by one, following a sequence dictated by the order of these Cartesian points in the original structured IFC data instance file. This visualization can be observed from a first-person view, a third-person view, or any arbitrary angle of view as defined. The view can also be changed in real-time based on learners' preferences.

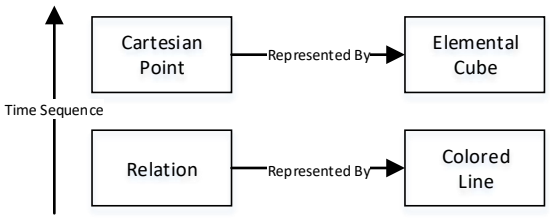

Figure 6. Proposed Cartesian point visualization method

4 Preliminary Experimental Testing

To test the effectiveness of the proposed method, a preliminary experiment was conducted by implementing the game simulation-based visualization of the cone frustum-shaped bridge pier object shown in Figure 5. The Cartesian points that represent the geometric information of the cone frustum shape were extracted manually from the source IFC instance file. The Unity3D game engine was used to implement the visualization based on the proposed method. The background was set to be an arbitrary white ground and a default blue sky. The visualization was created following a first-person view that can be adjusted in real-time based on the position and head orientation of the virtual observer. Figure 7 to Figure 10 show snapshots of the visualization during different stages of the game simulation, namely, the first Cartesian point, the first poly loop, side faces, and the completed shape. It can be seen that the virtual observer was observing from different angles of view in these snapshots.

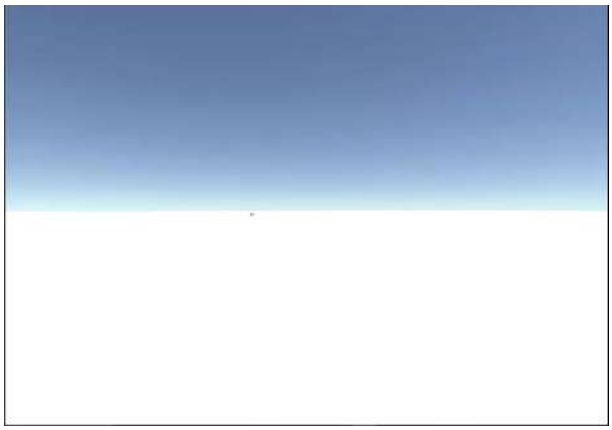

Figure 7. Visualization of the first Cartesian point in a cone frustum shape

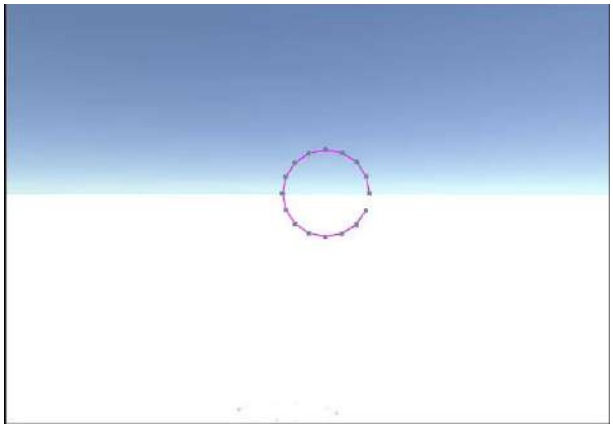

Figure 8. Visualization of the first poly loop in a cone frustum shape

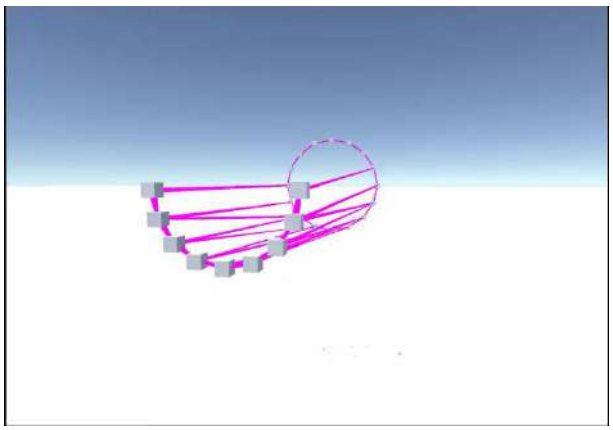

Figure 9. Visualization of side faces formed by Cartesian points in a cone frustum shape

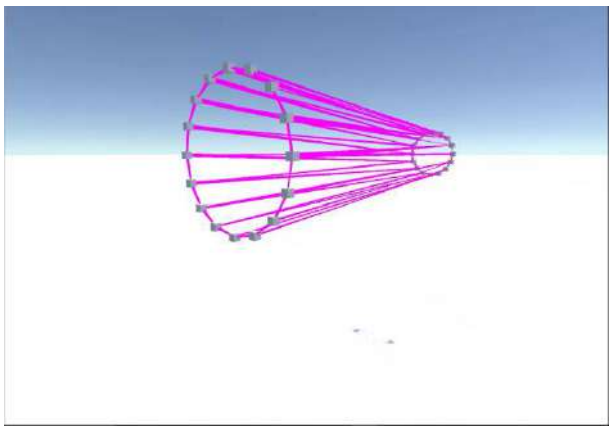

Figure 10. Visualization of the complete cone frustum shape formed by Cartesian points

The implemented visualization was tested by 14 graduate students at Purdue University and University of

Florida, who all have some research experience in BIM (Table 1). The game simulation was given to the participants together with and in comparison with an explanation material based on IFC specifications. Half of the students were asked to start with the game-based simulation, and then move to the written explanation material; the other half of the students were asked to start with the written explanation material, and then move to the game-based simulation to reduce the effect of multiple-treatment interference with the results. The explanation material included: (1) an explanation of the goal, (2) visualization of the cone frustum shape (Figure 5), (3) geometric representation of the cone frustum shape in raw IFC data (Figure 2; Figure 4), and (4) official explanations of the entities by buildingSMART.

Table 1. Participants' information

BIM research experience	Number of Participants
1 Year or Less	4
1-2 Years	4
2-3 Years	2
3 Years and above	4

5 Experimental Results and Discussion

The experimental results were shown in Table 2. The scale levels are: 1-Very difficult, 2-Difficult, 3-Neutral, 4-Easy, 5-Very easy. The maximum score, minimum score, and mean score for the easiness of understanding of the written explanation material were 3, 1, and 1.79, respectively. The maximum score, minimum score, and mean score for the easiness of understanding of the game simulation-based visualization were 5, 3, and 4.00, respectively. The game simulation-based visualization was much easier to understand than the written explanation material and the difference was significant at 99.9% confidence level based on paired t-test. The time taken to understand the written explanation material had a maximum, minimum, and mean values of 1,680(s), 225(s), and 545.89(s), respectively. The time taken to understand the game simulation-based visualization had a maximum, minimum, and mean values of 480(s), 80(s), and 130.37(s), respectively. It took much less time to understand the game simulation-based visualization than that in understanding the written explanation material and the difference was significant at 99.9% confidence level.

Some comments received during the test were: (1) the written explanation material was difficult to understand because of the needed background knowledge, (2) a slower speed in the visualization would make it easier to follow and understand, (3) the explanation material could be used to complement the visualization, and (4) adding audio to the visualization would make learners' understanding even easier.

Table 2. Easiness of understanding results

	Explanation material			Game simulation-based visualization		
	min	mean	max	min	mean	max
Easiness of understanding	1	1.79	3	3	4.00	5
Time taken to understand (*s*)	225	545.89	1,680	80	130.37	480

6 Conclusion

With the fast development and adoption of building information modeling (BIM), the demand in learning industry foundation classes (IFC) data – the ISO registered data standard of BIM, is increasing. In this paper, the authors proposed the use of a new method to help people learn the formation of geometric representations using Cartesian points in IFC data. The new method is based on game simulation technology and visualizing the Cartesian points and relations between the points in sequence. The new method was evaluated in a preliminary test where a cone frustum-shaped bridge component represented in IFC was presented using the method to 14 test participants. At the same time a written explanation of the same knowledge was provided to the participants. Collected results showed that the game simulation-based visualization was significantly easier to understand and took significantly less time to understand comparing to reading the explanation material.

7 Contributions to the Body of Knowledge

This paper contributes to the body of knowledge in that it is the first time that game simulation in first person view was used to help with understanding of geometric representation of IFC data with a focus on Cartesian points and the comparative effects were tested with respect to a written explanation material in a quantitative manner.

8 Limitations and Future Work

Two main limitations are acknowledged. In spite of the novelty of the proposed method, the test was only conducted on one shape and with a limited set of participants. More testing on more shapes and participants are needed to make the results more robust. The test was only conducted on first-person view, how other angles of views affect the understanding need to be further explored. In future work, the authors plan to extend the test to cover more shapes, more participants, and more angles of views.

Abstract –

The adoption of Building Information Modelling (BIM) has influenced the traditional methods of planning, design, construction and operation of a physical asset. Organizations in Canada have adopted BIM to improve designs, foster stakeholder collaboration, and facilitate construction processes. To understand the extent of BIM adoption and implementation in the industry, the University of Toronto Building Tall Research Centre conducted two annual BIM surveys. The 2018 survey, which was conducted in collaboration with tBIMc, focused on the Greater Toronto Area. In 2019, the survey was expanded nation-wide with support from Canada BIM Council, BuildingSMART Canada, and local BIM chapters. In this paper, the results of the 2019 nation-wide survey are presented and benchmarked against those in the 2018 survey. An in-depth discussion of the perceived benefits of and barriers to adopting BIM in Canada are also provided. This study serves as one of the milestones of the BIM transition process in Canada and aims to present a detailed view of the role that BIM plays in the future of the industry.

1 Introduction

In the past decades, the construction sector has been seeking alternatives to enhance efficiency during project design, planning and construction phases from the traditional project delivery [1]. As a result, Building Information Modelling (BIM) is gaining interest in the building industry. BIM can be defined as the process of creating, managing and utilizing the shared digital representation of physical and functional aspects of any built asset by project stakeholders [2]. BIM can be a reliable basis for decision-making throughout the lifecycle of the asset [2].

Recognizing the prominent values of BIM, the implementation and uptake of BIM around the world have gained great momentum over the last decade. Leading countries have developed specific strategies and mandatory requirements for BIM adoption. An overview of global BIM implementations in terms of degree of regulatory mandate over the past 5 years is illustrated in Figure 1, where the size of the circle that represents each country is proportional to its population.

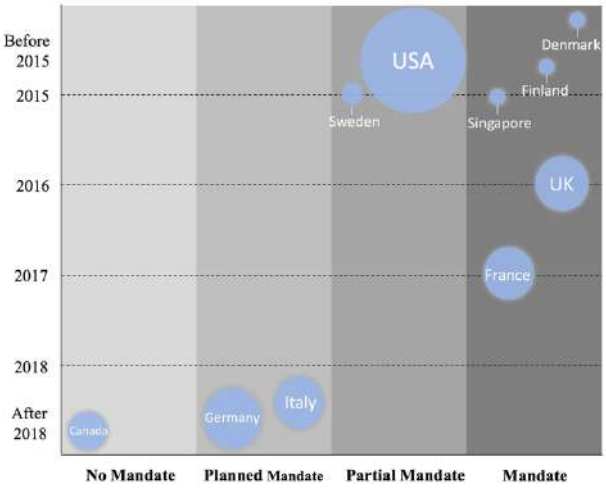

Figure 1. Global BIM Implementation Overview

Denmark was one of the earliest adopters of BIM in the world. They first mandated BIM for public projects in 2007 and extended the requirement to all projects in 2011 [3]. Similarly, Finland, Singapore, United Kingdom (UK) and France successfully mandated the full deployment of BIM in 2012, 2015, 2016 and 2017 respectively [3]. United States of America (USA) and Sweden represent partial BIM mandates, where BIM use was mandated only in certain regions and by specific government authorities [4]. Italy and Germany have specified plans to mandate BIM in 2019 and 2020, respectively [3].

In comparison to the aforementioned countries, Canada has neither an in-place BIM mandate nor clear national plans to implement BIM, and appears to be lagging behind the global trend of BIM adoption [5]. To better understand the extent of BIM adoption and implementation in the Canadian architecture,

engineering, and construction (AEC) industries as well as the issues in the current BIM adoption, the Second Annual BIM Survey was conducted in 2019 as a continuation of the First Annual BIM Survey in 2018 [6,7]. In collaboration with Canada BIM Council, BuildingSMART Canada, and local BIM chapters, the survey was disseminated across Canada and over 300 respondents participated this year. In this study, major findings obtained from the Second Annual BIM Survey are presented, along with benchmark analyses for the 2018 survey. The contribution of this study is to provide a holistic perspective of the adoption and implementation of BIM in Canada, with emphasis on the perceived benefits and barriers in the AEC industry.

2 Benefits of and Barriers to BIM Adoption

Compared to traditional project delivery methods, BIM brings many benefits and opportunities in the various project phases, namely, project design, construction and operation [1]. Major benefits identified in the project design phase include clash detection, enhanced visualization, cost estimation, design simulation, and automated code compliance checking [8,9,10]. During construction, BIM facilitates scheduling, activity sequencing, progress tracking, site safety assessment, and site logistics planning [11,12]. For the project operation phase, facility managers benefit from the information stored in the BIM database when performing space planning, facility maintenance, and refurbishment [13,14]. Finally, improved collaborations among stakeholders throughout the project life cycle can be achieved by adopting BIM [15,16,17].

Despite the numerous benefits and opportunities of BIM implementation, barriers and challenges were identified in previous research, which can be categorized into five major aspects, including technical, legal, cultural, financial and managerial [18]. Regarding BIM technologies, pertinent technical problems such as software compatibility were still unsolved. Some of the legal issues that hinder the adoption of BIM include stakeholders' liabilities on the accuracy and quality of data embedded in BIM models [5]; lack of regulations or guidelines on resolving any dispute that might arise due to BIM implementation [18]; intellectual property rights issues such as model ownership, copyright and authorization of model usage [19]. Cultural issues associated with BIM adoption that are most frequently mentioned by researchers include resistance to change and inadequate coordination among project stakeholders [18]. Financial barriers refer to the high initial investment in BIM technology [20], and the uncertain rate of return on investment [21]. Managerial barriers mainly come from the lack of confidence in BIM by management in an organization due to significant changes required in design phase workflow, project delivery methods [22], as well as software and hardware [23].

Successful implementation of BIM requires users to understand the values and issues associated with the technology, such that benefits can be reaped, and barriers can be eliminated. In addition, support and guidance from government bodies and related organizations would further speed up the adoption process [18].

3 BIM Surveys

To understand the status quo, barriers, and trends of BIM adoption in the AEC industry, several countries and organizations have conducted BIM surveys over the last decade.

3.1 Global BIM Surveys

In 2011, UK published its First National BIM Survey for understanding BIM adoption and implementation in the country. The National Building Specification (NBS), in collaboration with the Royal Institute of British Architects and the UK BIM Task Force, has been the main driving force for designing, collecting, and analyzing the surveys. Eight national reports have been published by NBS. The style and design of the UK national surveys questions were varied and adjusted throughout the years. For instance, the 2011 and 2012 national survey comprised a comprehensive list of questions, but the result analyses were relatively simple and straight-forward [24,25]. From 2013 onwards, the questions were categorized into sections, namely, BIM Experience, BIM and Government, as well as Attitudes toward BIM. In addition, more in-depth analyses and discussions on the survey results were included [26]. Simple comparisons with previous years' results were provided in the 2014, 2015 and 2016 BIM reports, and trends were identified [27,28,29]. Due to the launch of the UK's national BIM mandate in 2016, the main focus of the 2017 survey was shifted to examine the organizational engagement level of BIM implementation in the industry [30]. The latest 2018 NBS survey was similar to the previous one, with the emphasis on understanding the effect of government mandates and associated strategies [31].

In addition to the national BIM reports, NBS conducted two international BIM surveys in 2013 and 2016. Along with UK and Canada, New Zealand and Finland participated in the 2013 international survey while Denmark, Japan, and Czech Republic took part in 2016. There were only 78 and 127 respondents from Canada in the 2013 and 2016 international BIM surveys. The structure and design of the surveys were similar to the national surveys but significantly fewer questions were included in the international ones. Only common

and applicable questions were selected, and benchmark analyses among participating countries were presented in the two international BIM reports [32,33].

3.2 Local BIM Survey

In 2017-18, and in collaboration with the Toronto BIM Community (tBIMc), researchers from the University of Toronto Building Tall Research Centre conducted the First Annual BIM Survey to analyze BIM adoption in the Greater Toronto Area (GTA). Questions in the UK survey were adopted to facilitate benchmark analyses [7]. More than 250 respondents participated in the survey and a complete report of the key findings from the first annual survey was published in April of 2018 [6,7]. This survey serves as the baseline for BIM implementation in the Canadian market. As a pilot study, the first BIM survey was well-received by industry professionals and the results provided useful benchmarking indicators for future studies.

4 Second Annual BIM Survey

The Second Annual BIM Survey was a continuation effort. The goal of the 2019 survey was to collect a comprehensive understanding of BIM implementation from coast to coast in Canada.

The majority of questions for the Second Annual BIM Survey were adopted from the first survey with a few additional questions related to BIM application across Canada. An overview of the survey questions is presented in Table 1. Many of these questions had subsections, resulting in over 100 individual questions. The survey was structured into three sections: General Information, BIM Experience, and, Resources and Future of BIM. The demographics, background, and company information of the respondents were collected in section 1. Then, participants were asked to share their BIM experiences, such as the level of familiarity with BIM technology, the functionality of BIM, and perceived benefits and barriers for adopting BIM in project workflow. Finally, insights and opinions on BIM resources and the future trend of the construction industry were gathered in the last section.

Table 1. Overview of Survey Questions

Section 1: General Information
1. Which of these better explains your main role?
2. Years you been working in your discipline?
3. What is your age?
4. In what province is the office you primarily work?
5. In what city are you currently working?
6. How would you describe your organization type?
7. How many employees are there in your organization?
8. Where is your organization doing most work?
9. Which project types have you participated last year?
10. How familiar are you with BIM?
11. Which statements best describes your organization?
Section 2: BIM Experience
12. Ever involved in the following projects last year?
13. Level of confidence in BIM knowledge and skills?
14. What is your opinion on BIM-related beliefs?
15. Have you ever adopted BIM for projects?
16. What % of projects have you used BIM last year?
17. Number of parties you share BIM with per project?
18. What are your thoughts on Open BIM?
19. Which tools did you mainly use last year?
20. What do you use BIM for?
21. What are the main barriers to using BIM?
22. What is your opinion on the BIM benefits below?
Section 3: Resources and Future of BIM
23. Which sources of BIM information will you use?
24. Which Canadian BIM resources are you aware of?
25. How likely are the technologies to have significant influence on the industry over the next 10 years?

The Second Annual BIM Survey was first opened in October 2018 at a Toronto BIM Community event and closed in late February of 2019. The survey was promoted via social media channels and online platforms. It was also distributed through CANBIM and buildingSMART networks, Canada's two national BIM organizations. To further increase the number of participants for the survey, quick response (QR) cards that linked to the online survey were disseminated to AEC professionals across Canada. As Canada is bilingual, the survey was offered in both French and English.

5 Results and Discussions

In this section, an overview of the survey demographics will first be presented. The perceived benefits and barriers are identified from the survey and discussed in detail. Benchmarking analyses of the 2019 survey against the 2018 survey is also presented.

5.1 Demographics

The demographics of respondents for the Second Annual BIM Survey are shown in Figure 2. Of the 398 responses received, more than half (64%) are from Ontario (ON), perhaps because the survey was first launched and promoted in Ontario. Also, the BIM community in the Greater Toronto Area is very active

compared to other metropolitan centres in Canada. Response rates from Alberta (AB), British Columbia (BC), Quebec (QC) and outside of Canada are at 15%, 8%, 5%, and 5% respectively. A few industry professionals from Nova Scotia, Manitoba and Saskatchewan participated in the survey. For the scope of this paper, only responses from the top four participating provinces, namely, ON, AB, BC, and QC are included in the following discussions.

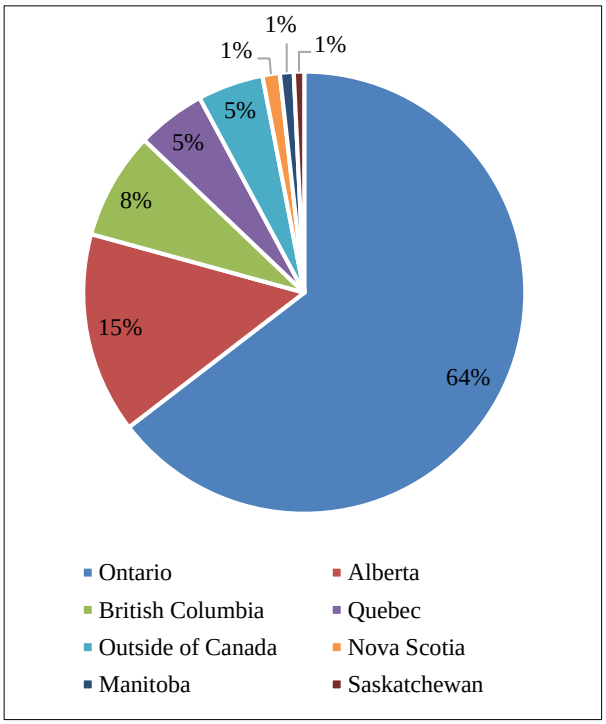

Figure 2. Demographics of 2019 Survey

5.2 Perceived Benefits of BIM Adoption

Question 22 focused on the perceived benefits of using BIM, where respondents were asked to agree or disagree with the statement that adopting BIM can:

- BN1: Improve visualization
- BN2: Bring cost efficiency
- BN3: Enable international collaboration
- BN4: Increase profitability
- BN5: Increase speed of delivery
- BN6: Enable new types of project

Figure 3 indicates over 80% of respondents agree that adopting BIM can bring visualization benefits (BN1). Second to visualization is the cost efficiency (BN2) that BIM can potentially provide in a project, especially if BIM is implemented with the support of all project stakeholders. The benefits from BN3 to BN6 also received over 50% agreement, whereby respondents generally agree with the perceived benefits of BIM.

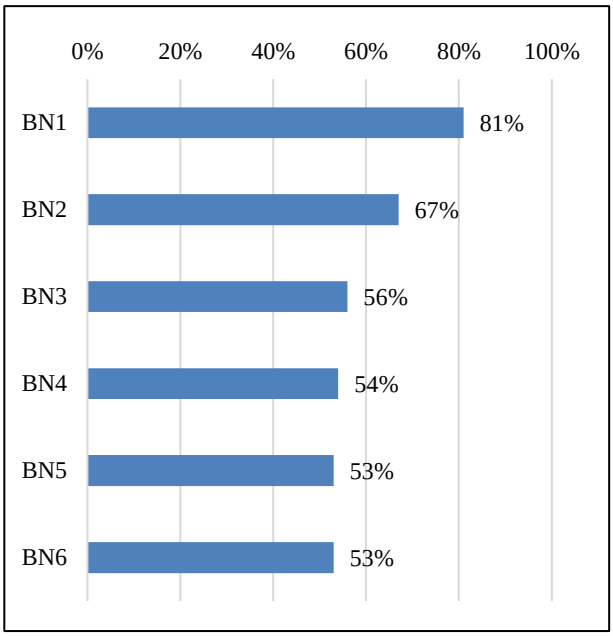

Figure 3. Overall Perceived Benefits of Respondents

Based on the demographics of respondents, Analysis of Variance (ANOVA) was adopted to analyze the differences among the four provinces with the $p<0.05$ threshold for rejecting the null hypothesis. ”Strongly Agree” and “Agree” were coded as “1” and “Unsure”, “Disagree” and “Strongly Disagree” were coded as “0”. Table 1 shows the P-values that were output when ANOVA tests were run for the six perceived benefits. All benefits (BN1-BN6) have P-values over 0.05, which means that there was no statistically significant difference towards the perception of the six BIM benefits among the four provinces. This shows a positive sign for the industry as the various benefits of BIM adoption are consistently perceived by different regions across Canada.

Table 1. P-Values for the Six Benefits

	BN1	BN2	BN3	BN4	BN5	BN6
P	0.447	0.673	0.766	0.594	0.792	0.680

5.2.1 Comparison of 2018 and 2019 Perceived Benefits in GTA Only

BIM users and non-users were identified in both years: BIM users are those who have used or currently use BIM on projects, and non-users are those who have basic BIM knowledge but do not use BIM on a regular basis [7]. Responses from the GTA region in 2019 were compared

to respondents in 2018, across the six identified benefits as shown in Figure 4. Comparison of 2018 and 2019 GTA Surveys, users have stronger beliefs than non-users such that users' experience provides better insights into the perceived benefits for adopting BIM in projects, workflow, and industry. Three benefits (BN1, BN2, and BN4) are well-perceived (over 80% agreement) by BIM users in both 2018 and 2019 surveys. Non-users generally have an increase in beliefs in the perceived benefits, except for visualization (BN2). However, the slight drop in visualization is not significant. The general increase in understanding for BIM benefits for users and non-users shows promising results for the future of the AEC industry.

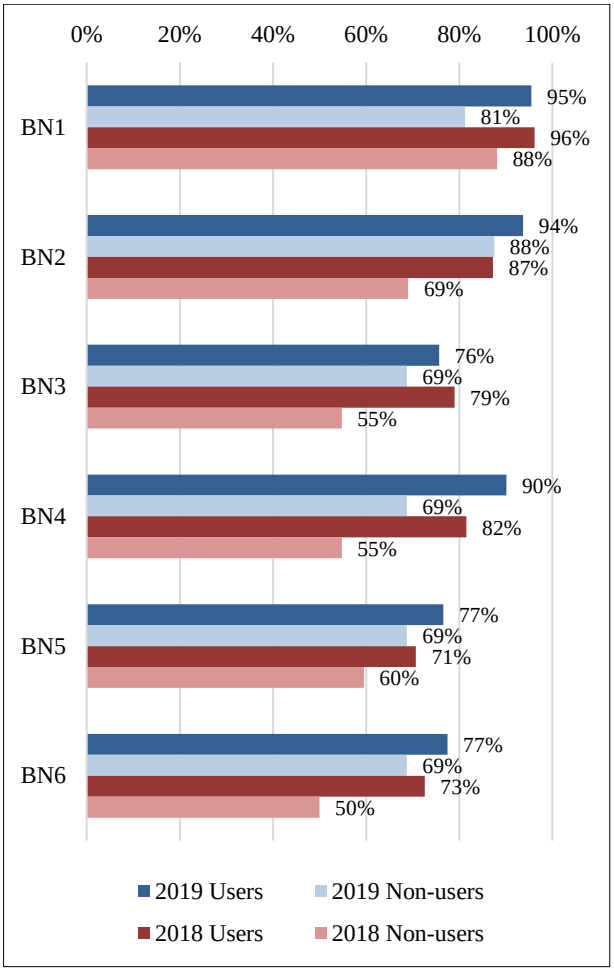

Figure 4. Comparison of 2018 and 2019 GTA Surveys

5.3 Perceived Barriers to BIM Adoption

Question 21 examined the barriers to BIM adoption. Respondents were asked to select the barriers they encountered from a list:

- BR1: Resistance to change
- BR2: Lack of knowledge/skill
- BR3: Software learning curves
- BR4: Lack of training
- BR5: Lack of mandate
- BR6: No client demand
- BR7: Lack of collaboration/cooperation
- BR8: Legal issues
- BR9: Doubts on return on investment
- BR10: Lack of perceived benefits

Based on the responses, top barriers to BIM adoption in ON, AB, BC, and QC are presented in Figure 5. Resistance to change (BR1) is the number one barrier throughout four provinces, which might imply that the local construction industry is ready for BIM implementation but there are still a lot of people refusing to embrace the technology. Lack of knowledge/skill (BR2) is another common barrier identified to BIM adoption. It was interesting to see that this barrier is more prominent in BC and QC comparing to AB and ON. In terms of software learning curves (BR3) and lack of training (BR4), the responses from BC, AB, and QC are rather close at around 50%. The results from ON for BN3-BN5 were significantly lower than the rest provinces, which might indicate that there are comparatively more software training opportunities available and more support from public authorities towards BIM adoption in Ontario.

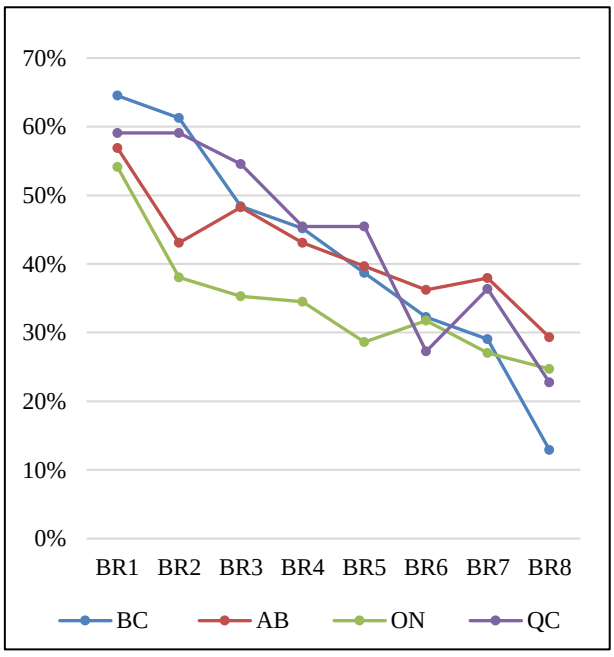

Figure 5. Comparison of Perceived Barriers in ON, AB, BC, and QC

In addition, around 30% of respondents agreed on the barriers of lack of client demand (BR6) and lack of collaboration/ cooperation (BR7). This indicates that joint efforts from the government, project stakeholders and clients are important but not crucial to ensuring BIM adoption. Lastly, legal issues (BR8), including ownership, liability, and licensing, are considered as a greater barrier in AB, ON and QC compared to BC.

5.3.1 Comparison of 2018 and 2019 Perceived Barriers in GTA Only

Top barriers to BIM adoption in GTA are presented in Figure 6. Comparing the barriers identified in 2018 and 2019, a growing trend in BIM adoption can be identified in the GTA region. In 2019, significantly more respondents are able to see the benefits of BIM and fewer are having doubts on the Return on Investment (ROI) of implementing BIM comparing to 2018. Even though a lack of mandate is perceived to be less of a barrier in 2019, industry professionals are seeing more demand from clients (as indicated by the reduction in No Client Demand) and starting to develop their own BIM Execution Plan within their company. With wider BIM implementation in the GTA region this year, barriers including lack of training, software learning curves and resistance to change are becoming more prominent.

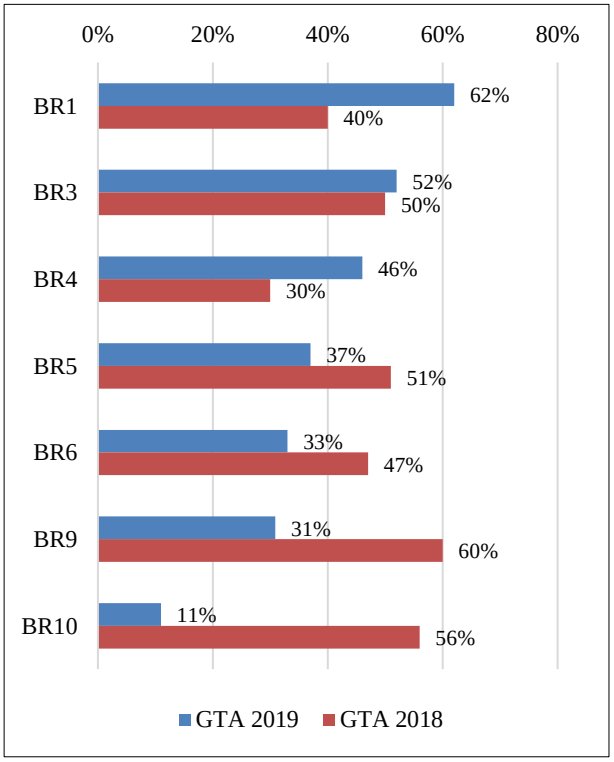

Figure 6. Comparison of 2018 and 2019 GTA Surveys

6 Conclusion and Future Work

Understanding the local and national barriers to innovation and new technologies can help streamline the adoption process. This paper first reviewed the global status of BIM implementation, worldwide initiatives on BIM surveys as well as some of the potential benefits and barriers in BIM adoption in literature reviews. Local BIM survey initiatives including the First Annual BIM Survey in GTA and the Second Annual BIM Survey in Canada were introduced in detail. The goal of the surveys was to capture and document the adoption status of BIM in the Canadian AEC industry.

In this paper, special attention was paid to the perceived benefits and barriers to BIM implementations. The complete survey results and analysis for the Second Annual BIM Survey will be published online at the Building Tall Research Centre (buildingtall.utoronto.ca) and tBIMc (tbimc.ca) websites. This BIM survey initiative will be repeated on an annual basis in the future to identify and monitor the trend of the BIM adoption in Canada, which serves as a milestone in the BIM transition process in the Canadian AEC industry.

Abstract –

A common problem when operating heavy hydraulic machines consists in low-frequency resonance phenomena that significantly limit the bandwidth of the closed loop position control. The interest in this topic is further motivated by the fact that the usage of traditional dynamic models of hydraulic actuators usually leads to the identification of very high-frequency resonances. This paper tries to explain the origin of low-frequency resonances by analysing the kinematic coupling between hydraulic actuators and structural links that can be found in typical hydraulically actuated machines. A novel formula for the identification of such resonance frequencies is derived. A realistic simulation environment is used to identify the resonance frequencies corresponding to different load masses and link lengths. Finally, the identified frequencies are compared to the results obtained using the two formulas, showing the superior accuracy of the newly proposed approach with respect to the traditional one.

Keywords –

Hydraulic systems, Hydraulic actuators, Motion Control

1 Introduction

Hydraulic actuation systems are characterized by multiple convenient features (namely high power density, reliability, and relatively low maintenance cost) that make them particularly fit to several application domains. Not by chance these actuators are the most widespread in the construction and earthworks machinery sector [1,2], in the mining industry [3], and also in the agriculture and forestry field [4]. In spite of the aforementioned advantages, hydraulic actuators are typically affected by low-frequency resonance phenomena. In addition, these resonances are further exacerbated by the large masses and inertias typically characterizing the components of a hydraulically actuated machine. Unfortunately, these resonance phenomena significantly limit the performance and the overall bandwidth of any possible closed loop control systems [5]. In order to address this problem, several control strategies have been proposed, that aim at suppressing the oscillations caused by these resonances [6,7,8]. Machine design solutions have also been proposed. For instance, in [9] the authors increase the resonance frequency (thus minimizing the resulting oscillations) by properly sizing the hydraulic cylinders and by computing the optimal distribution of the inertias along the kinematic chain of the machine.

Even though a significant effort has been spent trying to limit the effects of these low-frequency resonances, very few research contributions focusing on the explanation of these phenomena can be found. Some contributions suggest that the origin of these low-frequency resonances may lie in the variation of the oil compressibility [10], that in turn can be triggered by the presence of air contaminating the fluid [11].

Nonetheless, one of the most interesting aspects of these resonance phenomena consists in their incoherence with respect to the classical dynamic equations of the generic hydraulic servomechanism, whose manipulation usually results in the identification of very high resonance frequencies. Starting from this observation, our work tries to explain the low-frequency resonance phenomena from an alternative point of view. As a matter of fact, traditional formulations of the dynamic model of the hydraulic actuator represent the load as a point mass simply acting in either compression or traction on the actuator itself, while in a generic hydraulically powered machine (e.g. an excavator) hydraulic actuators are connected to the links they move

through rotational joints. By explicitly taking into account the geometry of the connection (and consequently, the configuration-dependent nature of the mechanical load), it is possible to refine the dynamic model of the hydraulic actuator and to develop a suitable formula for the estimation of the smallest resonance frequency. The proposed approach was tested in simulation on a 1-DoF system modelled using MATLAB's SimHydraulics Toolbox. Results confirm that the proposed formulation of the resonance frequency is coherent with respect to the behavior of the simulated system.

This paper is organized as follows. Section 2 describes the classical model of a hydraulic servo-mechanism, while Section 3 introduces a more realistic model, characterized by a non-trivial coupling between the actuator and the load. For both systems the transfer function between the valve control signal and a mechanical quantity (either the cylinder's stroke or its linear velocity) is provided, together with a formula for the computation of the smallest resonance frequency. Then, Section 4, shows a comparative analysis between the frequency values obtained with a realistic simulator and the ones computed using the aforementioned formulas. Finally, conclusions and future development are discussed in Section 5.

2 Hydraulic cylinder with a rigidly connected load

In this section the standard model of a symmetric hydraulic actuator connected to a load mass is briefly recalled (see Figure 1).

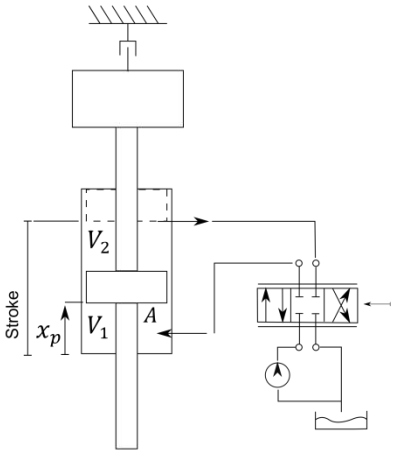

Figure 1. Hydraulic system with compressive load.

More specifically, after the derivation of the dynamical equations, the transfer function between the piston velocity and the valve control signal is presented, together with a rough estimation of the first resonance frequency of the system.

2.1 Hydraulic model

In order to derive the piston equation, we assume that:

- the oil is characterized by a finite compressibility defined by the nominal Bulk Modulus β;
- the thermal expansion of the oil is considered negligible;
- the oil density ρ is the same in the two chambers;
- the fluid losses to the external environment are negligible;
- the internal leakage q_L is proportional to the chambers pressure drop: $q_L = C_L(p_1 - p_2)$;
- the valve electro-mechanical dynamic is considered negligible.

Under these assumptions and according to [12], ρ can be considered equal to its nominal value ρ_0:

$$\rho = \rho_0 \left[1 + \frac{1}{\beta}(p_i - p_r)\right] \cong \rho_0 \tag{1}$$

(where p_i is the i-th chamber pressure and p_r is the initial pressure of the fluid). Therefore, the mass conservation equations for the cylinder chambers can be written as follows:

$$q_1 - q_L = \dot{V}_1 + \frac{V_1}{\beta}\dot{p}_1 \tag{2}$$

$$q_L - q_2 = \dot{V}_2 + \frac{V_2}{\beta}\dot{p}_2 \tag{3}$$

where p_i is the i-th chamber pressure and q_i is the i-th in/out volume flow rate. The two chamber volumes are given by:

$$V_1 = V_0 + Ax_p \tag{4}$$

$$V_2 = V_0 - Ax_p \tag{5}$$

where A is the piston area, x_p is the piston displacement and V_0 is the nominal chamber volume, computed when x_p corresponds to half of the cylinder's stroke.

Since the piston is symmetric the pressure drop

$\Delta p_m = p_1 - p_2$ can be considered as a state variable. Furthermore, by defining $q_m = q_1 = q_2$ and given the supply pressure p_p, the valve orifice equation can be written as follows:

$$q_m = \frac{K_v}{2} u \sqrt{\frac{p_p - p_m}{\rho_0}} \cong \frac{K_v}{2} u \sqrt{\frac{p_s}{\rho_0}} \tag{6}$$

where K_v is the discharge coefficient and u is the valve control signal. The overall hydraulic equation is then obtained as:

$$\frac{V_0}{\beta} \Delta \dot{p}_m = K_v u \sqrt{\frac{p_p}{\rho_0}} - 2A\dot{x}_p - 2C_L \Delta p_m \tag{7}$$

where C_L is the internal leakage coefficient. Finally, the resulting hydraulic force is given by:

$$F_p = A \Delta p_m \tag{8}$$

2.2 Mechanical equation

The mechanical equation is derived by considering a load mass rigidly connected to the piston rod:

$$(M_p + M_l)\ddot{x}_p + (D_p + D_l)\dot{x}_p + F_d = A\Delta p_m \tag{9}$$

where M_p (M_l) is the mass of the piston (load), D_p (D_l) is the damping coefficient of the piston (load), and F_d is a disturbance force (e.g. gravitational force).

2.3 Transfer function

By gathering the masses and the damping coefficients together in the terms M and D, respectively, it is possible to linearize equation (9) in a small neighborhood of the following equilibrium point:

$$x_p = 0 \quad \dot{x}_p = 0 \quad u = 0$$

This way, we obtain the following transfer function between the piston velocity and the control signal:

$$\frac{V_p(s)}{U(s)} = \frac{K_v \frac{\beta A}{V_0 M} \sqrt{\frac{p_p}{\rho_0}}}{s^2 + \left(2\frac{\beta}{V_0} C_L + \frac{D}{M}\right) s + 2\frac{\beta}{V_0 M}(A^2 + C_L D)} \tag{10}$$

Equation (10) represent a second order system whose resonance frequency can be roughly computed by simply neglecting the internal leakages ($C_L = 0$):

$$f_n = \frac{1}{2\pi} \sqrt{\frac{2\beta A^2}{M V_0}} \tag{11}$$

Notice that in case of a standard asymmetric piston the above relation slightly changes in:

$$f_n = \frac{1}{2\pi} \sqrt{\frac{2\beta}{M} \left(\frac{A_1^2}{V_{01}} + \frac{A_2^2}{V_{02}}\right)} \tag{12}$$

where A_1 and A_2 are the bottom-side and rod-side piston areas, respectively.

3 Hydraulically actuated mechanism

The above formulation clearly does not represent a system characterized by a non-trivial coupling between the actuator and the load. The case-study of this paper is indeed the 1-D.o.F. system shown in Figure 2, which is more similar to a real-world scenario (e.g. an excavator link).

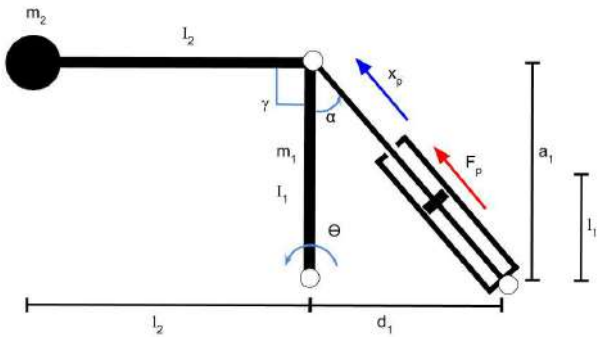

Figure 2. 1-D.o.F. hydraulically actuated mechanism

In this section we start by presenting the non-linear dynamical equations of the system, then we select a proper working point and, finally, we obtain the linearized model.

3.1 Kinematics

In order to retrieve the model as a function of the cylinder displacement, we can apply the cosine formula to the a_1-d_1-x_p triangle (see Figure 2):

$$\theta = \text{acos}\left(\frac{a_1^2 + d_1^2 - x_p^2}{2a_1 d_1}\right) = f_\theta(x_p) \quad (14)$$

3.2 Mechanical dynamics

The mechanical balance of the system can be obtained by assuming the piston mass and inertia to be negligible. Given these assumptions, the mechanism is equivalent to a 2-Link planar robot, where angle γ corresponds to the second DoF. Consequently, the dynamic of the mechanism can be computed according to [13]. In particular, given all the geometrical parameters shown in Figure 2 and defining m_i and I_i as the mass and the inertia momentum of the i-th link, the following equation is obtained:

$$B_1\ddot{\theta} + B_2\ddot{\gamma} + C_1\dot{\theta}\dot{\gamma} + C_2\dot{\gamma}^2 + G = \tau_1 \quad (15)$$

where:

$$B_1 = m_1 l_1^2 + I_1 + m_2 a_1^2 + m_2 l_2^2 + 2m_2 a_1 l_2 \cos(\gamma) + I_2 \quad (16)$$

$$B_2 = m_2 l_2^2 + m_2 a_1 l_2 \cos(\gamma) + I_2 \quad (17)$$

$$C_1 = -2m_2 a_1 l_2 \sin(\gamma) \quad (18)$$

$$C_2 = -m_2 a_1 l_2 \sin(\gamma) \quad (19)$$

$$G = m_1 g l_1 \cos(\theta) + m_2 g\, a_1 cos(\theta) + m_2 g l_2 \cos(\gamma + \theta) \quad (20)$$

and τ_1 is the equivalent torque provided by the hydraulic actuator:

$$\tau_1 = d_1 \cos(\alpha)\, F_p = d_1 \cos(\alpha)\, A \Delta p_m \quad (21)$$

A simpler formulation of the previous equations can be obtained by assuming:

- $I_1 = I_2 = 0$
- $m_1 = 0$
- $\gamma = {}^{\pi}/_{2}$ (fixed)

As a result, the dynamic equation reduces to:

$$m_2(a_1^2 + l_2^2)\ddot{\theta} + m_2 g a_1 \cos(\theta) - m_2 g l_2 \sin(\theta) = \tau_1 \quad (22)$$

Finally, the hydraulic dynamics is obtained according to Equation (7).

3.3 Linearized model

To compute the linearized model, the working point defined by $\theta_0 = \pi/2$ is considered. It is also useful to define the following quantities:

$$\delta x_p = x_p - x_{p_0} \quad (23)$$

$$\delta p_m = \Delta p_m - \Delta p_{m_0} \quad (24)$$

$$\delta u = u - u_0 \quad (25)$$

where:

$$x_{p_0} = \sqrt{a_1^2 + d_1^2} \quad (26)$$

$$\Delta p_{m_0} = \frac{m_2 g l_2}{d_1 \cos(\alpha_0)\, A} \quad (27)$$

$$u_0 = \frac{2C_L}{K_v}\sqrt{\frac{\rho_0}{p_p}}\Delta p_{m_0} \quad (28)$$

$$\alpha_0 = \text{atan}\left(\frac{d_1}{a_1}\right) \quad (29)$$

Moreover, the linear dependence of joint angle θ on piston displacement x_p can be defined as follows:

$$\theta = f_\theta\left(x_{p_0}\right) + \left.\frac{df_\theta}{dx_p}\right|_{x_{p_0}} \delta x_p = = f_\theta\left(x_{p_0}\right) + n_\theta \delta x_p \quad (30)$$

$$\dot{\theta} = n_\theta \delta \dot{x}_p \quad (31)$$

$$\ddot{\theta} = n_\theta \delta \ddot{x}_p \quad (32)$$

Therefore, the linearized mechanical equation is given by:

$$m_2(a_1^2 + l_2^2) n_\theta \delta \ddot{x}_p - m_2 g l_2 n_\theta \delta x_p - m_2 g l_2 \text{f}\left(x_{p_0}\right) = A d_1 \cos(\alpha_0)\, \delta p_m \quad (33)$$

and the linear hydraulic equation is:

$$\frac{V_0}{\beta}\delta \dot{p}_m = K_v\sqrt{\frac{p_p}{\rho_0}}\delta u - 2A\delta \dot{x}_p - 2C_L \delta p_m \quad (34)$$

3.4 Transfer function

Similarly to the previous case, it is possible to retrieve the transfer function of the linearized dynamics between the piston displacement and the valve control signal:

$$\frac{X_p(s)}{U(s)} = \frac{\mu}{Ks^3 + Fs^2 + Qs - H} \quad (35)$$

where:

$$K = \frac{V_0}{\beta} m_2 (a_1^2 + l_2^2) n_\vartheta \quad (36)$$

$$F = 2C_L m_2 (a_1^2 + l_2^2) n_\vartheta \quad (37)$$

$$Q = 2d_1 \cos(\alpha_0) A^2 - m_2 g l_2 n_\vartheta \frac{V_0}{\beta} \quad (38)$$

$$H = 2C_L m_2 g l_2 n_\vartheta \quad (39)$$

$$\mu = d_1 \cos(\alpha) 2AK_v \sqrt{\frac{p_p}{\rho_0}} \quad (40)$$

In addition, by neglecting the internal leakage ($C_L = 0$), it is possible to simplify the denominator, obtaining the following transfer function between the piston speed and the valve control signal:

$$\frac{V_p(s)}{U(s)} = \frac{\mu}{Ks^2 + Q} \quad (41)$$

Therefore, the resonance frequency can be estimated by:

$$f_n = \frac{1}{2\pi}\sqrt{\frac{K}{Q}} = \\ = \frac{1}{2\pi}\sqrt{\frac{2d_1 \cos(\alpha) A^2 - m_2 g l_2 n_\vartheta \frac{V_0}{\beta}}{\frac{V_0}{\beta} m_2 (a_1^2 + l_2^2) n_\vartheta}} \quad (42)$$

4 Numerical Simulations

In order to better understand the effect of the joint connected load, several simulations have been performed. In this section, the results of these simulations are presented and compared to the results of the previously explained formulas.

For this purpose, a realistic simulator has been developed in MATLAB/Simulink environment, using the SimHydraulics toolbox [14]. More specifically, the parameters of an off-the-shelf double-acting asymmetric cylinder and the ones of a commercial 4/3 valve have been considered. In addition, the mechanical system shown in Figure 2 has been reproduced. Finally, the pump behavior was assumed to be ideal, meaning that the supply pressure p_p was always constant. The simulations have been performed by feeding the valve with a sine sweep-shaped control signal and varying the load mass m_2 and the link length l_2 for a total of 40 different configurations. Then, resonance frequencies have been identified by analyzing the spectrum of the resulting cylinder's speed signal. As far as the "rigidly connected load" case is concerned, f_n is computed according to equation (11). For the sake of clarity, we replaced mass m_2 with an equivalent mass, computed on the basis of the average static load "sensed" by the hydraulic cylinder. In this way, we were able to incorporate in a single inertial parameter the effects of both m_2 and l_2. Figure 3 shows how the resonance frequency changes with respect to different load masses. Moreover, for each load mass value, five different link lengths have been considered. On the other hand, Figure 4 shows the dependency of the resonance frequency with respect to different link lengths. In this case, eight different values of load mass have been considered for each link length value. In both cases the identified frequencies are displayed in red, while the computed ones are pictured in blue. As expected, given the same load mass (link length), the resonance frequency tends to decrease as the link length (load mass) increases.

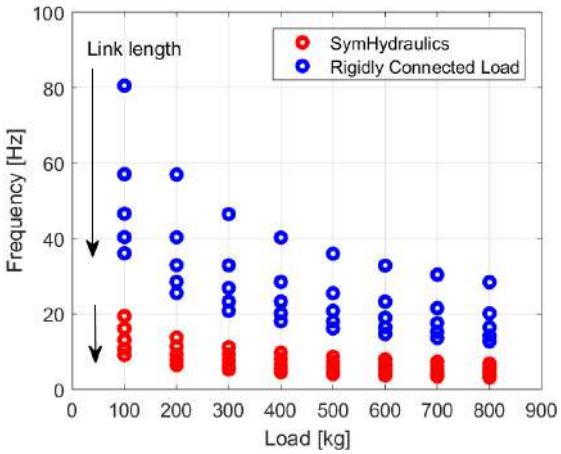

Figure 3. Resonance with varying load mass and rigidly connected load

Nevertheless, it is clear that the estimated resonance frequencies f_n computed according to equation (11) are significantly higher with respect to the corresponding identified frequencies. To this regard, Figure 5 and Figure 6 show the comparison among the identified frequencies and the ones computed according to equation (42). Clearly, the proposed formula is significantly more accurate than the traditional one. In addition, these results demonstrate how the kinematic coupling between the load and the actuator affects the natural frequencies of this system. Indeed, by means of Root Mean Square Error the following results are obtained:

$$RMSE_{rigid} = 23.4900\ rad/s$$

$$RMSE_{joint} = 0.0635\ rad/s$$

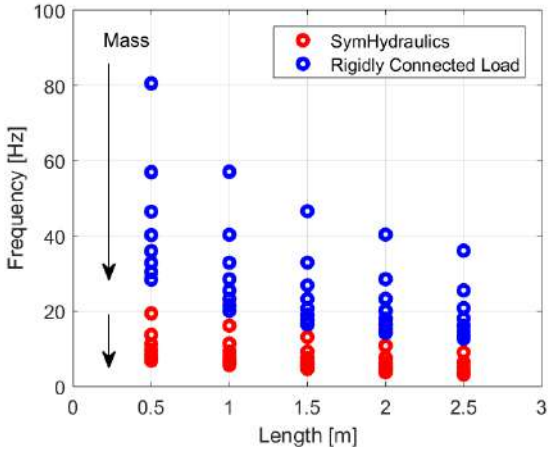

Figure 4. Resonance with varying length and rigidly connected load

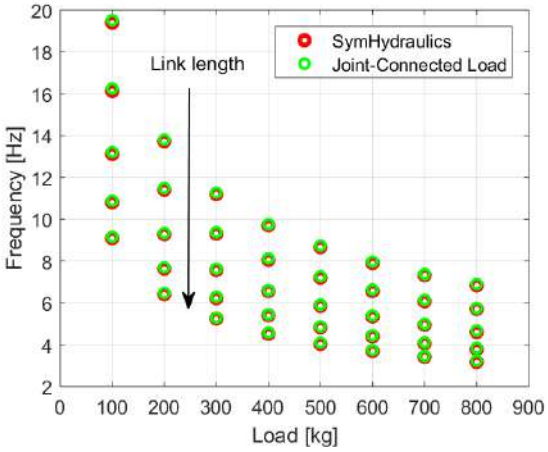

Figure 5. Resonance with varying mass and joint-connected load

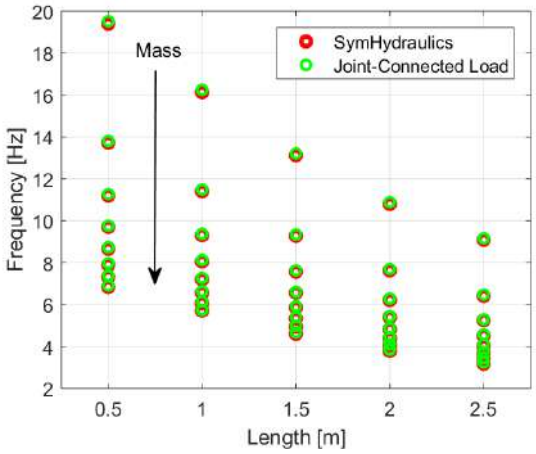

Figure 6. Resonance with varying link length and joint-connected load

5 Conclusions

This paper presents a study carried out on a hydraulic actuation system with the aim to achieve a better understanding of the causes of the low frequency resonances affecting the system. Starting from very simple models of the actuator and the load which it is connected to, the transfer function between the valve control signal and a mechanical quantity was computed and a formula to retrieve the resonance frequency was derived. Then, a more complex system characterized by a non-trivial coupling between the load and the hydraulic cylinder was considered. Once again, the model of the system was retrieved and, after linearization, a more complex formula for the estimation of the resonance frequency was computed.

Finally, a simulation environment of the joint-connected load was developed and several simulations were performed in order to obtain, via spectral analysis, an accurate estimation of the resonance frequencies corresponding to different load masses and link lengths. These estimated frequencies were compared to the results obtained using the two formulas, showing how critical is the impact of the kinematic coupling on the natural frequency of this kind of systems.

As far as future developments are concerned, the formula for the resonance estimation can be furtherly improved by taking into account the asymmetry of the hydraulic actuator and a more detailed description of the valve dynamics. To this regard, a promising solution could be represented by the adoption of object-oriented modelling strategies and tools [15], which allows to easily implement custom models such as the ones showed in [16].

Predicting Bridge Conditions in Ontario: A Case Study

M. Taghaddos[a] and Y. Mohamed[a]

[a] Department of Civil & Environmental Engineering, University of Alberta, Canada
E-mail: taghaddo@ualberta.ca, yasser.mohamed@ualberta.ca

Abstract –
Maintenance and repair of bridges represent significant costs in provincial and municipal government budgets. Prediction of bridge conditions can help managers in annual cost estimating and budget allocation. To assess Bridge Condition Index (BCI), each bridge component must be inspected every two years, tested if it is required, and rated. Bridge condition can be affected over time by different attributes such as material, structure, location, and use. This paper presents a study conducted to model and predict BCI based on a historical dataset of 2803 bridges in Ontario from 2000 to 2014. The paper describes the work related to data collection, cleaning and transformation. In addition, a comparison of the cross-validation performance of alternative BCI prediction models is presented and discussed.

Keywords –
Bridge maintenance; Bridge Condition Index (BCI); Prediction model; Cluster; Data analysis

1 Introduction

Bridges are essential infrastructures which are commonly used in transportation networks, and it is vital for them to function up to the acceptable level during their service life. However, to keep their functionality acceptable maintaining them and the corresponding cost is unavoidable. In the United States, the annual cost of rehabilitation is $7 billion [3]. To optimize the functionality of bridge infrastructure, continuous bridge access must be balanced with repair and maintenance costs as well as safety consideration [1]. Early identification of deterioration and following repairs enable decision makers to expedite the maintenance significantly with a lower cost and minimum disruption [4].

Continues bridge assessment can improve the maintenance of structure since it can accurately determine the structure condition, provide condition factor for load rating calculation, find the main reason of any deterioration and finally, determine appropriate rehabilitation process and corresponding budget [4]. Current tests for identifying bridge conditions are costly and time-consuming. Hence, a cost and time effective model for predicting bridge condition is beneficial from the budget allocation perspective.

The objective of this paper is to develop a framework to forecast the bridge condition for the future using historical data. Various prediction models are implemented and compared, and the best one is selected.

The advantages of the proposed approach are:

1. Enables managers to prioritize the bridges based on the level of urgent action required in a time and cost effective manner before formal assessments are conducted.
2. Helps to prioritize the expensive and invasive tests for the upcoming years.
3. Benefit ministries to proportionally allocate budget for repair and maintenance in advance.
4. Enable managers to evaluate different maintenance- scenarios over time to choose the best strategy.

2 Bridge Condition Index

One tool that can assist in the management of highway structure is Bridge Condition Index (BCI). BCI was developed based on two factors of the extent/severity factor Sf and element factor Ef, which both can have values between 1 to 10. Development of this index is entitled to High-Point Rendel and Taywood Engineering [5]. This index serves as a principle of resource allocation within a network [6] and can be helpful in various purposes naming [5]:

- It is an indication of a change in condition state over a period of time for the entire or part of the bridge
- By considering the entire bridge over a long period of time, the level of provided funding can be assessed to recognize its adequacy to keep the stock in a steady state
- By considering applied funding, BCI and type of material, the best and the most economic material of construction in the long run, can be assessed in each area
- By considering the level of funding and the BCI, it might be possible to achieve an

indication for the performance of agents who are responsible to take corrective actions.

Aside from these advantages, BCI has its own constraints in its applicability, such as [5]:

- BCI is not an indicator for the functionality of a bridge from a traffic point of view
- Safety is not a primary concern in BCI

Finally, since BCI is widely used in different countries including Canada, this paper considers BCI as a representative factor for the bridge conditions.

3 Case Description

The Ministry of Ontario adopted the BCI measurement system to evaluate the conditions of the bridge [7]. They inspected and assessed all bridges (2803 bridges) in Ontario from 2000 to 2014. In each inspection, experienced engineers and inspectors followed Ontario's Structure Inspection Manual (OSIM) which provides inspection procedures in great details. To identify maintenance procedure, they assess each bridge component comprehensively, such as barriers, sidewalks, deck asphalt, expansion joints, beams, pier cap, pier column, bearings, soffits, wingwall, and abutment. They performed a detailed visual inspection by checking the general condition of bridges, assessing components of each bridge, looking for any potential problem and reporting any safety issue (if there is any). Four common bridge test methods are used in the assessment.

1. External test using ultrasonic and magnetic particle tests, to identify hidden cracks in the structure.
2. Steel fatigue test using ultrasonic to identify cracks where steel parts are connected (it is common in older steel bridges).
3. Internal test using small samples for the test in the lab.
4. Bridge load capacity test with a driving special truck loaded with concrete blocks while instruments are attached to the bridge and record the movement to find the weight that bridge can safely carry at one time [7].

After scoring the bridge based on the BCI system, they assess the score according to Table 1 [7]. The Ministry of Ontario uses an innovative technology of rapid bridge replacement. In this method, crews lift the old bridges in a few hours and replace them with the new ones which are built nearby. Examples of this technology include Toronto 401 off-ramp bridge at Yorkdale Shopping Centre (2012), Ottawa - Island Park (2007) and Hamilton Aberdeen Bridge (2010) [7].

Table 1. The bridge condition index

BCI	condition	Maintenance
70-100	Good	Is not required in the next 5 years
60-70	Fair	Is required in the next 5 years
<60	Poor	required in the next year

4 Data mining

4.1 Explaining data set

This data set contains 2803 records for bridges in Ontario. Each record contains name, exact location, longitude, latitude, structural system (e.g. slab, beam/girder or frame), material, year built, last major and minor rehabilitation years, details of spans and measured BCI since the year 2000.

4.2 Proceeding data preparation

Preparing data is one of the most important parts of data mining problems. In this case study, data mining is a major consideration. Most of Bridge Condition Indexes are measured on a bi-yearly basis, meaning data organization is crucial. Many classification algorithms consider the gap years between measurements as "missing values," which is not true in this study because the measurements are not taken on an annual basis. To overcome this misperception, the BCIs are sorted chronologically based on the year in which they were measured and then assigned sequential numbers. One record is illustrated as an example in Table 2, which was then transformed into Table 3.

Table 2. Original dataset of one record for BCI

Year	2013	2012	2011	2010	2009	2008
BCI	88	-	89.9	-	96.2	-

Table 3. Transformed dataset of one record for BCI

Year	BCI1(BCI)	BCI2	BCI3
BCI	88	89.9	96.2

Many bridges have only minor or major rehabilitation, which affects the BCI. Although the better approach is to capture both, since the majority of bridges only have one type of rehabilitation, it will increase the missing data to a great extent. Therefore, it is decided to take the most recent rehabilitation (regardless of the type, either major or minor). Data

cleaning is coded in R [8], an open-source statistical environment.

4.3 Feature Selection

Feature selection is an essential step in machine learning, particularly in big data. Many gathered variables are irrelevant to the classification, and its relevancy is unknown unless tested [9]. Most importantly, using large feature sets data, slows down algorithms [9] and decreases its accuracy when numbers of utilized attributes are more than optimal [10]. Hence, from the practical perspective selecting small and possibly minimum feature set is highly desirable [9]. This problem considered a minimal optimal problem [11], which has been studied for several years to reduce the feature set. Although using more attributes may result in better accuracy, the model is hard to interpret, and overfitting is more likely. One of the feature selection methods is called wrapper, which finds the best combination of features (subset). Boruta feature selection is a wrapper built based on random forest algorithm. Its algorithm is coded in R- an open source statistical environment in a package called Boruta [8]. It helps find the most important attributes or recognize unimportant ones. This package iteratively compares the importance of each feature with the importance of shadow attributes, that is initiated by shuffling original dataset [9]. Then, those attributes that are significantly better than shadow attributes are confirmed; otherwise, they will be dropped. This process continues until the maximum run occurs or only the confirmed attributes are left. If the former one occurs, it is called Tentative. Hence, the user can increase the number of runs or decrease p-value. To calculate the importance measure of an attribute, first the loss of accuracy of classification for all trees of the forest (that have this attribute) is calculated separately. This loss of accuracy is the result of the random disposition of attribute values between objects. Then the importance measure would be the result of dividing the average loss by its standard deviation [9]. Although it has some deficiencies, it is a useful tool since it can count the fluctuations of the mean accuracy loss among trees in the forest [9].

In order to conduct the Boruta selection algorithm, first the dataset is cleaned, similar attributes were removed, and derived attributes are mutated. The result of this algorithm is shown in Figure 1. Based on this selection feature algorithm, the previous measure BCI (CI2) has the most crucial role in the prediction of bridge condition. Furthermore, different feature selection methods such as subset selection, forward and backward methods as well as filtering method (single factor analysis to evaluate the prediction power of each attribute) are also conducted. All these feature selection methods confirm that the most effective attribute is the most recent BCI.

Hence, the features that have importance value greater than 15 are selected for prediction model which are BCI2, BCI3 (the two recent BCI), the year of most recent rehab and age. Adding more attributes such as longitude and latitude (which implicitly is in the country), material or category, not significantly change the accuracy of the models. It is important to note that different models are conducted based on the result of other feature selection algorithms, namely subset selection, forward, backward, filter and Boruta selection (as each feature selection algorithm suggests a different set of attributes). Although all of them are common in BCI2, the Borouta model is the best based on its performance, hence, proposed.

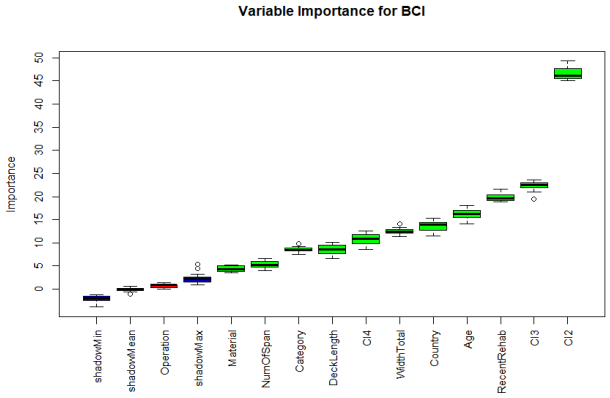

Figure 1. Boruta selection algorithm

4.4 Prediction Model

In this case study, in order to predict the BCI, different numerical prediction algorithms are conducted. Each model is tested in a cross-validation test. Then, the results are compared to choose the best one.

4.4.1 Model Development

The first step in developing the framework is to export the cleaned data from R [8] in a spreadsheet, which is the input for RapidMiner Studio as the Data-Mining Software [12] (Its graphical environment eases its usage for data mining users). As Figure 2 shows, linear regression, KNN, neural network, support vector machine, and random forest are modelled.

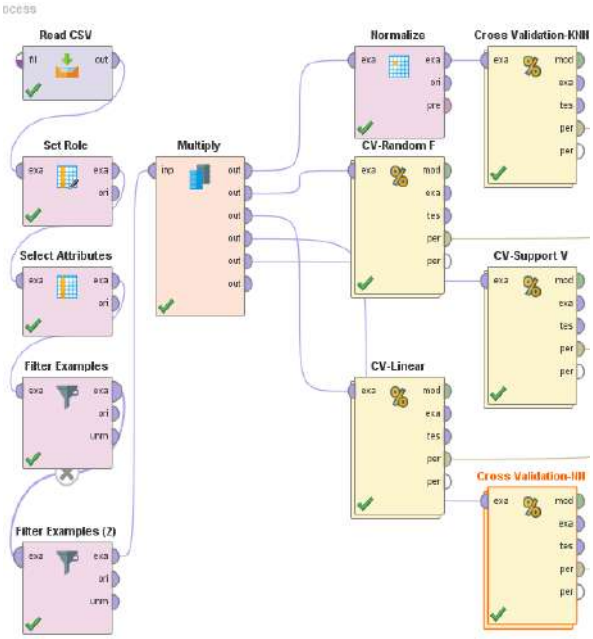

Figure 2. Classification model development

4.4.2 Linear Regression (LR)

In this classification, the relationship between attributes and target attribute is defined with a linear predictor function and their unknown parameters of this function are calculated from training dataset. Table 2 shows the statistical results of this model.

The formula to calculate the upcoming BCI for the next two years will be as equation 1.

$$Next\ BCI = 0.823 \times BCI2 - 0.075 \times BCI3 + 0.08 \times Year\ of\ Most\ Recent\ Rehab - 0.024 \times Age - 139.854 \quad (1)$$

In this equation, BCI is the predicted Bridge Condition Index for the next year, BCI2 and BCI3 are two formers measured BCIs for the past years. Year of the most recent rehab is the previous year of rehabilitation (either minor or major) and Age is the current year minus the year built of the bridges.

4.5 K-Nearest Neighborhood (KNN)

K-Nearest Neighbour (KNN) is a lazy classification algorithm based on the instances. The mechanism of this method is by calculating the distance for each instance from other instances and assigning them to a class based on k-nearest point. There are different equations for calculation distances such as Manhattan or Euclidian distance. In this study, Euclidian distance is used to measure. David William Aha studied KNN in his doctoral dissertation (1990) and suggested normalizing the values of each feature before applying the model [13]. That is because KNN is sensitive to the scale of data and if they have a different scale, the effect of bigger attributes may neutralize the value of small attributes. Finding the best K in the KNN method can be achieved by try and error as there is no precise rule for this purpose.

4.6 Neural Network (NN)

Artificial Neural Network (ANN or NN) is a data-driven model which is trained iteratively from a random state to estimate target value. This algorithm tries to mimic brain behaviour to learn through neurons. The neurons receive signals from other neurons through the links from the previous layer, which may strength or weaken through weights. When the signal excitation reaches to a certain extent, the neurons will react and fire. However, it is not clear what happens inside this algorithm completely as it is called a black box engine. NN is not depended on the distribution or probability; hence, is considered as a universal approximator [14]. It can be used for both classification (which is well known for it) and regression. It is important to note that by the iterative process, the algorithm finds the weights in a way that can minimize the error.

4.7 Support Vector Machine (SVM)

It is a supervised learning classification model that analyses data for classification or regression analysis. SVM finds the algorithm that had the best and well-separated categories with the clear gap (as wide as possible) between the classes, which increase the probability of a new sample to belong to only one group. Generally, in this algorithm, the wider the margin, the lower the generalization error [15].

4.8 Random Forest (RF)

Random forest is based on the idea of a random selection of features to generate trees. It is an ensemble learning method based on numerous decision trees in training. This algorithm can be used for classification or regression, and the predicted output will be the mode of the classes or mean of prediction, respectively [16, 17].

4.9 Model Selection and Comparison

To select the best model, the first step is to test the accuracy of the model. If there is an extremely big data set, the best practice is to use half of the data for training and the rest for testing. However, usually, data-limitation is a common problem. Thus, it is important to find the best approach for dividing the dataset into training and testing sets. That is crucial because if all data is used in training, although the model is highly accurate, the performance of the model facing new

unseen input is highly unknown (validity). On the other hand, if a small

portion of data is utilized for training, the model will not be precise enough. Cross-validation is a tool to overcome this difficulty by dividing data to n folds." The technique of cross-validation usually is recommended as a better test of the model because of the well-known bias induced by testing the predictive validity of a model on the same data that were used to estimate its parameters" [18]. Hence, by cross-validation, we can use all of the data-set in the model. Table 4 shows the error comparison of classifiers by cross-validation test.

Based on Table 5, the relative error of support vector machine is the lowest, root mean squared error of the random forest is the lowest, and correlation of random forest is the highest among all prediction models. However, statistically, there is not a meaningful difference in the accuracy of these models based on statistical t-test with alpha 0.05. Therefore, it is better to find the model which has the smallest range for the error. For this purpose, the box plot of accuracies, based on root mean square error is plotted in Figure 3.

As Figure 3 shows, although the ranges do not vary too much, support vector machine, KNN (K=4) and neural network have a relatively wider range. Based on Figure 3, the author recommends using random forest prediction model, which has a relatively denser box-plot, or linear regression because of its simplicity.

Table 4. Statistics of Linear Regression Model

5 Conclusion

Annually, Maintenance and repair of bridges impose significant costs to municipalities. Having a good prediction of bridge conditions can help to recognize the bridges that need an urgent repair, or require repair in a short interval of time. This can be highly beneficial for governments for budget allocation and sequencing the maintenance operation. Furthermore, it can be helpful for planners in order to have a targeted bridge inspection.

This study is based on the historical data of the Municipality of Ontario to find a predictive model for bridge condition index. After feature selection, four prediction models are assessed, namely, linear regression, random forest, neural network, KNN and support vector machine. Then, based on the corresponding accuracy between these models, random forest and support vector machine are suggested. As the study shows, this model can predict the next BCI with 97% accuracy having two former BCIs, age and the year of most recent rehabilitation. By annual update of the database, the suggested framework can enhance further to achieve better accuracy. If the historical data is available, this model can be conducted for a different location.

6 Limitation

The scope of this study is limited to develop a prediction model for BCI and excludes improvement of measurement in BCI experiment or incorporating safety in BCI. This model is not also for selecting the type of material or any design specification of the bridges.

Abstract –

Modularization in construction involves erection of large and heavy prefabricated modules at the job site. Modules, especially in industrial plants, are required to be lifted without any tilted angles vertically and horizontally to prevent applying bending moments to the lifting lugs and structural components. Configuration of rigging elements, which are the link between the crane hook and the module, plays a vital role in the load distribution to the rigging components. In practice, designing a rigging assembly to ensure safe and successful lifts is a time-consuming and tedious process relying heavily on guesswork, especially when the module's center of gravity is offset. In addition, the pitch angle of the module remains unknown until it is lifted, thus raising safety issues regarding the failure of rigging components. To overcome these limitations, this paper proposes a mathematical-based design framework which consists of: (1) collecting the module information; (2) designing a preliminary configuration by selecting the rigging components from the database; (3) Optimizing the number, size and capacity of the rigging components selected for the preliminary configuration in order to ensure that positions of module and spreader bars are set on parallel lines without tilted angles; and (4) reporting the list of used rigging components and visualizing their configuration as the output. To validate this framework, this paper uses a case study which designs the optimal rigging configuration for a 4-point pick module based on the inventory availability.

Keywords –

Crane rigging; Automation; Center of gravity offset

1 Introduction

Modularization is a growing trend in construction thanks to its efficiency in terms of time and cost. In industrial plants, the off-site constructed modules can typically be classified as pipe racks, cable trays and building modules [1]. These modules may have up to 16 lifting points. Once transported to the job site, the modules are lifted from the pick points to their set points. In order to prevent applying bending moments to the lifting lugs and structural components of the module, the modules are required to be lifted vertically and maintained in a horizontal position during the lift. Slinging arrangement of the rigging assembly determines how the load is distributed from the lifting lugs of the module to the crane's hook.

Anderson [2] enumerated three possible slinging arrangements of 4-point pick modules as they are shown in Figure 1.

In Figure 1-a, 4 shackles and 4 slings are used to transfer the load directly from the lifting lugs to the crane's hook. The alignment of the lifting lugs is important in this configuration. Each of them must be in plane towards the COG. Otherwise, according to the supplier's manual, a reduction in the capacity of the shackles might be needed based on the angle the shackles make with the slings to which they are attached [3]. It is recommended to design the lifting lugs, shackles, and slings in a way that two of them are able to carry the entire load due to possible differences in the angles between the slings and horizon when the COG is offset [2]. Sam [4], presented a spreadsheet to analyze and calculate the sling loads for this slinging arrangement with consideration of the variations in the COG location. Similar rigging configuration is used when the object is lifted from the bottom with vertical slings used to transfer the lifting points above the object. However, lifting from the bottom has the risk of instability especially when the object's COG is too high. Longman and Freudenstein [5] suggested an analytical necessary and sufficient criterion for Liapunov stability or asymptotic stability for the 4-point pick lift from below the load's COG. They defined an expression for the margin of stability in which the disturbance forces caused by crane hook motion during the lift can be tolerated.

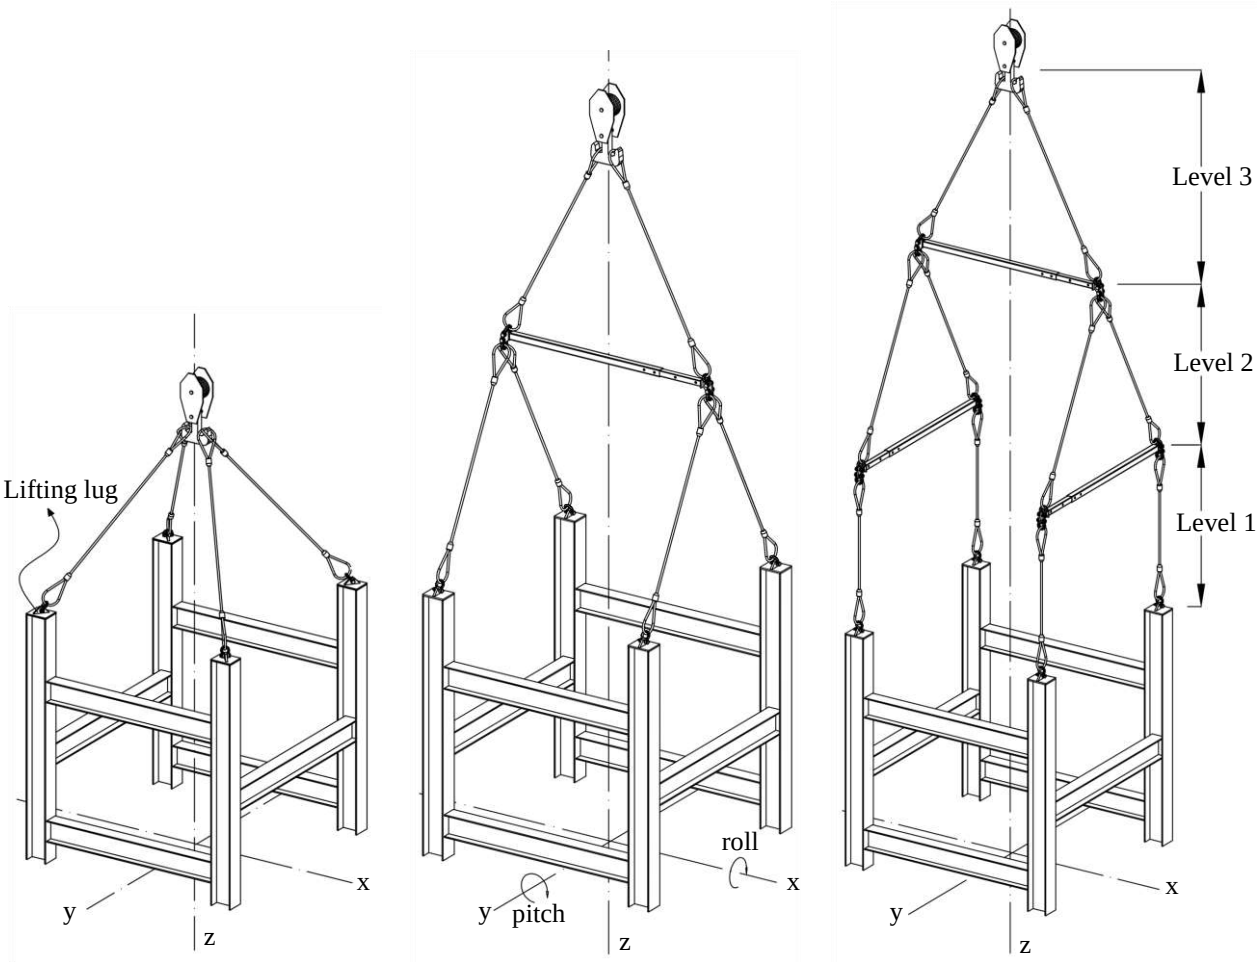

Figure 1-a Figure 1-b Figure 1-c

Figure 1. Three different slinging arrangements for a 4-poit pick module

In Figure 1-b, 8 shackles, 6 slings, and a spreader bar are used to first transfer the load from the lifting lugs to the spreader bar and from there to the crane's hook. The lifting lugs orientation needs to be along the y-axis of the module. In order to level up the module, the length of slings needs to be adjusted when the COG is offset. Regardless of the length of slings below the spreader bar, all of the slings will take the load [2].

In Figure 1-c, 16 shackles, 10 slings and 3 spreader bars are rigged in three levels. At the first level, the load is transferred vertically from the lifting lugs to two spreader bars along the y-axis of the module. From the second level to the crane's hook is virtually the same as Figure 1-b. When the COG is offset, in order to prevent the module from rolling and pitching (rotating around the x and y-axis of the object) the length of slings needs to be adjusted at the second and third level respectively. Needless to say, among the aforementioned slinging arrangement the latter is the only one that can ensure a vertical lift.

Operating two cranes and manipulating the length of their hoist lines could also be proposed as a way to control the pitch angle of the lifted module. However, operating a single crane is associated with a lower risk in comparison with operating two cranes or more. Thus, the lifting process is commonly accomplished by a single-crane operation unless the module, like vessels, necessitates vertical orientation at the set point [6]. In other words, it is not justifiable to add another crane only to have better control of the angle of lifted object considering the higher cost and risk of using more than one crane. In this regard, Chen et al [7] suggested a numerical model for manipulating the pitch angle of twin-hoisted objects with one crane. In their model, they adjust the length of the hoist lines of the boom and auxiliary jib to reach to the required pitch angle for the object during the lift. However, this model cannot be used to prevent the lifted object from rolling. In addition,

the available capacity of the crane becomes more limited when crane's auxiliary jib is used which is necessary for their model.

Designing the rigging assembly is a time-consuming and tedious process relying heavily on guesswork, especially when the COG is offset and sling length adjustment is required. When a module is not level after being lifted due to a wrong guess about the required sling length, the assembled rigging components need to be unrigged and adjusted again which leading to waste of time and decrease in productivity. In this respect, this paper presents a mathematical-based design framework which automates the design of the rigging assembly for 4-point pick modules. To ensure a vertical lift the third mentioned slinging arrangement is considered

2 Methodology

2.1 Overview

As it was mentioned earlier, if the Module's COG is offset in order to level up the module and spreader bars the length of slings needs to be adjusted at different levels of the rigging assembly. To compensate the offset toward y-axis of the module the two slings at the second level and on the opposite side of the COG are lengthened. Similarly, to compensate the offset toward x-axis of the module the sling at the third level and on the opposite side of the COG is lengthened. Lengthening the sling at the first level of rigging assembly is not desired since the spreader bars remain inclined.

As there are no slings with exact required lengths, the specified required length is made up using a standard sling and a number of shackles in chain. Each shackle has a specific inside length published in the supplier's manual. The question is: How many and what size of shackles should be used to reach the required amount of increase to the length of the slings. Added shackles have to meet the capacity requirement based on the sling they are attached to.

The research implements an automated design framework, written in C# language within Microsoft.Net framework. To find the angle of the forces acting upon the rigging components and also to find the required amount of increase to the length of slings, Wolfram Mathematica kernel is called within the code to solve a system of 12 nonlinear equations. Having the forces calculated, the framework selects the appropriate rigging elements from the Microsoft Excel database to which it is bound. The calculations are done in two perpendicular 2D planes of the rigging assembly (i.e. xz and yz).

As shown in Figure 2, the algorithm starts off by collecting the module information. In the next step, a preliminary rigging assembly is designed in which the module's COG is assumed to be at its center. Then by considering the COG offset and based on the calculations at the second and third level, the number, size, and capacity of the rigging components selected for the preliminary design are optimized to ensure that the module and spreader bars are maintained in a horizontal position during the lift. Finally, as the output, a list of used rigging components and the used percentage capacity of them, total height and weight of rigging assembly and the configuration figure in two 2D views is reported.

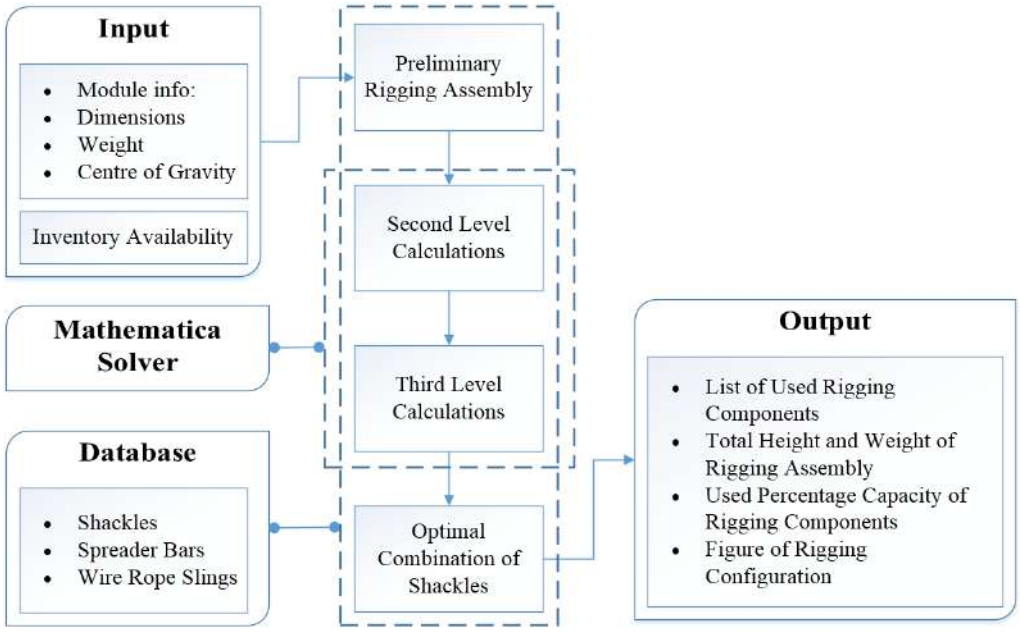

Figure 2. The framework algorithm

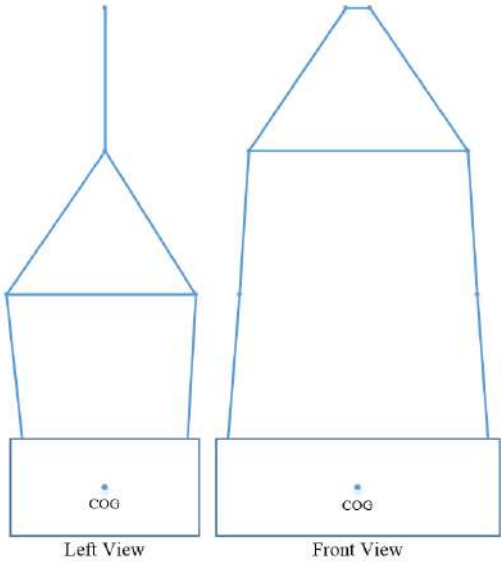

Figure 3. Left and front view of the rigging assembly for a 4-point pick module

2.2 Preliminary design

To design the preliminary rigging assembly, it is assumed that the module's COG is at its center. This will result in a symmetrical design in two perpendicular planes of the rigging configuration (Figure 3). The inclined lines in the figure represent the slings and the shackles they are attached to. The horizontal lines stand for the spreader bars except the top one in the front view which is the hook. Calculating the angles and in consequence, the forces acting upon the rigging components is straightforward due to the symmetrical configuration. Typically, the span of adjustable spreader bars has the intervals of one foot. Compared to the span of lifting lugs a shorter or longer spreader bar could be selected. This deviation in span will result in a non-vertical lift. In this case, the first four slings above the module, that are called drop slings, are lengthened to decrease their offset angle to the vertical line. The minimum acceptable offset angle is used as an input of the framework.

Based on the required capacity the minimum acceptable rated capacity is selected for each of the rigging components.

2.3 Second level calculations

The second level calculations are aimed at finding the angles between the slings and spreader bars and also calculating the required amount of increase to the slings when the COG offset is taken into consideration.

In either case shown in Figure 4, in order that the equilibrium conditions are satisfied the common point of inclined dashed red lines have to land on the vertical one. That is because the module's weight and the reaction force of the crane hoist lines to the hook is acting upon the vertical line; so the extensions of the inclined slings

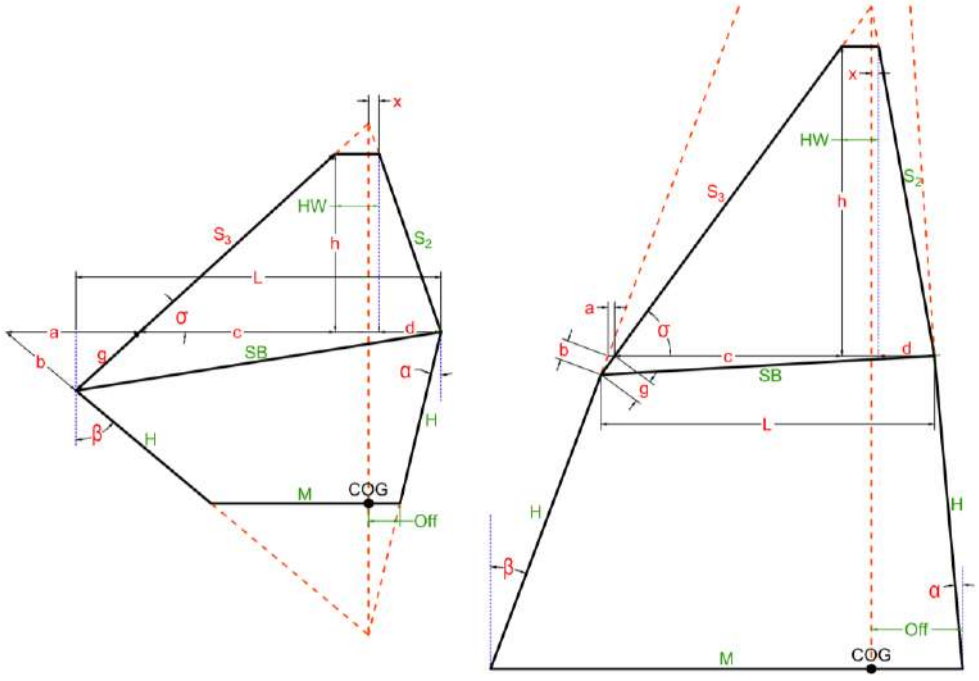

Figure 4. Schematic figure of rigging assembly when the spreader bar is longer (left figure) or shorter (right figure) than the distance between the lifting lugs

need to meet each other on the vertical line. To have a horizontal module, the spreader bar has a slight inevitable slope when the spreader bar and the module are unequal in length.

In Figure 4 (left) when the spreader bar is longer than the width of the module, there are 12 unknown variables, shown in red, which can be determined by solving a system of 12 nonlinear equations. The known and unknown variables are as follows:

Known variables: $\mathrm{HW}, M, \mathrm{Off}, \mathrm{SB}, \mathrm{S}_2, H$

HW: Width of the hook which is zero for the second level calculations.

M: Module width.

Off: The distance from the COG to the closer lifting lug in yz plane.

SB: Spreader bar length.

S_2: The total length of the sling and the shackles to which it is connected at the second level.

H: The total length of the drop sling and the shackles to which it is connected.

"HW", "ML" and "Off" are inputs of the framework. "SB", "S_2" and "H" are collected from the preliminary design.

Unknown variables: $x, \mathrm{S}_3, g, a, b, c, d, h, \alpha, \beta, \sigma, L$ as shown in Figure 4.

Where the equations are:

$$\mathrm{S}_2{}^2 = h^2 + d^2 \quad (1)$$
$$\mathrm{S}_3{}^2 = h^2 + c^2 \quad (2)$$
$$x/d = (\mathrm{HW} - x)/c \quad (3)$$
$$\mathrm{Off}/(H \operatorname{Sin}\alpha) = (\mathrm{M} - \mathrm{Off})/((H + b) \operatorname{Sin}\beta) \quad (4)$$
$$\mathrm{Off}/(x + d) = (\mathrm{M} - \mathrm{Off})/(a + c + \mathrm{HW} - x) \quad (5)$$
$$H \operatorname{Cos}\alpha = (H + b) \operatorname{Cos}\beta \quad (6)$$
$$b \operatorname{Cos}\beta = g \operatorname{Sin}\sigma \quad (7)$$
$$\mathrm{S}_3 \operatorname{Cos}\sigma = c \quad (8)$$
$$a = b \operatorname{Sin}\beta + g \operatorname{Cos}\sigma \quad (9)$$
$$L^2 + (g \operatorname{Sin}\sigma)^2 = \mathrm{SB}^2 \quad (10)$$
$$L = g \operatorname{Cos}\sigma + c + \mathrm{HW} + d \quad (11)$$
$$x + d = \mathrm{Off} + H \operatorname{Sin}\alpha \quad (12)$$

In Figure 4 (right), when the spreader bar is shorter than the width of the module equations 9 and 12 need to be replaced by the following two equations:

$$a + b \operatorname{Sin}\beta = g \operatorname{Cos}\sigma \quad (13)$$
$$x + d + H \operatorname{Sin}\alpha = \mathrm{Off} \quad (14)$$

And finally, when the length of spreader bar and the width of the module are the same, the value of a, b, g, α, β are equal to zero and S_3 is found using the following formula:

$$S_3 = \sqrt{\frac{(\mathrm{HW} - \mathrm{SB})^2(\mathrm{SB} - 2\mathrm{off}) + \mathrm{SB} \times S_2^2}{\mathrm{SB}}} \quad (15)$$

In any case, the required amount of increase (RAI) to the sling at the second level and on the opposite of the COG is equal to:

$$\mathrm{RAI} = \mathrm{S}_3 + g - \mathrm{S}_2 \quad (16)$$

That is, in fact, the difference between the length of two slings used above the spreader bar. In order to maintain the consistency at each level of the rigging configuration, identical slings are used and the required difference is made up by a chain of shackles.

After finding the unknown variables, the angles between the slings and spreader bars are calculated accordingly. Having the required capacity for each rigging component, the minimum acceptable rated capacity is selected from the database. If the COG is extremely offset, the angle of slings above the spreader bar will be very acute which increases the compression forces and bending moments applied to the spreader bar. In that case, there might not be any available spreader bar for the required capacity. So the next available longer sling will be selected for the slings above the spreader bar to increase the angle and decrease the required capacity.

2.4 Third level calculations

Similar to the second level calculations, the aforementioned system of equations is solved to find the RAI. However, some of the parameters have a different definition from their counterparts in the second level calculations.

M: Module length

Off: the distance from the COG to the closer lifting lug in xz plane.

S_2: The total length of the sling and the shackles to which it is connected at the third level.

H: the total height of the rigging assembly below the third level.

The rest of the parameters and equations are defined exactly the same as those in the second level calculations.

2.5 Optimal combination of shackles

In order to make up the optimal length with a chain of shackles, the goal function is defined as follows:

$$\mathrm{RAI} - \sum_{i=1}^{N} n_i d_i \leq 0 \quad (17)$$

Where:

RAI: The required amount of increase which calculated in the second and third level calculations.

N: The total number of shackles available with different size. Only those shackles which meet the capacity requirement based on the sling they are attached to.

n_i: The number of shackles i used in the chain.

d_i: The inside distance of shackle i.

This classic linear optimization problem is solved with a customized function using the Microsoft Solver

Table 1. The designed and used rigging components of rigging assembly on each level

	As Designed				As Used			
	Description	Required Capacity	Rated Capacity	Used Capacity	Description	Required Capacity	Rated Capacity	Used Capacity
Shackles attached to the lifting lugs	1-3/8 in (35 mm)	12.27 ton	13.5 ton	90.89%	1-3/4 in (44 mm)	12.27 ton	25 ton	49.08%

3 Case study

In order to validate the framework, the rigging assembly design of a 4-point pick module is taken into consideration as a case study. The following described module has been successfully lifted and erected in one of the NCSG Crane & Heavy Haul Corporation's projects. The module has 45 ft. (13.72 m) length, 17 ft. 7 in (5.36 m) width and 15 ft. 1 in (4.59 m) height. The lifting lugs of the module which are located at its bottom make a 25 ft. 2 in (7.67 m) by 17 ft. 7 in (5.36 m) rectangle. The module's COG is offset by 1 ft. 6 in (0.46 m) and 1 ft. (0.29 m) from the center of the rectangle towards x and y-axis of the module respectively. Thus, sling length adjustment is needed at the second and third levels of the rigging configuration. As the lifting lugs are at the bottom of the module, the length of the drop slings is needed to be greater than the module height. This is added to the design framework as a constraint. The rigging assembly is designed by the proposed framework and is compared to what was actually used on the job site. Table 1 represents the designed and used rigging components of rigging assembly on each level. As it is clear in the table, the design with the proposed framework is more efficient as the total height and weight of the automatically designed rigging assembly are 23.31% and 21.05% less than manually designed one respectively. In order to increase the length of slings at level 2 of the rigging configuration, a combination of one 25-ton and one 13.5-ton shackle is added to make up a chain with 12.25 in (31.12 cm) length. Similarly, a combination of one 55-ton and one 35-ton shackle is added to the slings at level 3 to increase the length of the sling by 18.25 in (46.36 cm). In the manually designed rigging assembly, one 55-ton shackle has been added to both second and third level to increase the length of slings by 10.5 in (26.67 cm). The designed shackles for the lifting lugs might not be suited in term of size. In that case, larger shackles could be replaced after completion of the design to match the size of lifting lugs.

4 Summary and future research

In this paper, a mathematical based design framework is presented which automates the selection of rigging assembly for 4-point pick modules. The framework collects the module information and calculates the required capacity for each rigging component using a mathematical-based solver and selects the most suitable rigging components from the database. The final

designed assembly ensures a vertical lift while the module and spreader bars are maintained horizontal during the lift. This results in a safe and time efficient lift in contrast to the current practice which is time-consuming and relies heavily on guesswork especially when the COG is offset.

This paper uses a case study in order to validate the practicality of the proposed framework. The case study proves that the automatically designed lift study is more efficient in terms of: total height and weight of the rigging assembly, inventory list of rigging components and detailed position of them.

The presented methodology is applicable to modules with 4 lifting points. In future research, the framework should be developed in order to automate the rigging assembly design for modules with more lifting points. As an instance, the rigging assembly for a module with 16 lifting points consists of 5 levels of rigging configuration which includes at least 270 rigging components [1]. This increases the complexity of the rigging system exponentially. In that respect, automation in rigging assembly design could be highly beneficial for large modules with more than 4 lifting points.

5 Acknowledgments

The authors would like to show their gratitude to the Natural Sciences and Engineering Research Council of Canada (NSERC) and NCSG Crane & Heavy Haul Corporation who supported this research.

Abstract –

As construction projects become larger and more complex and the amount of information increases, the necessity of introducing BIM becomes bigger and the importance of BIM-based drawing extraction is also increasing. In particular, the construction document (CD) stage draws and documents the subjects determined from the project planning stage so that actual construction can be possible. Therefore, information management and drawings using BIM in the CD stage have a great impact on the design, construction, and maintenance stages. However, in practice, the BIM results in the CD stage do not include all the necessary information in the construction stage, and the practical use of the drawings extracted from BIM is low.

To solve this problem, this study first analyzed the current status and level of BIM-based drawings in the CD stage by investigating projects that apply BIM in the Korean construction market. Next, the limitations and problems of BIM-based drawings are analyzed from a practical perspective by experts using the Delphi method. Finally, based on the results, methods to improve BIM-based drawings and work efficiency are discussed.

The results of this study can be interpreted based on how the BIM is perceived in different country. However, this study analyzes the current status and problems of BIM applications from general and practical perspectives. It will contribute to further activation of BIM in the architecture, engineering, and construction (AEC) industry if BIM-based drawing standards are established based on this study and follow-up studies are conducted on the development of quality and consistency review models for BIM-based drawings.

Keywords –

BIM; BIM-based drawings; Construction documents; Construction drawings; Construction document phase

1 Introduction

1.1 Research Background and Purpose

As construction projects become larger and more complex and the amount of information increases, two-dimensional (2D) based drawing information systems are switching to three-dimensional (3D) building information modeling (BIM) based information systems [5][11][17]. However, even with this change, drawings remain as a contract standard or legal unit; hence, creating and managing drawings in a BIM-based information system is important [4][7][9]. In particular, the construction document (CD) stage draws and documents the subjects determined from the project planning stage so that actual construction can be possible. Therefore, information management and drawings that use BIM in the CD stage largely affect the design, construction, and maintenance stages. However, in practice, an inefficient and limited collaborative environment exists among the participants, and the BIM results in the CD stage do not include all the necessary information in the construction stage [1][3][10].

To solve this problem, our laboratory has researched rational methods to extract drawings from BIM in the CD stage and investigate the consistency between the BIM results and design drawings in the CD stage. As part of this study, this paper presents the analysis results of our previous works.

First, we analyzed the current status and level of BIM-based drawing in the CD stage according to the construction work and drawing types by investigating an actual BIM application project in the Korean construction market. Second, we analyzed the limitations and problems in BIM-based drawings from the practical viewpoint of experts using the Delphi method. Finally, from the analyzed results, methods to improve BIM-based drawings and work efficiency are discussed.

The results of this study may be different depending on how BIM is implemented in each country. However,

this study aimed to analyze the current status and problems of the BIM application process from a general and practical perspective. If a BIM-based drawing standard is established and follow-up studies on the quality of drawings and development of a consistent review model are carried out according to the results of this study, it would help enable the automation of drawing extraction and verification in the CD stage using BIM. Therefore, the results of this study will strengthen the BIM-based design process and further promote the activation of BIM in the architecture/engineering /construction (AEC) industry.

1.2 Research Scope and Method

In this paper, we present the necessity and direction of BIM-based drawing plans by discussing the analysis of actual practical problems and the current situation regarding BIM-based drawing works in the CD stage.

To investigate the current status of the BIM-based drawings, actual drawings and BIM performance reports of three office buildings where BIM was applied in public construction projects in Korea were analyzed. In addition, a survey among experts was conducted using the Delphi method to analyze the problems and limitations of BIM-based drawings. The Delphi method statistically and systematically analyzes survey results using two or more questionnaires provided to an expert group in a specific field of expertise [6][12]. This is an efficient method for analyzing results when empirical evidence is lacking or when objective data collection is difficult [6][12]. Therefore, in the present study, two surveys and interviews were conducted with 10 design experts and five construction engineers who are experienced in BIM-based drawings in the CD stage. In the first survey and interview, the problems and limitation factors of BIM-based drawing-extraction works from a practical viewpoint were derived. The second survey, which applied a five-point scale (very low: 1 point to very high: 5 points) on the drawing-hindrance factors obtained from the first survey, was carried out to analyze the average values and stability (standard deviation/calculated average). From this analysis, we verified the severity and reliability of BIM-based drawing-hindrance factors.

2 Literature Review

Despite the advantages of using BIM and its major technological advances, BIM has not been fully established in the Korean construction industry because of practical problems and limitations [5]. In particular, as the necessity for effective linkage between BIM and existing 2D drawings in the design-process stage has increased, studies on the problems of introducing BIM into the design process and development plan of BIM-based drawings have been carried out. According to literature reviews, the problems of extracting drawings using BIM can be divided into the following three categories:

1. Inevitable additional work

- In BIM, additional information should be supplied to the first automatically generated drawing to complete the drawing [2][4][9][10][19].

2. Limitations of drawing representation according to the level of details

- The level of details expressed by a BIM model does not reach the level of existing drawings [2][3][10][19].

3. Slow working speed

- If the level of details is increased to that of existing 2D drawings, the modification and creation of the BIM model become slow [2][10].

To solve these problems, Chae and Lee [2] developed alternative solutions for the problems of existing drawing-representation methods using Korean and American cases when introducing BIM to architectural drawings. They also suggested an improvement plan for drawing licensing and delivery efficiency that are applicable to the Korean construction industry. In addition, Oh et al. [17] proposed the need for a BIM-based integrated design system to solve problems such as data loss, communication difficulties, and poor work efficiency resulting from the use of different BIM-based software among designers in the design stage. Lee and Jeon [11] also suggested a BIM-based integrated design process to improve the inefficient drawing-generation process due to institutional constraints. Kwon and Jo [9] proposed the development direction of 2D electronic drawing standards for effective introduction of BIM-based drawings.

Studies were also made on specific BIM software. Song and Jeon [18] classified the main functions provided by the Revit BIM software and conducted a survey on architectural design offices relative to the user perception of the BIM process and the current status and problems of BIM design works. Lee, Jeong, and Oh [10] compared the method of applying Revit to construction drawings of wall-type apartments with the existing 2D-based work method to analyze the additional work required and the work efficiency of BIM-based construction drawings. Cho and Lee [3] verified the possibility of printing the working-design drawings to the same level as those that used existing computer-aided design (CAD) systems when printing drawings using Revit.

To maximize the efficiency of BIM, Kim et al. [8]

developed an automatic 2D drawing program at the level of design development (DD) stage. Studies on the automatic generation of BIM-based drawings mainly focused on drawings for licensing at the DD level and extraction of shop drawings for production of specific materials. Zaki [19] developed a parametric model for automatic generation of shop drawings and detailed quotations for block walls in BIM. Manrique et al. [15] proposed a parametric and BIM-based automatic extraction of detailed drawings (FRAMEX) for wood members. Liu et al. [13] presented a solution that can automatically extract the layout configuration and material-cutting plan for a light residential building using BIM.

Previous studies related to BIM-based drawings presented methods to improve the efficiency of BIM drawing by deducing the problems that arise from a specific construction work field (referred to as "work type") or specific BIM software. However, research on the problems and application in the CD stage has been insufficient. Studies have been conducted on the extraction of drawings in the DD stage or shop drawings for product fabrication; however, no studies on BIM-based drawing automatic generation have investigated drawing extraction in the CD stage. Therefore, the present study aims to analyze the practical problems and limitations of BIM-based drawing works from a practical point of view, instead of focusing on the specific construction or software problems in the CD stage.

3 Analysis of current status of BIM-based drawings

3.1 Application of BIM-based drawings by work type

To investigate the current status and level of BIM-based drawings in the CD stage in terms of the construction work type and to identify the problems of each type, actual drawings and BIM performance reports of three office buildings, which are public construction projects in Korea, were analyzed. The analyzed work types were architecture, structure, machine equipment, electricity, and fire protection where BIM was applied during the CD and construction stages in the three cases.

3.1.1 Architecture and structure

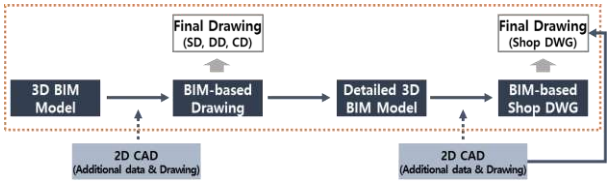

Figure 1. Current status of BIM-based drawings in the field of architecture and structure

In the architectural and structural work cases, BIM-based drawing work was performed using a 3D BIM model. Here, depending on the drawing type, additional 2D CAD work or 2D CAD drawings were performed. Extracting the drawings in the schematic design (SD), DD, and CD stages and the shop drawings during the construction stage could be possible.

3.1.2 Machine equipment

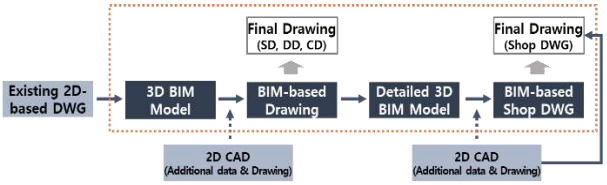

Figure 2. Current status of BIM-based drawings in the field of machine equipment

In the machine equipment case in the Korea AEC industry, the 3D BIM model was constructed from existing 2D CAD drawings, and the constructed model was processed using BIM, if necessary. Similar to the architectural and structural works, during the BIM-based drawing, extracting the drawings in the SD, DD, and CD stages and the shop drawings in the construction stage was possible, depending on the drawing type, using additional 2D CAD works or 2D CAD drawings. However, implementation of the BIM-based drawing work was low during the design stage.

3.1.3 Electricity and fire protection

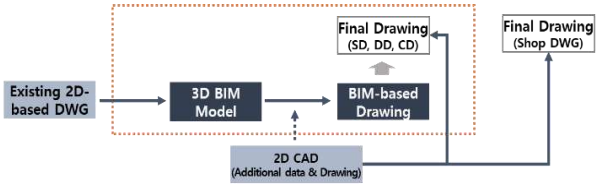

Figure 3. Current status of BIM-based drawings in the field of electricity and fire protection

In the electricity and fire protection work cases, similar to the machine work, the 3D BIM model was constructed from existing 2D CAD drawings, and the constructed model was processed using BIM, if necessary. During the BIM-based drawing, depending on the drawing type, extracting the drawings in the SD, DD, and CD stages was possible by performing additional 2D CAD works or 2D CAD drawings. In the shop drawings in the construction stage, 2D CAD drawings were utilized in most cases.

3.2 Utilization of BIM-based drawing according to drawing type: Architecture and structure

The level of utilization of a BIM-based drawing is different according to the work type. For the architecture and structure work types, the BIM model was not built according to the 2D CAD drawings, but the BIM-based drawing was performed after the BIM model was developed.

On this basis, this section presents our analysis of the BIM-based drawing extraction methods according to the drawing type of the architectural and structural works. The BIM-based drawing extraction result in the CD stage according to the three drawing methods is listed in Table 1.

Table 1. BIM-based drawing methods according to the drawing type

Classification	Drawing method
① BIM	Extraction of drawings from BIM
② BIM + CAD	Additional 2D CAD work on the BIM-extracted drawings
③ CAD	Drawing using CAD

3.2.1 Architecture

In the architectural work cases, 10% of the drawings were extracted from BIM, 54% of the drawings were completed by additional 2D CAD works on the BIM-extracted drawings, and 36% of drawings were CAD drawings. In other words, according to the characteristics of each drawing, 64% BIM-based drawing work was performed, and 36% was performed using CAD (Table 2). The drawing-extraction methods for each type of drawing were classified as listed in Table 3.

Table 2. Current status of the BIM-based drawing methods: Architecture

Classification	Percentage (%)		Note
① BIM	10	64	BIM utilization
② BIM + CAD	54		
③ CAD	36	36	CAD utilization
Total	100	100	-

Table 3. Drawing method according to the type of drawing: Architecture

Classification	Drawing type
① BIM	Floor plan, elevation, main section, window section, etc.
② BIM + CAD	Plot plan, plan drawing, enlarged plan, enlarged cross-section, plane/elevation details, etc.
③ CAD	Site planimetric map, interior material finish schedule, other detailed drawings, etc.

3.2.2 Structure

In the case of structural works, 10% of the drawings were BIM-extracted drawings, 44% were completed by additional 2D CAD works on the BIM-extracted drawings, and 46% were CAD drawings. In other words, 54% of BIM-based drawing work was performed, and 46% was performed using CAD (Table 4). Compared with the architectural works, the utilization rate of the CAD drawings was relatively high. The drawing-extraction methods in each drawing type are classified as listed in Table 5.

Table 4. Current status of BIM-based drawing methods: Structure

Classification	Percentage (%)		Note
① BIM	10	54	BIM utilization
② BIM + CAD	44		
③ CAD	46	46	CAD utilization
Total	100	100	-

Table 5. Drawing method according to the type of drawing: Structure

Classification	Drawing type
① BIM	Structure plan, column center plan, structure cross section, etc.
② BIM + CAD	Enlarged structure plan, Enlarged column center, partial structure cross section, etc.
③ CAD	Structure general items, schedule, detailed drawings, etc.

4 Limitations and problems of BIM-based drawing from a practical perspective

From the analysis of the BIM-based drawing applications discussed in Section 3, the problems and limitations of the BIM-based drawing-extraction work in the CD stage were investigated. For this purpose, the BIM model and the extracted drawings from the BIM project were analyzed. In addition, a survey using the Delphi method was conducted twice from 10 design experts and five construction engineers who were experienced in BIM-based drawings in the CD stage. In the first survey and interview, the problems and limitation factors of the BIM-based drawing-extraction works from a practical viewpoint were obtained. To verify the severity and reliability of each item in the drawing-inhibition factors obtained from the first survey, the average and stability (standard deviation/calculated average) of each item were analyzed through the second survey, which applied a five-point scale (very low: 1 point to very high: 5 points). Thus, the present study verified the severity and reliability of the BIM-based drawing-hindrance factors. The limitations and problems of the BIM-based drawing obtained in this process from the practical viewpoint are described in the next section.

4.1 Functional problems in BIM software

Because of the functional limitations of the detailed expressions of BIM-based drawings using the BIM software, cases arise where drawings created using 2D CAD are used as they are, or drawing elements extracted from the BIM model are used after being modified using the BIM software (Table 6).

Table 6. Results of the Delphi analysis of the limitations or problems: 1

Limitations or problems	Average	Standard deviation	Stability
Inevitable additional work	4.60	0.49	0.107
Functional limitations for detailed drawings of BIM software	3.20	0.75	0.234

The plan and cross sections of the delivered architectural and structural works of the three analyzed projects were created from the BIM drawing-extraction method (Tables 3 and 5). From the analysis results of extracting the expression elements in each drawing using the following two methods, extracting approximately 75% of the architectural plan without additional work using BIM was made possible. In the structural cross section, 80% of the drawing elements could be generated by additional work using BIM (Table 7).

- Method 1: Automatic extraction
  - Elements that can be used as drawing elements without additional work after extraction from the BIM model
  - Examples: grid, architectural wall, window, elevator, etc.
- Method 2: Additional work
  - Elements that require additional work after extraction from the BIM model
  - Examples: leader line, structural wall, parking lamp, equipment-related facility, etc.

Table 7. BIM-based drawing element-extraction method

Drawing type		BIM-based drawing-work method according to element (%)		
		Automatic extraction	Additional work	Total
Architecture	Plan	75	25	100
	Section	56	44	100
Structure	Plan	60	40	100
	Section	20	80	100

4.2 Differences in the application and utilization level of BIM according to work type

Participant collaboration and integrated management among works are the main purpose and greatest advantage of utilizing BIM [4][14][16]. However, because the utilization level of BIM-based drawings among works is different (as discussed in Section 3), limitations exist in integrating project management using BIM-based drawings. In particular, in the mechanical, electrical, and plumbing (MEP) field, which corresponds to machine equipment, electricity, and fire-protection work types, the capacity of the BIM model was approximately three times larger than that of the architecture or structure type. In addition, restrictions on the drawing work in the CD stage appeared because a detailed model was not determined. Furthermore, the participant ability to perform BIM was lower than that in the architectural and structural works. Therefore, BIM was performed by the service supplier, and utilization of the BIM model was low. In the MEP case, fitting and route changes frequently occurred at the construction site. Hence, confidence on the pre-verification using BIM was lacking. Because according to the contract, the specialized company was not responsible for the quantity, it did not empathize with the need to confirm the interference and to calculate an accurate quantity in advance using BIM.

Table 8. Results of the Delphi analysis on the limitations or problems: 2

Limitations or problems	Average	Standard deviation	Stability
Different utilization level of drawing according to work	4.60	0.49	0.107
Determination of MEP detailed model (design plan) at construction stage	4.60	0.49	0.107
Lack of ability of participants to perform BIM	4.50	0.50	0.111
MEP BIM model capacity size	4.40	0.66	0.151

4.3 Process and institutional issues

Problems are encountered in using BIM-based drawings from the process and institutional perspectives (Table 9). When a public organization that makes an order (owner) requests a delivery form based on existing 2D drawings and the criteria and guidelines of the delivery form of the BIM drawing and BIM-based drawing are not specified, delivering and utilizing the drawings extracted from the BIM are difficult. In particular, when a professional subcontractor who performs practical construction work participates in the construction stage, new design plans and decisions are often made, such as capacity to construct and interference. The resulting modification in the BIM model and the drawings represent considerable hindrance factors in BIM-based drawing-extraction work. In addition, when the service cost is not clearly specified according to the BIM work and application scope, BIM is passively utilized, resulting in a low BIM application effect.

Table 9. Results of the Delphi analysis on the limitations or problems: 3

Limitations or problems	Average	Standard deviation	Stability
Frequent design changes	4.60	0.49	0.107
Request delivery of 2D CAD form drawings (double drawing work)	4.10	1.22	0.298
Lack of criteria and guidelines for BIM-based drawings	3.80	0.40	0.105
Lack of BIM service costs due to low-cost bidding	3.40	0.80	0.235

5 Discussion

In this section, the factors that must be considered for promoting the use of BIM in the construction industry and improving the efficiency of BIM-based drawing work using the current status of BIM-based drawing works (Section 3) and analysis of actual problems

(Section 4) are discussed.

5.1 Establishment of a standard BIM delivery process

Establishing a standard BIM delivery process is necessary by standardizing the roles and responsibilities of each participant in each step of a BIM application project. Therefore, the BIM work system should be evolved into a system centered on the design and construction practitioners, rather than on the BIM-specialized service companies, by improving the drawing and delivery standards using BIM in the CD stage that serve as the BIM guidelines for practitioners.

5.2 Development of drawing templates

As presented in Sections 3 and 4, cases arise where some 2D CAD drawings are used or elements extracted from BIM are used as drawing elements through additional work in the BIM-based drawing-extraction process. Therefore, defining the minimum essential expression element for each drawing is necessary through the following: 1) considering the work efficiency from a practical viewpoint, 2) classifying and presenting the elements utilizing 2D CAD drawings and the elements that use the BIM model, and 3) gradually reducing the range of 2D CAD utilization factors that require unnecessary additional work. In addition, BIM-based drawing templates for each design stage should be developed so that the drawing-extraction work can be efficiently performed according to the work method in the BIM environment.

5.3 Automation of quality inspection and drawing extraction

The drawings extracted from BIM should be automatically updated when the BIM model is used. However, when the drawing element is not automatically extracted during the drawing extraction, additional works should follow. Therefore, examining the consistency between the BIM model and drawings is necessary. If the drawing elements in each drawing are defined and reviewed by classifying the extraction method for each element, the quality of the drawing (as well as the consistency), can be examined. Thus, if a checklist for the extraction method of each drawing type can be derived (and software can automatically check it), quality inspection and drawing-extraction automation will be possible.

6 Conclusion

This paper has presented the analysis results of previous works as part of a study to develop a rational method of deriving CD stage drawings using BIM and a model for examining the quality and consistency of the drawings derived from BIM.

First, we analyzed the current status and level of BIM-based drawing in the CD stage by investigating an actual BIM project case in the Korean construction market (Section 3). As a result, the level of utilization of BIM-based drawings in terms of the construction work type was different. The level and method of utilization according to the drawings also varied depending on the characteristics of the drawing and efficiency of the work.

Second, the limitations and problems of the BIM-based drawing works were derived from a practical viewpoint using the Delphi method involving experts. The derived limitations and problems can be categorized into the following three characteristics: 1) functional issues of the BIM software, 2) difference in the BIM application and utilization level in terms of the construction work type, and 3) process and institutional issues. The limitations and problem factors of each item were analyzed by applying a five-point scale. All stability values were 0.5 or less; therefore, the validity and reliability were determined.

Application of the results of this study may be different depending on the implementation in each country. However, this study is significant because it analyzed the current status and problems of the BIM application process from a general and practical perspective. In addition, stimulating BIM utilization in the AEC industry and improving the work efficiency of BIM-based drawings are possible if follow-up studies are conducted by considering the work environment and reality according to the status and problem analysis results. These studies should include the following: 1) establishment of standard BIM delivery process, 2) development of BIM-based drawing templates, and 3) automation of BIM drawing quality inspection and BIM-based drawing extraction.

Abstract –

Automated construction involves complex interactions between machines and humans. Unless all possible scenarios involving construction and equipment are carefully evaluated, it may lead to failure of the structure or may cause severe accidents. Hence monitoring of automated construction is very important and sensors should be deployed for obtaining information about the actual state of the structure and the equipment. However, interpreting data from sensors is a great challenge. In this research, a methodology has been developed for monitoring in automated construction. The overall methodology involves a combination of traditional model-based system identification and machine learning techniques. The scope of this paper is limited to the machine learning module of the methodology. The efficacy of this approach is tested and evaluated using experiments involving the construction of a steel structural frame with one storey and one bay. The construction is carried out by a top-to-bottom method. During the construction of the frame, 99 base cases of normal operations are involved. 158 base cases of possible failures have been enumerated. Failure cases involve, for example, certain lifting platforms moving faster than others, improper connections of joints, etc. Strain gauges and accelerometers are installed on the structure and the data from these sensors are used to determine possible failure scenarios. Preliminary results indicate that machine learning has good potential for identifying activities and states in automated construction.

Structural Monitoring, System Identification, Machine Learning, Automated Construction Monitoring

1 Introduction and Background

The construction industry is one of the oldest and biggest industries in the world. Diffusion of the latest technology is difficult in construction compared to other industries due to diverse parties and uncertainties involved in construction projects. Development of construction technologies is highly influenced by the innovative technologies in other fields. Introduction of robotics and automation in construction is inevitable due to advantages such as improvement of productivity, reliability and quality, enhancement of working conditions, safety, component standardization, workforce simplification and savings in lifecycle cost as well as labour cost [1].

Automating the construction processes involves a lot of complexities in micro-level details. Machines cannot anticipate certain conditions which may look obvious to a human being. This may lead to either failure of the structure being constructed or severe accidents or both. Hence monitoring of automated construction is of paramount importance.

2 Automated Monitoring of Construction

Sensors are widely used for automated monitoring of constructed structures as well as structures under construction. In structural health monitoring, constructed structures are measured to check for the presence of defects or reserve capacity [2]–[4]. Construction activities are being monitored for ensuring various requirements such as safety practices [5], the productivity of the workers [6] and the progress of the work [7]–[9]. Sensor-based monitoring to ensure the stability of the structure is rarely studied. Cho *et al*. used strain measurements to predict the conditions of collapse for scaffolding structures using machine learning [10]. This method requires an accurate model of the scaffolding as input, which might not be available in most of the construction sites. Other than temporary structures, there are cases of monitoring of construction of high-rise buildings. Choi *et al*. studied column shortening effects of high-rise buildings with wireless strain sensing system in real-time [11]. The sensors are embedded in the column while it is being constructed. Measurements with the sensors and transferring the measured data through a wireless sensor network are automated through this system. However, from the monitored column shortening data the managers have to

take appropriate corrective actions manually.

It is evident from various examples discussed above, that conventional method of construction can be improved with an automated monitoring system. For ensuring safety and reliable operations, an automated monitoring system is a necessity for automated construction. The degree of automation which can be attained in construction depends on to the extent to which micro-activities can be automated. This also depends on how well the control information is collected and coordinated to achieve overall monitoring of the entire structure. However, Sensor-based monitoring of safety and stability of an entire structure being constructed is not well explored yet.

3 System Identification in Construction

Automated construction requires rigorous monitoring to ensure the safety and stability of the structure. Appropriate sensors at optimum locations on the system will give necessary data about the system. The main research question is: How do you make sense of data from the monitoring system to take decisions about the construction process? For this, the actual state of the structure being constructed has to be identified. This can be achieved by System Identification.

System Identification appears to be a promising methodology which can be adopted for monitoring of automated construction. This methodology is widely adopted in various fields of engineering, especially for structural health monitoring in civil engineering [12]–[15]. The measurements from already existing structures are used for assessing their condition by system identification. Various methods for identifying the state of the constructed facilities are discussed in detail in a report published by ASCE in 2011[16]. However, the possibility of applying system identification in monitoring automated construction and stability of the structure being constructed has been not explored so far. Successful interpretation of measured data is highly dependent on the measurement system as well. In order to gain maximum useful information with minimal cost, the measurement system has to be systematically designed.

Most of the well-established system identification methods in construction require models or prior information about the structure. But in ongoing construction, the structure changes continuously. In this context, a rigorous approach free of models would be much more appropriate for monitoring. Machine learning techniques which are entirely data-driven opens up a possibility here.

A machine learning technique, Support Vector Machine (SVM) is proven to be successful in solving various complex construction management problems and acts as an efficient support system for decision making[17]–[22]. With careful selection of parameters, SVM gave better identification of construction activities compared to conventional system identification methods from strain sensing data [8].

4 Objective

The overall objective of this research is to develop a framework based on system identification which can be used to monitor automated construction of a structural frame. Conventional model-based system identification methods, as well as model-free approaches based on machine learning, were explored for this task. However, this paper focuses only on a machine learning based framework for monitoring. In particular, the feasibility of using support vector classification is explored. More complex deep learning models such as convolutional neural networks will be studied in the future. The machine learning module will eventually be integrated with conventional system identification techniques in order to develop a hybrid strategy that is most effective for the task of automated construction monitoring.

5 Methodology

The methodology adopted in this research involves experiments and data analytics. A prototype of an automated construction system was developed and experiments were conducted in controlled settings.

Figure 1. The partially constructed structural frame on the automation system

The automated construction methodology adopted in this study follows a top to bottom method of

construction [23]. In this method, the structural frame for the roof is constructed first and the lower part is constructed sequentially by adding one module of a column at a time, followed by the coordinated lifting of the finished structure. The advantage of this type of construction is that all the activities are performed at the ground level and heavy equipment such as tower cranes are not needed. Currently, the coordinated lifting operation is automated, whereas the connection of modules of the members is done manually. Higher levels of automation are planned for the future.

The structural frame used in this study consists of circular pipe sections with couplers as connectors (Figure 1). The scaled model of a one bay one storey structural frame has six columns (Figure 2 and 3). The automation system consists of 6 lifting machines at each column position (Figure 1). Each individual machine in the system has 2 ton lifting capacity.

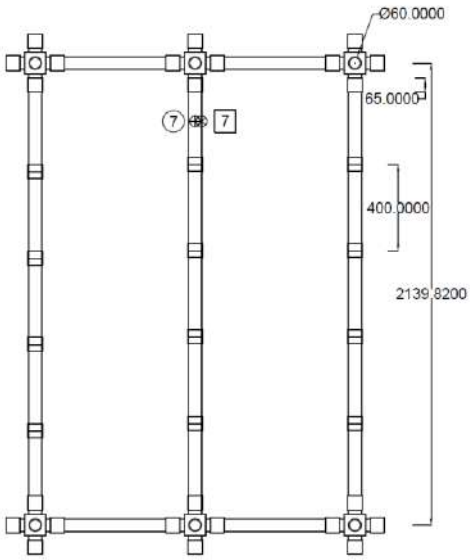

Figure 2. Front view of the structural frame with the location of sensors (All dimensions are in mm)

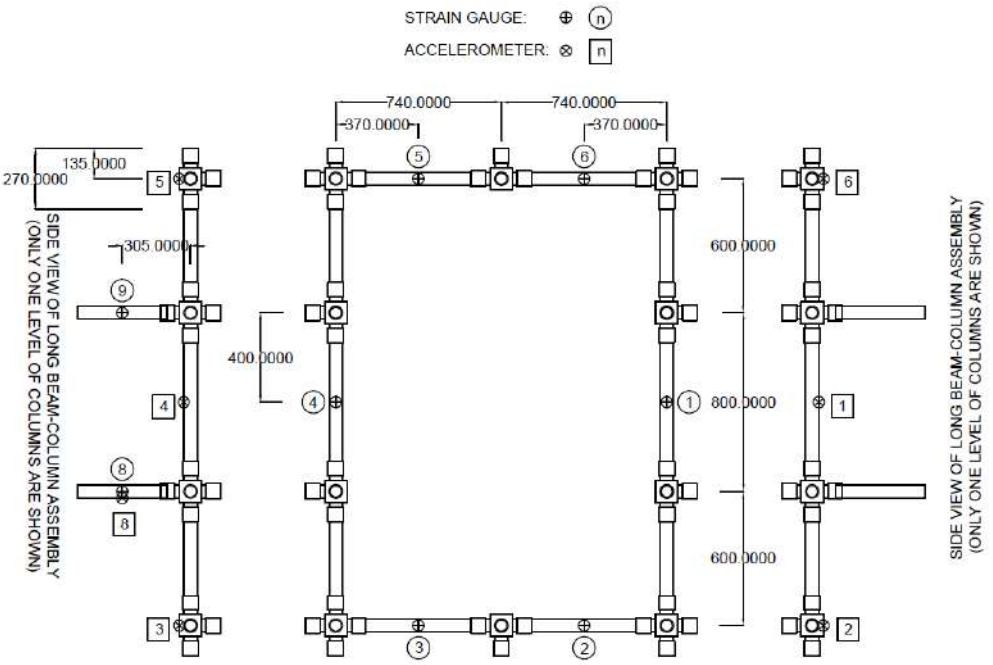

Figure 3. Plan of structural frame with the location of sensors (all dimensions are in mm)

6 SVM based framework for Monitoring Automated Construction

To monitor the state of the structure being constructed and the construction operations, a machine learning based monitoring framework is adopted in this study (Figure 4). This involves two major steps, training and predictions. During the training phase, the automated construction of the structural frame is carried out in controlled conditions within the limits of technical feasibility. Measurements from various sensors deployed in the structure are collected

continuously during the automated construction process. The measured signals are analysed and features for recognising the patterns are extracted. The patterns of measurements (PTij) recorded during the tests for each combination of measurement location (i) and operating condition (j) are used to train the algorithm. This involves patterns of measurement during normal operating conditions as well as failure conditions. SVM identifies each operation state by binary classification. The data corresponds to the operation to be identified is labelled as positive class and all other operations are labelled as negative class. In linear classification, the function or discriminant which separates the classes will be a hyperplane. The equation of the discriminant is obtained by maximizing margin, which is the distance between the nearest data points from either class to the surface.

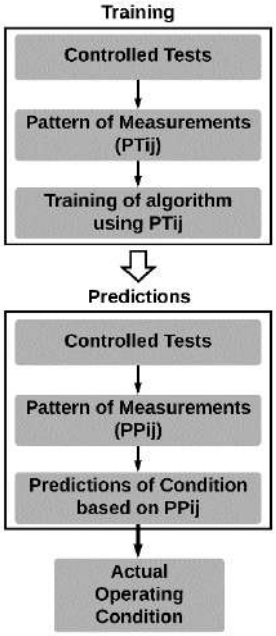

Figure 4. Machine learning based **system identification methodology**

Then controlled tests are performed and measurements are recorded (PPij). Based on the training data set, the algorithm will predict the operating condition.

7 Experimental Validation

Accelerometers (AM) and strain gauges (SG) are placed on the structure for measuring the vibration and strain during automated construction. The locations of sensors are shown in Figure 2 and 3. Totally 9 strain gauges and 8 accelerometers are deployed on the structure. 6 strain gauges are placed on the top of beam members at midspan and 3 strain gauges are placed on the top-level column modules at mid-height. 120-ohm linear strain gauges with 5 mm gauge length are used for the study. Monoaxial piezoelectric accelerometers are used for vibration monitoring. It has a measurement range of -5 g to +5 g with 1000 mv/g sensitivity. 4 out of 8 piezoelectric accelerometers are placed under the universal joints at each corner, 2 are placed under the long beams at midspan and rest of the 2 are placed on first level columns at mid-height.

First, the structure is constructed in perfect lifting conditions without errors in the assembly. Later, various failure criteria such as differential settlement and overturning are systematically introduced. Table 1 shows all the normal operating conditions and potential failure conditions involved in the construction of a one bay one storey structural frame with 5 levels of column modules. There are totally 257 cases of operation involved in constructing the structural frame in the current configuration with the automation systems developed. However, only a limited number of cases can be tested experimentally.

Considering the symmetry of the structure and practical operating conditions, the cases which have to be experimentally tested is limited to 70 without losing major details. The wired sensors are placed at the first level of the beam and column assembly in the current set of experiments. Hence connection of the beam assembly is not tested in this stage. Future experiments in which wireless communication strategy is used, the beam assembly will also be tested. While testing the failure cases, faulty conditions which will lead to potential failure of the structure during construction will be incorporated. Then the automated construction is continued and measurements will be taken. If we introduce a faulty condition, for example, an improper connection between modules of a column member, the pattern of strain and vibration will be different compared to the patterns of measurements corresponding to normal operation cycle.

The measurements taken during normal as well as failure cases will be analysed to arrive at features to train the algorithm. Each case of operation is repeated 6 times. 5 sets of data are used for training and 1 set of data is used for prediction. Starting time, ending time and duration of each operation is recorded manually in a time tracking excel sheet. Results of prediction are compared with this recorded data. The accuracy of prediction is calculated as a percentage of the total number of data points classified. Linear SVM classifier with an error penalty value 10 is used for this study.

Table 1. Total normal operating conditions and failure conditions in the automated construction

Sl. No.	Cases	Conditions of Operation	Number of Cases
	NC	Normal Operating Conditions	
1	NC1	Connection of Beam Assemblies	2
2	NC2	Coordinated Lifting of Finished Structure	7
3	NC3	Lowering of Supports	30
4	NC4	Addition of Column modules	30
5	NC5	Lifting the support until it takes the load	30
		Total Number of Normal Cases	99
	FC	Failure Conditions	
1	FC1	Non-contact of Supports after adding Column modules	30
2	FC2	Support moving faster during Co-ordinated Lifting	42
3	FC3	Improper Connection of Column modules	36
4	FC4	Improper Connection of Beam modules	40
5	FC5	Accidental Loading on the structure	10
		Total Number of Failure Cases	158
		Total Number of Cases	257

More than 50 operations are involved in the construction of a structural frame in 3 different levels of assembly by top to bottom automated construction method. This paper shows the classification of 3 different operation states. The idle state is the condition when the machine is switched on and the constructed structure is supported by all lifting supports, but no other construction activity is going on. This state gives the ambient vibration readings of the constructed structure. The normal coordinated lifting of finished structure (NC2) is the lifting of the constructed structure equally by all lifting supports for the assembly of next level of column modules beneath it. The failure condition considered is one of the supports moving faster during coordinated lifting (FC2). If this condition continues beyond a certain time, it leads to the overturning of the structure. The failure conditions are tested carefully in such a way that it will never be extended until the actual failure of the structure.

The data is acquired at a sampling frequency of 200 Hz. Millions of data points are generated from each experiment. Observing the pattern of strain and vibration measurements, average (AV) and standard deviation (SD) over moving time windows are found to be suitable features for recognizing the pattern of measured signals. In order to capture the change in pattern during sub activities, measurement data corresponds to each operation at each location is divided into 3 time windows and AV and SD are calculated for each part. These features are used to train the algorithm. Results of the study are discussed in the next section.

8 Results and Discussion

Six different parameters (3 AV values and 3 SD values) at each measurement location are used for training the algorithm. The algorithm is trained to identify three different scenarios; i) idle condition and a normal operating condition, ii) a normal operating condition and a failure condition and iii) a failure condition and idle condition. The prediction results are summarized in Table 2.

It is interesting to see that, just by using the SD of accelerometers, the algorithm can predict all operations with 100% accuracy. This will help us reduce the number of sensors used for monitoring. SD is a strong parameter for pattern recognition from vibration data. However, SD could not give good results with strain data while identifying Idle and FC2. This might be due to the small number of data points in support moving faster condition as it is a severe failure case which cannot be extended for a long-time during experiments. AV is not a reliable parameter as it might not give good results in all conditions. All the cases selected here for classification has average acceleration reading close to zero. In fact, including AV in certain cases might not even influence the prediction results.

Among the measurement type, vibration is more useful in accurate prediction. Strain data sometimes get affected by a minor level difference in the structural

frame, temperature or defect in the deployment of the sensor. In terms of prediction accuracy, the best results are obtained for separation between normal and failure cases (NC2 and FC2) among all the three cases. The clearly differentiating pattern over time ensures best predictions irrespective of parameters used.

Table 2. Prediction results for normal and failure conditions. Each column reporting the percentage of accuracy corresponds to a specific combination of features and the type of measurement

Operations Classified	Percentage of accuracy						
	AV and SD of AM and SG	AV of AM and SG	SD of AM and SG	AV of AM	SD of AM	AV of SG	SD of SG
Idle and NC2	100	83.33	100	50	100	66.67	83.33
NC2 and FC2	100	100	100	50	100	100	100
Idle and FC2	100	83.33	100	50	100	66.67	66.67

9 Conclusions

Automated construction of a structure has to be monitored continuously and accurately. Sensor data have to be appropriately interpreted to take control actions during automated construction. The challenge of making sense of a large amount of sensing data can be achieved by system identification methods. These methods have been used in structural health monitoring applications. Automated monitoring of a structure using this methodology has not been explored. Most of the conventional system identification methods in construction are limited by the prior information required to apply it. Data-driven techniques in machine learning are one of the best possibilities for addressing these limitations. Machine learning techniques such as SVMs have been proven to be capable of solving complex problems in construction. However, the quality of sensor data collected drives the performance of these methods.

Results from the present study show that an SVM based framework for monitoring automated construction is feasible. In the current set of experiments, the framework has a prediction accuracy of 100% with appropriate parameters for training. Depending on the type of measurement and operation, training parameters (features) have to be selected appropriately. Standard deviations of measurement data over moving time windows have been found to be very effective in accurate prediction. Among the measurement types, vibration is found to be more useful than strains.

Research is currently in progress on the use of more sophisticated machine learning models such as convolutional neural networks. Formulation of a robust framework for automated construction monitoring which combines a conventional system identification methodology with machine learning techniques is also in progress.

Acknowledgement

Authors wish to extend their sincere gratitude to all the faculties, staff members and project interns at Structural Engineering Laboratory, Building Automation Laboratory and Civil Engineering Department Fabrication Facility, IIT Madras for their unparalleled help and support in fabrication, installation and instrumentation required for the project. Abstract –

This research aims to develop a conversation-based system for school building safety inspections. The safety of school buildings requires routine and additional post-disaster inspections. However, the inspections are often complicated due to various timings and sets of checkpoints for different situations. In addition, the traditional paperwork process is not convenient for assessors to add additional images for detailed descriptions. Moreover, managers may face the inefficiency of grasping situations from numerous paper reports. To solve these problems, we developed a chatbot to notify, guide, and assist assessors to complete safety inspections, and a dashboard for managers to consume reports in order to determine whether further assessments or retrofits are required. In this research, we digitalized the process of safety inspections and developed a chatbot to notify and guide the assessors to complete their tasks. When an earthquake occurs, the chatbot notifies the assessor if the intensity scale of the earthquake meets the school building's safety threshold. The chatbot then guides the assessor to complete the inspection. The assessor may interact with the chatbot for further instructions and upload pictures of damaging. The system collects the reports from all schools, analyzes the data, and displays via the dashboard we designed for the managers which enables the managers to efficiently and correctly consume the reports for making decisions. The conversation-based system provides an effective interface for reducing the inefficiency of school buildings' inspections, featuring automatic notifications for assessors, a conversation-based interface for guiding assessors to accomplish inspections, the integration of intuitively concatenating the whole process of inspections, the acceptability of multimedia for lowering possibility of inspection mistakes, and the view of data visualization for decision supporting of the manager.

1 Introduction

The earthquake occurrence is quite frequent in Taiwan since Taiwan is located on the circum-Pacific seismic zone. The annual average number of earthquakes recorded from 1991 to 2004 increased to 18,649, of which approximately 1,047 were felt [1]. Despite the common occurrences of earthquakes, the majority barely causes bare damage to buildings and infrastructure. However, there were some destructive earthquakes, such as the magnitude-7.3 Chi-Chi Earthquake in 1999, which destroyed nearly half of the school buildings in Central Taiwan, and eventually damaged over 600 school buildings [2].

Due to the frequent occurrences of earthquakes in Taiwan, the Ministry of Education has ordered all public schools to establish "safety inspection task forces" for evaluating the seismic resistance of existing school buildings [3]. The safety inspection task force of each school is composed of the principal, the president of the parents' association, the director of general affairs, and other staffs of the school. Besides routine inspections once a year, additional inspections on irregular bases are required, especially after the occurrences of disasters including earthquakes that meet the critical safety thresholds. Based on the results of inspections, the managers who make decisions of budget allocation determine how to allocate resources for school building repairing.

The number and spatial complexity of school buildings make it tedious for assessors to repeat the inspections multiple times on different buildings. In addition, paperwork restricts forms of reporting inspections; multimedia such as images and videos are hardly accepted even though they provide richer information about building damages. Moreover, such numerous paper-form reports hinder managers to grasp the situation of potential damage. Currently, the

evaluations are paperwork and cover at least 20 checkpoints. Also, the members of safety inspection task forces usually do not have expertise in structural or civil engineering. The process of inspections may be quite a burden to the assessors, and the results may not completely illustrate the building damages to the managers.

The evolution of information and communications technology (ICT) has enhanced developments in communications and electronic devices. Wireless protocols and techniques make it possible to connect to the Internet regardless of time and location. In addition, electronic devices are smaller and more powerful than in the past; nowadays, people can access, process, and produce information online via smartphones at anytime and anywhere. Electronic devices are adapted to constructions problems to eliminate the difficulty due to paperwork; for example, iSafe, an iPad application, improves day-to-day practices and management of safety inspections, and allows consistent data collection that can eventually be used to aid the development of advanced safety and health data analysis techniques [4]. However, despite the popularity of smart devices to access the web, traditional designs of user interfaces are not ideal for the reduced size of the screen and keyboards of smart devices [5]. Graphic user interfaces designed for tablets may not fit with smartphones, which are more popular than tablets [6].

On the other hand, the growing popularity of smartphones has triggered the growth of messaging applications. The number of people using messaging applications has surpassed the number of people using social networks since 2015 [7]. Such a phenomenon has promoted chatbots as a new trending solution for trivial problems in people's life and work. Recently, chatbots are widely used in several areas, including economic, medical, and disaster management [8].

For construction projects, most chatbots are aimed to assist the management of work sites. Some chatbots are adapted to assist scheduling future works and remind managers to fulfill scheduled daily tasks; for example, ConBot, a construction site data assistant produced by Botmore Technology in the UK [9], and SafeTrack, developed by Talania Ltd in New Zealand [10], allows workers and managers to submit daily reports and information of accomplished works via dialogue. In addition, there are other chatbots that focus on site safety issues, such as Workplace Safety Bot, a chatbot developed by the Robust Tech House of Singapore, which allows users to report hazards easily and broadcasts safety reminders to users [11].

Chatbots have lower resistance than smartphone applications for users because of the needless of additional downloads and installations. It is not necessary for users to download any additional application which may occupy storages of devices. Only adding chatbots to contact lists is required for acquiring services. For most messaging applications, adding chatbots to contact lists is equivalent to adding true people. Also, conversations can be opened simply to offer specific services. Since chatbots are based on dialogue interface, users don't need extra efforts to be familiar with how to use the services. By contrast, it takes more time for users to learn how to use smartphone applications.

According to an online survey report [12], chatbots outperformed applications in the following five benefits categories: quick answers to simple questions, getting 24-hour service, quick answers to complex questions, ability to easily register a complaint, and getting detailed/expert answers. The detailed survey results are listed in Table 1. The percentages represent the proportion of respondents who associate the category with communication with business.

Table 1. Comparison of the top five benefits of chatbots which are associated with communication with business

Category	Chatbot(%)	Application(%)
Quick answers to simple questions	69	51
Getting 24-hour service	62	54
Quick answers to complex questions	38	28
Ability to easily register a complain	33	24
Getting detailed / expert answers	28	27

In conclusion, the convenience to access and capability to interact with users have made chatbots a new and feasible solution to integrate smart devices to all fields. Such benefits of chatbots make it a feasible solution to the complication of inspections, the inconvenience of the paperwork process, and the inefficiency of management for Taiwan's school building safety inspections.

2 Objectives

This research aims to reduce the complication of safety inspections, the inconvenience of the paperwork process, and the inefficiency of management. The safety inspections are often complicated due to various timings and sets of checkpoints for different situations. In addition, the traditional paperwork process is not convenient for assessors to add additional images for detailed descriptions. Moreover, managers may face the inefficiency of grasping situations from numerous paper reports.

In this research, we developed a system to solve the problems above. The system uses a chatbot as an interface to notify, guide, and assist assessors to accomplish safety inspections, and a dashboard as the other interface for managers to consume reports in order to determine whether further assessments or retrofits are required. The developed system includes the following features:

1. **Automatic notification** for notifying the assessor to accomplish inspections after earthquakes if the safety threshold of the school is reached.
2. **Conversation-based interface** for guiding the assessor to accomplish inspections in a non-professional-friendly way.
3. **Integrated tool** for concatenating receiving notifications and the inspections task in a single tool or application in order to improve the intuitiveness of the whole inspection process.
4. **Acceptability of multimedia** for allowing the assessor upload images or videos for showing damages directly in order to lower the possibility of mistakes in inspections.
5. **Data visualization** for decision supporting of the manager in order to enhance the quality and accuracy of budget allocation for building retrofit.

3 Methodology

In this research, we digitalized the process of safety inspections and developed a conversation-based system to notify and guide the assessors to accomplish their tasks. The system includes 3 modules: (1) the notification module, (2) the conversation module, and (3) the display module. The system architecture is illustrated in Figure 1. All 3 modules connect to the database, storing data including intensity scale thresholds of areas, assessors' contact information of schools, earthquake records, and inspection reports. The notification module and the conversation module interacts with assessors in the form of the chatbot we developed. The display module is accessed via web browsers by managers.

The notification module is activated by receiving earthquake information when an earthquake occurs. The intensity scale of each area is considered when selecting critical schools to announce safety inspections. The system looks up in the database to select the schools which locate at areas of which intensity scale thresholds are reached and sends notifications for safety inspections to the registered assessors of the schools via instant messaging applications in the form of the chatbot.

The conversation module interacts with the assessor via the instant messaging application in the form of the chatbot. The assessor starts a new inspection after receiving the notification from the chatbot. The chatbot guides the assessor to complete the pre-designed checkpoints in the inspection. The assessor may interact with the chatbot for further instructions and upload pictures of damaging. The chatbot collects the inspection, confirms the content with the assessor, and submits the inspection to the system. The system stores the inspection reports in the database.

The display module manages the dashboard for managers to check out the status of inspections via web browsers. The display module reads the inspection reports from all critical schools, analyzes the data, and displays via the dashboard we designed for the managers which enables the managers to efficiently and correctly consume the reports for making decisions.

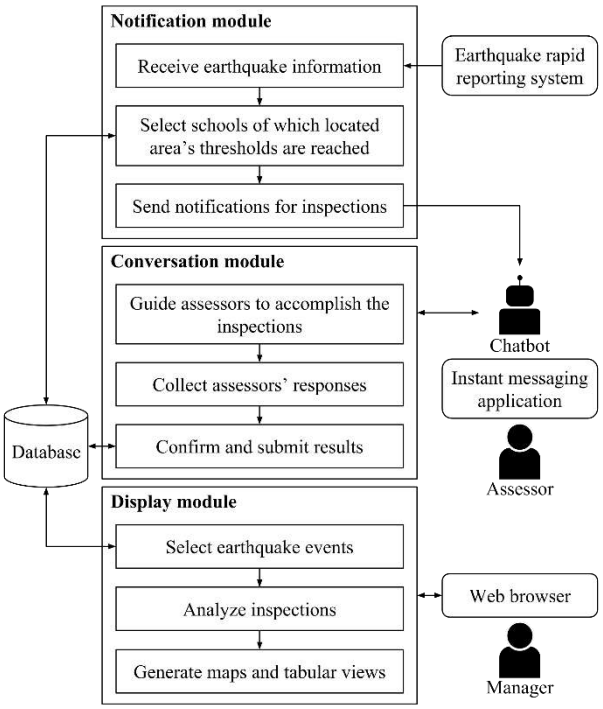

Figure 1. The system's architecture

3.1 Notification Module

The major task of the notification module is to inform the assessors whose schools locate in areas having higher intensity scales when an earthquake occurs. The procedure is illustrated in Figure 2. The notification module, connecting to the system's database, digitalizes the process of determining which schools require inspections and send notifications to the registered assessors of those schools, reducing the time of checking schools' thresholds and notifying assessors manually. The direct notifying messages sent to assessors' messaging applications are accomplished by the chatbot in their contact list as if they are sent by real people; the assessors may start the inspections smoothly by replying the chatbot when they receive the messages without

switching to another application, improving the intuitiveness from receiving notifications to starting inspections.

When an earthquake occurs, the system receives the information including the center, the magnitude, and intensity scales of different areas. The notification module determines the areas which are critical by the intensity scale threshold of each area which is defined by experts considering the sensitivity of the area. The schools in the critical areas will be selected to announce safety inspections after the earthquake. Notifications are then sent by the chatbot via instant messaging applications. The assessors' messaging application accounts are bind with their schools when they add the chatbot to their contact lists initially. After the critical schools are selected, the notification module sends instant messages to announce the assessors of the critical schools for accomplishing safety inspections. For the schools that do not locate in critical areas, the notification module does not send messages to the schools' assessors since such schools do not require inspection.

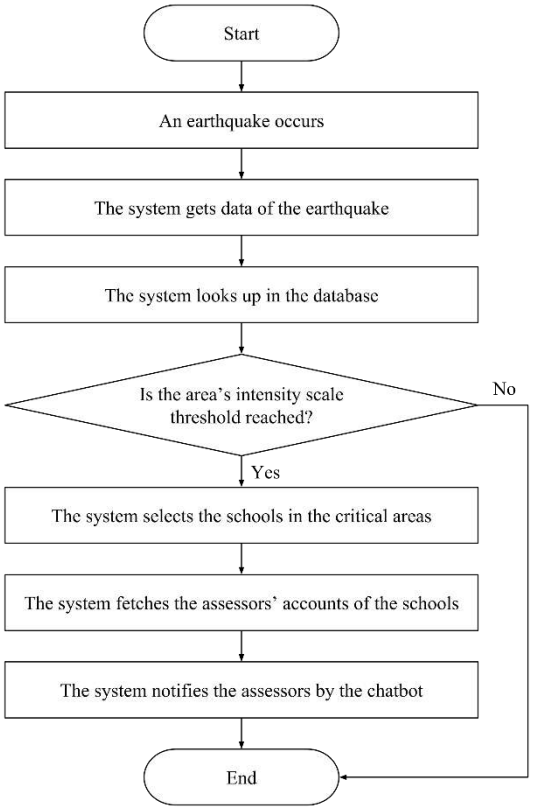

Figure 2. The process of the notification module

3.2 Conversation Module

The major task of the conversation module is to interact with assessors in the form of conversation in order to lower difficulties of assessors accomplishing the inspection. The procedure is shown in Figure 3. Since most assessors do not have expertise in structural or civil engineering, they may not be capable of accomplishing the complicated and tedious inspection checkpoints efficiently and correctly. The conversation module interacts with assessors with the chatbot, making inspections similar to having conversations with real people. The module guides assessors to accomplish the inspections, replacing the traditional paper-based procedure which lacks guidance for the non-professional assessors. The module also accepts multimedia file sent from assessors to the chatbot for clearer reports of damages, reducing the potential mistakes of inspection.

The assessors start the inspection by sending commands in text messages to the chatbot when receiving notifications. The chatbot asks assessors "questions" referring to the pre-designed inspection checkpoints. The inspection checkpoints are divided into 4 categories: overview, about indoor facilities, about outdoor facilities, and about facilities in corridors. The categories are set by roughly dividing building facilities. Assessors are allowed to start the inspection from anyone of the 4 categories. They answer the questions sequentially in the form of sending messages to the chatbot. They may pause in the inspection and continue accomplishing the remaining checkpoints later at any time they want since the conversation module manages the process of filling out the checkpoints; data of filled checkpoints will not be lost. In addition, assessors are allowed to send images and videos as if they are having conversations with real people via messaging applications. The chatbot collects the multimedia files as the answers to the checkpoints. The chatbot summarizes the contents into a message after accomplishing the inspection and presents it to the assessor for final confirmation. If modifying is required, the assessor may select the checkpoints to be modified and correct the answers. Finally, after the corrections are accomplished and confirmed, the system saves the results to the database.

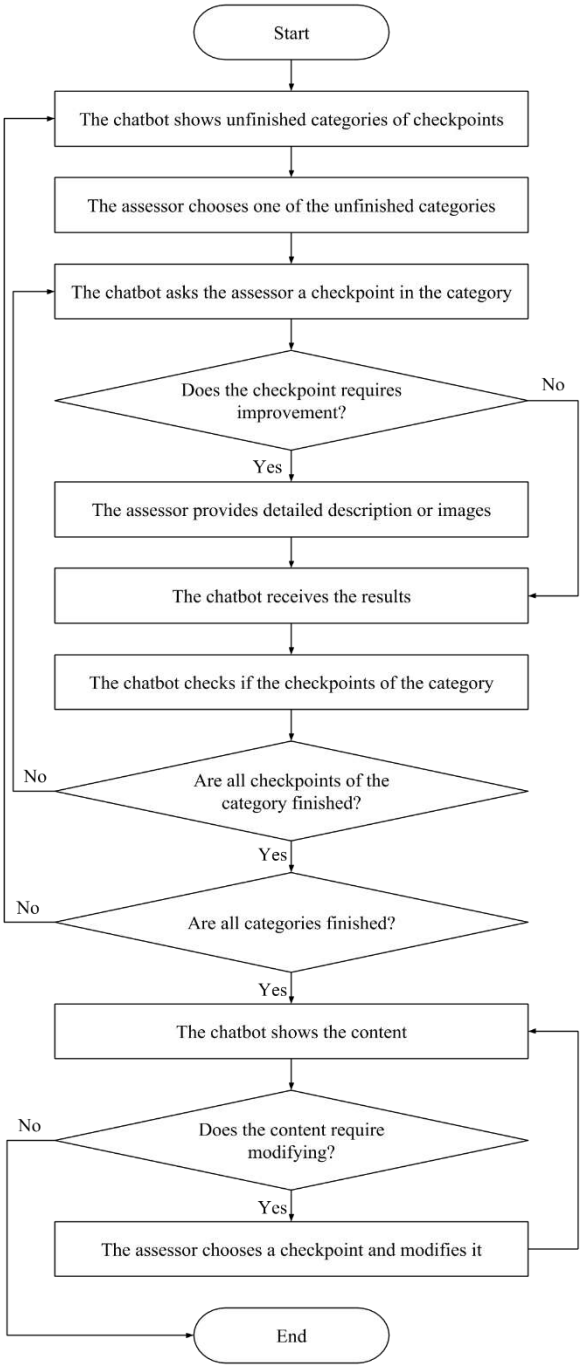

Figure 3. The process of the conversation module

3.3 Display Module

The major task of the display module is to demonstrate the results of the inspections by visualization in order to lower the inefficiency and difficulty for the managers to consume the data for making high-quality decisions. The procedure is illustrated in Figure 4. Managers need to grasp the situation of school building damages after an earthquake occurs and determine the budget allocation for building retrofit. The display module assists managers in selecting digitalize reports, analyzing the reports, and visualizing the results for decision support.

The dashboard is designed to access with web-browsers. The dashboard is composed of an interactive map showing the number of expected reports and a list of detailed inspection reports that are actually accomplished. First, managers select one of the earthquake events on the dashboard. Next, the system retrieves the reports of the selected earthquake event from the database and then shows them on the dashboard. The map demonstrates the number of critical schools in the areas by coloring them, while the tabular view lists all schools and their reports. By clicking one of the areas on the interactive map, reports of schools in that specific areas will be filtered and highlighted to emphasize the severe levels. Finally, managers consume and utilize the information shown on the dashboard to make decisions about allocating budgets and resources to retrofit the damaged school building.

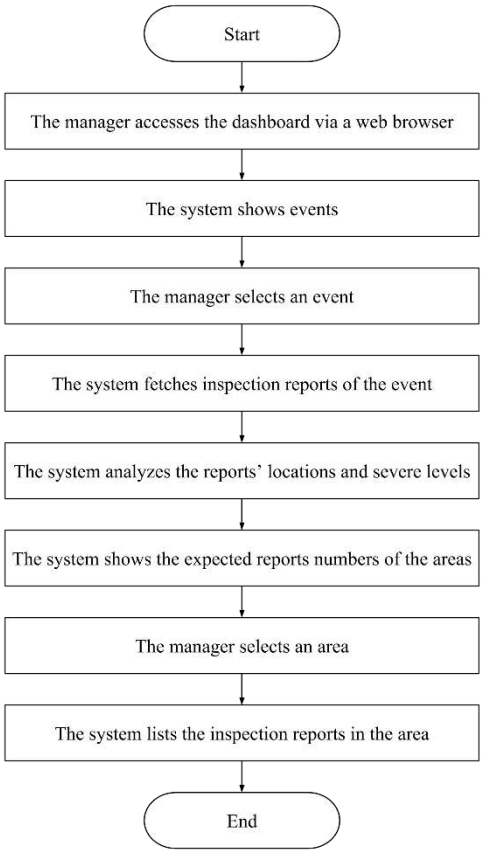

Figure 4. The process of the display module

4 Implementation

We implemented the conversation-based system as a

chatbot via LINE, a commonly used messaging application in Taiwan. LINE Messaging API provides various types of messages include confirming button and accepts multimedia as users' responses [13]. These features are utilized in our developed system. Flask, a micro web framework written in Python [14], is used for implementing the system as an HTTP service to control the process of interaction with LINE Messaging API and host the web-based dashboard. The web-based dashboard is constructed using HTML/CSS/JavaScript in order to be accessed via any web browser.

Screenshots of part of the chatbot are shown in Figure 5. The chatbot interacts with assessors using diverse formats of messages provided by LINE Messaging API. The system informs assessors to start inspections after an earthquake occurs. The assessor selects one of the question categories and starts to fill in the report. Entire questions are displayed as confirming buttons. If the assessor selects "no problem", the next item for inspection will popup sequentially; if "require improvement" is chosen, the chatbot will be switched into input mode. The assessors are allowed to make detailed descriptions in text or with multimedia. After accomplishing the inspection, the system summarizes the current contents and presents it to the assessor for final confirmation. If modifying is required, the assessor may select the items to be modified and correct the answers. After the corrections are accomplished and confirmed, the system saves the results to the database.

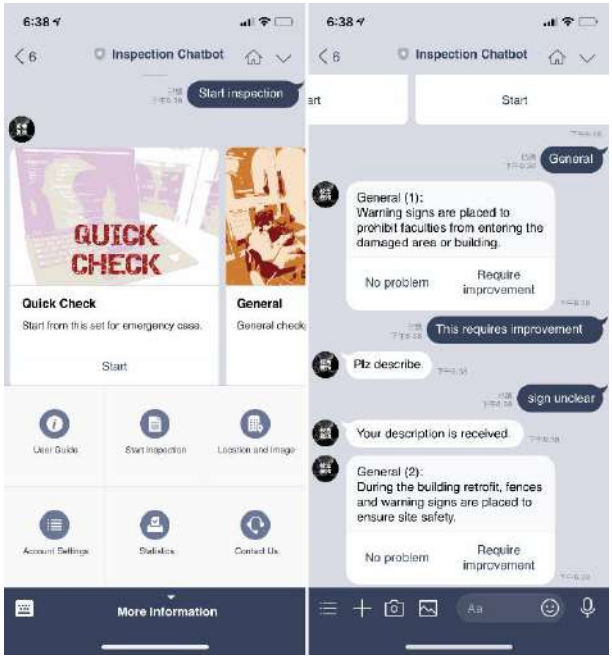

Figure 5. Screenshots of the chatbot

The dashboard for managers is shown in Figure 6. The dashboard is web-based and composed of an interactive map and a tabular list. The managers first select an earthquake event using the select bar, and then by clicking a district on the map, inspection reports of schools related to the earthquake event in the district will be listed with links to detailed results. The color demonstrates the severe level of each school according to the inspection records; the more checkpoints fail in the inspection, the darker the color of the report is. By clicking on one of the links to a specific detailed result, the result will be shown as in Figure 7. By default, only the items reported to be "require improvement" and their descriptions are displayed in the detailed result.

Figure 6. A screenshot of the dashboard

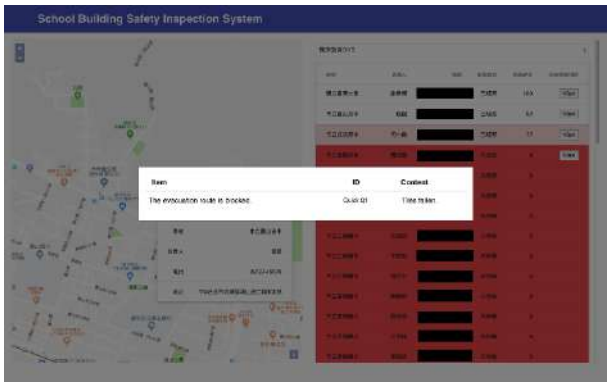

Figure 7. A screenshot of the dashboard after clicking on one of the inspection report for more details

5 Conclusions

In this research, we digitalized the process of safety inspections and developed a conversation-based system for notifying and guiding the assessors to accomplish their tasks. The system includes the notification module, the conversation module, and the display module. The notification module is activated by receiving earthquake information when an earthquake occurs and sends

notifications for safety inspections to the registered assessors of the schools via instant messaging applications. The conversation module interacts with the assessor via the instant messaging application in the form of a chatbot which guides the assessor to complete the pre-designed checkpoints in the inspection. The display module reads the inspection reports from all critical schools, analyzes the data, and displays via the dashboard for the managers. The research provides a conversation-based solution to reduce the complication of safety inspections, the inconvenience of the paperwork process, and the inefficiency of management. The developed system features automatic notifications for notifying assessors, a conversation-based interface for guiding the non-professional assessors to accomplish inspections, the integration of intuitively concatenating receiving notifications and the inspections task, the acceptability of multimedia to show damages directly without possibility of mistakes, and the view of data visualization for decision supporting of the manager in order to enhance the quality and accuracy of budget allocation.

In future work, to improve our developed system and enhance managers' efficiency of grasping information, interviews with the managers for evaluating the design of the dashboard is required. Also, techniques of natural language processing may be adapted to analyze text in inspection reports in order to obtain more accurate severe levels of the inspection reports, which may support the managers determine the budget allocation. In addition, techniques of image recognition may be adopted to find damages from assessors' uploaded images automatically and reduce the time for managers to check the images manually. Furthermore, to obtain the accurate positions of building damages, a method to clearly describe the positions is required. Although by utilizing interactive image messages of LINE, assessors may report the positions of damages by clicking on an image of the site plan, the scale of images and the process of inspections require further discussions.

6 Acknowledgment

This work was financially supported by the Taiwan Building Technology Center from The Featured Areas Research Center Program within the framework of the Higher Education Sprout Project by the Ministry of Education in Taiwan. The authors are grateful to Mr. Hung-Kai Kung, Mr. Cheng-Yu Ho, Mr. Chun-Mo Hsieh, and Prof. Yun-Cheng Tsai of National Taiwan University for their assistance in the development of the system.

Abstract –

Digitization and automation in construction are increasing particularly due to the establishment of Building Information Modelling (BIM). The models of BIM contain geometric as well as semantic information. The level of abstraction ranges from coarse models up to detailed modeled technical components of the buildings. So far, BIM has been developed and used for the planning and construction phase of the building's lifecycle. In order to fully use the benefits of BIM also for the operation and refurbishment phase, BIM models need to provide a reliable data basis of the as-built and respectively the as-is situation. However, up to now many properties have neither been planned nor constructed using BIM, at times not even digital planning information is available. Therefore, the digital model must be created from the real world.

The author's research proposes the development of an automated as-is capturing process of existing buildings as well as the data integration into BIM as a basis for property management. Suitable capturing techniques have been analyzed. Up to now, these techniques and the subsequent data transfer are still characterized by lots of manual work. Accelerating this process requires methods for the automation of data segmentation, classification and the modeling process. Conventional data capturing techniques such as laser scanning measure only visible surfaces. However, knowledge about inbuilt materials, constructional layers or thickness of e.g. walls is also important for optimized planning and utilization.

This paper summarizes the results of a joint research project in cooperation with a property management company.

Building Information Modeling, BIM, Automation and Robotics, Data Sensing, Computing

1 Introduction

For property management of buildings such as facility management (FM) a vast amount of data about functional, technical, descriptive as well as commercial aspects is needed. These are geometric data (e.g. for space management, the thickness of walls) or semantic data (e.g. fire ratings or the material of the walls). In many disciplines worldwide, digitization and automation are on the rise. In construction, a main aspect of digitization is the Building Information Modelling (BIM). During the past years BIM has been more and more introduced into the planning and construction phase of buildings. However, the planned situation usually differs to the built situation. Furthermore, BIM models of existing buildings often do not exist. In the following sections we discuss the requirements, techniques and steps for creating a suitable as-is model for the maintenance respectively operation phase of a building for the purposes of property management.

For development of such models, the following topics have been identified relevant: BIM systematics like as-is-terminology, level of development for BIM objects, computer aided facility management, data filtering and exchange. For each topic the paper gives a general overview based on state of the art literature and proposes additional systematics with focus on not yet met FM demands. Furthermore, capturing technologies and modeling systematics for the captured data are discussed. Here, experimental evaluation as well as concepts for a proposed modeling approach are added to a review of the current state of the art. Thereby, first results of the research project are described. Generally, the project is focused on two aspects – the integration of

geometrical information as well as semantic information using available scanning techniques. The overall objective of the project is the development of an automated as-is capturing process for existing buildings as well as the data integration into BIM. The resulting BIM model shall be the foundation for the property management. This paper focuses on the aspect of the integration of geometrical information.

2 As-built vs. as-is BIM

BIM models should not only serve as a planning tool but also for managing tasks over the whole lifecycle of buildings. However, BIM is still an upcoming paradigm. Up to now, it is most frequently used in the earliest stage of the lifecycle, the planning phase [1]. Nevertheless, the operation phase is the longest lifecycle phase of a building. Consequently, extending BIM for use in this phase requires the introduction of additional BIM model specifications [2–4].

If BIM is also used for the facility operation it is crucial to keep the underlying model updated even after construction [5]. Currently, most existing buildings are not documented using BIM due to their planning and construction date before the rise of this method. The consequence is the necessity of creating digital models for existing building structures. In research journals, literature and professional's magazines these models, which represent the current geometric and semantic conditions, are called as-built or as-is models. Often the differentiation between as-built and as-is is not always clear. Therefore, we propose definitions to differentiate between these two terms.

[6] show in their literature review the different possibilities of creating as-built models with and without having an as-planned model. We hold the view that the existence of an as-planned BIM should be the fundamental characteristic for differentiation between an as-is and an as-built model. The as-built model arises during or after the construction phases by updating the as-planned model due to the observed accordances or differences between the actual as-built situation and the as-planned model. The as-is model in contrast represents a model which has been created from an existing in-use building, for which no reliable planning documents exist.

In particular, this means that an as-built modelling process takes place during or immediately after the BIM-supported construction phase. In between construction steps, it is also possible to get information about hidden building elements, such as the arrangement of concrete reinforcement layers. In contrast, the as-is modelling process describes the goal of creating the model of an existing in-use building. This scenario limits the possibilities of capturing information especially about hidden building elements. The fact that the building is in use and equipped with multiple (mobile) assets leads to more difficult conditions for data capturing.

3 Level of development (LOD)

With their Building Information Modeling Protocol Exhibit in 2008 the American Institute of Architects (AIA) established the levels of development (LOD) for describing the level of completeness to which a model element is developed [7]. In the updated document "Project Building Information Modeling Protocol Form" the AIA defines the LOD 500: "The Model Element is a field verified representation in terms of size, shape, location, quantity and orientation. Non-graphic information may also be attached to the Model Elements." [8]. BIMforum, the American chapter of buildingSMART, used these LODs to develop the Level of Development Specification Guide [9]. In general, this specification framework supports the design process by providing tools for a collaborative work environment. This guide serves as a communication tool for the standardized definition of the contents required in the design phase, in order to make them available to all project participants in a standardized way.

Within the LOD level system, LOD 500 can be considered as the as-built LOD. Figure 1 and 2 are depicting LODs and associated BIM lifecycle phases: planning LODs in green and as-built LOD in yellow.

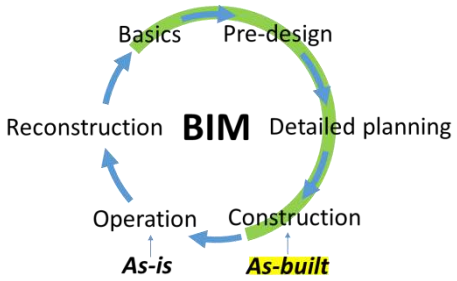

Figure 1. As-is and as-built BIM in lifecycle

Figure 2. The different LODs of a precast structural column out of the LOD Spec. Guide, extended by a self-made illustration of LOD500.

LOD500 should represent the geometric verification e.g. by a laser scan. [9]

LOD 500 marks the conclusion of the planning and construction phases by representing in general the geometric update of the as-planned model after the building's construction.

In our research, we develop a specification framework for existing buildings without existing planning and construction models. There is no need to define stepwise requirements for building elements as during the planning phase. Rather, the challenge is to filter the relevant data out of an existing building. Therefore, we developed the level of as-is documentation (LOAD), which is described in the next section.

4 Level of as-is-documentation (LOAD)

Before making use of the benefits of BIM in operation, the data required for the BIM applications has to be defined. BIMForum developed a framework (Level of development specification guide [9]) for specifying BIM model contents with standardized specifications for planning and construction. Due to the fact that it is hardly possible to use these frameworks for an as-is documentation (see section 2) we present the level of as-is documentation (LOAD).

The LOAD is divided into three parts. The first part is the level of as-is geometry (LOAG) representing the specification for geometric requirements. The level of as-is information (LOAI) defines requirements for semantic data, which focus on the attribution of model elements. The last part is the level of accuracy (LOA), which has been contributed by the U.S. Institute of Building Documentation and defines the tolerance for the geometric deviation between reality and BIM model [10].

4.1 Level of as-is geometry (LOAG)

The LOAG is structured into four increments of ten beginning with LOAG10 and extending to LOAG40. The LOAG10 represents the simplest version of a building element, usually a one or two-dimensional one. The LOAG20 serves for describing the optimized bounding box (OBB) of a building element. For many applications, only the OBB of building elements is needed, e.g. for the management of available spaces. The LOAG30 and LOAG40 are geometric representations of higher detail, where the step from LOAG30 to LOAG40 requires a higher modelling effort. In figure 3 the LOAGs of columns are shown. The LOAG30 is modelled with an idealized constant profile, whereas the LOAG40 represents the highest geometric depth of detail, most closely to a true-to-deformation model.

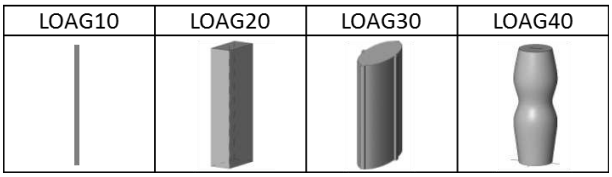

Figure 3. The four LOAGs of a column.

4.2 Level of as-is information (LOAI)

In contrast to the LOAG structure, the LOAI is non-hierarchical and represents semantic requirements related to attribute sets. These attributes refer to the different applications of the BIM model. The actual selection of required semantic attributes depends on the specific use case. When transferring data, proprietary formats do not cover all data interfaces. In such cases, the open standard format Industry Foundation Classes (IFC) [11] has been identified as best practice. The IFC documentation already provides a minimum quantity of different attributes, which can be attached to building elements in a standardized way. These attributes are organized in different property sets. For example, walls have the property set Pset_WallCommon, with the attributes of this property set being "Reference, Status, Acoustic Rating, Fire Rating, Combustible, Surface Spread Of Flame, Thermal Transmittance, Is External, Extended To Structure, Load Bearing and Compartmentation". For adding new attributes from the IFC documentation, so-called custom property sets can be created. Such custom property sets allow for the description of any arbitrary information, though their non-standardized way may limit their interpretation.

4.3 Level of Accuracy (LOA)

The U.S. Institute of Building Documentation provides the LOA in the USIBD Level of Accuracy (LOA) Specification Guide [10]. The LOA is structured into five levels, LOA10 to LOA50, with accuracy requirements increasing at each level.

Table 1. Levels of Accuracy defined by USIB

Level	Upper Range	Lower Range
LOA10	User defined	5cm *
LOA20	5cm *	15mm *
LOA30	15mm *	5mm *
LOA40	5mm *	1mm *
LOA50	1mm *	0 *

*specified at the 95 percent confidence level.

It is important to understand that the LOA Spec. Guide differentiates between different types of accuracy.

- *Measured Accuracy:* Standard deviation range that is required from the final measurement.
- *Represented Accuracy:* Standard deviation range that is required once the measurements are processed into a model.
- *Absolute Accuracy:* Standard deviation related to a given reference frame (e.g. whole building, floor or object)
- *Relative Accuracy:* Standard deviation related not to a fixed superior datum, but within an object´s region.

Consequently, it becomes possible to choose different LOAs for specific object types or regions. The following example shows how to use the different accuracies. For a Computer Aided FM (CAFM) project, a model with low accuracy for the global position of a building asset is sufficient, but the asset itself should be captured and stored with a high accuracy. It means that the absolute accuracy requirements for an asset are low (e.g. LOA10), but for the relative accuracy are much higher (e.g. LOA30). Thus, a suitable measurement technique has to be chosen due to the needed LOA. E.g., mobile laser scanning reaches only minor absolute accuracies (up to multiple decimeters) but – with some systems – relative accuracies within one centimeter can be achieved.

5 BIM for Property Management

In comparison to design and construction, the operation phase is the longest phase in a buildings' lifecycle. The pre-operation phases design, detailed planning and construction take about 2-5 years. In contrast to this, a building is in operation for a minimum of 20 years [12]. The main task during the operation phase is the FM , as it ensures the maintenance and value preservation of the building. CAFM systems store FM-related building data and allow for a methodized access to this data. Hence, it can be used for management of inventory documentation, spaces, contracts, energy, sustainability and other tasks that require assessing, controlling and maintaining building data [13].

For setting up these CAFM systems, BIM is capable of providing the database, since a building information model is in particular a unified information base and a location-aware model of building assets attached with information [14]. Furthermore, the data of a BIM model can be transferred to the CAFM application, such that time-consuming and error-prone efforts on manual data input can be bypassed, ultimately improving the final data's quality[15]. The automatic transfer mechanism data updates, e.g. in the case of reconstruction or renovation [16]. For these purposes, Gnanarednam et al. [17] present suitable data exchange formats such as the IFC and the Construction-Operations Building information exchange (COBie).

Apart from the synergies between BIM and CAFM, there are advantages to creating BIM models of existing structures, such as the reduction of errors to minimize risks for reconstruction [2] or the use of BIM models for building performance simulations [18]. In principle, this framework is a synthesis of encountered challenges and lessons learned from the presented case study. The framework proposes questions for identifying important data and ensuring interoperability between the different interfaces.

The mentioned literature in context of BIM and FM focus on setting up BIM models for aspects of FM during the planning phase [5,12,16,17]. They show significant benefits of the data exchange from BIM to a FM system. However, research on setting up BIM models in the later lifecycle phase is scarce and does not highlight the workflows of capturing and organizing on-site data for the BIM model [19]. Instead they propose the use of floor plans [15], which are often not representative of the actual state of the property situation.

For FM software applications several exchange formats haven been developed. COBie [20] was developed by the buildingSMART alliance and focuses on providing information about type and location of assets. For identifying and maintaining the asset, it defines requirements for identification tags and typecasting as well as for needed information about e.g. installation date, warranty and scheduled maintenance. COBie attributes can be added to model elements in BIM software. The associated standard exchange format is a spreadsheet application file with data organized in different sheets. Another standard for defining attributes for the use of CAFM are BIM profiles of CAFM-Connect [21]. The aim of CAFM-Connect is to grant interoperability between different software which are in use throughout the whole lifecycle management of buildings. The recently released BIM profile is CAFM-Connect 3.0, which delivers a framework for classifying documents, space usage and building components. This framework uses IFC as a programming platform for documenting FM relevant data. The attributes of the IFC entities are filtered and extended with additional attributes in the BIM profiles. Research already observed that there might be a lack of utilities in COBie to satisfy CAFM information requirements. Progress can be made by utilizing IFC for that purposes [17].

5.1 Data filtering and exchange

For proper usability of CAFM systems, great amounts of as-is information with high LOAD content not only need to be stored with the help of BIM but also

have to be filtered to allow for a user-friendly FM operation or for sufficient exchange with other stakeholders. Thereby FM can make use of general BIM concepts for restricting models into partial-, aspect- or submodels such as the Information Delivery Manual (IDM) methodology developed by buildingSMART [22,23]. The IDM defines standardized exchange of information in several steps by participants and the coordinator in form of a handbook. The purpose of the IDM process is to filter the essential information for a partial model to generate the Model View Definition (MVD) and to establish an exchange requirement (ER). Thereby all participants of the different sectors agree on a certain communication. Based on the ER, automatic data management can be developed which will positively affect the interoperability of any collaboration [23].

One of the key components of the IDM process is the capturing of workflows with the participants. BuildingSMART refers to the method of Business Process Model and Notation (BPMN) as a guideline for the design of graphical Process Map documentation. The BPMN uses a flowchart and a column division to describe the overall process with the tasks of the various participants, as well as when and which data needs to be exchanged [22,24].

6 Data capturing techniques

For getting information about the actual geometric state of buildings, one common method today is the use of terrestrial laser scanning for data capturing. Different studies identified terrestrial laser scanning as a valid and popular method [2,25]. Multiple scan positions are registered to each other and the point cloud of the captured area will be processed. Another scan method is mobile laser scanning. Mobile laser scanning uses the simultaneous localization and mapping (SLAM) algorithm for continuous scanning [26]. This leads to enormous time saving during on-site capturing. The downside is a decreased accuracy. In this project, one goal was to find easy-to-use scanners, which provide fast data capturing. They should guarantee a sufficiently high accuracy while at the same time being rather affordable. Thus, we evaluated BLK360 from Leica [27], an easy to use low cost terrestrial laser scanner and mobile laser scanner ZEB-Revo RT from Geoslam [28].

First part of the evaluation of the two scanners was an accuracy check. In case of BLK360 we compared a single as well as a multiple scan setup. The reference laser scanning instrument for this evaluation was VZ-400 from RIEGL [29], a high accuracy surveying instrument. We calculated cloud-to-cloud distances, the minimized sum of distances between points of two point clouds, using the software CloudCompare [30]. The distances distribution classified in LOAs is shown in table 2.

Table 2. Relative distribution of cloud-to-cloud distances in single scan and multi scan scenario

Level of Accuracy	Single Scan	Multi Scan
LOA50 (0-1mm)	19.39%	15.83%
LOA40 (1mm-5mm)	54.23%	44.18%
LOA30 (5mm-15mm)	22.13%	33.29%
LOA20 (15mm-5cm)	4.25%	7.71%

The results show that 94.75% (single scan position) and 92.29% (multi scan position) of the distances achieve the requirements of LOA30 (or better), while only 4.25% and 7.71%, respectively, do not. Hence, we decided that the BLK360 could fulfil the accuracy requirements of LOA30. For the Zeb Revo we present initial investigations. For a simple visual analysis, we superimposed two point clouds, one captured with BLK360 and one captured with Zeb Revo (Figure 4).

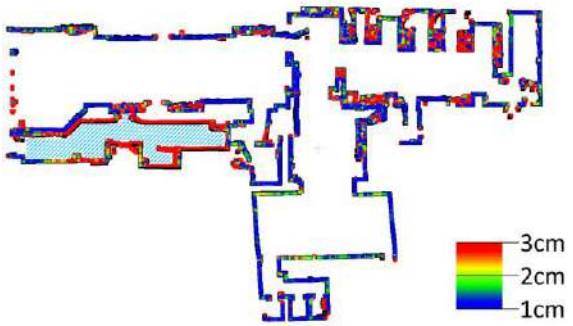

Figure 4. Point to point distances. Colored – Zeb Revo. Black (underlaid) – BLK360.

The colored points (enlarged for presentation) represent the point cloud surveyed with Zeb Revo. The colorization depends on the deviations to the point cloud captured with BLK360. Deviations here represent to the absolute accuracy. Apart from the highlighted corridor the deviations were almost everywhere below 1 cm. The scan of the corridor was drifting (absolute accuracy here appx. 10 cm). Nevertheless, we found out that there was overall a relative accuracy according to LOA30 (5-15mm).

We validated BLK360 to be accurate enough for retrofits requiring a LOA30 (absolute and relative accuracy). The ZEB-Revo RT shows a good relative accuracy but in a given reference frame the absolute accuracy is up to multiple decimetres. Therefore, we decided to use this technique when a fast but not too accurate survey is needed.

7 Automation in modelling

The captured laser point clouds generated by the equipment described in the section before are then used as the basis for the modeling process. Common suitable building information modeling software accompanies much manual work. However, with manual modeling being a time-consuming and costly process, automation in modeling would save much time and money.

Automation takes different forms which can roughly be divided into modeling aids and partial or even full reconstruction methods. Modeling aids are mostly concerned with solving specific tasks without necessarily reconstructing geometry. Such methods could include techniques for point cloud alignment, filtering or the extraction of features. These can ease both, manual and automated modeling processes. Despite contributing to the modeling process, the aforementioned methods have in common that they are neither meant for nor capable of fully reconstructing building geometry. Fully automated methods aim to fill this gap requiring at most only minimal user input. In fact, a detailed review of the various steps required for automated modelling has been outlined in [31,32].

In context of the project's tasks, we investigated various strategies used during the automated reconstruction process, which can be categorized into preprocessing and segmentation methods.

Preprocessing is generally used as an optional step and aims to simplify and ease subsequent steps. Point cloud denoising, axis-alignmend and downsampling in particular are most illustrative of this issue, as each of these methods addresses common problems present in raw point cloud data. Denoising is usually performed through use of filters which are already known from image analysis like the bilateral filter [33] and are meant to mitigate the effect of outliers in the point cloud. Usually, this effect helps segmentation algorithms to extract sharper point clouds segments, however in case of low-quality data denoising can be absolutely mandatory. Not only does denoising help to improve the data's visual quality, it also eases the software supported manual modeling process. Point cloud axis alignment addresses the problem of incorrectly aligned point clouds and is best applied to man-made structure with dominant rectangular geometry. Similar to denoising, alignment methods simplify manual modeling, reorienting point clouds in a way that their major walls are oriented along the global coordinate system axes. Despite this benefit appearing to be marginal from a user perspective, it offers a significant benefit to automated methods. Voxel-, supervoxel- and octree-based data structures [34,35] which are being used for downsampling or fast neighborhood lookups are themselves axis-aligned. They are thus more compact and offer better performance for axis-aligned point clouds.

With the former steps offering ways of cleaning up point clouds, they generally fall into the category of modeling aids, but as mentioned earlier, they also have a notable impact on segmentation algorithms. Segmentation and feature extraction methods in particular stand in close relation with them, as both usually involves octrees or voxelgrids for neighborhood lookups and deliver more precise results for denoised point clouds. Commonly extracted features include structure indicators such as linearity, planarity and scatter values and surface normals. Structure indicators are particularly useful for extracting features such as edges. Figure 4 illustrates the results of feature line segmentation. Such methods lend themselves to the category of semi-automated modeling aids, as they create geometry meant for guiding manual modeling.

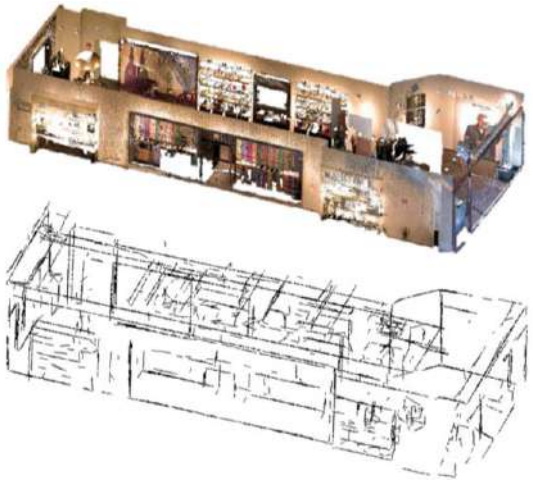

Figure 4. Top: Laser scan (ceiling removed for visibility). Bottom: Simplified model based on extracted feature lines.

In terms of plane segmentation, in other contributions [36,37] normal estimations and the RANSAC paradigm has been applied. Both help estimate local planes oriented along surface in point clouds. The extracted planes can directly be used to extract wall and floor segments, thus letting these methods fall into the category of fully automated reconstruction methods.

Figure 5. Point cloud segmentation for planar segments. Left: Input point cloud. Center:

Outlines of detected plane surfaces. Right: Exploded view, the single points being mapped to their respective plane

Figure 5 shows, how a successful plane extraction can lay out the foundation for this step. Other creative methods involve the removal of extracted planes as a preliminary step to detecting and reconstructing pipes [38].

8 Conclusions and Outlook

Within this paper we presented first results of our research concerning the needed requirements, techniques and steps for creating a suitable as-is BIM model for the maintenance respectively operation phase. Future work will now focus on detailing and optimizing the capabilities of the presented techniques and workflows. For data capturing e.g. in-depth investigation in the field of mobile laser scanning and the reachable accuracies are intended. Furthermore it should be researched in how far a point to point distance calculation is representative to verify accuracy in a real survey scenario where multiple scans get registered.

Automated modelling methods still offer much potential not only for reconstructing geometry, but also deriving semantic information. Future work with previously described techniques will involve a combined approach which will most certainly lead to a more robust segmentation with less outliers and improved performance. With the current approaches being capable of e.g. associating point cloud regions to detected planes, going beyond geometry-based point cloud analysis becomes an intriguing possibility. Traditional texture analysis techniques employed in the field of image analysis are well-established and, in combination with machine learning, have led to solid results in the fields of object recognition and classification [39]. Applying these techniques with respect to point cloud colour information for identifying, segmenting and classifying surfaces to derive additional semantic information, seems quite intriguing.

Another perspective would be a survey on how automated methods are capable of dealing with input data of varying quality. Further investigations with mobile scanning devices would prove interesting, especially when it comes to techniques for denoising the data and comparing automatically reconstructed models of capturing devices with varying accuracies.

Either way, with capturing techniques becoming more accurate and inexpensive and automated methods becoming less reliant on user interaction while at the same time providing more detailed and semantically rich results, the BIM process for capturing the as-is state of existing buildings will grow more attractive and more popular in the future. Furthermore, the described strategies for the implementation of as-is geometry information into the BIM context will now be used for implementing semantic as-is information alike. Both aspects will then be combined to allow efficient property management of existing buildings based on a reliable geometric and semantic data basis.

Abstract –

IoT based platforms are enhancing decision-making capabilities in many sectors. The impact of IoT in construction has not been significant because of the unstructured nature of the process and the project-based approach to construction. Further, the technology platforms available today do not support high data flow from distributed locations as required for construction. However, it is anticipated that the use of IoT in construction will increase significantly when standards such as 5G are implemented for widespread usage. The first objective of this paper is to identify the potential usage of IoT technology for various construction project processes based on the PMBOK framework for construction. Several works on the applications of IoT which have been published are reviewed, and a framework for construction domain is proposed. The second objective is to identify and discuss the barriers raised by connectivity issues within this framework and influence of 5G technology in overcoming this barrier is elaborated. A comparative quantitative analysis of sample processes is presented to show the potential advantage that 5G technology will bring over 4G with the help of an example.

Keywords –

IoT, 5G, Digital Construction, Wireless Technology, Connectivity in Construction

1 Introduction

IoT is one of the disruptive technologies in recent years which have brought groundbreaking improvement to commercial, consumer, industrial and infrastructure applications. IoT based platforms can gather data to make the decision-making process faster and more efficient. IoT has brought significant change in operations and decision making in several sectors such as manufacturing, healthcare, agriculture, energy, etc. Unlike construction, these sectors involve repetitive processes mostly in a closed working environment which makes the adoption of this technology.

On the other hand, the construction sector is different as it involves complexities like unstructured processes, erratic work environment, and remote construction sites. Construction is also a highly fragmented as well as a multi-disciplinary industry. Therefore, the adoption of IoT in construction will require significant effort in ensuring appropriate changes at policy, technology and project implementation.

In construction, the technology succession planning has not been managed well. Woodhead suggests the construction industry needs to undergo a pivotal shift to digitized processes to make the project delivery process cost-effective. Companies that don't embrace this shift will not be able to ensure sustained business growth due to significant productivity losses [1].

The process of digitalization has brought with it an improvement in many domains including productivity, agility, innovation, consumer experience, quality, costs and revenue [2]. Even though there have been significant advancements in construction techniques, materials, automation of the worksite, scheduling techniques and collaborative platforms like BIM, concerns have been expressed on the resistance to adopting such technology in the construction sector.

The applications of IoT are vastly spread across all domains. Although other sectors are integrating it into their everyday process, the construction industry is lagging in adopting an IoT eco-system. A recent study by Burger identifies several areas for application of construction projects such as remote operation, supply replenishment, construction tools and equipment tracking, equipment servicing and repair, remote usage monitoring, augmented reality (AR), Building Information Modelling (BIM), predictive maintenance, progress monitoring, construction safety & quality monitoring [3].

Woodhead stated that construction companies which are using IoT for decision-making process are using it more as a point-based model for solutions to some of their problems and not developing an ecosystem for all-around integrated business decision support [1]. For

example, an IoT based early warning system was proposed by Ding et al. for safety management in an underground construction project in China [4]. Another application is of an IoT enabled BIM platform (MITBIMP) by Zhong at el. to achieve real-time visibility and traceability in prefabricated construction [5]. There are many such examples of specific applications of IoT in construction in the field of quality, safety, inventory management, etc.

In spite of proven advancement in IoT technology, there remain certain barriers in IoT implementation. These include connectivity issues, such as high latency, low speeds, and large connection density. There are also technological issues such as presently used ERP systems which lack tools for integration of IoT in their design.

Applications of IoT in construction today are scattered, and due to the remoteness of sites and work locations, there are connectivity barriers. Hence with these capabilities of IoT which can revolutionize construction, an IoT framework specific to construction appears to be the need of the hour. Further, the shortcomings due to connectivity standards to that framework should be addressed for smooth implementation. Therefore, this paper attempts to:

1. Identify the potential usage of IoT technology for through a holistic framework which encompasses various processes of a construction project.
2. Identify and discuss the barriers raised by connectivity issues within this framework and the influence of 5G technology in overcoming these barriers.

This paper is broadly divided into three sections; the first section describes the potential applications of IoT platforms in construction management based on the established PMBOK framework. The second section proposes a layered structure of IoT ecosystem for construction and explains in detail about the various layers. The third section of this paper highlights the benefits that 5G standard of connectivity can bring to address the existing barriers and challenges in the implementation of IoT technology. This discussion will emanate from a general context of IoT technology but will move on to focus on the construction sector in particular. In the final section, the conclusions and future implications of this study are presented.

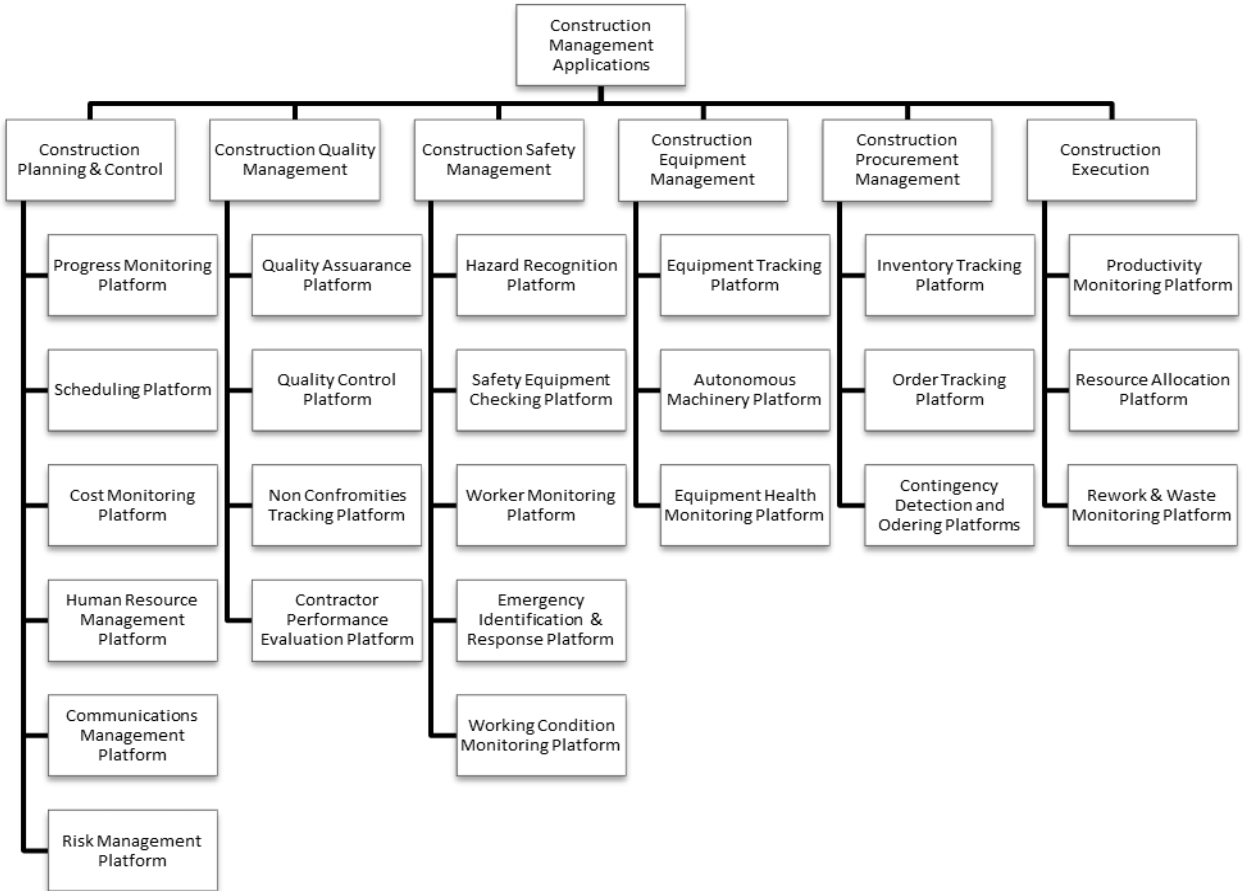

Figure 1. Applications of IoT platforms in construction phase of a project

2 Framework of IoT Application in Construction

For proposing a holistic framework for construction processes, this paper adopts the widely accepted PMI-PMBOK framework for project management. The PMBOK framework has been developed with the inputs from numerous project management professionals and covers all the essential processes required for construction under eh following six categories [6].

1. Construction Planning & Control
2. Construction Quality Management
3. Construction Safety Management
4. Construction Equipment Management
5. Construction Procurement Management
6. Construction Execution

Figure 1 shows the few of the applications for which IoT platforms can be installed to facilitate these areas in the construction phase of the project. There can be many more applications depending on the characteristics of the project.

Each of these platforms can be embedded in a different type of data collecting devices. Example, a progress monitoring platform can be embedded in imaging devices, bar codes, RFID tags or even laser scanners. A study from MIT on construction safety by Bernal et al. demonstrated application of various sensors to monitor a worker's health, the worker's vest and jacket can be embedded with many sensors to monitor the working conditions [7]. Similarly, data can be obtained from installing sensors in worker's shoes, helmet, etc. These data can be stored in the company's database and can be accessed for monitoring by the safety team; they can identify dangerous situations and can alert the worker, worker's team or site supervisor. A GPS based sensor can be used for tracking and collecting information on equipment.

2.1 Structure of an IoT Ecosystem

Figure 2 represents a proposed network outline for the flow of data for Integrated IoT applications on construction sites. A construction project can have *n* numbers of sites where execution is going on simultaneously. Within these sites, there can be *m* number of processes or activities going on. The integrated IoT system will capture data for all the departments (m*n data types); hence there should be a combined embedded system of sensors, actuators and other IoT things fitted for each processing environment. The sensors for the respective departments capture the needed information, and this data can be accessed by the concerned department or the management staff in the project office to facilitate decision making.

Figure 3 illustrates a proposed structure of IoT Ecosystem for decision making in construction management. The Integrated IoT in projects can be enabled by five layers which connect with one and another sequentially to form IoT platforms.

2.1.1 Physical Layer or Sensing Layer

It is the bottom-most layer which consists of the devices that capture or senses the information. This layer is also called the perception layer as it perceives the data from the environment [8]. These devices consist of several sensors, actuators, RFIDs, mobile devices, etc. which forms a network of things.

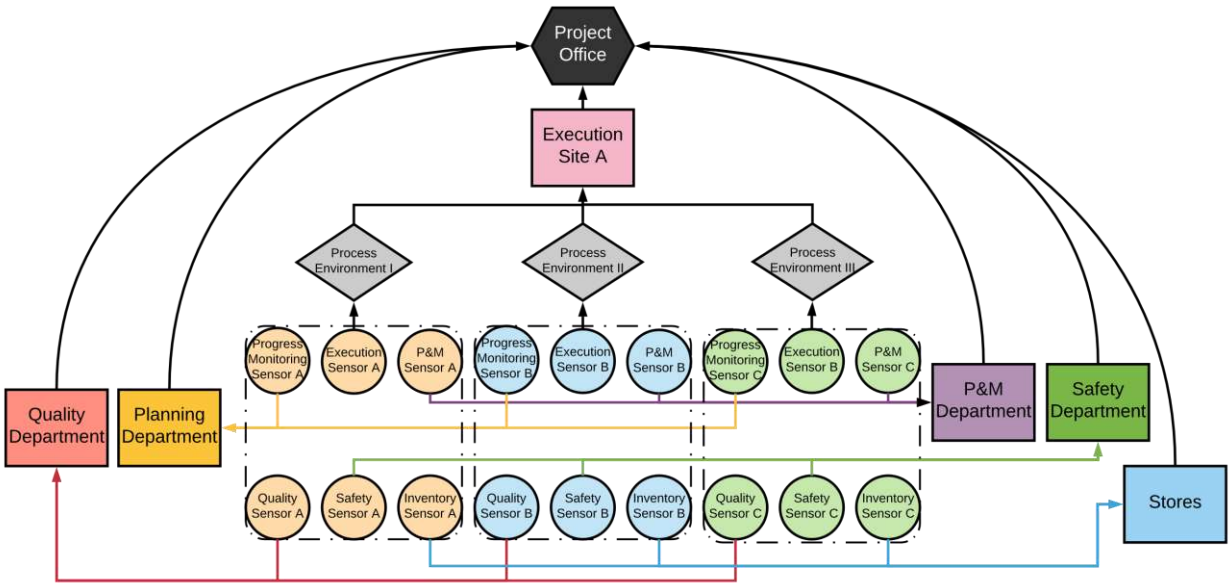

Figure 2. A proposed network outline for data flow for integrated IoT application on construction sites

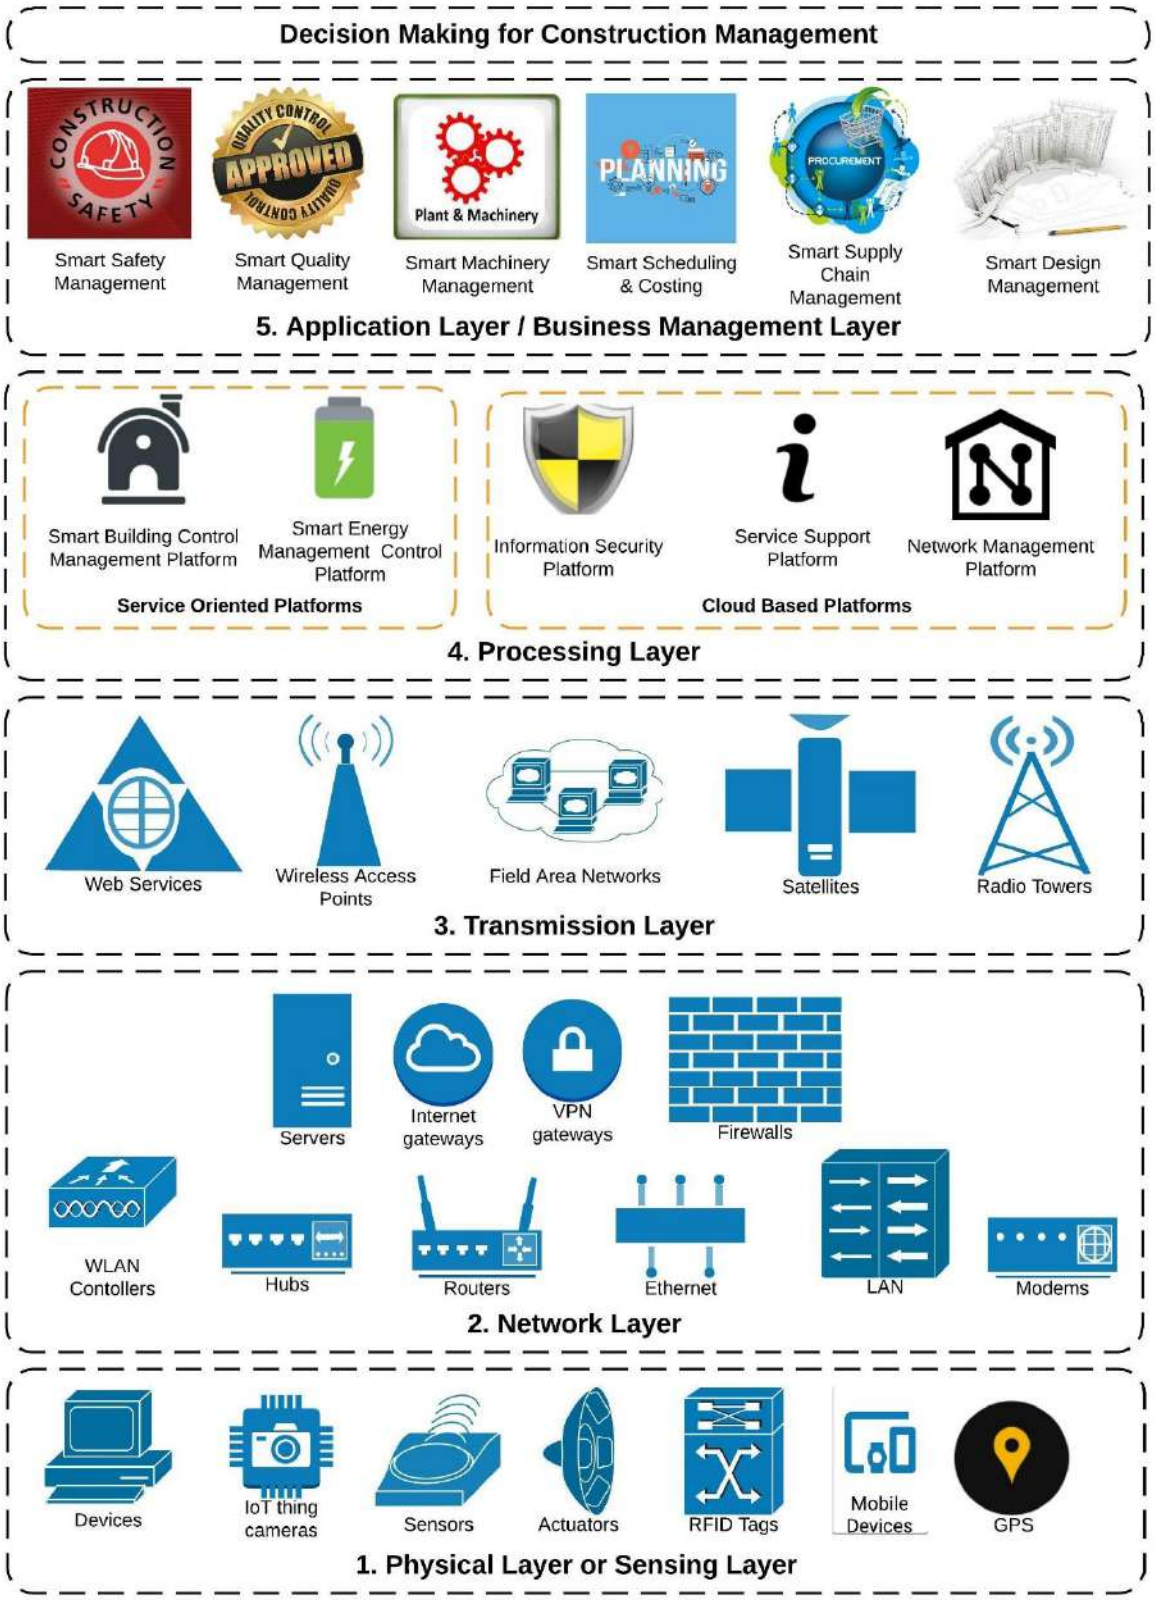

Figure 3. A proposed structure of IoT ecosystem for construction project management decision making

These can be of two types, static and mobile. In a construction project environment, these can be placed anywhere in the site, inside offices, integrated with the machinery, in the hands of site engineer or elsewhere from where it can capture valuable data. These things are connected directly or indirectly to the IoT network after signal conversion and processing. These devices form nodes of the network. In the sensing layer, the nodes are subject to different constraints such as energy limitation, the reliability of wireless medium, security, and privacy [9].

2.1.2 Network Layer

The network layer is one of the two sublayers of the connectivity layer which comprises the local networks of routers, hubs, LAN controllers, servers and other necessary network forming devices. This layer acts as the interface between nodes and the internet. The nodes or things are connected to the gateways present in this layer. The VPN gateway serves as a jurisdiction to the nodes under it and assigns a local address to them in a local area network. IPv6 is commonly adopted for addressing IoT nodes. From that point data flows through a proxy server if internet access is required and then to a web socket in the next layer. When these nodes are needed to interact with each other, or they are transmitting data, they send it to destination nodes. The data first must be transferred to the local network and then if the intended destination is outside the local network, then it is sent through internet gateways.

2.1.3 Transmission Layer

The transmission layer is the second sub-layer of the connectivity layer. This layer acts as interphase between the network and cloud platforms when the data is stored and analyzed. It focuses on end-to-end communication and provides features including reliability, congestion avoidance, and guaranteeing that packets will be delivered in the same order that they were sent [10].

2.1.4 Processing Layer or Cloud Layer

This layer consists of backend services like analytics and cloud computing. Here, the analog data from the devices is converted into a format that is easy to read and analyze. These analysis algorithms can be based on machine learning, artificial intelligence or neural networks. Combining cloud computing with service-oriented architecture (SOA) could provide an efficient middleware for IoT supporting a high level of heterogeneity and flexibility [9].

Additionally, it provides information about the usage of IoT products and handles issues related to the quality of service within operations revealing which device generates problems, revealing data patterns and trends and providing reports and analysis of anomalies [9].

2.1.5 Application Layer or Business Management Layer

The application layer includes people and businesses for collaboration and decision making based on the data derived from IoT computing. It can be merged with the company's ERP system as well as can be made available to the different departments as mobile applications to access data set customizable standards for various activities and make timely changes if necessary. It can include options for auto-actuation or manual actuation for critical machinery works.

3 Shortcomings of IoT in Construction

Usually, construction sites are in remote areas, and their company offices are in cities, constant communication is required between the various workforces within site to the site office as well as site office to home-office and offices of other stakeholder involved in the projects that are located away from the vicinity. Due to limitations in network performance at various places, the connectivity and communications get disrupted in the work environment.

Even in construction sites, basic IoT systems which are meant only for data transfers generally fall short of the expectations as they are not able to provide enough speed and lower latency to undergo primary tasks. Below are a few examples where unnecessary delay causes due to network issues: -

- Data transfer between parties taking longer than expected
- Remote meetings voice and video delay maybe halted
- A significant delay in voice conferencing allowing users to talk over one another
- ERP system resulted in timeouts if remotely accessed
- Slow loading of website and platforms and longer wait time to load or download things

The number of 'things' involved in IoT network is large, so it is much different from a computer network, as the number of nodes increases the complexity of the network increases. In IoT ecosystems, the sensors, actuators and other gadgets are dependent on the responsiveness of the system or network to work effectively. Gerber validates that high latency means delayed responsiveness, and with that comes the inability of things to function to their full capacity [10]. Some IoT systems are designed to respond in case of emergencies, and delayed responsiveness can result in life or deaths. Example: - A delayed response of an actuator intended to close the valve at a certain temperature can result in overheat or even an explosion.

Also working with unmanned machinery in hostile environment needs real-time precision and speed, with present-day network specifications it is not possible to deliver these critical tasks with reliability.

IoT devices usually run on batteries or are self-powered, so they save energy by switching over to energy saving mode, this intern reduced the performance and impacts in slower speeds. Therefore, a low power low latency solution is required [13].

The current system architecture was not designed with IoT in mind. Many systems with their current architecture cannot handle the traffic caused by millions of IoT devices [14]. In construction, most companies are dependent on an Enterprise Resource Planning (ERP) System for project management. These systems have become standard and process designed based on them. For adapting IoT architecture, ERP platforms need to be reconfigured and redesigned. They need an upgrade for the technology which bonds the Layer 1, 2 and 3 of data collection and transmission with the layers 4 and 5 of data analysis and application. (Refer to Figure 3). Though the initial cost of installing an IoT ecosystem is high for small and medium level firms and these firms, need to understand the long-term benefits in decision making and process improvements they will get at later stages.

Additionally, there is an exponential rise in the trend of the number of IoT devices worldwide, and it is expected to rise. Various studies have been conducted to forecast the number of IoT devices, the results of one such study BY Statista estimates that by 2025 almost 76 billion IoT devices will be connected to the internet which is almost three times the devices connected in 2018 [15].

Therefore, combining all these factors there is a critical need for the upgradation of the IoT components and the connectivity skeleton to be able to sustain and meet the growing demand of the future. It is anticipated that the upcoming 5G technology can handle the three connectivity issues, i.e., data traffic, latency, and data transfer issues.

4 Wireless Connectivity: 5G

The International Mobile Telecommunications (IMT) framework of standards is set by the International Telecommunications Union (ITU) for mobile telephony. ITU issued the IMT-Advanced specifications in 2008 as a requirement for the 4G standard. Now, with the growing need of technology upgrade ITU have set a benchmark as IMT-2020 specifications issued in 2017 for the 5G standard.

The 5G technology is divided into three categories based on usage [14]:-

1. **Enhanced Mobile Broadband Service (eMBB):** It will be used for data-driven applications requiring high data rates across a wide coverage area which will enable platforms for immersive VR and AR applications, 360-degree streaming and Ultra HD video.
2. **Ultra-Reliable Low Latency Communication (URLLC):** This is the second phase of 5G which will have strict requirements on latency and reliability for mission-critical communications, such as autonomous vehicles or the tactile internet.
3. **Massive Machine Type Communication (mMTC):** It will be used for supporting many devices in a small area, which may only send data sporadically such as IoT use cases.

4.1 4G Vs. 5G: Head to Head Comparison

Figure 4 shows a comparison of chief KPIs of 4G (IMT-Advanced) and 5G (IMT-2020) network.

This paper uses the theoretical values of KPIs obtained in a test environment for the 5G and 4G networks; these values can be different than what users practically get depending on the quality of network they are connected to and the connection density.

Some of these KPI's are discussed below in detail.

1. **Very Low Latency:** Reduced latency of the 5G standard is expected to be about 1ms, in that case, construction firms can now hope for real-time operations for autonomous machinery used in critical remote tasks. 4G has a latency of about 30-50ms.
2. **Improved throughput:** Throughput refers to the ratio of data transmitted in a unit time. It is expected that 5G can handle the throughput of

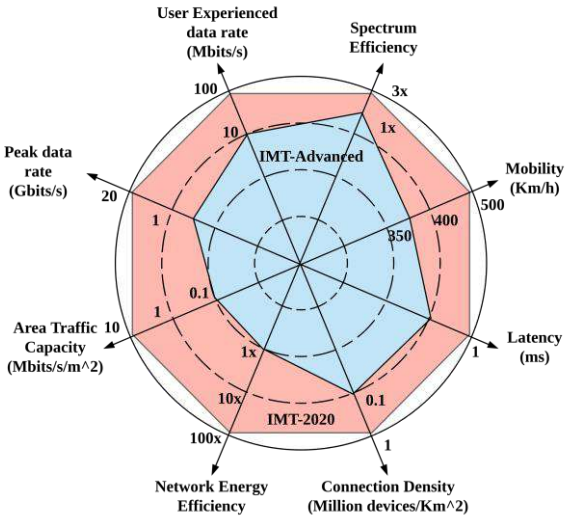

Figure 4. A quantitative comparison of KPIs of 4G and 5G standards (Source: IMT-2020, Network High Level Requirements)

about 10Gbps per connection in comparison to 100Mbps by 4G. That means downloading and uploading speed will be up to 100 times faster. Sometimes having a high-speed network isn't always beneficial especially when it consumes high power, therefore, 5G will phase in new devices like 'Category M1' and 'Narrow Band (NB-IoT)' which will enable lower-power, battery-driven devices as well as far-reaching coverage for remote locations and penetration deep into buildings [16]. These devices will be working on mMTC Technology.

3. **High User Mobility & Improved Reliability:** The eMBB technology of 5G is expected to enhance user mobility up-to 500km/h in moving vehicles, heavy construction machinery. High-quality data at high mobility will allow construction firms to collaborate on various platforms. eMBB will provide broadband access everywhere which will facilitate enhanced connectivity making remote area coverage more reliable.
4. **High user density:** 5G will be able to handle the connection density up-to 1 million connections per square kilometer compared to ten thousand devices by 4G. It is necessary because of the exponential rise in the number of IoT devices per square kilometer. Also, in large construction sites located in cities, where the density of things rises these 5G networks will be able to handle the load smoothly with its Massive-IoT enabling technology.

4.2 Comparative Analysis: Construction Progress Monitoring

Construction managers work under enormous pressure of delivering projects on time, and they tend to monitor schedules more closely and strictly for making better as well as timely decisions. Due to the development of IoT technology, automated daily progress monitoring systems have become a possible (Refer to Figure 1) and as well as necessary tools for managers. Also, BIM platforms require the data to be centralized in a remote server for two reasons, firstly for the collaborative decision making by all the stakeholders and secondly for saving the on-site costs of installing a local server and investing in additional human resource to maintain it. Hence there is a critical need for safe and efficient data transfer mechanism.

Pushkar conducted a study for masonry activity of construction, though this can be easily extended to other construction activities [17]. The data acquisition was made using the commercially available stereo camera as a video file as a part of the input to the planning department, and the setup is as the one describes in Figure 2.

The videogrammetry data size generally depends on the resolution of the video captured and the frame rate but is usually in the range of Gigabytes to Terabytes of data per day. Here is a small piece of time calculation, for the above scenario, the resolution of the camera was set to 720p, and the frame rate was 30fps. Following was the data obtained,

$$Size\ of\ 1164\ frame\ video = 1.3\ GB \quad (1)$$

Converting the frames into the duration captured using frame rate, Therefore

$$Size\ of\ 39\ sec\ video = 1.3\ GB \quad (2)$$

Hence, $$Size\ of\ 1{-}minute\ video = 2\ GB \quad (3)$$

Considering that the Camera captures a one-minute video every 30 minutes cycle, for an 8-hour work day, we will require 16 cycles of data capturing (first video captured after 30 minutes from the start).

$$Total\ Data\ to\ be\ captured\ per\ day = 2\ GB * 16\ cycles = 32\ GB \quad (4)$$

Considering the user experience data rates for the transmission of data, over a 4G network the speed is 10 Mbits/s

$$Time\ to\ transfer\ 1GB\ Data = 13.33\ Minutes \quad (5)$$

Over a 5G network, expected speed is 100 Mbits/s

$$Expected\ Time\ to\ transfer\ 1GB\ Data = 80\ sec \quad (6)$$

*1 Megabit= 0.125 Megabyte

**1 Megabyte = 1000 Gigabyte

The speed being ten times faster can save up to 12 minutes per GB of data transmitted. So, with our single camera, the previous calculation 32GB of data is being transferred to the cloud server in a day then a 5G network can save about 6.4 hours of data transmission time.

Table 1. Time savings for data transfer for multiple cameras

Description	Number of stereo Cameras Collecting data simultaneously									
	1	2	3	4	5	6	7	8	9	10
Data Generated for 1 day (GB)	32	64	96	128	160	192	224	256	288	320
Uploading Time over 4G Network (hours)	7.1	14.2	21.3	28.4	35.5	42.7	49.8	56.9	64.0	71.1
Uploading Time over 5G Network (hours)	0.7	1.4	2.1	2.8	3.6	4.3	5.0	5.7	6.4	7.1
Time Savings (Hours)	6.4	12.8	19.2	25.6	32.0	38.4	44.8	51.2	57.6	64.0

Considering a construction site with ten stereo cameras and daily progress monitoring scenario, we get

the results of time savings as shown in Table 1. Results show that instead of 71 hours the 5G network can transfer the same data over the cloud in 7 hours which will help construction managers to get the analyzed results as a report the next morning itself.

As demonstrated in Figure 2 construction sites consist of many activities going parallelly, there will be many sensors capturing the data simultaneously. The amount of data obtained will be huge, even the BIM files which are to be sent over the cloud for processing are of considerable size and takes time for uploading through the different layers of IoT structure as shown in Figure 3. The 5G data speeds can help us to save a considerable amount of time in data transfer and hence resulting in timely decision making.

If sensors are placed for real-time monitoring purpose over a 5G network, the latency will be in the order of 1ms, which is equivalent to the real-time scenario, whereas using a 4G network gives a latency of 30-50ms. The 5G network is expected to provide more reliability than a 4G network, so the data packets will not be lost during the transmission which sometimes results in an erroneous or incomplete data while processing.

This speed of data transmission, lower latency, availability to bear high connection density makes the 5G network more efficient and reliable than the present 4G network. It can result in a considerable amount of savings in time and cost by facilitating timely decision making.

5 Conclusion

Implementation and effective use of IoT in the construction environment will not be an easy task. Within the next ten years, IoT networks will face prominent challenges because the networks will denser, more complex and heavily loaded than today. The continuous evolvement of IoT is needed along with developing and embracing new paradigms as it should continue to meet consumer and enterprise expectation and mission-critical applications in the coming future. However, a properly planned map to its deployment will smoothen the transition of the construction industry into the IoT ecosystem.

One of the challenges is the need for a faster, reliable, robust connectivity network. 5G implementation can be one of the technological upgrades to overcome these issues. The future connectivity standards will focus on improvement in connection density to handle the massive number of IoT devices, pervasive coverage to reaching challenging locations, low-power consumption and reducing network complexity. These technological challenges if dealt with planned and proper approach will make an ambient environment for wide-scale 5G adoption. In addition to this, the governments and private players should join hands to understand the economic growth the 5G standard can bring and should work closely for all the necessary technological upgradation necessary.

IoT has prospects to be the backbone of the construction industry, and therefore, there is a significant need to understand and address the challenges and barriers in IoT implementation and usage to foresee a future where IoT will be embedded as a ubiquitous tool to support the businesses and projects.

The future research can be focussed upon the applications of IoT in construction management that have been proposed in this paper. These applications will collect data from numerous resources and will have to integrate it collaboratively for better decision making. The five layers of IoT are the backbone to any IoT platform, and each has a high potential for exploration and improvement. The data processing capabilities using cloud computing and tools such as AI and Machine learning have shown a significant trend in usage and are a potential area of research to make IoT further useful for decision making.

Abstract -

Asphalt operations are equipment-intensive, highly-coordinated, and context-sensitive. To ensure high-quality asphalt, operators need to be mindful of, among others, the degree of compaction required/achieved, temperature of the asphalt mixture, its cooling rate, other equipment, and the supply logistics. However, the current training program for the operators of asphalt equipment is inadequate because (1) the training heavily depends on the use of actual equipment for the training and because of the cost/safety risks involved in using actual equipment, novice trainees do not get enough opportunity to develop the required skills; and (2) given the sensitivity of the asphalt operations to the environment, the type of the asphalt mixture, logistics, etc., it is very difficult to allow trainees become sensitized to all the influential parameters in a limited time provided for the practical training.

In recent years, Virtual Reality (VR) based training simulators are employed to help train operators in a safe environment. However, scenarios used in the construction simulators are mostly hypothetical. The context of operation in these scenarios is static and devoid of dynamism common in a construction site. This is a major oversight, particularly in highly-collaborative asphalt operations. Therefore, it seems crucial to better represent the actual work context in the training simulators. Given the myriad of parameters involved in the asphalt operations, designing a training scenario based on pure modeling is very challenging.

This research proposes an approach for developing a training simulator based on the data collected from actual asphalt operations. The collected data will be analyzed and translated into a training simulator that can better capture the interaction between various operators of asphalt operations. A prototype is developed and a case study is conducted to demonstrate the feasibility of the proposed approach. It is shown that actual data can be used to effectively generate realistic training scenarios.

Keywords -

Virtual Reality; Context-realistic; Operator Training; Asphalt operations

1 Introduction

Hot mixed asphalt (HMA) is the dominant material of choice for road construction all over the world. However, the quality of HMA is very sensitive to the construction operations [1]. For HMA to be of desirable quality, the compaction must be executed over a limited period when the asphalt is within a certain temperature window, which depends on the type of the mix. Compaction below and above this temperature window results in suboptimal quality [2,3]. Therefore, operators of asphalt operation equipment (i.e., paver and compactor) need to be aligned with one another. Additionally, operators need to be able to process a wide range of information (e.g., the temperature of the asphalt, the number of desired and achieved compaction, the speed of pavers, the movement of compactors, etc.) to be able to deliver a high-quality operation. This requires a high degree of coordination and operational skills.

Operators of asphalt construction equipment go through rigorous training before they are certified to work on the site. However, there are several limitations that compromise the effectiveness of the current training programs. First and foremost, since the practical training with the equipment is expensive, trainees may not have the chance to sufficiently train with actual equipment for work in different types of operations. Second, given the sensitivity of the HMA quality to multitude of environmental (e.g., weather), design (e.g., type of mix), and operational (e.g., the size of the team) parameters, the current training programs cannot sensitize the trainees to all the influential parameters in a limited time provided for the practical training.

Virtual Reality (VR) based training simulators have been used in other industries (e.g., aviation) to address the very same problems. The construction industry has also started to use VR for training in recent years [4,5]. These simulators can considerably reduce the cost and

risks involved in on-equipment training[6]. However, to the best of the authors' knowledge, a comprehensive training simulator for asphalt operation is missing. Besides, the available construction simulators (dominantly focusing on excavators and cranes) mainly focus on the dexterity and equipment handling skills of the operators. Accordingly, a lion share of the developers' attention is placed on the graphical fidelity and realistic kinematics of the equipment. While very important, this steers the focus away from capturing the realistic context of the training. In other words, the current simulators place the trainee in a mostly isolated and static site where the trainee can move freely and unhindered. For a highly collaborative work such as asphalt operations, this is a major oversight because operators need to perform the tasks in view of many peripheral parameters about the operation of other equipment, the behavior of the asphalt layer, and weather condition. For instance, when considering the trajectories of other compactors in the team, what could have been an optimal path for a single compactor may become very unsafe or inefficient in tandem compaction. Additionally, since the focus is too much on kinematics, many other aspects of physics in the simulators are left out. Current simulators use theoretical principles to develop the physics of the scene. Even though these theoretical principles are very effective, they are normally simplified and can hardly account for the complex interaction between the behavior of the of the asphalt layer, the type of the mix, weather condition, and the compaction regime. Capturing this complex interaction through physics-based modeling is very difficult.

Recent advancements in sensing technologies and Internet of Things (IoT) allow for the collection of a wide range of data about various aspects of actual construction sites. The authors have previously indicated the potentials of using various types of sensors to track and monitor asphalt operations [7]. The collected data from actual site capture various aspects of the context of asphalt operations that are not represented in the current hypothetical training scenes. This includes the context-specific cooling rate of the asphalt as well as the movement and motions of all the equipment in the asphalt operation team. It is argued that these data can be used to reconstruct the actual asphalt operations in a VR environment. Because the virtualized scene incorporates several elements of the operational context, the training scene created in this fashion is expected to be more realistic in terms of fidelity to the context. Trainees can use these simulators to become more sensitized to the collaborative nature of asphalt operations and to delicacies involved around compaction at the right temperature.

The authors have previously proposed a generic framework for data-driven context-realistic training simulator for construction operations [8]. However, the previous work of the authors is generic and not focused on a specific operation. Besides, the previous work of the authors assumed that most of the feedback about the performance of trainees is provided at the end of the session. This is a limitation because novice trainees and early-stage learners can benefit from mid-training guidance to build up competency about the development of compaction strategy.

Therefore, the primary objective of this research is to present an approach for developing an asphalt-specific training simulator using the previously presented framework for context-realistic training simulators. In this research work, the focus is placed on asphalt operation and the generic framework is retrofitted to adapt to the requirements of training simulators for asphalt operations. In particular, the paper extends the previous work of the authors to incorporate mid-training guidance targeted at novice and early-stage learners.

The layout of the paper is as follows: first, the proposed approach is presented. Next, the implemented prototype and case study is introduced. Finally, the conclusions and future work of the research is presented.

2 Proposed Approach

Figure 1 shows the overview of the proposed approach for the generation of context-realistic training simulators for asphalt operations, focusing on mid-training guidance. As stated in Section 1, this framework is retrofitted from the generic framework presented in the previous work of the authors [8] to customize the training simulators for the purpose of asphalt operations.

A training simulator focusing on the asphalt operation should be able to sensitize trainees to the importance of compacting asphalt at the right temperature. Given the complexity involved in simulating the behavior of asphalt on the construction site, the application of context-realistic simulators seems to be appropriate and helpful. The proposed approach has four main steps, namely, data collection, context generation, scene reconstruction, and context-based feedback.

2.1 Data Collection

During the data collection step, all the relevant data for the representation of the context of asphalt operation need to be collected. The context of asphalt operation is defined as the combination of environment, mobile equipment, and behavior of the asphalt.

In recent years, many municipalities and provincial government of large cities provide either the 3D models of their jurisdictions or the essential data needed for the reconstruction of 3D models. For instance, CityGML models of many major cities are now publicly available [9,10]. These models can be used to represent the

environment of the actual construction sites in the VR.

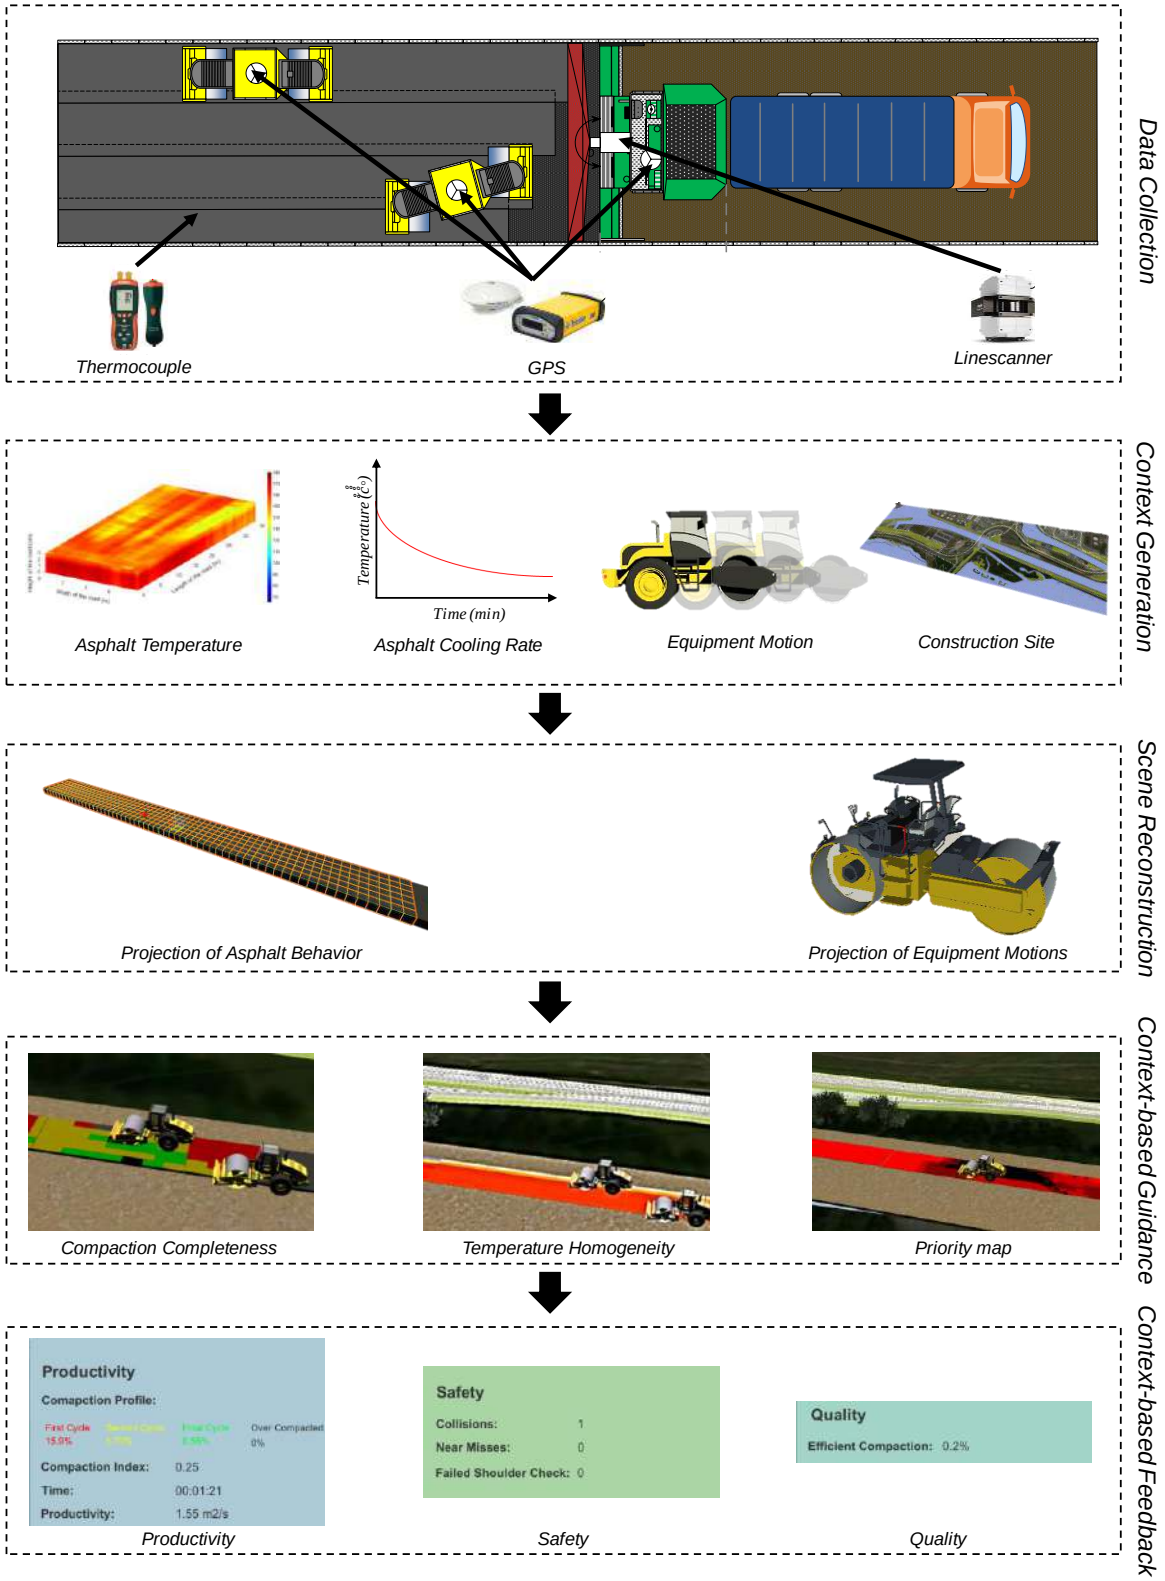

Figure 1. Overview of the proposed approach for context-realistic asphalt operation training simulators

For tracking mobile equipment, Global Positioning System (GPS) can be used. Since the kinematics of pavers and rollers are rather simple, 2D tracking is enough for representing mobile equipment in the VR scene. GPS rovers can be installed on each equipment. The data collected from GPS rovers can later be projected to the local coordinate of the VR scene. As for the asphalt behavior, the proposed simulator only focuses on the temperature of asphalt and the cooling rate. These two pieces of information indicate the temperature of the asphalt layer (at surface and core) and the rate at which it cools down. These data are critical for effective compaction and they are sensitive to various parameters such as weather condition, layer thickness, logistics, and type of asphalt mix, which makes them context-sensitive.

The previous work of the authors provides a comprehensive account of how this data can be collected from asphalt operations [1,7]. However, for the completeness, a brief description will be provided here.

The surface temperature of the laid asphalt mixture is collected using linescanner mounted at the rear of the paver, as shown in Figure 1. The width of the asphalt layer is split into several points and the temperature of each point is measured. By synchronizing GPS and linescanner data, the surface temperature data is geo-referenced. To be able to determine the cooling rate of asphalt, a set of thermocouples in combination with infrared camera are used to continuously measure the core and surface temperature of the asphalt layer at a fixed location. It should be noted that the cooling rate of the asphalt is not a constant value but rather a non-linear function, as shown in Figure 1.

2.2 Context Generation

Using the continuous stream of core and surface temperatures at the fixed location (i.e., the output of the thermocouples) and the initial surface temperature of different parts of the asphalt mat (i.e., the output of linescanner), we can interpolate the core temperature of the asphalt at any other points on the mat. With all the measured and calculated data, the 3D temperature contour of the asphalt mat and the cooling curve of the asphalt at the core and surface can be determined. These two types of data can be fed into the simulator to realistically represent the thermal behavior of asphalt in the context. Since this behavior is extracted from actual construction sites, the asphalt behavior captures the complex causal relationships that impact the thermal behavior of asphalt (e.g., weather condition, layer thickness, type of asphalt mix, etc.) without requiring to model these relationships mathematically.

Another element of context in asphalt operation training simulator is the 3D model of the site. As stated before, the data required for 3D modeling of the site can be extracted from public data (e.g., CityGML). Depending on the Level of Detail (LoD) of the available data, the 3D model may need some adjustment such as draping and minor geometric adjustment. Also, additional pieces of information such as new buildings and underground utilities can be extracted from relevant asset information models such as Building Information Models (BIM). Asset information models can be incorporated into CityGML model using available tools for BIM and GIS integration (e.g., Infraworks [11]).

The final element of context in the simulators is motions of different pieces of equipment. For this element, GPS data need to be corrected. Authors have previously presented an approach for enhancing the quality of the location data [12].

2.3 Scene Reconstruction

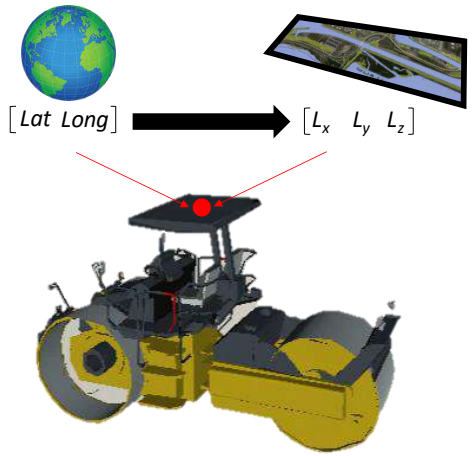
In the next phase of the proposed approach, the context data and the 3D model of the site need to be integrated. Game engines can be used for this purpose. The first step in this phase is to import the 3D model of the site into the game engine. In many cases, when the 3D model is imported into the game engine, the native coordinate system is distorted. If this happens, the 3D model needs to be re-scaled and re-positioned. This process is explained in the previous work of the authors [12].

The next step in this phase is data synchronization. Depending on the used sensors, different types of data have different resolution and frequency. To improve the consistency of the scene, it is best to unify the update rate of different types of data and align the timeframe across all the data. This can be done through averaging the data and interpolation.

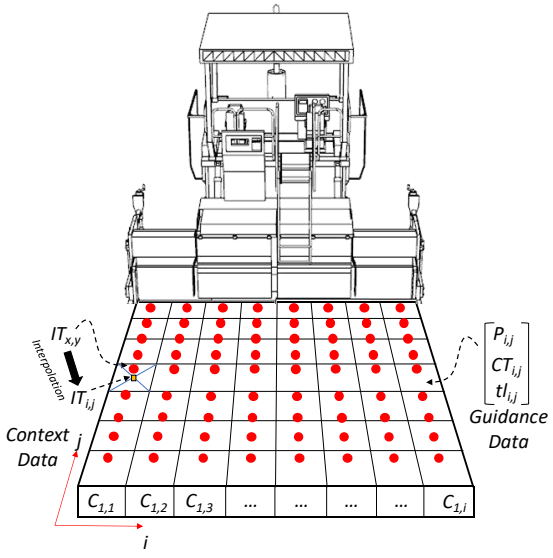
Upon the completion of data synchronization, temperature, cooling rate, and mobility data should be integrated into the scene. Figure 2 presents an overview of how these types of data are integrated into the VR scene. As shown in Figure 2A, the first step is to translate the latitude and longitude data coming from GPS to the local coordinate of VR scene, using the method explained in the previous work of the authors [8]. Since pieces of equipment used in the asphalt paving operations have rather simple kinematics (i.e., 1 controllable degree of freedom for transitional movements), the project time-stamped coordinate data can be linked to a single point hinged to the 3D model of the equipment at the same location where GPS rover was installed on the actual equipment.

To incorporate the temperature ($T_{x,y}$) and cooling rate (dT/dt) data into the scene, first, the geo-location of each data point needs to be projected to the local coordinate of the VR scene, similar to the previous step. Then, the 3D model of the asphalt layer needs to be discretized into a grid, as shown in Figure 2b. Since the data collected by

linescanner, i.e., red dots in Figure 2b, (1) are not necessarily projectable into a uniform grid and (2) have a very high update rate that may render the VR scene very slow if they are supposed to be used as is, the grid size in the VR scene is determined by human modeler. Then, by intersecting the coordinates of the temperature data ($IT_{x,y}$) with the user-defined grid and applying interpolation the initial temperature of each cell of the asphalt layer in VR scene ($IT_{i,j}$) is determined. In the VR scene, each cell becomes visible only when it collides with the paver for the first time (i.e., when it is placed on the mat on actual site). From that moment, the temperature cools down according to the measured cooling rate.



(a) GPS data integration



(b) Linescanner data integration

Figure 2. Overview of the proposed approach for context-realistic asphalt operation training simulators

2.4 Context-based Guidance

Upon the integration of data in the VR scene, the next step is to develop a guidance mechanism inside the scene. The guidance is supposed to help trainees (particularly novice learners) develop better compaction strategies by observing the behavior of the asphalt and the impact of decisions made on the site. To this end, three types of guidance are provided to the trainees: (1) compaction completeness, (2) temperature homogeneity, (3) proximity, and (4) compaction priority map. These three types of guidance are provided on-demand, meaning that the trainee can choose which of the three types of guidance he/she wants to see on the main screen and which one of the guidance types he/she wants to see in small side windows. More experienced trainees can choose not to use any of the guidance types at all.

Compaction completeness measures the number of times each cell in the grid is subject to compaction ($P_{i,j}$), as shown in Figure 2b. This index is calculated by counting the number of times the drum of the trainee-operated roller collides (i.e., come to contact) with each cell. This type of guidance is displayed through the use of a color coding scheme. This means that based on the required number of compaction, which is a function of the type of the asphalt and the thickness of the layer, different colors in the spectrum of dark red to dark green indicates the number of compaction achieved at each cell. Also, the cells that are over-compacted can be indicated by changing the color to black. The user uses this guidance to (1) evaluate his completed work and (2) devise a plan for compacting the reminder of work.

Temperature homogeneity guidance displays the current temperature of each cell. As shown in Figure 3, this is done by considering (1) the initial temperature of the cell and (2) the simulation time (t) passed from the moment each cell is placed on the mat.

The cooling curve of the asphalt, which is generated at the end of the data gathering phase, is used to determine the current temperature of each cell at each frame of the VR scene ($CT_{i,j}$). Similar to the compaction completeness index, the temperature of the cell can be visualized using a color coding scheme. Trainees can use this form of guidance to determine whether or not a cell is still within a compactable temperature zone and how much time there is before a cell becomes too cold for compaction.

Proximity guidance indicates the distance of the trainee-operated equipment to other pieces of equipment. Additionally, when the trainee-operated equipment become hazardously close to any other equipment/workers in the scene, a warning is generated. The trainee can use this guidance to become sensitized to situation awareness required for safe execution of the job.

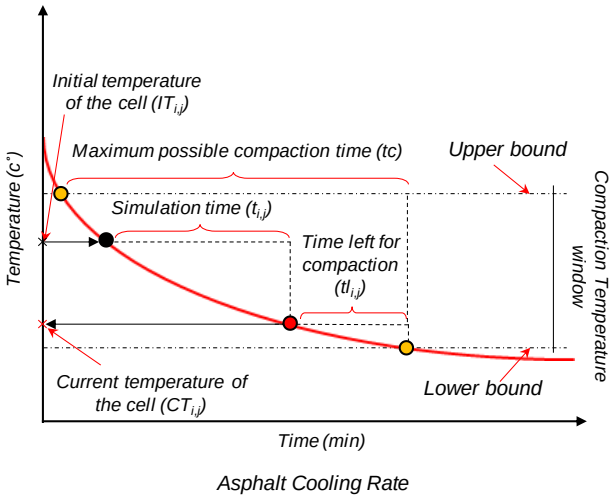


Figure 3. Calculation of the current temperature of each cell based on the initial temperature and the cooling rate

The last type of guidance that can be provided to the trainee is the compaction priority map. While the previous two guidance types merely indicate the state of asphalt layer in terms of compaction and temperature, the priority map tries to combine the two state data into guidance about how compaction of different parts of the asphalt needs to be prioritized. In order to generate the priority map, two parameters are considered. The first parameter is the time left for the compaction of a cell. As shown in Figure 3, this is determined by calculating the time left to the lower bound of compaction temperature window ($tl_{i,j}$) for each cell at every frame of the VR scene. The second parameter is the number of compaction achieved so far for each cell ($P_{i,j}$). These two parameters are translated to a priority index using Equations 1 to 3.

$$R_{i,j} = CP_{i,j} \times TP_{i,j} \quad (1)$$

$$CP_{i,j} = \begin{cases} \frac{PD - P_{i,j}}{PD} & PD \geq P_{i,j} \\ 0 & PD < P_{i,j} \end{cases} \quad (2)$$

$$TP_{i,j} = \begin{cases} 0 & tl_{i,j} > t_c \\ \frac{t_c - tl_{i,j}}{t_c} & 0 < tl_{i,j} \leq t_c \\ 0 & tl_{i,j} = 0 \end{cases} \quad (3)$$

Where:

$R_{i,j}$ =*Priority of cell i and j*
$CP_{i,j}$ =*Compaction priority of cell i and j*
$TP_{i,j}$ =*Temperature priority of cell i and j*
PD =Desired number of compaction
$P_{i,j}$ = *Compaction achieved at cell i and j*
tc= Maximum possible compaction time
$tl_{i,j}$ = *Time left for compaction of cell i and j*

The priority value ($R_{i,j}$) is displayed using a color coding scheme in the spectrum of light to dark red, corresponding to high and low priorities. Trainees can use this form of guidance to plan the compaction path.

2.5 Context-based Feedback

The next phase in the proposed approach is to provide relevant feedback to trainees, i.e., after the training session is completed. Feedback helps trainees better pinpoint areas of attention in their practices. Additionally, feedbacks and the metrics used to assess the performances of the trainees can help track the progress of the trainees throughout the training program. Based on the scope, feedbacks can be categorized in 3 classes: (1) productivity-related, (2) safety-related, and (3) quality-related. Productivity-related feedback measure the overall compaction time, proportion of under, adequately, and over compacted cells, average compaction, and productivity. Safety-related feedback indicates the number of collision with other objects/equipment, the near misses, and failed shoulder checks (i.e., if VR goggle is used). Finally, quality-related feedback measures the ratio of cells that have been properly compacted within the compaction temperature window to the overall asphalt area.

3 Implementation and Case Study

To demonstrate the feasibility of the proposed approach case study is conducted. The case study is built upon the previous case study presented by the authors [8]. For completeness, the description of the case study is repeated in this paper.

The data collected from a surface rehabilitation of a part of a highway (A15) near Rotterdam is used. The collected data included the GPS of the paver and two compactors and the temperature/cooling of the asphalt. The principles explained in the earlier work of the authors are used for data collection [1].

The 3D model of the site is generated using Infraworks and Unity 3D, as explained the previous work of the authors [12]. The data collected from linescanner and GPS rovers are integrated with the asphalt cells and the 3D model of equipment, respectively.

The scene is designed so that one trainee can operate one of the rollers in the scene. Depending on the purpose of the training, the trainee can decide to be the leader or follower in the compaction process. The details of the two possible scenarios and how they are implemented in the scene can be found in the previous work of the authors.

As stated in Section 1, the main focus of the paper is to generate mid-training guidance to the trainees. Therefore, the principles explained in Section 2.4 is implemented in the VR scene. Figure 4 shows different types of mid-training guidance that trainees will receive.

As shown in this figure, the discretization of asphalt into cells can help provide easy guidance to the trainees. Also, the dangerous proximity of the trainee-operated equipment to other equipment is warned using the highlights in the real-time proximity indicator.

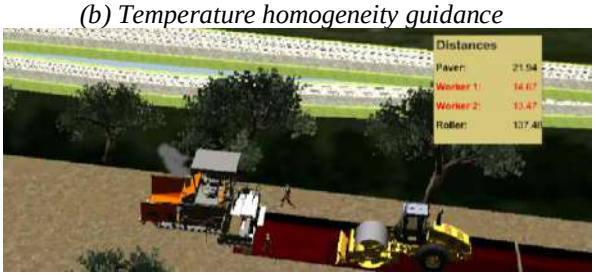
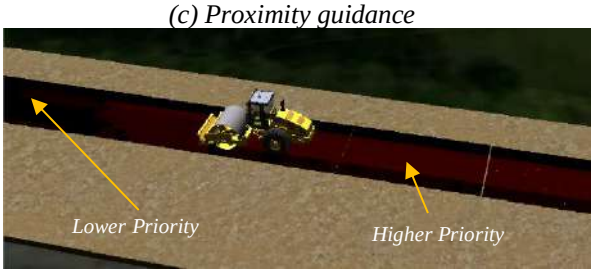
(b) Temperature homogeneity guidance



(c) Proximity guidance



(d) Compaction priority map

Figure 4. Overview of different types of mid-training guidance that can be provided to the trainees in the context-realistic training simulators

4 Conclusions and Future Work

In this paper, an approach for the generation of context-realistic training simulators for paving operation was presented. A generic framework developed by the authors was tailored to the specific characteristics of paving operations. Additionally, special focus was placed on the incorporation of mid-training guidance for early stage learners. A case study was conducted to demonstrate the feasibility of the proposed approach based on actual data collected from a paving operation.

The result of the case study indicated that the actual data collected from paving operations can be easily used to generate context-realistic training simulators. It is shown that a variety of real-time calculations can be applied to provide early-stage learners with various types of guidance. These mid-training guidance can be used by trainees to hone the skills required for developing compaction strategies faster.

While the results are promising, the positive impact of mid-training guidance on the development of compaction skills needs to be validated in a case study with a group of actual trainees. This would be the future focus of this research.

Abstract –

Machine Learning Algorithms (ML) offer a high potential with low manual effort to discover appropriate energy efficiency measures for buildings. Although many building automation systems (BAS) record a high amount of data, technical systems such as boilers provide only a few data points per building. However, machine-learning algorithms require training based on a sufficient number of instances of a technical system in order to enable cross-building use.

In contrast to electrical systems, few data sets of actual operation of thermal systems are publicly available. Since 2012, the monitoring system in our test object has continuously provided threshold-based data with a maximum resolution of 1 minute. We monitor the plants, energy consumption and comfort parameters with 9239 data points in total. In this paper, we show how our published data set from this building is structured. In order to facilitate the use of ML, each data point receives a uniform label according to a previously developed approach.

Since the documentation of ML data sets varies in the building sector, we show an approach to standardize data sets with special datasheets for thermal systems to provide sufficient information for application of ML.

We use the Brick Schema, a unified ontology standard for the description of topology in buildings, which is part of the future ASHRAE Standard 223P. We couple this with an approach we developed for the structured labeling of data points in buildings.

We show how to semi-automatically generate physical models based on an open-source Modelica library from this ontology-based model. We show that the models, enriched with real time series data and data sheets, are in good agreement with the measured data.

Finally, we show with an ML example that our approach based on Brick Schema and Modelica is able to deliver ML compliant data sets.

1 Introduction

Machine Learning Algorithms (ML) are increasingly finding their way into building energy systems (BES) in order to increase the systems' energy efficiency. One application of ML algorithms in BES is the optimization of the control system. Further applications are the modelling and prediction of behavior of energy systems or energy consumption [1]. They can support the normalization of metadata of data points [2] or fault detection [3]. Since different disciplines use the term "data point" differently, we use the following definition, which we derived from the use in building automation (BA): a data point is an information carrier that continuously provides information about a state. The use cases and methods for the application of ML in energy technology are manifold. [4] and [5] give an overview for the application of supervised learning in energy systems.

Each data point receives a label in the building, the so-called data point identifier. Therefore, there is no common standard or exchange format for data point identifiers for all buildings. This leads to the fact that applications in the building are not or only with difficulty transferable to other buildings. Thus for ML, most time series from BES are unstructured.

However, a large amount of structured data is required for the development and application of most ML use cases in BES. These data should be retrieved from as many different systems as possible, so that a comparison with different building types is possible [6]. Some technical system types exist only in small numbers within a building, e.g. often there is only one heat pump in a

building. In order to develop special classification applications for these technical systems, a clearly sufficient number of structured time series is necessary.

[7] shows an approach to structure or classify data points of BA in 22 classes. In practice, the data points in BA have a higher differentiation.

Published data sets on buildings or building operation originate mainly from the electrical monitoring [8][9] or the comfort [10]. If the operation in thermal systems is covered, then mainly in 15-minute samples [11][12] or for special applications, such as air handling units [6] or subways [13]. The 15-minute rate is not sufficient to reflect the technical monitoring in control as described in VDI 6041 [14].

In existing simulative approaches for virtual data sets, models of buildings were used to generate a virtual data set for the comparison of building consumption [15] or synthetic data for Non-intrusive Load Monitoring (NILM) were produced [16].

For the testing and benchmarking of ML algorithms, it has become standard practice to use test data sets. According to [17], developers and users of ML approaches need a precise description of the data sets in order to interpret them correctly. The existing approaches for the description of building datasets provide information for a limited number of use cases. In particular, the data sets do not describe the difficulties of data collection or data application. [17] developed a comprehensive questionnaire for describing ML data sets. However, the use of BES data in ML algorithms requires more information that is special. Therefore, in our questionnaire, we added suitable questions and removed unsuitable questions for BES in [17].

Physical simulation models can supplement existing data or multiply existing time series with variants of technical systems for the application of ML. For example, simulations support different operating conditions of a wide range of technical systems. However, the creation of such simulation models is a very time-consuming process, and the reuse of existing data point identifiers can significantly reduce this effort.

Here, the use of a unique machine-readable data point identifier is necessary. There are currently countless standards and norms that promise universal descriptiveness of building data. However, no standard can support all requirements for the simple creation of simulation models of BES. Building Information Modeling (BIM) with IFC4 could help here. However, IFC4 describes only few tags in the description of metadata for data points [18] and, in a survey conducted by the German Architects' Association [19], only 12% of the respondents used BIM in projects at all. The approach for naming and which we described in [20], together with the Brick Schema [21] which will be included in the future ASHRAE Standard 223P [22], fulfils the requirements for simulation and ML.

However, to the best of our knowledge, there is no combined approach for real-life and simulated time series data for the training of supervised learning algorithms for classification of rare time series in BES.

In this paper, we show how to standardize real time series data sets in building energy system (BES) with a unique machine-readable data point identifier for usage in Machine Learning (ML). We propose a questionnaire for BES that a data set provider should fill out to support the use for ML practitioners. We show that our developed toolchain can extract information from data point identifiers and use it for the semi-automated creation of a simulation model. We also present how our toolchain can create a simulated data set of rare time series in the BES. In a use case, we demonstrate how ML applications can use our simulated data set for the classification of rare time series in BES. We point out whether the developed approach is suitable for application in ML.

2 Standardized data sets for timeseries data

2.1 Questionnaire for Time Series Data Sets in Building Energy Systems

In order to standardize the description of data sets, we defined a set of questions that an owner of data sets, who intends to publish the sets, should answer. We used an existing approach [17] and added questions suitable for BES. We want to make a user aware of the obstacles in the use of the data set.

The main aspects of these questions are as follows:

- Motivation for data set creation.
- Data set composition
- Data collection process
- Data preprocessing
- Data set distribution
- Data set maintenance
- Legal & ethical considerations

The static or dynamic boundary conditions under which the data was recorded helps the user of ML in BES. This is one question of the questionnaire: “What information (static and dynamic) can be given about the system(s) in which the data was recorded?”

The structure and design of the BES has a high influence on the energy efficiency of the individual components. It is not only decisive which components in what dimension the BES contains, but also their actual connection plays an important role. A graph-based system offers the possibility to map the topology of data points and facilities. The topology offers the possibility that e.g. all data points of a special plant are searchable.

An insight into the influences of connected systems is thus conceivable. Related questions are therefore as follows: "Are relationships between instances made explicit in the data? Are schemas of the technical equipment included? Is there a representation of the schemas as a graph model?"

Time series data often have gaps or are not complete. Therefore, we have added questions to this questionnaire in the section "Data Collection Process": "How many gaps are in the data set? How can a user of the dataset recognize them?"

As the full questionnaire is very extensive, readers may refer to the corresponding Github repository for the complete questionnaire (https://github.com/RWTH-EBC/JUDO).

2.2 Just Unified Data set for building Operation (JUDO)

The building selected for this paper is the E.ON ERC main building in Aachen, Germany. It has a variety of different energy systems, providing a representative example of the building landscape. The energy systems include, among others, a combined-heat and power unit, a boiler, a geothermal field with 41 boreholes and comprehensive monitoring, a chiller, a sorption system, facade ventilation units, concrete core activation, underfloor heating, radiators. The zones of the building include offices, seminar rooms, computer rooms, workshops and laboratories. This data set contains different usage behavior of different systems at different times. More information about the building and the operation strategy of the building can be found in [23].

We added information about the dimensions of the BES and the connection of the systems with the Brick Schema to this dataset. We also provided instructions on how to interpret the data in the data set. The dataset includes all existing data points of the selected plants. This includes, for example, all status messages, valve positions and set points. Therefore, the data set shows the overall picture of the operation of the plants.

For the first standardized data set, we selected the time series of 765 data points of 31 technical devices in four representative months. Each of these months represents one of the four seasons. The name of this data set is JUDO (Just Unified Data set for building Operation) and is available at https://github.com/RWTH-EBC/JUDO.

This set includes the data points sorted by technical system (Table 1) and types (Table 2).

Table 1. Data points in JUDO sorted by technical system (main examples)

Technical System	Number of Data Points
Geothermal field	221
Heat Pump	181
Glycol cooler	68
Heat Exchanger	57
Concrete Core Activation	56
Boiler	29
Combined Heat and Power	26
Chiller	8

Table 2. Data points in JUDO sorted by data point type (main examples)

Data point type	Number of Data Points
Command	240
Temperature sensors	189
Status	81
Alarm	65
Volume Flow	58
Position	26

3 Process overview of generating generic simulated data sets

The whole process of generating Modelica simulation models from an ontology-based model (BrickModel) is a tool-chain of various special-purpose tools. Figure 1 shows the various steps of the process. First, a user fills out an Input Data File. Based on this file, a tool called BuToOn creates a brick model and a data property file, in which the user has the possibility to enter further information. At the same time, the tool BouGen determines the time series data for the boundaries of the model. OnWithData creates a common Brick model for all inputs. OnToMo converts the Brick model into a Modelica model.

The whole toolchain is written in Python. The subsystems of the simulation models are taken from the open source Modelica library Aixlib [24].

In the following, we describe the underlying data schema approaches of the toolchain and describe the toolchain itself.

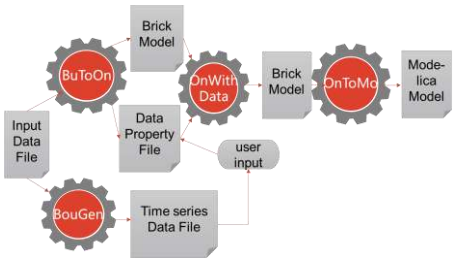

Figure 1. Process of generating Modelica simulation models from an ontology-based model

3.1 Used approaches

3.1.1 BUDO Schema

In this work, data points named by "buildings unified data point naming schema for operation management" (BUDO) [20] are used for the modelling. A BUDO key consists of several parts as shown in Figure 2. Each part provides a hierarchy level for the topology model and the corresponding simulation model. Information in system, subsystem, subsubsystem, medium/position and type of the BUDO key can be extracted to determine entity types in BrickModel.

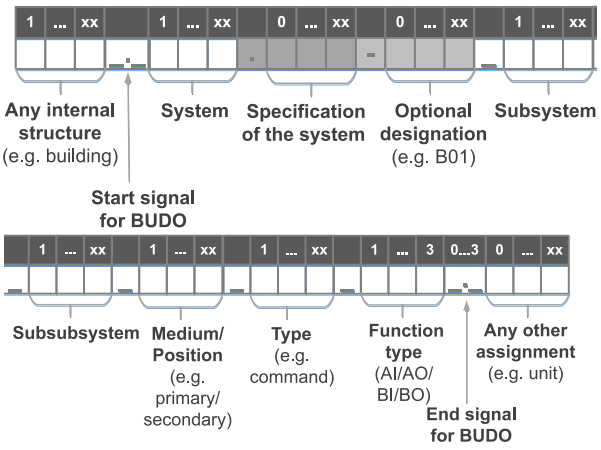

Figure 2. Structure of BUDO Key

3.1.2 BrickModel

The BrickModel is based on the Brick Schema developed by Balaji et al (2018) [21]. Figure 4 displays a sample of Brick's class hierarchy. Two classes of Brick are important for BrickModel: Equipment and Point. However, Brick can only describe which components are connected, but falls short in describing more detailed positions of the individual components, for example whether the primary or secondary side of a heat pump is connected to another equipment. In addition, the Modelica language uses connectors between two components. In order to describe the physical connection between equipments more precisely and meet the requirements of Modelica, we developed another class named Port to complement this ontology. One definition of these three important classes is as follows.

- Equipment: "Physical devices designed for specific tasks controlled by points belonging to it. E.g., light, fan, AHU" [21].
- Point: "Points are physical or virtual entities that generate time series data. Physical points include actual sensors and setpoints in a building, whereas virtual points encompass synthetic data streams that are the result of some process which may operate on other time series data, e.g. average floor temperature sensor" [21].
- Port: Ports represent the boundary and the physical connector of physical devices and store related static design data such as nominal mass flow.

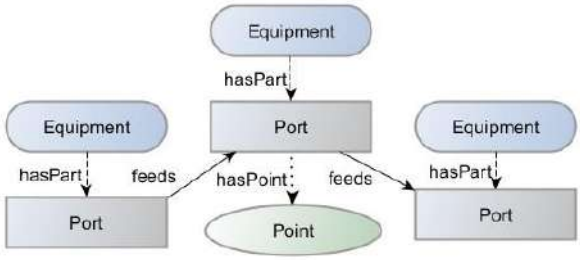

Figure 3. Information Concepts in BrickModel

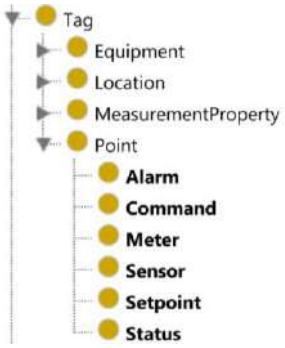

Figure 4. A subset of the Brick hierarchy [21]

As shown on the left side of Figure 5, we defined ports for heat flows, flows, electric currents, weather, equipment, comfort, transfer to rooms, control and fuels. Ports for heat flow are the most used in this work. Primary and secondary ports define the physical position of ports. In addition, we defined several data properties, which represent the design data of equipments and devices. On the right side of Figure 5, there is a subset of the data property hierarchy.

Data properties such as nominal mass flow, nominal temperature and nominal pressure difference are defined,

which can be used to set corresponding parameters required in Modelica simulation model. Furthermore, relationships in Brick connect the different entities in the building and describe the physical topology. Table 3 summarizes the definitions of relationships used in BrickModel. Figure 3 demonstrates how relationships connect entities of different classes with each other in BrickModel.

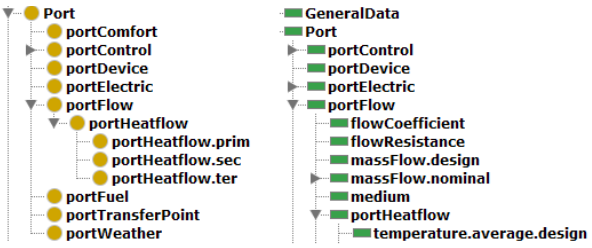

Figure 5. A subset of the port class and data property hierarchy

Table 3 List of the used Brick relationships and their definition

Relationship (Inverse)	Definition	Endpoints
hasPart (isPartOf)	A has some component or part B (typically mechanical)	Equip./Port Equip./Equip.
hasPoint (isPointOf)	A is measured by or is otherwise represented by point B	Equip./Point Port/Point
feeds (isFedBy)	A "flows" or is connected to B	Port/Port

3.2 Generating the BrickModel

The starting point for the workflow is manually gathering information and storing them in an Excel file. In addition, users can choose to specify the period of the time series and the data points they want to integrate into the Modelica simulation model.

If the user has filled out the Input Data File, BuToOn generates a BrickModel. The first generated BrickModel still lacks some information required by the Modelica simulation model. Therefore, BuToOn generates a data property file at the same time. The user has to input corresponding parameter values for the Modelica Model in this file. A tool named BouGen extracts the corresponding data from the time series data set and writes them into a file readable by Modelica. For the requested period, the time series database provides the corresponding time series for each data point and BouGen stores them in a Modelica-compatible format.

The tool OnWithData combines the Brick Model from BuToOn with the additional information from the data property file and the generated files of the time series data from BouGen and creates a BrickModel from all previous information.

3.3 Transformation To Modelica model

In the final step, the tool OnToMo extracts the information of the BrickModel and generates the corresponding Modelica model. We developed this tool using a code templating tool (CoTeTo) [25] and the SPARQL Protocol And RDF Query Language (SPARQL) [26].

The approach to generate Modelica code is template-based. CoTeTo supports the template engine Mako [27] that allows users to predefine templates for the corresponding Modelica code and conveniently store templates for each Modelica module in a separate template document.

SPARQL queries specify constraints and patterns of triples, and traverse the BrickModel to return those that match. Table 4 shows two examples of extracting information from BrickModel.

The first example demonstrates a SPARQL query for searching an instance of class Pump. The query searches in BrickModel for instances that match the triple pattern and return them.

The second example shows the extraction of the physical topology of the model, which is used to connect the modules. The existence of the Port class provides sufficient connection information for Modelica. This query returns the port, which is fed by the specified pump port as result.

After extracting information from BrickModel, the toolchain generates the Modelica simulation model.

Table 4. SPARQL Query Examples

```
SELECT ?instance
WHERE {?instance rdf:type brick:Pump.}
```

```
SELECT ?port
WHERE {
ex:BL-4120_._HX-H03_PU-M02_WS.H.SEC_PH
bf:feeds ?port.}
```

4 Modelling Use Case

To prove the functionality of the tool-chain, several use cases are developed based on the main building of E.ON Energy Research Center. In total, 13 simulation models, 244 modules and 211 connections between modules were established and 2153 lines of Modelica code were automatically generated. In this section, only one selected use case is illustrated: a heat pump system with real time series data. As shown in Figure 6, the heat pump system consists of one heat pump and four

temperature sensors. Figure 7 shows the corresponding Modelica model. During the modelling process, our developed approach transforms and connects all the modules automatically and correctly. In addition, this model successfully integrates time series data of temperature and mass flow from a database as boundary conditions. Moreover, for the control of the heat pump, the time series data of the electrical power of the compressor are integrated into the model of the heat pump. The heat pump does not provide a control signal. This creates uncertainty if the signal integrated into the model will affect the real behaviour.

Figure 8 compares the simulated and actual measured return water temperatures of the condenser side of the heat pump. The blue curves are the simulation results and the green curves represent the measured data. It is obvious that the simulated data of the heat pump model are in good agreement with the measured data, although there are still occasional deviations. The Root Mean Square Error (RMSE) of the return temperature on the condenser side is 1.414 K and the Normalized Root Mean Square Error (NRMSE) amounts to 0.086. For the evaporator side, the return temperature reaches a RMSE of 2.040 K and a NRMSE of 0.156.

We use this model to generate more rare time series for a classification approach. For this purpose, we scale the power and mass flows of the heat pump shown here.

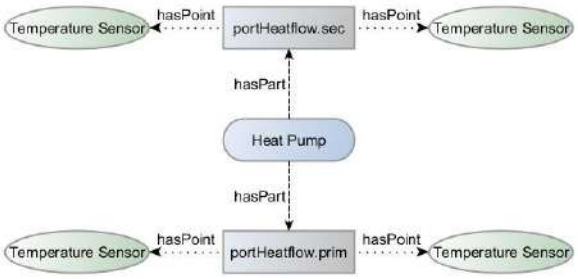

Figure 6. BrickModel structure of a heat pump system

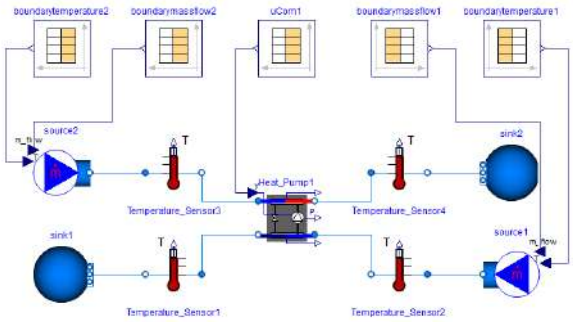

Figure 7. Modelica simulation model of a heat pump system

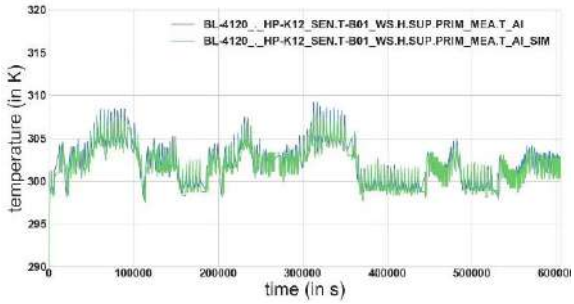

Figure 8. Comparison of simulation result with measured data of heat pump return water temperature on condenser side. Corresponding to Temperature_Sensor4 in Figure 7

5 Classification Use Case

In this section, we demonstrate how generated data sets can be used to train algorithms for classification of real time series classification. We train ML classifiers with both real and generated data points. For this purpose, two heat pump temperature time series (T_HP.Cond, T_HP.Evap) are generated with the model illustrated in Figure 7. We used the following further classes from real measurements:

- room air temperatures (T_AIR)
- temperature of concrete core activation in room automation (T_RA_CCA)
- temperature of concrete core activation in distribution (T_DIST_CCA)
- façade ventilation units in room automation (T_RA_FVU)

Due to the small temperature difference, the flow and return of the CCA and FVU data points are combined in one class in each case. The final data set contains the following data points:

- 180 samples from each T_HP.Cond and T_HP.Evap
- 340 samples from T_AIR
- 76 samples from T_RA_CCA
- 120 samples from T_ DIST_CCA
- 100 samples from T_RA_FVU

Each sample consists of the data point's label and time series data of one month. The used time series have a resolution of one minute. We detect and eliminate outliers with hampel filter [31].

For the training of the classifiers except of heat pump, we split the data set into 70% training data and 30% testing data. We extract six statistical features, following the recommendations published in [28]. We have also sorted out time series that did not have any usable statistical characteristics. We apply nine of the most suitable classifiers for real world classification problems

according to, using the implementations provided by scikit-learn [29]. In Figure 9, we present the classification scores of the algorithms when applied to the test data set.

Four out of the nine algorithms reach more than 70 % classification accuracy [30]. The best performing classifier is "Gradient Boosting" with 80.7% top score.

For the second test case, we use 10 real temperature measurements from both T_HP.Cond and T_HP.Evap to our test data set. Figure 10 shows the classification done by classifiers. "AdaBoost" classifier correctly assigned 9 of 10 of T_HP.Cond and 8 of 10 T_HP.Evap.

We conclude that the training of classification algorithms with simulated data also has a high potential for data point mapping in modern building automation systems. However, for a robust application in building automation further investigations are necessary.

6 Conclusion

In this paper, we presented a data set extracted from the real operation of a multifunctional building with various energy plants, the Just Unified Data set for building Operation (JUDO). We extended a special questionnaire for Machine Learning (ML) users with specific questions for Building Energy Systems (BES) and filled it in for JUDO. This questionnaire can be used for further data sets from BES. Consequently, we named the data set with a labelling schema for building data (BUDO). In future, we provide a Brick model of this.

We were able to show that our developed toolchain can semi-automatically generate simulation models using the standardized data point identifiers of time series data sets from the operation of BES. Finally, the toolchain creates an ML-compatible simulation data set. An extension to arbitrary periods and facilities of this and other buildings is possible.

We were able to apply this approach to the ML application of data classification. The current approach showed first good results but there is still a great need for research. We expect that a combination with calibration methods could increase the automation and accuracy of the approach. We will expand the considered technical facilities so that we can simulate a wider field of BES. We will extend the existing data set of currently 765 data points by further data points. We also consider an automatic generation of the currently required static information of the technical equipment from data sheets.

Abstract –

The world's population is aging at an unprecedented pace. Aging society is not only a severe crisis in the developed world such as Germany and Japan, but also a rigorous challenge in emerging economies such as China. Many age-related diseases are fostered by the lack of physical, cognitive, and social activities. Increasing the activity level has many benefits for the elderly and can improve their independence. The research project REACH (funded by European Union's Horizon 2020 Research and Innovation Program under grant agreement No. 690425) aims to develop a service system that will turn clinical and care environments into personalized modular sensing, prevention, and intervention systems that encourage the elderly to become healthy through activities (e.g., physical, cognitive, socializing, personalized food, etc.). As a core research partner, the Chair of Building Realization and Robotics at Technical University of Munich developed a series of Personalized Intelligent Interior Units (PI²Us), which are a special type of smart furniture, that materialize the REACH concepts and functionality seamlessly into the different REACH use case settings. Specifically, the design and functions of the PI²Us, which consist of the PI²U-SilverArc, PI²U-MiniArc, PI²U-Bed, and PI²U-iStander, will be described in detail. In addition, a modular apartment integrating all PI²Us and key technologies in REACH is designed and simulated to create a total interior living and care environment for elderly users. Due to its modularity, parts of the apartment can be easily adapted and rapidly deployed in different REACH use case settings in four European countries, which will then help the REACH consortium execute a series of testing activities. In conclusion, this research project provides a systematic and innovative example for the world to mitigate the impact of aging society.

1 Background

The world's population is aging at an unforeseen rate. Aging society is a crisis that is experienced all around the globe, including developed countries such as Germany and Japan, and emerging economies such as China. For instance, the health expenditure in the EU is expected to rise by 350% by 2050 compared to an economic growth of only 180% in the same timeframe [1]. The Directorate General for Economic and Financial Affairs reported that the provision of long-term care (LTC) in particular will pose an increasing challenge to the sustainability of public finances in the EU, due to an aging population [2]. Evidently, many age-related diseases are fostered by a lack of physical, cognitive, and social activities. Increasing the level of activity has many benefits for the elderly and can improve their level of independence [3]. Therefore, the project REACH represents a solution that seeks to protect elderly citizens against loss of function and a decline in ability to independently perform Activities of Daily Living (ADLs), which ultimately lead to entering LTC. REACH will allow European industries, including small- and medium-sized enterprises, to capitalize on the European high-tech knowhow, make Europe a world leader in prevention technologies, services, and underlying healthcare ICT platforms, and meanwhile tackle the ultimate crisis of rising healthcare expenditures.

2 Introduction to REACH

REACH stands for Responsive Engagement of the Elderly promoting Activity and Customized Healthcare.

With a project duration of four years, it is a cross-disciplinary, multi-partner, EU-funded research project that develops the future generation of technologies and services for a value-based and prevention-oriented health care system. The key elements and concepts of REACH will be explained as follows.

2.1 Objectives and the consortium

In the project REACH, an experimental, cross-disciplinary sensing-monitoring-intervention system is developed that can be placed in an unobtrusive way in various care settings and living environments of elderly citizens. The system aims at 1) using a variety of sensors to detect specific vital signs, behavioral patterns, and health status; 2) predicting future health status, risks or events; and 3) anticipatorily providing a series of customized health products and services that support and promote physical activities. As a result, the Healthy Life Years (HLY) of the elderly would be increased, and their time spent in LTC facilities would be reduced. The REACH consortium consists of six research partners who serve as the scientific backbone of the project; seven industry partners who undertake various tasks from sensor and rehabilitation device development, to ICT platform integration, standardization support, and business model generation; and four application partners who take on the real-world deployment of the technologies developed in REACH in their exemplary care environments [4].

2.2 Touchpoints and Engine concept

As a major achievement of the first project year, the REACH consortium developed the "Touchpoints and Engine" concept as a comprehensive solution of REACH's system architecture. It further guides the detailed structural relation between the subsystems of REACH. With the "Touchpoints and Engine" concept, REACH´s product-service-system architecture is divided into six manageable research and development clusters: four Touchpoint (TP) clusters (in other words, work groups each focusing on a specific topic within the project, including TP1: Personal Mobility Device, TP2: Active Environment, TP3: Socializing & Nutritional Monitoring/Intervention, and TP4: Gaming & Training System) that represent tangible connections between users (e.g., seniors, caregivers, physicians, etc.) and the REACH system; one "Engine" cluster which is a cloud-based digital platform serving as the brain of the project; and one "Interface" cluster which is composed of a set of means that allow the TPs and other products and services to interact with the Engine. Each cluster is associated with a dedicated and independent development team coming from the project consortium members (see Figure 1).

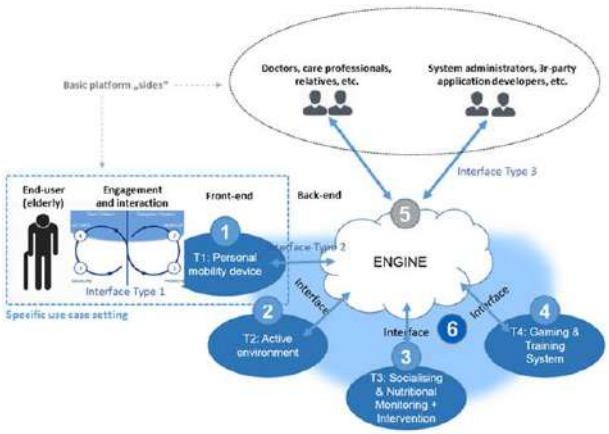

Figure 1. "Touchpoints and Engine" concept in REACH

3 Personalized Intelligent Interior Units

The Personalized Intelligent Interior Unit (PI²U) is a special type of smart furniture that seamlessly integrates the REACH concepts and functionality into the different REACH use case settings. This paper focuses on a series of PI²Us developed by the project team in TP2 (i.e., the "Active Environment" work group of the project). The relevant PI²Us include PI²U-SilverArc, PI²U-MiniArc, PI²U-Bed, and PI²U-iStander.

3.1 PI²U-SilverArc

The PI²U-SilverArc was developed for the use in a large kitchen or dining space (e.g., a community kitchen). It offers an interactive projection area in the kitchen, where recipes and games can be displayed. It also has a foldaway projection area where a training program can be displayed (see Figure 2). The round shapes, wood material, and bright colors give the PI²U-SilverArc a warm and inviting appearance.

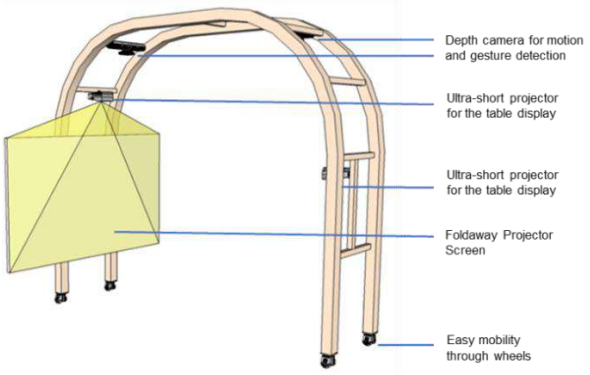

Figure 2. Preliminary design of the PI²U-SilverArc

The design of the PI²U-SilverArc cannot be directly converted into a prototype. For example, the material of the prototype and the final product differ substantially. After evaluation, it was decided that MayTec's modular aluminum profile system is suitable for building the prototypes (maytec.com.de). MayTec offers a wide range of modular profiles, accessories, and different connection possibilities. Simple changes can readily be made after the first test by using the aluminum profile system. Furthermore, in order to lower the costs, the curves were omitted in the prototypes because they mainly serve an aesthetic function and are not necessary for the testing.

Figure 3 shows in detail how the technical equipment is integrated into the prototype. An ultra-short projector is fixed above the projection screen. It was purposely decided against a mounting under the projection area, since the dust load for the projection lens would increase. Depth cameras are attached to a sliding system so that their positioning can be adjusted.

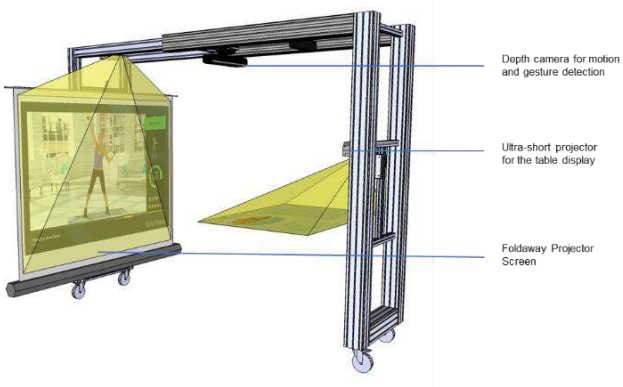

Figure 3. Prototypical version of the PI²U-SilverArc

3.2 PI²U-MiniArc

The PI²U-MiniArc can be considered as a flexible and smaller variant of the PI²U-SilverArc, which is designed to assist in the training and moving of the elderly who are in hospital or live in smaller apartments. An ultrashort projector can project the user interface on its foldaway table or on a separate table as needed. In addition, a motion-sensing camera (Microsoft Kinect) is integrated to detect the user's gestures, enabling the interactive gaming function. There is another projector on top of the device that can project extra information onto a wall. This prototype is equipped with wheels and thus is mobile. Figure 4 and Figure 5 respectively demonstrate the preliminary design and the final prototypical version of the PI²U-MiniArc.

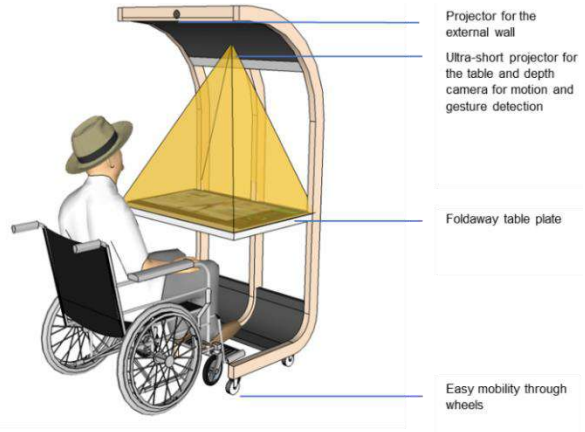

Figure 4. Preliminary design of the PI²U-MiniArc

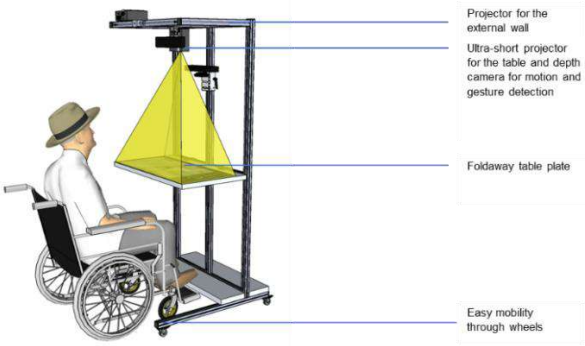

Figure 5. Prototypical version of the PI²U-MiniArc

3.3 PI²U-Bed

As shown in Figure 6, the first design of the PI²U-Bed resembles a normal bed for private use. A special feature is an arc-shaped frame that covers the entire length of the bed, which allows for an easy integration of sensors and technologies such as a thermal camera for breath detection and a projector for the bed. The height of the bed can be adjusted. On the one hand, this feature makes it possible for the caregivers to work at a height that is comfortable for their torsos. On the other hand, the lowest height of the bed facilitates the transfer of the patient from the bed to other functional units such as a wheelchair. The bed can be set to both a sitting and a vertical position. The sitting position allows the bed to support the patient and the nurse in many tasks such as eating, while the vertical position is especially apt for patients in an Intensive Care Unit (ICU) who must perform the transfer from lying to vertical position. The passive standing that is enabled by a standing frame aims to improve respiratory function and cardiovascular fitness, increase the levels of consciousness, functional

independence, and psychological well-being, and reduce the risk for delirium and the adverse effects of immobility [5].

In order to adapt the bed system to each patient's needs, a modular docking system was integrated into the design. Modules providing additional functions such as a toilet, physical training, transfer, and mobility can dock at different positions in the frame of the bed and are symmetric and self-guided. For example, with the Leg-curl Training Module (see Figure 6), the patient can rest on their abdomen and use their legs to move the weight up and down. Training muscles is important to the performance of daily tasks.

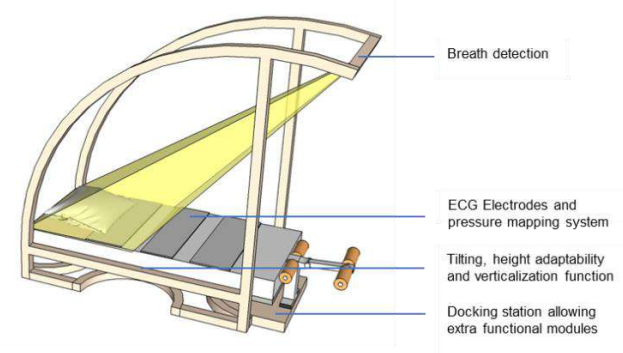

Figure 6. Preliminary design of the PI²U-Bed

To validate the concept of the PI²U-Bed, a prototype was planned and built. Figure 7 shows the final design of the PI²U-Bed prototype that was manufactured.

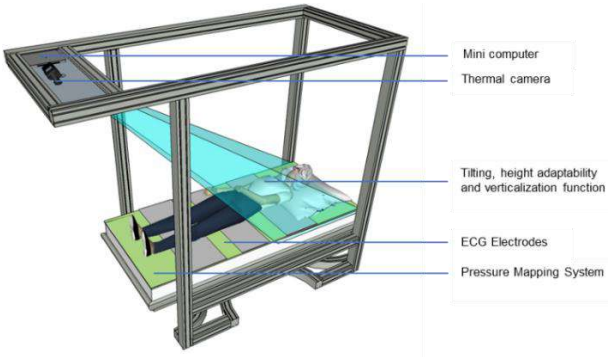

Figure 7. Prototypical version of the PI²U-Bed

3.4 PI²U-iStander

The PI²U-iStander is designed to activate the physical and mental activity of people of old age whose daily activity level has reduced. It is used to prevent elderly people from falling and provides effective support for cognitive processes through the combination of physical and cognitive exercises. Due to its flexibility and reasonable size, the system can be easily deployed in spaces such as living rooms and bedrooms (see Figure 8). The device is equipped with a mechanism to assist the elderly user to stand up and to perform movement exercises of the ankles, knees, and hip joints. A special corset and a seat ensure safety during the exercises that strengthen the back and abdominal muscles by lifting the legs. It also allows the user to maintain a safe, upright standing position and perform balance exercises as well as exercises where the upper body parts are activated using the ActiveLife gaming platform (see Figure 9) [6].

3.5 Major sensing, monitoring, and analysis activities using the PI²Us

As mentioned in the previous section, the project team in TP2 developed a series of Personalized Intelligent Interior Units (PI²Us), which are a special type of smart furniture that materialize the REACH concepts and functionality seamlessly into the different REACH use case settings. The PI²Us consist of the PI²U-SilverArc, PI²U-MiniArc, PI²U-Bed, and PI²U-

iStander. The PI²U prototypes are manufactured, currently deployed, and tested for major, sensing, monitoring, and analysis activities in REACH in the laboratory of the Chair of Building Realization and Robotics (BR2) at Technical University of Munich (TUM) (see Figure 10).

Figure 10. The prototypes of various PI²Us (e.g., PI²U-SilverArc, PI²U-MiniArc, PI²U-Bed, and PI²U-iStander) deployed and tested in the laboratory

The electrocardiogram (ECG) sensors, which are embedded in the PI²U-Bed, will provide the medical staff with data regarding the patient's heart activity during the sleeping period. Additionally, this aspect can support the early detection aspect of the REACH project. Figure 11 presents the sensor integration on the PI²U-Bed, which resulted in the ECG measurement signals in the second image (Figure 11 middle). In order to implement such sensors, flexible plastic material was used to improve patient comfort and measurement (Figure 11 right). The ECG implementation uses two electrodes to produce the ECG signal.

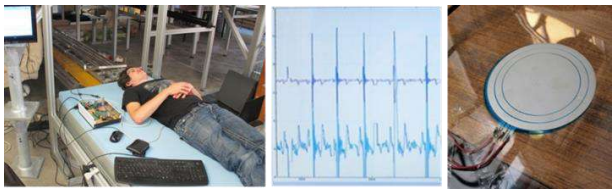

Figure 11. Testing of the ECG sensors on the PI²U-Bed

An important issue when considering an immobile patient's care is the prevention and management of pressure ulcers or decubitus. In order to implement the early detection and prevention aspects of REACH in the PI²U-Bed, it was decided to integrate a pressure-sensing mattress. This mattress monitors the peak pressure points of a person lying on the bed. Using this data, the REACH Engine can monitor peak pressure points and inform the care personnel for repositioning the patient before they develop decubitus. This sensor provides other functions as well. Using this sensor, a breath frequency monitor mainly for patients sleeping on their abdomens (see Figure 12) as well as a micro-mobility monitor are currently under implementation. Additionally, the project team is currently investigating the possibility of monitoring heart rate.

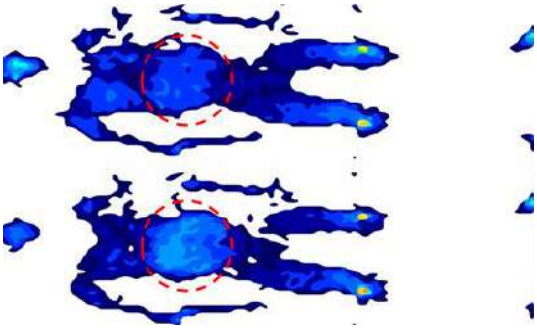

Figure 12. Pressure change on diaphragm when inhaling and exhaling (generated by the pressure-sensing mattress)

The thermal camera targets two major objectives: 1) breath frequency monitoring over the nostrils during sleep on the back, and 2) body temperature detection/monitoring over the eyes (see Figure 13 and 14). In the first implementation of these modules in TUM's laboratory, the results showed the following: breath frequency monitoring is possible and implemented via the nostrils and that the body temperature monitoring is implemented (monitoring the body temperature via the eyes is, naturally, only possible before the patient goes to sleep). There is a small limitation regarding the implemented prototype; due to the resolution of the current thermal camera, it is only possible to monitor these factors in a range of approximately 50cm distance from the patient's face. As a result, the thermal camera must either be mounted at the appropriate distance to the face, or the thermal camera must be replaced with a higher quality camera.

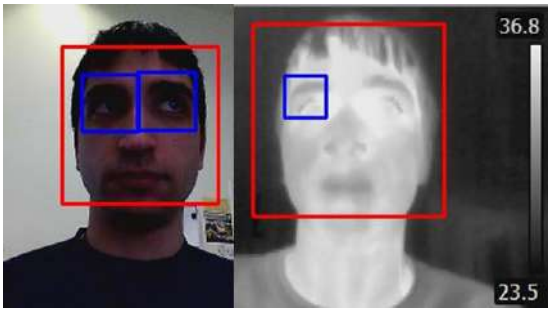

Figure 13. Eye following and body temperature measurement

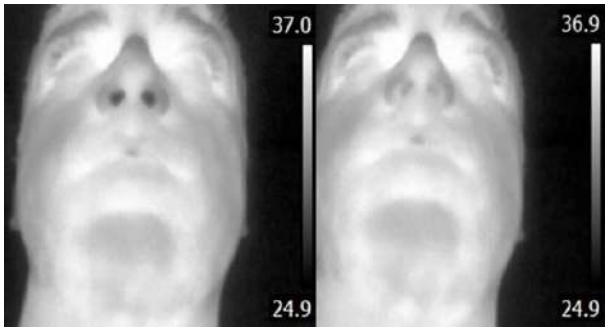

Figure 14. Respiration rate monitoring and body temperature measurement

The Kinect sensors, integrated into the PI²U-MiniArc and PI²U-SilverArc, are used for gesture recognition by considering the hand motions from the user side (see Figure 15). The Kinect was programmed by using the standard libraries from Microsoft. Therefore, it is necessary to continue with Microsoft Windows as the operating system since the libraries of the Kinect are not compatible with other operating systems. The control program of the Kinect gesture recognition was programmed using visual studio and was developed separately from the Graphical User Interface (GUI). Furthermore, the software development of the mounted Kinect on the PI²U-MiniArc is finalized including the adjustability for recognizing gesture at two different distances (i.e., standing table surface and sitting table surface).

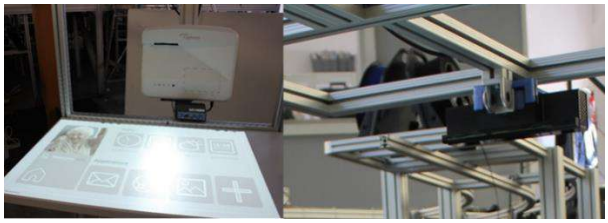

Figure 15. User interface and Kinect sensor in the PI²U-MiniArc

Designed and implemented as “battery-based” and “plug-and-play”, the stand-up counting sensor is mounted on the Alreh Medical device in a specific way, so that the clinical certificate of the device will not be undermined (see Figure 16). This sensor counts the number of "stand-up" events and transfers this count to a local server via WiFi. In addition, this sensor is implemented with consideration of its exceptionally low power consumption. With the implemented battery, it will run for more than three months without the need for recharging the battery.

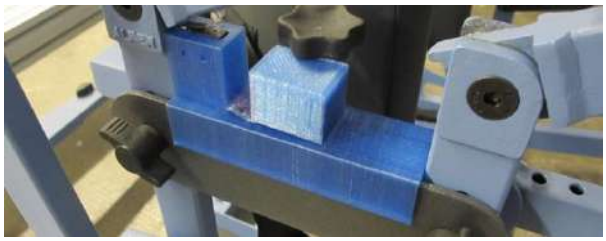

Figure 16. Stand-up counter embedded in the PI²U-iStander

It is planned to implement an activity sensing system for the Alreh Medical device (see Figure 17). This activity sensing system will be fused with the current gaming interface of the Alreh Medical device in order to enable lower body interactions with the games. In the first trial, the electromyography (EMG) sensing was implemented and tested. EMG is an electrodiagnostic medicine technique for evaluating and recording the electrical activity produced by the muscles. This was planned to serve as the controller interface for the legs allowing the user to steer a training or rehabilitation game via gestures (e.g., by the Kinect sensor) and leg movements. After the initial implementations and tests in TUM’s laboratory, the results showed immense amounts of noise when reading the EMG signal over the clothes. As a result, the project team planned to change the approach with the sensor electrodes and read the user activity from different sensors (e.g., touch sensors as previously mentioned). Afterwards, such inputs can be used to steer a training or rehabilitation game via foot gestures. Additionally, it will implement early detection, monitoring, and activation for the elderly.

Figure 17. Activity monitoring sensors used in the PI²U-iStander

Currently, the overall testing of the PI²Us was successful. Based on the feedback from the testing, the PI²Us will be further revised and eventually resemble the proposed furniture design. After the early prototype testing of functionality and the first data collection, TUM proposed a design of a modularized apartment integrating all PI²Us and key technologies in REACH’s four TPs to create a total interior living and care environment for elderly users. This design demonstrates the comprehensive REACH platform and can be adapted and implemented partially or entirely to different use case settings in an easy and rapid manner.

4 The REACH Apartment integration and simulation

As mentioned in the previous section, the project team in TP2 developed a series of Personalized Intelligent Interior Units (PI²Us), which are a special type of smart furniture, that materialize the REACH concepts and functionality seamlessly into the different REACH use case settings. The PI²Us consist of PI²U-SilverArc, PI²U-MiniArc, PI²U-Bed, and PI²U-iStander. Based on the current outcomes from four TPs, TUM designed a modularized apartment integrating all PI²Us and key technologies in REACH to create a complete interior living and care environment for elderly users (see Figure 18).

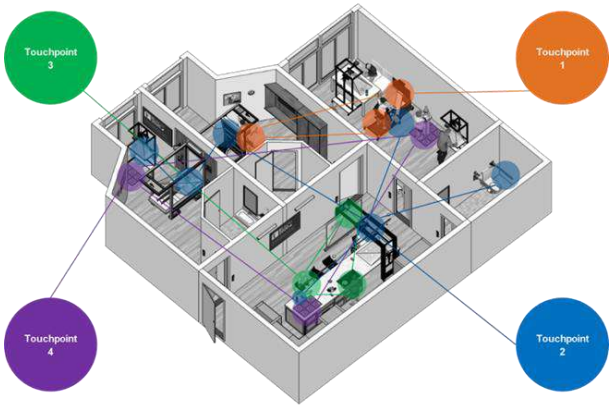

Figure 18. Technologies from four Touchpoints (TPs) distributed and integrated in the REACH apartment

Adopting barrier-free design principles, the apartment consists of a community kitchen, an activity room, and two patient rooms. In these living spaces, the Alreh Medical rehabilitation devices in TP1, smart furniture in TP2, socialized nutrition solutions in TP3, and gaming/training devices in TP4 are seamlessly integrated to create a comprehensive experience of the REACH platform for the users. Due to its modularity, parts of the apartment can be easily adapted and rapidly deployed in different REACH use case settings in four European countries, which will then help the REACH consortium execute a series of testing activities.

4.1 The community kitchen

The community kitchen serves as a key space for one of the most important daily activities – cooking and eating. It provides an ideal application space for technologies, particularly from TP3 (i.e., the "Socializing & Nutritional Monitoring/Intervention" working cluster of the project). The elderly users of the community kitchen can cook and eat together with the help of state-of-the-art technologies. As shown in Figure 19, the PI²U-SilverArc (or alternatively PI²U-MiniArc) will project an interactive cooking table allowing the elderly to cook in a smart and interactive way. Furthermore, the elderly in the kitchen are encouraged to use a series of smartphone apps. In addition, healthy and customized food developed by Biozoon [7] will be provided to the elderly who use the kitchen. As a result, the elderly are expected to become more socially active and nutritionally healthy through using the community kitchen.

Figure 19. Simulation of the community kitchen

4.2 The activity room

One of the major research goals of the REACH project is to promote the activity level of elderly people. Therefore, the activity room provides a flexible space for the elderly to become more physically and mentally active. In this room, the ActivLife gaming platform and the PI²U-iStander training device (developed by Alreh Medical), the PI²U-MiniArc in both table mode and mobile mode, and the Playware Moto Tiles (moto-tiles.com) will be implemented to provide the elderly with an active environment to improve their physical and mental health (see Figure 20).

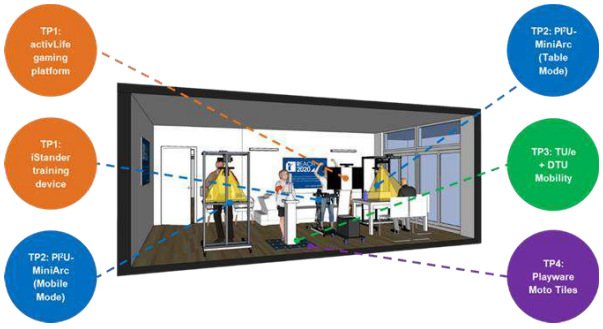

Figure 20. Simulation of the activity room

4.3 The patient rooms

In the patient room, the elderly can independently live, exercise, and play cognitive games using the PI²U-

MiniArc. Meanwhile, when the patient is resting on the PI²U-Bed, the bed can monitor the user's body temperature and respiration rate by using a thermal camera, the body pressure can be measured using the Pressure Mattress, and ECG data can be monitored by using ECG sensors on the bed (see Figure 21).

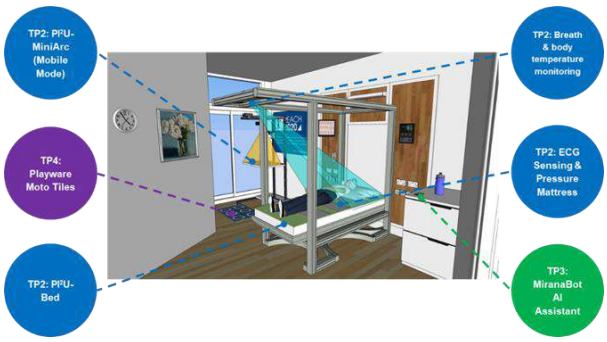

Figure 21. Simulation of the patient room type A

Figure 22 shows a variant of the patient room, in which the PI²U-Bed rises to a vertical position, helping the user stand up easily and transfer into a PI²U-iStander with or without the help of a caregiver. The PI²U-iStander serves as a training device for standing up as well as a mobility device to help the user move to other areas easily (e.g., bathroom, kitchen, activity room, etc.).

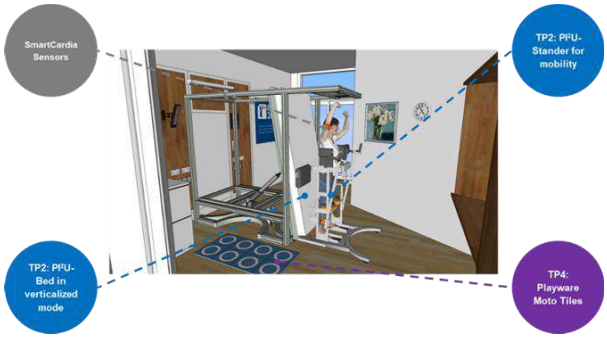

Figure 22. Simulation of the patient room type B

5 Conclusion

In this paper, the overall information of the REACH project as well as the detailed designs of the PI²Us and their prototypes are reported. The PI²U-SilverArc has two interfaces that can be adapted to any large kitchen. Training programs and culinary recipes can be played on the interfaces. The PI²U-MiniArc is a smaller and more mobile version of the PI²U-SilverArc. Both PI²Us aim to increase the social inclusion of their users. The PI²U-Bed is a patient bed which can assist the patient and caregivers in various daily tasks. With the PI²U-iStander and the ActivLife gaming platform, the elderly can safely train their leg muscles without the risk of fall and train the upper body with ease and comfort. Furthermore, the main testing, sensing, monitoring, and analysis activities using the PI²U prototypes are smoothly undertaken in TUM's laboratory. Based on the functionality validation of the PI²Us, a comprehensive REACH apartment design integrating all PI²Us and technologies of REACH is proposed, which can later be adapted and implemented partially or entirely to different use case settings. As of writing this paper, the testing in TUM's laboratory is performed mainly with young healthy individuals. The usability and performance of these devices will be further validated by elderly testing persons, and the results will be revealed in subsequent experiments and research.

Acknowledgements

This project has received funding from the *European Union's Horizon 2020 research and innovation programme* under grant agreement No 690425. The authors would like to thank all partners of the REACH consortium for their contributions to the presented work. Furthermore, the authors would like to express their gratitude to Mr. Andreas Bittner, Ms. Charlie Zhao, and Dr. Katharina Langosch for their support in this project.

Abstract –

To increase the energy efficiency of building energy systems, many control strategies have been investigated in recent years. Researchers apply control strategies to different building energy systems in order to evaluate their performance. However, the scientific community lacks a commonly accepted reference building model and evaluation criteria.

In this paper, we therefore propose a simulation-based benchmark to rate different control strategies for building energy systems. Based on identified requirements for benchmarking, we design a building model on which researchers can apply different control strategies and compare them with each other. The building consists of five different rooms and an energy system with several heat and cold generators. A concrete core activation and a central air-handling unit with additional decentralized cooling and heating registers supply each room individually. To benchmark a control strategy, the model calculates the consumed energy, the primary energy costs and the indicators of indoor air quality. We apply the benchmark to two different control strategies. The benchmark provides reproducible quantitative assessments of the performance of the tested control strategies. The diversity of the energy system as well as the individual air-conditioning of the rooms allow complex and sophisticated control strategies to demonstrate their potentials.

Building control strategies; Building automation; Benchmark; Modelica

1 Introduction

In the last decades, plenty of control strategies, e.g. Model Predictive Control (MPC), Fuzzy Logic Control, Neuronal Network Control and Cyber-physical control [1], promised to increase the efficiency of building energy systems in order to reduce CO_2 emissions and energy consumption [2]. To evaluate the developed control strategies, many researchers compare the developed control strategy with a standard control strategy such as On/Off control, PID control [3] or an ideal controller [4]. They point out the achieved savings with the newly developed control strategy in comparison to the standard one. However, the scientific community lacks a commonly accepted model for benchmarking control strategies. The controlled energy systems as well as the reference control differ in almost all case studies. Thus, the calculated performance or relative energy savings for newly developed control strategies are not comparable with each other.

The focus of this work is the design of a building model including its energy system that serves as the core of a benchmark for control strategies in the building domain. Additionally, we propose evaluation criteria in order to rate the achieved performance. We implement the designed building in the modeling language Modelica in order to provide a simulation based benchmark.

1.1 Related Work

To rate the performance of a controller, researchers commonly use criteria like the IAE (integral of time-multiplied absolute value of error) or the ISE (integral squared error), especially in control theory or PID tuning [5]. Nevertheless, other criteria are of greater importance in the building sector. DIN EN ISO 50001:2011 [6] defines benchmarking as a process of analyzing and comparing power data of comparable activities with the aim to compare the energy-based power data. Besides the energy consumption, criteria like carbon emissions, indoor air quality [7] or operation costs [8] are research topics. Recent work focuses on methods to benchmark the operation of a building based on the above-mentioned evaluation criteria. Borgstein et al. [9] present static, dynamic and statistical methods in order to calculate the energy consumption of non-residential buildings. Du et al. [4] developed an exergy-based method to calculate the theoretical minimal energy consumption to compare it with the energy consumption of the tested controller. However, all methods lack a specified building model, which other developers could use to rate their control strategy and compare them with each other.

Sänger et al. [10] suggest an approach to tackle this

problem: they developed a toolchain for benchmarking control strategies. Within the toolchain, the user can select different building types and create a control strategy. The control strategy consists of different combinable blocks and modules (e.g. hysteresis). However, the proposed toolchain does not support complex and advanced control strategies (e.g. MPC).

2 Benchmark Model

Benchmarking is a method frequently used in the information technology (IT) to quantify the performance of a computer, central processing unit (CPU) or graphics processing unit (GPU). According to Gray [11], domain-specific benchmarks are needed that are tailored to the system to be tested. For instance, a benchmark in the IT domain is not directly applicable to a benchmark for building control strategies. Nevertheless, Gray defined four general key criteria for a domain-specific benchmark, which we will transfer to the building controller domain:

- Relevant
- Portable
- Scalable
- Simple

Relevant means that the benchmark calculates relevant criteria (e.g. performance or price in the IT domain). A benchmark is portable if it is applicable to different systems. Additionally, the benchmark must be scalable to large and small computer systems in the IT domain. Finally, the benchmark has to be understandable (simple). [11]

In building domain, a relevant benchmark has to include typical building operations and measure the performance of the system in a relevant unit, e.g. energy consumption. Portable means in our use case that the benchmark is applicable to different control strategies. A scalable benchmark allows the evaluation of controllers of different size or complexity. To be understandable, the controller decisions have to lead to reasonable reactions in the performance measurement.

2.1 Benchmark Requirements

A benchmark for building control strategies should fulfill the above-mentioned criteria. To provide portability and scalability, we developed a simulation-based benchmark. In contrast to a real-life experiment, a simulation can produce reproducible boundary conditions, e.g. weather or occupancy, and is often executable at a lower price. In order to develop an understandable (simple) benchmark, we design the building model based on standards and real-life data.

In general, a benchmark measures the performance of a specific task, e.g. the needed time for mathematical operations. The complexity of the task has a major impact on the meaningfulness of the benchmark. For instance, measuring millions of instructions per second cannot point out the potential of a multi-core CPU in comparison to a single-core CPU [11].

Transferred to our case, controlling the building and its energy system is part of the tasks the controller needs to solve. The task's difficulty and thus the complexity of the building needs to be sufficiently high: a simple task could be solved with a sufficient accuracy even by poor control strategies. For instance, a building has less optimization potential, if its building energy system (BES) includes only an electric heater without any heat storage. Another example for a simple system is a room that has low requirements regarding the thermal comfort.

A simple benchmark system will not identify the potentials of sophisticated and advanced control strategies. Therefore, the complexity of the energy system as well as the requirements for thermal comfort need to reach a certain level. However, the complexity of the system must not exceed an engineer's understanding to create an understandable/simple benchmark.

2.2 Building Type

In general, buildings can be divided into residential and non-residential buildings. Residential buildings account 75 % of the net floor area and consume 68 % of the total final energy use in buildings in Europe [12]. The energy systems of European residential buildings are often simple and often provide only heat. Non-residential buildings contain a higher amount of different energy generation and distribution components including heating, cooling, ventilation, and air-conditioning (HVAC), which makes them more interesting for the benchmark.

In Europe, 28 % of the area of non-residential buildings belong to wholesale and retail buildings, 23 % offices, 17 % educational buildings, 11 % hotels and restaurants, 7 % hospitals, 4 % sport facilities and 11 % other buildings [12]. In our opinion, wholesale/retail buildings and offices are most relevant because of their large percentage. Furthermore, the advantage of offices are standards concerning the area and climate comfort. Offices usually consist of several rooms with heating, cooling and air conditioning. Thus, their energy system provides the necessary complexity for our purposes. Additionally, office rooms have high disturbances, e.g. changing internal gains due to occupancy and solar radiation, especially if there is a high share of glass in the facades. The disturbances set a difficult task to the controller in order to keep the set-point temperatures and humidity in a certain range.

Therefore, we chose an office building as the building type for the benchmark model.

2.3 Building Physics

The building model should consist of typical rooms in order to be relevant and understandable. In contrast to a real building, the number of rooms needs to be smaller in order to achieve a scalable and simple benchmark. If the number of rooms exceeds, it would take a lot of work and time to apply a control strategy to the benchmark.

The ASR A1.2 [13] describes different room types and their typical area, usage and number of persons. We consider large-scale office rooms as open-plan office rooms and both single offices and small multi-person office rooms as shared offices rooms. Conference rooms are special regarding the space requirements and occupancy. The fluctuating occupancy leads to high changes of the internal gains. Additionally, the set-point temperatures and humidity can vary during the day, e.g. if the room is empty for some hours.

Further room types that are common in office buildings are hallways, stairways, toilets, entrances and storage rooms. Due to the short time a person stays in these rooms, the climate comfort is less relevant, and the internal gains are approximately constant. Hence, we do not include any of these rooms.

In order to provide rooms with different comfort requirements, temperature levels and internal gains, we added a workshop and a canteen to the benchmark building. Workshops and canteens require, due to emissions, a high ventilation rate, which makes them interesting for our benchmark.

All in all, the benchmark building consists of five different rooms with typical specifications for the selected room type:

- Open plan office
- Shared office
- Conference room
- Canteen
- Workshop

Each room has different requirements regarding usage, energy demand and comfort. Figure 1 shows the floor plan. The dimensions of the rooms are based on ASR A1.2 [13]. The height of the rooms is three meters.

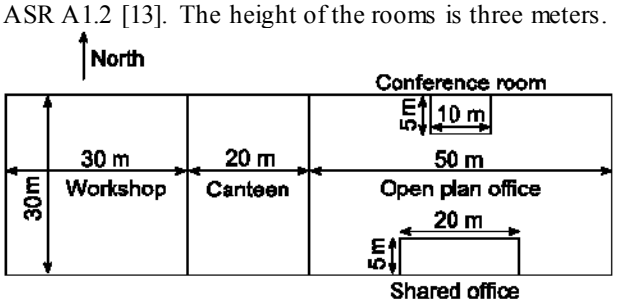

Figure 1. Floor plan of the benchmark model

2.4 Building Energy System

The energy system aims to heat, cool and ventilate the building in order to achieve a comfortable climate in the rooms. The energy system of our model should contain typical components to be relevant and understandable. Additionally, the energy system should cover the requirements concerning its complexity. Figure 2 illustrates the designed energy system. In the following, we describe the design of the energy system.

Each of the five rooms of the benchmark building contains a ventilation unit with heating and cooling registers in order to supply the room with conditioned air. A central air-handling unit (AHU), which consists of a heater, cooler and humidifier, supplies the decentralized ventilation unit. Additionally, each room can be heated and cooled by a concrete core activation (CCA).

In order to supply the concrete core activation, the air-handling unit and the decentralized ventilation units with heat and cold, the energy system provides hot water at two temperature levels (high temperature and low temperature) and cold water at one temperature level. A boiler and a combined heat and power unit (CHP) produce heat at the high temperature level. The CHP offers an efficient simultaneous electricity and heat production, but its operation is bounded by minimal on and off times. In contrast, the boiler can be switched on and off faster to respond to a changing demand more dynamically. Both the CHP and the boiler are supplied with gas.

A central element of the energy system is a heat pump. The heat pump produces low temperature heat as well as cold for the cold-water supply. A geothermal field as well as an outside air heat exchanger with a fan serve as a heat source. The geothermal field provides a constant temperature (13 °C) whereas the outside temperature fluctuates. Thus, depending on the outside temperature, using the geothermal field or the outside air as a heat source is more efficient.

The geothermal field and the outside air can be used for free cooling as well; if there is only a small cold demand, the building can be cooled without using the heat pump. Additionally, the outside air serves as a heat sink for the heat pump.

In order to decouple the heat/cold generation and the consumption, the system contains one storage at each temperature level. The high temperature and low temperature heat storage can be used at two temperature levels; both can be supplied by either the heat pump or the CHP and boiler. The three storages allow a flexible operation of the heat/cold generators, thus predictive control algorithms could show their potentials.

Besides the thermal generators and consumers, the benchmark building contains electrical components. The CHP and a photovoltaic system (PV) produce electricity. The produced electricity can be fed into the grid or used

for the building operation. Electrical consumers in the building are the heat pump, the air-handling unit, fans, pumps and all appliances inside the building such as computers and lights. The electrical consumption of the energy system is directly influenced by the control actions, whereas the consumption of the appliances inside the building is based on the occupant behavior (see section 2.5).

We dimensioned the heat/cold generators and consumers as well as the piping network according to DIN EN 12831 [14]. In a first step, we need to define the placement of the building. We chose the region 12 around the city Mengen in Germany because of the unsteady weather with higher temperature peaks in comparison with other regions of the DIN EN 12831. Based on the weather conditions, we determine the heat demand according to DIN EN 12831. The static heat demand for the whole building amounts to 94.5 kW. In order to use a night set back, which allows the reduction of the room temperature to 15 °C, an additional heating power of 139.7 kW is needed for reheating the building.

The calculated cooling demand is 166.7 kW according to DIN V 18599-2 [15] and DIN V 18599-10 [16]. The concrete core activation and the ventilation units cover equal shares of the cooling demand.

Based on the calculated demands, the pipe and air duct diameters can be specified according to DIN EN 10255 [17]. According to Laasch et al. [18], we assume a maximum water flow velocity of 2 m/s in the pipes and a maximum air flow velocity of 4 m/s in the air ducts.

Based on the heating and cooling demand, we defined the power of the boiler, CHP, heat pump and outside air heat exchanger.

The photovoltaic system fills half of the roof area and the power of the AHU fans is assumed to be 3 kW/(m³/s) [19, 20]. Table 1 lists the power levels of the components. The electrical power of the 24 pumps are in the range of 75 W up to 4700 W.

The storages allow decoupling heat/cold generation and consumption. In order to provide a flexible and predictive use, we dimension very large storages. The two heat storages are able to cover the heat demand for the reheating of the building. Each heat storage has a volume of 22 m³. The cold storage can cover the maximum cold demand for three hours and has a volume of 46 m³.

In summary, the energy system consists of 30 valves, 24 pumps, a central ahu and the components boiler, CHP, heat pump and outside air heat exchanger with a fan that have to be controlled.

Table 1. Power of the components

Component	Power in kW
Boiler	19.9 – 66.2 (thermal)
CHP	46 (thermal), 26 (elect.)
Heat Pump	96.6 – 193.2 (thermal)
Chiller	67 – 235 (thermal $\Delta T = 15$ K)
PV	112.5 (elect.)
AHU Fan	10.1 (elect.)

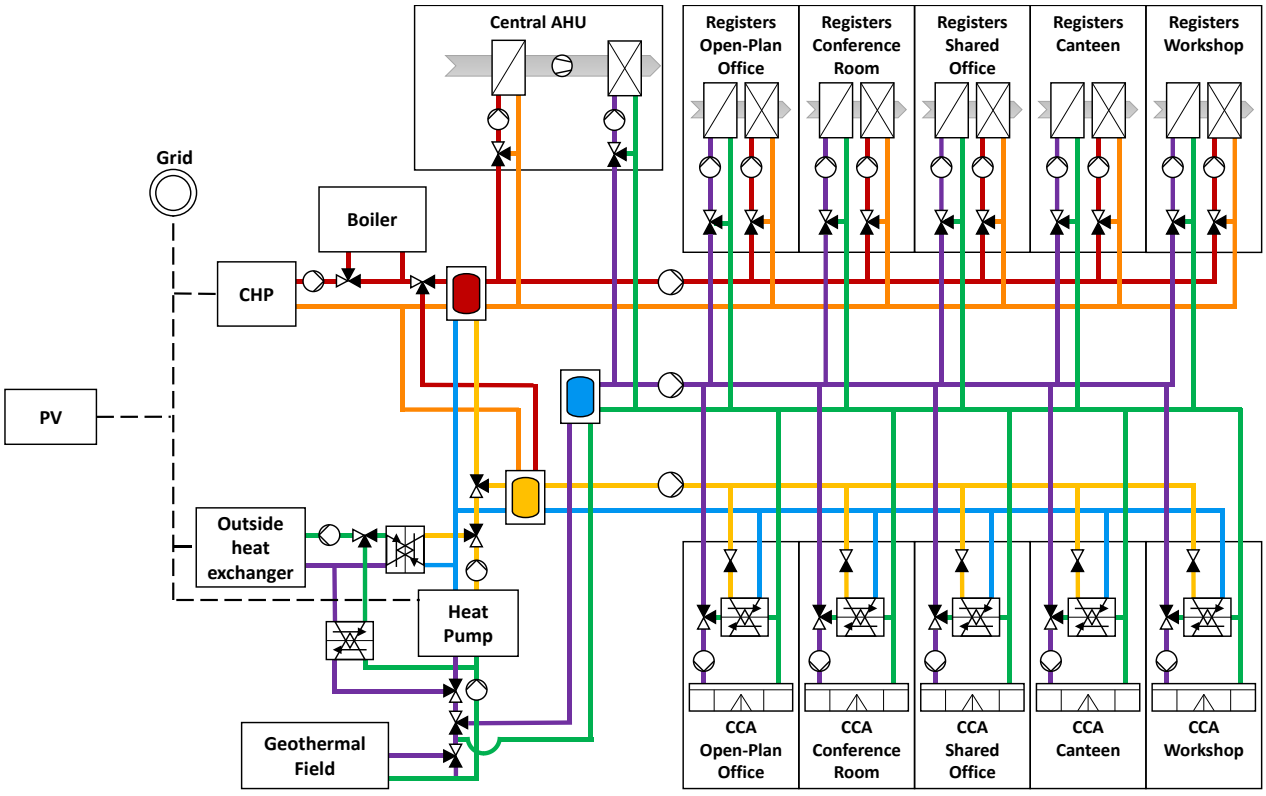

Figure 2. Energy system of the benchmark building model

2.5 Internal Gains

Internal gains are emitted heat caused by occupants and electrical appliances such as lighting and computers. Fluctuating internal gains challenge the controller to reach given set-point temperatures. Hence, we define varying occupancy profiles for each of the five rooms of the benchmark building. We assume five days per week with eight hours working time. In Germany, the absence of an employee per year is 20 days due to holidays [21] and 14.6 days due to illness [22]. We calculate the presence for each day with a probability distribution based on holiday and illness. The start time for the open plan office and the shared office is between 8:00 and 9:00 am, for the canteen between 8:45 and 9:15 am and for the workshop between 6:00 and 6:15 am. The arrival of each employee is random within the start times. The conference room is used randomly on an hourly basis. Figure 3 shows the resulting occupancy profiles for one exemplary day.

To calculate the produced heat of the occupants, we assume an activity level according to DIN EN ISO 7730 [23] of 2 met in the workshop and 1.2 met in the other rooms. The clothing level is 1 clo for all rooms and occupants. The resulting heat amounts to 209 W per occupant in the workshop and 125 W per occupant in the other rooms.

Based on the occupancy profiles, we calculate the electrical internal gains. In accordance with [24], we assume an illumination of 400 lx for the open plan office, the shared office and the conference room, 350 lx for the canteen and 500 lx for the workshop. Based on the floor area and an assumed luminosity of 95 lm/W [25], the lighting power amounts to 5684 W for the open plan office, 210 W for the conference room, 420 W for the shared office, 2210 W for the canteen and 4737 W for the workshop. Lights switch on if at least one person is present.

Laptops (20 W) and screens (30 W) cause further internal gains. We assume that laptops and screens are on if the associated employee is present. In the conference room, there are no screens available.

The power demand in the canteen is estimated in accordance with Renggli and Horbaty [26]. We add the minimum power for cooking (0.15 kWh/guest) to the power for cleaning (0.09 kWh/guest) and divided the result by the mean duration of stay (0.875 h). Since the study of Renggli and Horbaty is from the year 1992, we reduced the power consumption for cooking and cleaning by 22 percent. This value corresponds to the efficiency increase from class D to A [27]. The final power consumption in the canteen is 213 W/guest. In the workshop, we assume a power consumption of 200 W/employee for using tools.

We assume that the total consumed electrical power is converted to heat.

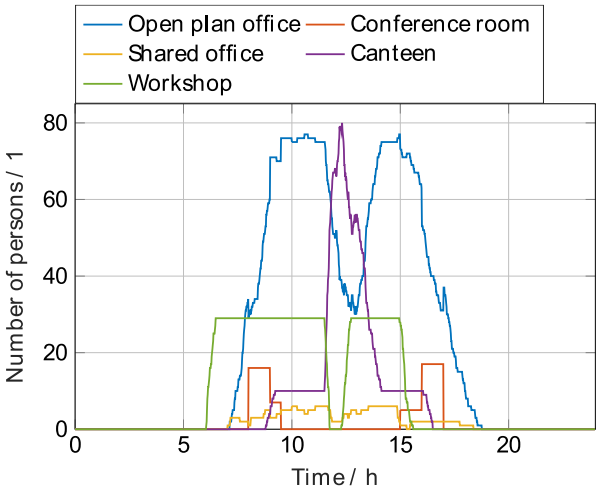

Figure 3. Occupancy profile of the building for one exemplary day

2.6 Weather

To set a difficult task to the controllers, the weather needs to have high fluctuation in order to disturb the energy system by a changing temperature and solar radiation. To achieve this, we use weather data from the city Mengen in Germany. In order to keep the execution time of the benchmark small, we need to reduce the simulation period as simulating a whole year would last more than one day. Thus, we reduce the total simulation period to eight weeks, using two characteristic weeks in winter, spring, summer and autumn, respectively. The characteristics of the eight weeks are high fluctuations in temperature, solar radiation and wind velocity. The start and end temperature, solar radiation and wind velocity of each week is adjusted so that the resulting weather profile is continuous. Figure 4 shows the resulting temperature profile.

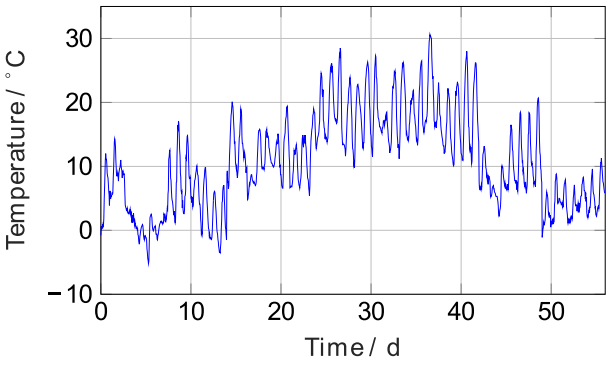

Figure 4. Outdoor temperature profile for the simulation period

2.7 Evaluation Criteria

The evaluation criteria are a basic part of the benchmark. To rate a control strategy, the benchmark model calculates the frequently used criteria comfort, energy consumption and energy costs.

The control of a building aims to provide a certain comfort to the user. Thus, the comfort is a key factor in building control strategies that we include in the benchmark. To rate the thermal comfort, Fanger [28] defined the predictive mean vote (PMV), which divides the comfort level into seven groups (hot, warm, slightly warm, neutral, slightly cool, cool, cold). Since each person's sense of comfort is different, the predicted percentage dissatisfied (PPD) shows a statistical distribution of the PMV. To rate the thermal comfort, the benchmark calculates the PMV and PPD.

Furthermore, the benchmark calculates the total final energy. The final energy consumption includes the gas and the electricity from the grid. The power fed into the grid is calculated as a negative energy purchase.

Besides the energy consumption, the energy costs for operating a building are vitally important; a highly energy efficient control strategy will rarely be implemented if it leads to uneconomical high costs. Thus, the benchmark needs to consider the operating costs of the energy system.

The energy system of the benchmark building uses electricity and gas. We define the price based on the electricity and gas market in Germany. According to a pricing list of the energy provider Werl [29], we split the electrical tariff into a high-rate tariff and a night tariff. The high-rate tariff is 29 ct/kWh and active between 6:00 am and 10:00 pm. The night rate is 19 ct/kWh. The two different tariffs enable a more cost-efficient operation by producing and storing heat and cold at night.

According to [30], the produced electricity of the CHP can be sold at a price of 12.34 ct/kWh. If the produced electricity is consumed by the building, a surcharge of 4 ct will be paid. The selling price of the produced electricity of the photovoltaic system is set to 10.5 ct/kWh. Based on [31], we assume a gas price of 6.09 ct/kWh.

3 Results and Discussion

We implemented the developed building and its energy system in the modeling language Modelica [32]. Modelica is an object orientated language and thus is suitable for modeling complex energy systems. The benchmark model is published in the open source library AixLib [33]. To simulate the benchmark model, we used the software Dymola.

3.1 Benchmarked Control Strategies

We apply the benchmark to two different control strategies to evaluate the meaningfulness of the benchmark. The control strategies are not optimized to be particularly energy or cost efficient. They should rather demonstrate the benchmark and serve as a first reference.

The first control that we apply to the benchmark is a basic control. The basic control has a heating and cooling mode with a fixed set-point temperature for the ventilation units and the concrete core activation. The mixing and throttling valves in the ventilation units and in the concrete core activation (CCA) are controlled by PID-controllers. All heat and cold generators have fixed flow temperature set points. Additionally, two-point controllers switch the heat pump, boiler and CHP on and off depending on the storage temperatures. The air-handling unit and all pumps operate at nominal power.

The second control is a night tariff control. It aims to decrease the electricity costs. The heat pump operates only at night trying to load the heat and cold storage. Additionally, the air-handling unit is switched off at night (between 10 pm and 6 am) to further reduce the electricity consumption. All other components are controlled in the same way as in the basic control.

3.2 Results

Figure 5 shows the total energy consumption and the operation cost for the two benchmarked control strategies. Further, Figure 5 shows the mean PPD and absolute mean PMV values. The mean PPD and PMV values do not allow a detailed analysis of the comfort. Nevertheless, the mean values represent the comfort level in general. Smaller values for the PPD, PMV as well as the energy consumption and operational costs indicate a better control of the benchmark building.

The basic control consumes 3.7 GJ energy and produces 16800 € costs. The thermal comfort reaches a high level with a mean PPD of 6.3 % and an absolute mean PMV value of 0.25.

In contrast, the night rate control saves around 42 % energy (2.16 GJ) and 46 % (9100 €) of the operational costs. However, the thermal comfort decreases in comparison to the basic control. This is caused by using the heat pump only at night. The heat pump is not always able to charge the cold storage at night. This leads to higher room temperatures in periods with high internal gains caused by high outdoor temperatures and solar radiation. Therefore, the thermal comfort is smaller for the night rate control than for the basic control.

The results show that the developed benchmark provides a standardized evaluation of control strategies. The complexity of the designed energy systems provides a wide range of different control options leading to different energy consumption, costs and thermal comfort.

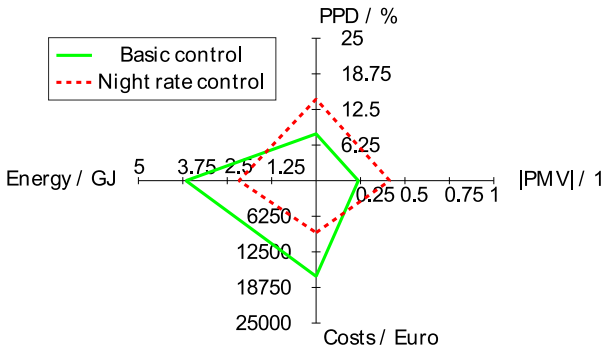

Figure 5. Results of the two benchmarked control strategies

Thus, the benchmark model is able to figure out the potentials of efficient and performant control strategies. In our example, the basic control reaches higher thermal comfort but less energy efficiency compared to the night rate control. However, figuring out which control performs better in total depends on the prioritization: a building operator would prefer the night rate control whereas occupants would prefer the basic control.

A disadvantage of the benchmark model is its complexity caused by the high number of actuators, which leads to a high effort to apply a control strategy.

Further, a benchmark holds the risk of overfitting. A control strategy could be tailored to the benchmark so that it only achieves good results in this benchmark. Applied to other systems, such a control could lead to low control performance. To avoid this problem, we suggest developing a bunch of different building models as standardized benchmark systems.

Furthermore, benchmarking control strategies based on standardized building models leads to comparable results. With a growing number of applied control strategies, the benchmark could become more and more useful.

4 Conclusion

In this paper, we presented a simulation-based benchmark model to rate the performance of different controllers and control strategies in the building energy domain. The core of the benchmark is a specially designed office building. The building consists of five representative rooms and an energy system with various heat and cold producers. The complexity of the system offers a high range of operating modes. Thus, the energy system sets a challenging task to the controller. Therefore, the benchmark is able to investigate the potential of advanced and efficient control strategies in comparison to other control strategies.

We applied the benchmark to two simple control strategies in order to evaluate the usefulness of the developed benchmark system. The first control strategy is a simple mode-based control in combination with PID control. The second control strategy extends the first one by exploiting a night rate. The benchmark model calculates higher costs and energy consumption for the basic control in comparison to the night rate based control. By contrast, the average comfort is higher in the basic control. As a conclusion, the benchmark is able to point out strengths and weaknesses of the tested control strategies.

Further work aims to improve the evaluation criteria. Besides, the energy consumption, costs and thermal comfort, the carbon emissions as well as the electricity consumption of the control algorithm itself could be considered. Additionally, a standardized criterion that combines all other criteria in one value could facilitate the rating of different control strategies.

Abstract -

A common problem when operating heavy hydraulic machines consists in the inability of performing accurate motion. In the last few years the development of non-linear control techniques and the production of increasingly more accurate and cheaper hydraulic drives induced a steadily growing interest towards the development of controlled hydraulic systems. Clearly, this interest is also motivated by the possibility to exploit the huge power density, which is an intrinsic feature of hydraulic systems. This paper specifically focuses on the development of several position control schemes, whose aim is to guarantee accurate motion of a standalone hydraulic servomechanism. By relying on an experimentally validated mathematical model of the servomechanism itself, different control schemes have been synthesized and the resulting control performances have been verified and compared together.

Keywords -

Hydraulic systems, Hydraulic actuators, Motion Control

1 Introduction

Nowadays the vast majority of high performance servomechanisms is composed by electrical servomechanisms. Nevertheless, hydraulic actuation systems are characterized by multiple convenient features (namely high power density, reliability, and relatively low maintenance cost) that make them particularly fit to several application domains, like for instance: construction and earthworks machinery [1, 2], mining industry [3], agriculture and forestry [4]. Typically, hydraulic servomechanisms are controlled either manually by human operators opening and closing valves, or by using heavily approximated linear controllers.

Specifically in case of linear controllers, obtaining accurate motion of such kind of servomechanisms is a quite complex task, mainly due to the highly non-linear dynamics describing the behaviour of valves, and to high parametric uncertainty affecting the mathematical models of the different system components. Given this situation, the resulting motion is often characterized either by very low accuracy and repeatability or by a limited bandwidth of the closed loop system due to a rather conservative design in order to ensure stability. Despite the mentioned problems, linear controllers are still implemented for hydraulic servomechanism [5] because of their simplicity and the consolidated well-known theoretical background [6].

However, recent research developments in the field of non-linear control finally allowed to overcome some of the aforementioned limitations and to guarantee reasonably good performance. Among these non-linear control strategies, Sliding Mode Control (SMC) is probably the most widespread solution when dealing with hydraulic actuators [7, 8]. More recently, in [9] a 1^{st}-order SMC scheme was applied to control a 1-DoF hydraulic crane, while in [10] a 2^{nd}-order SMC scheme for the same system was proposed. Dynamic switching functions have been introduced in [11] and also adaptive SMC laws have been proposed [12, 13] in order to improve the robustness of the controller of an hydraulic motor. Finally, a comprehensive discussion of the various application of SMC to hydraulic systems is given in [14], while alternative approaches based on backstepping [15] and cascaded adaptive control [16, 17, 18, 19] have also been proposed.

With respect to the mentioned scientific literature, the main contribution of this work consists in an experimentally-based comparative evaluation of the performance levels of an advanced P-PI linear controller and an approximated 1^{st}-order SMC, both applied on a standalone hydraulic servomechanisms. First, the paper details the development and the validation of the mentioned control strategies aiming. Then, a comparative evaluation of the performance of the proposed control strategies is discussed. In particular, starting from a previously validated dynamic model of a generic hydraulic servomechanisms [20], a linear cascade control with static compensation of the dead-zone and a 1^{st}-order SMC have been synthesized. The tracking performance of time-varying reference signals of the SMC scheme has been improved by introducing a model-based feed-forward action. In addition, the high frequency chattering (caused by the SMC action) has been reduced by approximating the discontinuity inside the SMC law with a sigmoid function. Finally, the performance of the different closed-loop control systems have been tested on an experimental test-bench.

The paper is organized as follows. Section 2 briefly introduces the dynamic model of the hydraulic servomechanism, while Section 3 describes the linear controller scheme synthesized on the basis of the linearized dynamic model. Then, Section 4 details the development of the proposed SMC schemes and Section 5 shows the experimental validation of all the proposed control schemes and discusses the performance levels achieved by each solution. Finally, conclusions and future developments are presented in Section 6.

2 Hydraulic Servomechanism Model

The dynamic model of the generic hydraulic servomechanism used as a basis to develop the proposed control algorithms is defined as follows:

$$\begin{cases} \dot{x}_p = \dot{x}_p \\ \ddot{x}_p = \frac{1}{M}[A_1 P_1 - A_2 P_2 - f_r(\dot{x}_p) - D\dot{x}_p - \zeta \dot{x}_p^2 - Mg] \\ \dot{P}_1 = \frac{\beta}{V_1(x_p)}(Q_1 - A_1 \dot{x}_p) \\ \dot{P}_2 = \frac{\beta}{V_1(x_p)}(-Q_2 + A_2 \dot{x}_p) \end{cases} \tag{1}$$

$$Q_1 = \begin{cases} c_1(P_p - P_1) - c_2(P_1 - P_t) & d_z^- < x_v < d_z^+ \\ k_1^+(x_v)\frac{\pi}{4}\frac{d^2 x_v^2}{\sqrt{1-x_v^4}}\sqrt{\frac{2}{\rho}(Pp - P_1)} & x_v \geq d_z^+ \\ -k_1^-(x_v)\frac{\pi}{4}\frac{d^2 x_v^2}{\sqrt{1-x_v^4}}\sqrt{\frac{2}{\rho}(P1 - P_t)} & x_v < d_z^- \end{cases} \tag{2}$$

$$Q_2 = \begin{cases} c_3(P_p - P_2) - c_4(P_2 - P_t) & d_z^- < x_v < d_z^+ \\ k_2^+(x_v)\frac{\pi}{4}\frac{d^2 x_v^2}{\sqrt{1-x_v^4}}\sqrt{\frac{2}{\rho}(Pp - P_2)} & x_v \geq d_z^+ \\ -k_2^-(x_v)\frac{\pi}{4}\frac{d^2 x_v^2}{\sqrt{1-x_v^4}}\sqrt{\frac{2}{\rho}(P_2 - P_t)} & x_v < d_z^- \end{cases} \tag{3}$$

where:

- x_p, $\dot{x}_p$, $\ddot{x}_p$: hydraulic cylinder position, velocity and acceleration, respectively;
- M: mass of the mechanical load;
- A_1, (A_2): bottom(rod)-side chamber internal surfaces;
- V_1, (V_2): bottom(rod)-side chamber internal volumes;
- P_1, (P_2): bottom(rod)-side chamber internal pressures;
- $f_r(\cdot)$: Coulomb friction function;
- D: viscous friction coefficient;
- ζ: dynamic pressure loss coefficient;
- g: gravitational constant;
- β: mineral oil bulk modulus;
- Q_1: flow rate from tank to bottom-side chamber;
- Q_2: flow rate from rod-side chamber to tank;
- c_i: valve static pressure loss coefficients;
- P_p: pump pressure;
- P_t: tank pressure;
- x_v: valve PWM, acting as control signal;
- $k_1^{\pm}(\cdot)$, ($k_2^{\pm}(\cdot)$): bottom(rod)-side chamber valve opening function2;
- d: valve orifice diameter;
- ρ: mineral oil density;
- d_z^-, d_z^+: valve negative and positive dead-zones.

A more detailed discussion of the dynamic model (along with its experimental validation) can be found in [20].

3 Linear Controller

In this Section a linearized version of the previously introduced dynamic model is given, allowing to synthesize a linear control scheme.

3.1 Dynamic Model Linearization

Starting from equations (1)-(3), the linearized model can be computed. The equilibrium point has been chosen by considering the valve opening outside of the deadzone region and by taking the middle position of the cylinder as working point:

$$\begin{aligned} &\overline{x}_v < d_z^- \quad \vee \quad \overline{x}_v > d_z^+ \\ &\overline{x}_p = \frac{{x_p}^{MAX} - x_{p\,min}}{2} \\ &\overline{V}_1 = A_1 \overline{x}_p, \quad \overline{V}_2 = A_2 \overline{x}_p \end{aligned} \tag{4}$$

consequently, the following set of linear equation is obtained:

$$\begin{pmatrix} \delta\ddot{x}_p \\ \delta\dot{P}_1 \\ \delta\dot{P}_2 \end{pmatrix} = \begin{pmatrix} \frac{-(D+2\zeta\dot{x}_p)}{M} & \frac{A_1}{M} & \frac{-A_2}{M} \\ \frac{-\beta A_1}{\bar{V}_1} & \frac{\beta\lambda_1}{\bar{V}_1} & 0 \\ \frac{\beta A_2}{\bar{V}_2} & 0 & \frac{-\beta\lambda_2}{\bar{V}_2} \end{pmatrix} \begin{pmatrix} \delta\dot{x}_p \\ \delta P_1 \\ \delta P_2 \end{pmatrix} + \begin{pmatrix} 0 \\ \frac{\beta\lambda_3}{\bar{V}_1} \\ \frac{-\beta\lambda_4}{\bar{V}_2} \end{pmatrix} \delta x_v \tag{5}$$

where $\lambda_1, \lambda_2, \lambda_3, \lambda_4$ are the linearization coefficients of the valve:

$$\begin{aligned} \delta q_1 &= \lambda_1 \delta P_1 + \lambda_3 \delta x_v \\ \delta q_2 &= \lambda_2 \delta P_2 + \lambda_4 \delta x_v \end{aligned} \tag{6}$$

Finally, the state space formulation can be turned into the corresponding transfer function between the valve opening and the cylinder velocity:

$$F(s) = \frac{\delta \dot{x}_p(s)}{\delta x_v(s)} = k_f \frac{\tau_1 s + 1}{(\tau_2 s + 1)(s^2/\omega^2 + 2Ds/\omega + 1)} \tag{7}$$

and the transfer function between the valve opening and the cylinder position can be obtained by simply integrating the cylinder velocity:

$$G(s) = \frac{\delta x_p(s)}{\delta x_v(s)} = \frac{F(s)}{s} \tag{8}$$

3.2 Controller Block Scheme

After linearization of the dynamic model, the cascaded control scheme has been developed (see Figure 1). A proportional-integral (PI) controller with anti-windup block was chosen for the inner velocity loop, while a pure proportional (P) controller was selected for the outer position loop. On the top left part of the digram it is possible to see a derivative block that outputs a velocity feed-forward term that helps improving tracking performance. On the other hand, since a direct measure of the cylinder velocity is not available, another derivative block is needed in order to indirectly compute $\dot{x}_p$. Clearly, each derivative block is equipped with a tunable low pass filter in order to ensure that the transfer function of the complete system is proper. Moreover, the filter inside the feed-forward derivative block ensures that the control action is not too aggressive, while the one on the measurement line mitigates the effect of the noise. Finally, the saturation blocks ensure that the value of the valve opening stays inside the admissible range $[-1,\ +1]$, while the "*sig*" block contains the dead-zone compensation function $sig\,(u)$, defined as:

$$sig\,(u) = d_z^- + \frac{d_z^+ - d_z^-}{1 + e^{-\eta u}} \tag{9}$$

in order to avoid chattering of the controlled variable. For the sake of completeness, to tune the control gains it is sufficient to neglect the effect of the non-linear blocks and to apply the Bode criterion to both the internal velocity loop and to the external position one.

4 Sliding Mode Controller

The parametric uncertainties and the intrinsic high non-linearities of hydraulic systems can greatly deteriorate the performances of classical linear controllers, especially when the state configuration of the system is far from the linearization point. For this reason SMC can be a suitable alternative for the realization of an accurate position control. In this Section, after a brief overview of the SMC theory is given and the control law adopted for our system is presented and. Finally, the condition that guarantees the overall stability of the closed loop is discussed.

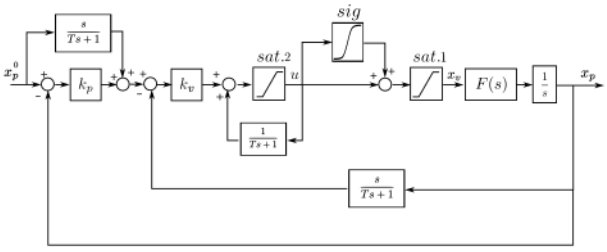

Figure 1. P-PI cascaded control scheme with anti-windup, feed-forward and dead-zone compensation.

4.1 Sliding mode control overview

The main properties of SMC are the robustness with respect to both external disturbances and parametric uncertainties, and the capability to constrain the system state within a specific a-priori defined state subspace. This subspace is called "sliding surface" and it is defined by:

$$S = \{\mathbf{x} : \sigma(\mathbf{x}) = 0\} \tag{10}$$

where $\mathbf{x} \in R^n$ is the state vector of a given system and $\sigma(\mathbf{x}) : R^n \rightarrow R$ is the sliding variable, a function properly defined in order to achieve the desired performances. Given a generic non-linear SISO system with bounded state:

$$|\dot{x}_i| < U_i, \quad |x_i| < Ub_i, \quad x_i \in \mathbf{x} \tag{11}$$

Lyapunov's theory can be used in order to compute a control signal that forces the state movement on S:

$$V(\mathbf{x}) = \frac{1}{2}\sigma(\mathbf{x})^2 > 0, \quad \dot{V}(\mathbf{x}) = \dot{\sigma}\sigma \tag{12}$$

Usually, by making proper manipulation, the first derivative of the sliding variable can be expressed as a function of the control variable:

$$\dot{\sigma} = \dot{\sigma}(u) \tag{13}$$

Then, by choosing the following discontinuous control law:

$$u = k_s sign(\sigma) \tag{14}$$

with a sufficiently large k_s, it's possible to guarantee $\dot{V} < 0$.

Note that the 1^{st}-order sliding mode is characterized by a discontinuous control law. When the system reaches the

sliding surface, a chattering phenomenon on the control variable will be triggered at an ideally infinite frequency. This fact entails a very intense use of the control variable and determines the presence of undesired vibrations on the overall system, that can also damage physical components. These phenomena can be reduced, either by approximating the sign function or implementing an higher order SMC.

4.2 A different formulation of the model

In order to design a proper control law, a different formulation of the model has been adopted. Ignoring momentarily deadzone and internal leakages, the valve model can be written as follows:

$$\Phi_1 = S(\nu)\lambda_1^+\sqrt{Pp - P1} + S(-\nu)\lambda_1^-\sqrt{P_1 - P_t} \quad (15)$$

$$\Phi_2 = S(-\nu)\lambda_2^-\sqrt{Pp - P2} + S(\nu)\lambda_2^+\sqrt{P_2 - P_t} \quad (16)$$

$$\lambda_1^- = k_1^-(x_v)\frac{\pi}{4}d^2\sqrt{2/\rho} \quad \lambda_1^+ = k_1^+(x_v)\frac{\pi}{4}d^2\sqrt{2/\rho} \quad (17)$$

$$\lambda_2^- = k_2^-(x_v)\frac{\pi}{4}d^2\sqrt{2/\rho} \quad \lambda_2^+ = k_2^+(x_v)\frac{\pi}{4}d^2\sqrt{2/\rho} \quad (18)$$

$$\nu = f(x_v) = \frac{x_v^2}{\sqrt{(1 - x_v^4)}}sign(x_v) \quad (19)$$

where $S(\nu)$ is the Heaviside step function. Therefore, the flow rates can be expressed as $Q_1 = \Phi_1\nu$ and $Q_2 = \Phi_2\nu$. Also, a new state vector can be defined:

$$\mathbf{z}^t = \begin{pmatrix} e & \dot{e} & P_1 & P_2 \end{pmatrix} = \begin{pmatrix} z_1 & z_2 & z_3 & z_4 \end{pmatrix} \quad (20)$$

where $e = {x_p}^0 - x_p$ and $\dot{e} = \dot{x}_p^0 - \dot{x}_p$ are the position and speed tracking errors, respectively. By defining the following quantities:

$$H_1 = \frac{A_1\Phi_1}{V_1(x_p)} + \frac{A_2\Phi_2}{V_2(x_p)} \quad H_0 = \frac{A_1^2}{V_1(x_p)} + \frac{A_2^2}{V_2(x_p)} \quad (21)$$

z_2 can be expressed as a function of the hydraulic force first derivative:

$$z_2 = \frac{\dot{F}_p}{\beta H_0} - \frac{H_1}{H_0}\nu + \dot{x}_p^0 \quad (22)$$

Finally, the new formulation is obtained by writing (1) with respect to the new state vector:

$$\begin{cases} \dot{z}_1 = \frac{1}{\beta H_0}\dot{F}_p - \frac{H_1}{H_0}\nu + \dot{x}_p^0 \\ \dot{z}_2 = \frac{1}{M}[F_{loss}(\dot{x}_p^0 - z_2) - A_1 z_3 + A_2 z_4 + g + \ddot{x}_p^0] \\ \dot{z}_3 = -\frac{\beta}{V_1(x_p^0 - z_1)}A_1(\dot{x}_p^0 - z_2) + \frac{\beta}{V_1(x_p^0 - z_1)}\Phi_1\nu \\ \dot{z}_4 = -\frac{\beta}{V_2(x_p^0 - z_1)}A_2(\dot{x}_p^0 - z_2) - \frac{\beta}{V_2(x_p^0 - z_1)}\Phi_2\nu \end{cases} \quad (23)$$

where $F_{loss}(\dot{x}_p) = f_r(\dot{x}_p) - D\dot{x}_p - \zeta\dot{x}_p^2$.

4.3 Evaluation of the control law

The design of the control law starts with the definition of a proper sliding variable and a candidate Lyapunov function. A common choice is:

$$\sigma(\mathbf{z}) = C_1 z_1 + z_2, \quad V(\mathbf{z}) = \frac{1}{2}\sigma(\mathbf{z})^2 \quad (24)$$

In order to ensure $\dot{V}(\mathbf{z}) < 0$ the aforementioned control law can be used:

$$\nu = k_s sign(\sigma) \quad (25)$$

Unfortunately with the current experimental set-up the measure of z_2, which depends on $\dot{x}_p$, is not available. However at the increasing of C_1, the dependency of $\sigma(\mathbf{z})$ of z_2 becomes negligible, therefore the time derivative of $V(\mathbf{z})$ can be written as:

$$\dot{V}(\mathbf{z}) = \sigma(z_1)\left[-\frac{C_1 H_1}{H_0}\nu + \frac{C_1\dot{F}_p}{\beta H_0} + C_1\dot{x}_p^0\right] \quad (26)$$

and the control law changes into:

$$\nu = k_s sign(z_1) \quad (27)$$

The numerical value of k_s is computed accordingly to the absolute upper bound of the hydraulic force time derivative(UB_{dF_p}) and reference velocity ($UB_{\dot{x}_p^0}$).

$$k_s > \frac{H_0}{H_1}\left[\frac{UB_{dF_p}}{\beta H_0} + UB_{\dot{x}_p^0}\right] \quad (28)$$

The maximum speed achievable by the load depends on the supply pressure and it can be set as the upper bound of the reference speed. Also both UB_{dF_p} and $UB_{\dot{x}_p^0}$ can be estimated by several simulations of the validated model, as suggested in [21].

In addition, control law (27) can be improved by adding feed-forward and proportional actions:

$$\nu = k_p z_1 + k_s sign(z_1) + \frac{H_0}{H_1}\dot{x}_p^0 \quad (29)$$

therefore the condition on the time derivative of the candidate Lyapunov function becomes:

$$\sigma(z_1)\left[-\frac{H_1}{H_0}(k_p z_1 + k_s sign(z_1)) + \frac{UB_{dF_p}}{\beta H_0}\right] < 0 \quad (30)$$

In order to compute k_s the worst case can be considered. More specifically, the value of the control signal ν is minimum when the proportional action tends to zero ($z_1 \approx 0$), thus the condition on k_s can be re-written as follows:

$$k_s > \frac{UB_{dF_p}}{\beta H_1} \quad (31)$$

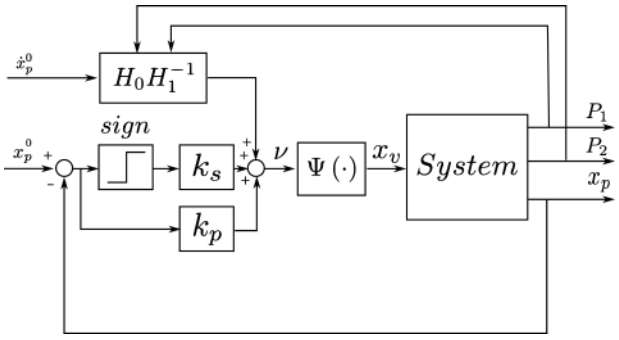

Figure 2. Sliding mode control scheme with proportional term, feedforward model based and sigmoid

Figure 3. Hydraulic test-bench.

By using the proposed control law (29) a less stringent condition has been retrieved:

$$\frac{UB_{dF_p}}{\beta H_1} \leq \frac{H_0}{H_1}\left[\frac{UB_{dF_p}}{\beta H_0} + UB_{\dot{x}_p^0}\right] \tag{32}$$

Consequently, smaller values of k_s can be adopted and in general smaller oscillations can be induced with respect to the ones determined by control law (27) .

Furthermore, the introduction of the proportional term and of the model-based feed-forward action entails a faster time response and an improvement of the dynamic tracking performances.

Moving to the dead-zone, its effect can be considered by means of a further condition on k_s. In particular, with reference to the worst case, the following condition must be always satisfied:

$$k_s > max\{|f(d_z^+)|, |f(d_z^-)|\} \tag{33}$$

Moreover, in order to reduce the undesired oscillations, triggered by the presence of the $sign(\cdot)$, a sigmoid approximate function is usually adopted:

$$sign(x) \approx sig(x) = -1 + \frac{2}{1 + e^{-\epsilon x}} \tag{34}$$

Finally, once ν is computed, it is possible to find the corresponding valve opening by directly inverting function f:

$$x_v = \Psi(\nu): \quad f(\Psi(\nu)) = \nu \tag{35}$$

The result is a smooth control action at the price of a partial loss in terms of robustness and accuracy (see [21]). Nevertheless, as shown in the next discussion, this choice does not significantly compromise the overall tracking performance.

5 Experimental Validation and Performance Analysis

In this Section the experimental validation platform is described, experimental results are presented, and, finally, the performance levels achieved by each control solution are compared together.

5.1 Hydraulic Test-bench

The hydraulic test-bench used to test the proposed control schemes is pictured in Figure 3. The system is composed by two independent hydraulic servomechanisms. The rod-side of each cylinder is rigidly connected to the load, which consists in a plate (constrained by vertical motion guides) on top of which it is possible to load a generic weight. More in detail, the test-bench comprises:

- 2 asymmetric hydraulic cylinders: one with a traction load and one with a compression load;
- 2 directional valves with 4 ways and 3 positions;
- 1 hydraulic pump powering the entire system;
- pressure relief valves to ensure operational safety;
- 2 linear potentiometers that measure the position of each cylinder;
- 5 pressure sensors installed at the outlet of the pump and inside the four chambers of the two cylinders;
- 2 load cells installed between the rod side and the plate.

5.2 Experimental Validation - Linear Controller

The control scheme pictured in Figure 1 has been tuned in the following way:

$$k_p = 1, \quad k_v = 0.108, \quad T = 0.002, \quad \eta = 50 \tag{36}$$

All the transfer functions have been discretized using the Backward Euler method and the experiments have been

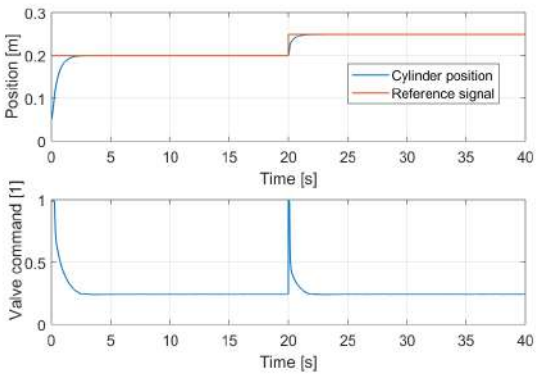

Figure 4. Linear Controller: response to step set-point.

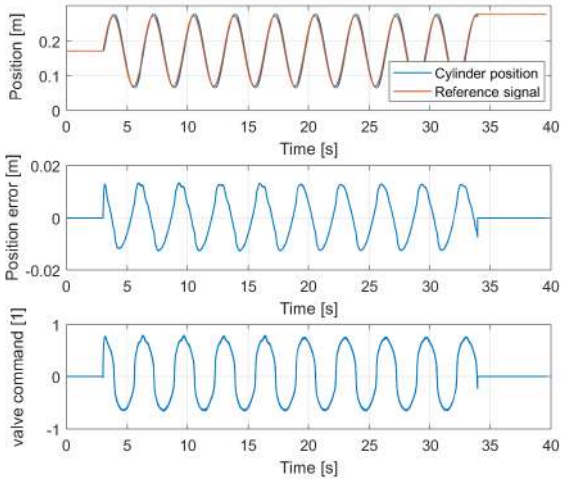

Figure 5. Linear Controller: response to sine reference signal.

performed on the actuator with a compression load mass of 282 kg.

Figure 4 show the system responses to a step set-point. The control action is not affected by any chattering and the system converges to the desired set-point value without oscillating.

On the other hand, Figure 5 shows the results of a tracking experiment during which a sinusoidal reference signal is sent to the control system. The control action seems not to be affected by significant chattering phenomena. Nevertheless, the not completely accurate compensation of the valve dead-zone determines a relevant tracking error, that reaches up to 13.4 *mm* where the sign of the speed changes.

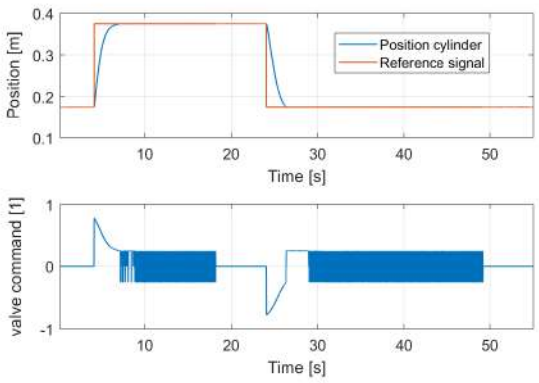

Figure 6. SMC: response to step reference signal.

5.3 Experimental Validation - SMC

At first, a simplified version of SMC law (29) was implemented in the hydraulic test-bench:

$$\nu = k_p(x_p^0 - x_p) + k_s sign(x_p^0 - x_p) \tag{37}$$

with:

$$k_p = 4.5 \quad k_s = 0.067 \tag{38}$$

The response to a step set-point is shown in Figure 6. The system is able to converge to the imposed set-point with zero static error. Nevertheless, as soon as the state reaches the sliding surface, the control variable starts to chatter at high frequency.

In order to improve the dynamic tracking performance, the feed-forward term was added to equation (37):

$$\nu = k_p(x_p^0 - x_p) + k_s sign(x_p^0 - x_p) + \frac{H_0}{H_1}\dot{x}_p^0 \tag{39}$$

In addition, to simplify the implementation, the following assumptions have been made:

$$\frac{H_0}{H_1} \approx \frac{A_1}{\Phi_1}, \quad k_1^+ = 0.052, \quad k_1^- = 0.045 \tag{40}$$

Figure 7 shows the response of the system to a sinusoidal reference signal. After the initial peak, the position error rapidly decreases with a maximum of 3.3 *mm*. The chattering phenomenon of the valve opening is still visible. To remove these undesired oscillations, the final SMC law (29) was implemented choosing $\epsilon = 4000$.

Figure 8 shows the response of the complete SMC law to a trapezoidal set-point profile, while Figure 9 shows the response to a sinusoidal reference signal. In both cases, we can see that good performance in terms of position error are achieved (maximum tracking error on sine signal is equal to 6.4 *mm*) and that the use of the approximating sigmoid function enforces a smooth control action, without any significant chattering.

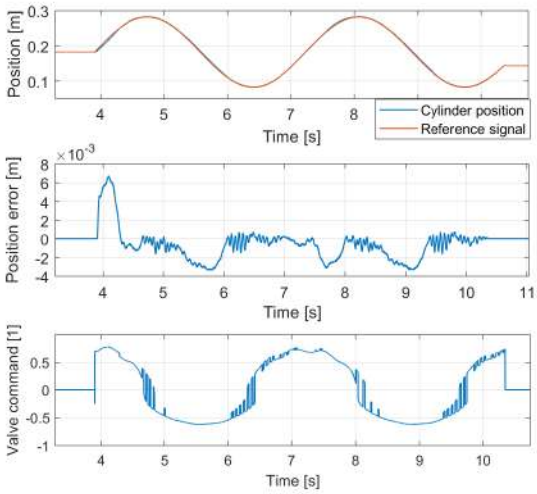

Figure 7. SMC with feedforward: response to sine reference signal.

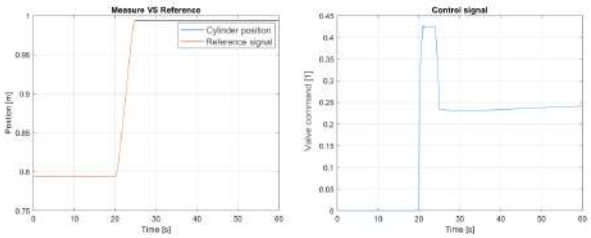

Figure 8. SMC with feed-forward and sigmoid: response to trapezoidal set-point profile.

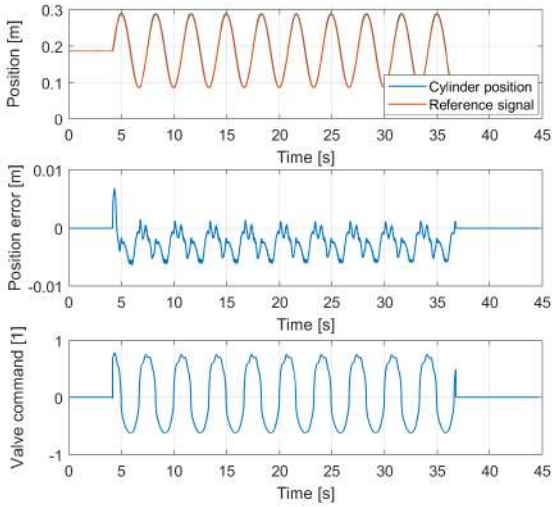

Figure 9. SMC with feed-forward and sigmoid: response to sine reference signal.

5.4 Comparative Evaluation of Performance

Generally, we can state that the linear controller is able to achieve good static performance, but it also entails poor tracking capabilities. Moving to the classical SMC controller, this solution is able to guarantee the best performance both in steady-state and in tracking, but the control action is heavily affected by chattering. Finally, the introduction of the feed-forward term and of the sigmoid approximating function allows to eliminate the chattering problem, without significantly undermining the performance in terms of both convergence time and tracking error.

6 Conclusions and Future Developments

This paper describes the research activities leading to the development of several position control schemes for a standalone hydraulic servomechanism. Starting from a previously validated mathematical model of the hydraulic actuator, several control laws have been synthesized and validated on an real system. Various experiments have been performed in order to verify the performance of each control schemes with respect to both step set-points and sinusoidal reference signals. Experimental results suggest that the SMC schemes (both the classical one and the one with sigmoid approximation) are able to guarantee better performance with respect to the linear cascade control scheme. Moreover, the intrinsic robustness of the SMC strategy leads to a high level of accuracy of the closed loop system.

As far as future developments are concerned, at first a decentralized position control system for an hydraulic manipulator will be designed on the basis of the SMC schemes here discussed. Then, possible alternatives in terms of control strategies will also be evaluated, like for instance the SuperTwisting algorithm (which is an example of 2^{nd}-order SMC) [22], and the linear control with adaptive compensation of the dead-zone [23].

Abstract –

We present a roadmap for guiding public officials on establishing platforms for citizen empowerment in the smart city. The proposed roadmap is not a technical architecture. Rather, a set of paradigms, guidelines and references to advanced technology approaches that can support building a technical architecture. We start from the perspective that the smart city architecture is not a venue for services, but a domain of innovation. We advocate encouraging citizen science to co-create new solutions—in contrast to engaging them to inform them or to evaluate solutions developed by professionals. We advocate giving equal attention to structured and unstructured data analysis. We also encourage the adoption of adaptable data orchestration tools to help navigate and organize the complexity of city data. Finally, we provide an outlook on the future trends (such as Blockchain and cognitive computing) in urban systems decision making.

Keywords –

Smart city; Citizen science; Socio-semantic analysis

1 Introduction

Traditionally, cities take a *control-room approach, to* centrally manage and optimize urban systems. The target is to develop and use technical operational policies that can make cities more sustainable, efficient, comfortable and enjoyable (de Waal & Dignum 2017). This is a *service-user model*, where citizens are considered as subjects, or, at best, customers. However, the concept of e-citizen is far more transformative. First, a smart city effectively tracks and is highly responsive to its citizens' opinions, behavior and objectives. Support for behavior changes can be the most valuable resource for meeting the challenges of climate change and sustainability. This is because there is a limit to the extent of possible efficiency gains that smarter hardware can achieve. In contrast, a limited savings in energy at the individual level, if adopted by the crowds, will provide effective and lasting impact. Engaging citizens can help find the best approaches to support such behaviour change. For example, what incentives can be offered to citizens to encourage the use of public transit, what new technologies or motivations for energy saving can be implemented.

Second, and more importantly, we should move citizens from a reactive role of service-recipients to co-creator of policies. In post-modernist planning theories, knowledge is distributed with citizens possessing equally valid knowledge to that of professionals. The role of planners is not to decide, but rather to seek and actualize multiple knowledge(s) to support transformative decision making. Collaborative planning approaches span four major categories (Linnenluecke et al. 2017): predictive (using forecasting); adaptive (adjusting to changing conditions); visionary (generating alternatives); and transformative planning (co-creation of solutions). Transformative planning is not limited to the idea of co-creation and harnessing community knowledge. It aims to empower communities, promote social learning/ innovation and foster behavior change.

We aim to provide a high-level map for 1) the issues that should be considered in developing a socially-savvy e-city platform, and 2) illustrate the value, relevance and interactions between available enabling technologies. It is expected that a city manager or a director of capital projects will use the map as a benchmark or a starting point for scoping an actionable policy for engaging citizens, collating their input and supporting their collective deliberations and innovation.

We present here a set of requirements and an initial architecture for augmenting sensor data about the physical city systems with that of people: their views, needs, ideas. The objective is to establish a repository of data for the access, use and analytics of (unstructured) data in the context of smart city.

2 The Smart City

The complexity of the fusion of data about the physical systems (attributes of the infrastructure) with that of its citizen (input, views, ideas) is not limited to computational issues, but, more fundamentally, to the very definition of a smart city. Pardo and Nam (2011) view a smart city from three perspectives: i) a mandatory technological perspective with a general reference to smart hardware and information technology tools.; ii) citizen creativity perspective that considers the role of citizens in using and generating smart city data; and iii) an institutional dimension that refers to cooperation of societal institutions with governments to co-develop policies and decisions. These three perspectives corresponds to the terms Digital City, Knowledge City and Smart Community, respectively.

In a departure from the control-room approach, citizens and civic organizations are empowered to use digital technologies to create solution to advance city systems. They not only have the right to a share of decision making powers, but also an equal right to being the source of knowledge and innovation—technical and otherwise. Examples of this approach has inspired several new applications and concepts: citizen sensor networks, DIY-citizenship (Ratto and Boler 2014), tactical urbanism (Lydon and Garcia 2015) or hackable city-making (de Waal et al. 2017). Such state-of-the-art practices use interactive citizen science for pooling citizen knowledge across all phases of city management including data collection, selecting amongst proposed alternatives, definition of the problems to consider, generating solutions, initiation of decision making, and monitoring actual implementations. This infuses more democracy into decision making, harness social innovation and allow citizens to act as agents of change.

In fact cities of the future are described to be "*territories with high capability for learning and innovation, which is built-in the creativity of their population, their institutions of knowledge creation, and their digital infrastructure for communication and knowledge management*" (Komninos 2006). The co-creation of knowledge by citizens and institutions is in fact "*continuous creation, sharing, evaluation, renewal and update of knowledge*" (Ergazakis 2004).

2.1 Collaborative Social Innovation

Several recent initiatives showcase that a paradigm shift towards citizen science in urban areas is viable and valuable—for example, Hackerspace (with 1330+ physical sites); include Network of 'Science Shops': scientific research in cooperation with citizens and local and national civil society organizations; DESIS-network: over 30 design labs supporting 'social innovation towards sustainability'; Global Ecovillage Network: network of 500 ecovillages; and Transition Towns: 450 grassroots community initiatives working on "local resilience". These advocate using sensing tools to enhance perception of environmental conditions (ex, Extreme Citizen Science); diffusion of solution and implementation tools (ex. Citizen Cyberlab); creating new sets of data (ex. Mapping for Change); provide open access to data (ex. DataShare); collection of idea (ex. IdeaConnection); taking collective actions (ex. Hacking the City). These efforts entwine electronics, media and humans, into co-agents in data and knowledge-production and decision-taking (Parikka, 2011).

2.2 Data Challenges for the Smart City

Smart city data is categorized into structured and unstructured data. Structured data follows a formal pre-defined data model and typically relates to physical and technology data—for example sensor and camera data or vehicle location. Unstructured data does not adhere to specific models. Unstructured data such as social media and popular media contents or citizen reviews is a fundamental input to any socio-technical analysis of smart city systems. This makes unstructured data more essential to citizen science, because it helps in understanding user needs and in customizing data delivery to them. For example, structured data can be used to define patterns of use of autonomous vehicles (AV) to support predicting traffic volumes or to correlate electric vehicles travel patterns to determine best location for electric charging stations. Unstructured data can be used to represent citizen willingness to support efficient mobility and energy usage; best means to operate an AV system or fix a broken pipe.

In general, one of the main challenges for serving data to citizens is the manipulation of data (especially the unstructured), due to the following challenges:

Complexity: The complexity of issues to consider in any urban decision is increasing. For example, Lambert et al. (2011) developed a model to prioritize major civil infrastructures projects. It included the following fourteen indicators: create employment, reduce poverty, improve connectivity and accessibility, increase industrial/agricultural capacity, improve public services and utilities, reduce corruption/improve governance, increase private investment, improve education and health, improve emergency preparedness, improve refugee management, preserve religious and cultural heritage, improve media and information technology, increase women's participation and improve environmental and natural resource management.

Multidisciplinary analysis: In addition to complexity, the issues are multidisciplinary. For example, considering the scope of assessment knowledge, Kabir and Khan (2013) enumerated 300 different possible issues for analysis. They span seven classes (each class is

followed by the number of related issues): hydrological resource systems (68), potable and wastewater (54), transportation (56), bridges (58), buildings (33), underground infrastructures (11) and urban systems (21).

Subjectivity: many of these issues are quite subjective in nature. To help quantify the assessment, a variety of quantification approaches have been developed (Hoogmartens et al. 2014), including life cycle analysis (LCA), life cycle costing (LCC) and cost–benefit analysis (CBA). Domain-specific methods were further explored, including environmental LCA (eLCA), social LCA (sLCA), financial LCC (fLCC), environmental LCC (eLCC), full environmental LCC (feLCC), societal LCC (sLCC), financial CBA (fCBA), environmental CBA (eCBA) and social CBA (sCBA).

3 The Proposed Architecture: Overview

The proposed roadmap aims to maximize the contribution of smart city systems (hardware and data) to empower citizens to lead innovation and knowledge generation within the city. The focus is on the know-how dimensions, which spans the creation of platforms to enable data management, processing, protection, visualization and analytics. It is out of scope for this roadmap to consider the know-why dimension, which models and understands the externalities that impact the development and effective management of smart city, including economic, legal, political, social and ethical issues. Also out of scope is the know-what dimensions which focuses on developing policies to create technical and process-based standards, and skill development and training (Cuquet et al 2017).

A high-level map that describes the main elements relevant to a typical smart city architecture is shown in Figure 1. Raw active data is ingested, curated and archived in long-term storage. Then data is catalogued and metadata and context information are extracted and used to tag/ annotate data. This enables searching through the "data lake." This workflow can be divided into detailed lower-level workflows that span each step; for example data upload and ingestion requires its own sub-workflow and User Interface.

The main pillars in the proposed map are as follows:

- The acquisition and ingestion of intrinsic data. Securing access to diversified and easy to use data. That is, the data has a higher value if it can be fused with other relevant data.
- Computational services. Much like an API or an "app store", this pillar offers citizens services to process data. Here, we assume that a citizen or a decision maker is using such data to create new products or conduct certain analyses.
- Modeling Pillar. Much like IFC (industry foundation classes), we need formalized models of data: rules that describe their behaviors, and basic relationships between datasets. How does the available data cohere to each other and how does the data relate to typical city analyses. Such conceptual models of data will require technical expertise, which is not easily available to citizens. For example, creating a bridge between IoT raw data and BIM-based software will enable users to access and develop a large number of applications without having to manipulate the technical architectures of this data (such as understanding IFC). Still, a savvy user can use the bridge to generate higher order models—without worrying about interoperability between the two data models.

4 Pillar 1: Data Acquisition

We identify below a set of challenges for acquiring smart city data and suggestions for possible solutions based on recent advances in data management approaches.

4.1 Data Heterogeneity

Establishing meaningful data from a multitude of structured and unstructured data will remain a challenge. For example, how to make sense and integrate CCTV data, with sensor data with citizen data. While ontologies can be very effective in handling this, their static nature will limit their ability to be exhaustive. Different types of tools were proposed to solve this problem:

Fact-finding platforms such as YAGO2 contains 350, 000 classes, 10 million entities and 120 million facts extracted automatically from online sources, with an accuracy of 95% (Hoffart et al. 2013).

Linked data and distributed stream computing help manage the high-variety and high-volume data within high-velocity activities (Hasan and Curry 2014). The combination of linked data tools and stream computing tools with machine learning tools will facilitate the semantic coupling of know-how knowledge with real time data. This creates a realm of self-improving data models and associated learning/analytics needed to support spot decision making (Curry et al. 2013).

Edge computing: Decision-embedded analytics that have real-time access to big data will facilitate in-network and in-field analytics (called edge-computing). In conjunction with enterprise-level analytics, these tools are poised to create higher levels of customization (for example, which driverless car is best choice for each commuter), real-time operational (what are the best evacuation routes for each commuter in the case of emergency), and even new business models (for example, carbon tax refunds based on usage of energy within/outside home)

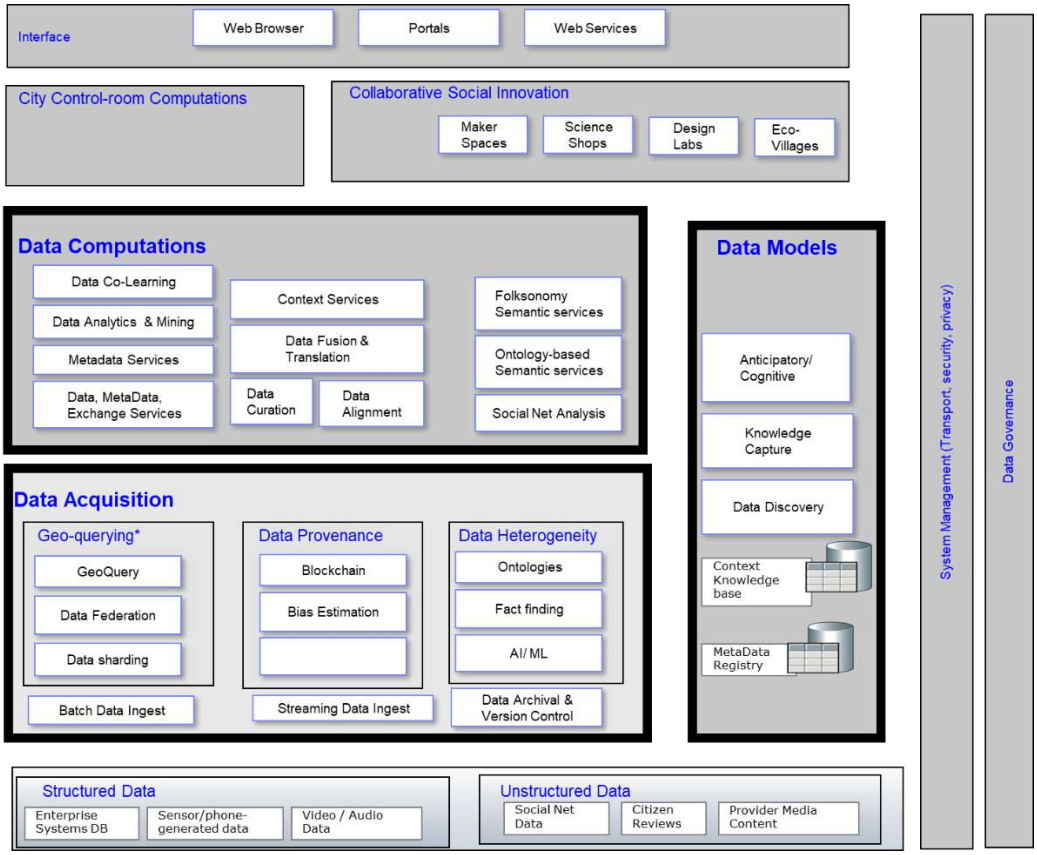

Figure 1. Overview of the proposed roadmap

4.2 High-Performance Data Access

Access can be provided by customizable and intelligent sharding of the data streams based on application and infrastructure requirements. Technologies such as Apache Kafka already provides an ability to shard relative to the memory capacity of the system conducting the analysis. Two of the key challenges that must be addressed by any smart city architecture are contextualization and federation.

The architecture needs to enable and include a process of contextual sharding. A set of intelligent mechanisms at the network edge are required to understand specific applications. This ranges from understanding their data structures to identifying access rights to specific users.

Another challenge is data federation. How to accommodate data query and retrieval functionality from multiple individual platforms. MicroELement (MEL) is a simplified software used to describe a basic IoT computation (Ranjan et al. 2018):

1. MicroServices: functionalities deployed/migrated across different infrastructures (e.g., Docker) available across Cloud, Edge, and Things layers;
2. MicroData: contextual information about i) devices, protocols for collecting and sharing data, ii) the specific type of data (e.g., temperature, vibration, pollution) it needs to process, and iii) data management steps, such as storage and access rules.
3. MicroComputing: executing analysis tasks based on historic and real-time data through tools such as NoSQL, stream processing, batch processing, etc.);
4. MicroActuator: interfaces with actuator devices for changing or controlling object states in the IoT.

MEL will need to expose a uniform programmatic interface (APIs) to models and analytics, hence, reducing the barriers to data ingestion. The new federated API suite may utilize the Apache Spark SQL API to benefit from its existing interoperability features, in addition to other Apache libraries such as Samza and Kafka. The API must be lightweight, and enable integration with services supported by other vendors.

4.3 Data Provenance

Traditional data provenance techniques require collection and transmission of large data volumes, which is impractical for IoT applications that warrant sub-second decision making and data processing latency. Hence, new techniques are required which can reduce and enhance the efficiency of provenance and metadata

collection, recording, and transmission. Understanding how provenance relationships can be derived from IoT data processing activities is a challenge, as precedence relationships identifying which output was a consequence of an inputs may be difficult to establish.

One possible opportunity is to develop IoT data provenance technique based on Blockchain's Distributed Ledger Technology (DLT) to record lifecycle activities on data as it travels through the IoT ecosystem. Another hard challenge to solve will be to develop provenance techniques than can verify complying with data privacy regulation such as GDPR (Berberich & Steiner 2016). Undertaking GDPR compliance for statically held data (e.g. user information) can be easier to manage, however extending this to a dynamic data stream (which may be context dependent) remains a challenge. Another challenge is when IoT deployments involve more than one vendor. Finally, the authenticity of data and protecting it against organized campaigns is important. The roadmap recommends investing in technology to detect and eliminate misinformation and bias (amplified through the viral nature of social media) using algorithms like WSARE (What's Strange About Recent Events) and platforms such as SwiftRiver (Yu et al. 2016).

4.4 Access Control

It is important to identify application actors: Information flows between actors is modelled as message passing. Such messages are to be stated explicitly along with identification of the content of such messages. This makes it possible to discover which actors have access to information items necessary for answering provenance use case questions.

Of equal important is to map out actor interactions. This is a network of data items, users with access to them, and platform components processing them.

Finally, identify knowledgeable actors. Any actor that has access to an information item is known as a knowledgeable actor. The team will associate every information item (within a use case) with an actor. For each, the necessary provenance functionality is to be set. When an information has not been exposed in the interactions between actors through message exchanges, use cases (in data management system) must be revised.

4.5 Geo-Distributed Cross-Querying

In smart city applications, there is a need to curate data based on its geo-location. The challenge is to design multi-query planning algorithms that can not only map queries to different parts of an IoT infrastructure but also map that to the requirements of data analytics applications. The algorithms are required to also optimize end-to-end QoS associated with the query plan, to improve resource utility and meet users' SLAs. Existing geo-distributed querying systems were designed for managing only static data. They neither consider heterogeneous processing infrastructure, nor execute queries using standard heterogeneous models (e.g., stream processing, NoSQL, SQL, batch processing).

Event Processing Language (EPL) can enhance the performance of existing geo-distributed querying systems, EPL can limit the query data size to guarantee real-time processing. Hence, EPL has been used in majority of stream process platform such as Apache Spark, Kafka, Flink and Esper. Similar to SQL, however, one of the core limitations of EPL-based querying approaches is that they cannot handle heterogeneous data stored across multiple types of storage platforms and/or programmed using multiple types of storage and analytics programming models.

A more dynamic approach is to find data linkage through bottom-up discovery of association patterns. New tools such as blockmodeling (part of network analysis techniques) allow a platform to detect data clusters. Studying the patterns of repeated clusters can help discover and designate a set of data templates: a set of typical heterogeneous data that can be seen as complementary. This can span both the semantic and structured data. Machine learning approaches can also be very effective in this regard.

5 Pillar 2: Computation and Generation of New Knowledge

The computation pillar aims to create a bottom-up environment to foster collaborative analysis and re-mixing of data through collaboration between citizen scientists. This pillar spans the following features.

- Data representation: Structure and represent the data to facilitate multiple modalities (i.e. different models of data logic), exploiting the redundancy of different data sources.
- Data translation: Interpret data from one modality to another, i.e., a translator allows the modalities to interact with each other for enabling data exchange.
- Data alignment: bridges among modalities.
- Data fusion: integrate data from different domains
- Data co-learning: transfer modality knowledge between users.

The following are some relevant approaches to support bottom-up analyses of city systems:

5.1 Citizen Sensor Networks

Scientists and engineers are already providing interactive cloud-based models to help users (with limited or no technical background) to learn, conduct or study the use of some of these assessment methods. This

can cover purely technical issues such as environmental modelling; visualization systems through interactive 3D modelling and GIS maps; and even tools to help connect mental models with quantitative system dynamics (Voinov et al. 2016). Examples includes (Evers al. 2016): stakeholder participation in developing an agent based model to profile social values; and modelling through role playing games (Haase et al. 2013); enhance acceptability of environmental models (Wassen et al., 2011); and environmental models validation (Newig et al., 2008). Kishita et al. (2016) developed a review of scenario generation for sustainability analysis, which is very relevant to supporting citizen science.

5.2 Gaming

Gaming has been used to help in recruiting and sustaining participants. Evolving as a venue for interactive co-creation, games galvanize partnerships and provide opportunities for peer-to-peer learning. They are also some of the best tools to study "choice molecules" (action-outcome combinations) especially when non-linearities make it hard to communicate system features and reactions in conventional learning and dialogue processes (de Suarez et al. 2012).

Cases for the use of games in co-creating and studying alternative futures include, for example, the game "Paying for Predictions". It helps in risk assessment in relation to resource shortages and disaster management in light of climate change. "Ready!" is a game that uses narrative to help identify solutions to environmental problems. The Rockefeller "Resilience game" addresses the disconnection between decisions and actions: government or communities not following options selected. The game "Before the Storm" generates decisions as players think through the various options that may be available to them when a particular disaster strikes. "Upstream, Downstream" game promotes consensus building and social learning through providing players with the ability to assign risks based on individual views. Through repeated reviews by all, a better collective understanding of risk can emerge. The game "Dissolving Disasters" considers choices in the context of changing probability of, say, rainfall. It is designed to rush players into decision making. Later, players are given time to reflect on the problem, and, more importantly, the decision making process.

5.3 Application Orchestration

An IoT application is typically expressed as a collection of multiple self-contained data analysis activities (e.g., MEL). These activities are orchestrated to execute in a specific order with specific rules that respond to user requirements. To realize a dynamic environment for citizens to collaborate on creating new knowledge, there is a need for platforms that can enable application orchestration, including the following:

- Choosing storage and analytics programming models (e.g., stream processing, batch processing, NoSQL) and data analysis algorithms to seamlessly execute in highly distributed and heterogeneous IoT;
- Dynamically detecting faults across multiple parts of the IoT infrastructure;
- Dynamically managing data, and software available in "Things, Edge and Cloud" layers driven by IoT.

6 Pillar 3: Modelling

Established models (such as IFC, for example) add context and structure to data. Such models represent the best means by which technical experts can communicate their knowledge to citizens in an indirect way. Because such models are limited to the data level, they allow users to benefit from the basic rules embedded in the data model, but, at the same time, they do not mandate specific analysis approach on the users. They act as connectors and check-system on data. This is similar to the IFC-BIM relationship. Users can be very innovative in their programming of BIM without worrying about the basics of data structures (they are served through IFC)

Using flexible data structures foster social learning. The proposed roadmap advocate balancing the top-down approach of data standards with a bottom-up discovery means. For example, the roadmap advocate using ontologies (formalized and programmed conceptual model) and, at the same time, using folksonomies (ad hoc, bottom-up and loose model of concepts).

On the long term, lifelong Machine Learning is a central paradigm in smart city systems. How to discover knowledge based on smart search, conduct intelligent analysis, and constantly re-train algorithms based on newly found knowledge. Recent trends in Transfer Learning and multitask learning are task-specific and domain-agnostic (Liu 2017). Such smartness is rooted and supported by the surge in synthesis research and the advancement of knowledge capture and representation tools. Synthesis is a type of inferential reasoning that recursively integrates inductive thinking (combine observations into a larger model) with deductive analysis (examining the consistency of a general model to real cases). Emphasis in recent years is focused on automating the inductive part given the mushrooming number of models in all domains.

6.1 Knowledge Capturing and Representation

Thanks to amazing advancement in semantic systems/ algorithms, the field of knowledge acquisition and representation has evolved into extensive and efficient levels. Probase (and its successor Microsoft

Concept Graph) is a probabilistic taxonomy (with 5.4 million concepts) that constantly assesses the typicality of knowledge using probabilities, which in turn is used to support probabilistic reasoning (Zang et al. 2013). YAGO2 is an informatics ontology based on WordNet and Wikipedia YAGO2 contains 10 million entities and 120 million facts, which were extracted automatically from Wikipedia, GeoNames, and WordNet. YAGO2 stores extraction rules in text files, which allows easy extension without changing source code. Human assessment of facts in YAGO2, showed that it achieved an accuracy of 95% (Hoffart et al. 2013). Freebase was a scalable graph database used to structure general human knowledge. The data in Freebase could be collaboratively created, structured, and maintained by people and software. Freebase provided automatic suggestion to help the user enter new knowledge. It was replaced by Googl's Knowledge Graph, which contains 70 billion facts!

Open Information Extraction (OPEN IE) is a protocol for extracting a large number of relations from arbitrary text on the Web without specifying the targets to be extracted (Fader et al. 2011). KnowItAll is a scalable and domain-independent system that uses OPEN IE for extracting facts from the Web in an unsupervised manner. It ran for four days on a single machine and extracted over 50 000 facts (Etzioni et al. 2004).

6.2 Cognitive and Anticipatory Computing

One of the most promising technologies in citizen science is cognitive computing. It refers to computers learning how to complete tasks traditionally done by humans. The focus is on finding patterns in data, carrying out tests to evaluate the data validity. A key technology in this regards is natural language generation (NLG). NLG is not like traditional natural language process (NLP) systems. NLG tools are able to transform unstructured data into readable summaries with synthesis of key takeaways. Advanced NLG offers traceability: why the system chose to communicate in a particular manner. Bots (a short name for software robots) are used for live chat with customers. Story Engine is a program that can read through unstructured data and summarize conversations, including the ideas discussed, the frequency of the communication and the mood of the speakers. Interestingly, some newspapers are starting to use some of these Bots to summarize sport events based on transcripts of commentators' speech.

The next frontier is anticipatory/assistive computing. In this regards, the computer moves from reacting to explicit commands into understanding implicit queries and anticipating questions and actions. Bot help search engines exploit big data analytics to infer similar/related strings of searches/questioning by other users (Reed et al. 2012). They exploit advances in inductive (logic) programming, which is predicated on finding solutions to problems/queries in the same manner humans would do through predicting next steps and inductively collating related facts from the web. Some of the most successful and sophisticated examples of Bots that deploy cognitive and anticipatory computing include Apple's Siri, Amazon's Alexa, Microsoft's Cortana, and Google's Google Home and Facebook Messenger. These and IBM's Watson apply deep learning for superior knowledge acquisition and representation. .

7 Discussion

Our aim here was not to build a technical architecture for smart city and citizen science applications. Rather, collate and organize relevant paradigms, governance issues and analysis approaches into a roadmap that can guide cities in developing the technical architecture. We advocated that smart city architecture has to balance the use of structured and unstructured data. They also have to be able to provide processed data and means to process data. A user, based on their technical agency can have the choice of using either approach. One of the main technical roles for a smart city architecture is in providing computational services (apps) that enables users to mix and match data analyses to produce new original contribution. Another significant contribution is to provide users with basic models that can create minimal and meaningful structure to data. This can include data models and ontologies or folksonomies.

The proposed architecture places special attention to machine learning and cognitive computing. These are very promising approaches in enabling smarter and easier analyses and, at the same time, customize the access, delivery and usage of data (including BigData) to user profiles.

Abstract –

Infrared Thermography (IRT) is a widely used non-destructive method for energy audits. However, plenty of research indicates that the performance of passive thermography is influenced by the method of data collection. Unmanned Aircraft Systems (UAS) has been successfully employed for conducting RGB photogrammetry, but the data collected from an infrared thermal camera and an optical camera differ from one another. The infrared Thermal camera usually has a lower display resolution, is more likely influenced by ambient condition, and is limited to the distance between camera and objects. UAS is being utilized for reducing the time and complexity of data collection and for capturing detailed thermal images on large areas like university campuses or entire city districts. Meanwhile, it is important to investigate the impacts of factors such as camera angle, flight patterns, and overlap of pictures when auditing energy of a group of buildings within a district. This paper introduces the preliminary results of a study that tested factors that affect 3D thermal mapping by using a UAS. To measure the performance of mapping, this research compared the quality of rendered images generated from a mapping model constructed by drone acquired data with images acquired directly from a thermal camera. The efficiency of different UAS flying configurations were investigated. The investigation showed that the adjustment of flying configurations can improve the quality of rendered images for energy audits, even though rendered images were not as high-quality as images captured directly from a thermal camera.

Keywords –

Thermal mapping; Unmanned aircraft system (UAS); Flying configurations; Energy audits

1 Introduction

Energy audit has been used to reduce energy loss from buildings and distribution networks for many years. There are plenty of ways in auditing energy loss, including simulation methods, data-driven methods, and Infrared Thermography methods (IRT)[1][2]. Infrared Thermography (IRT), as a non-destructive approach, has been widely utilized for both a quantitative type of approach [3][4] and a qualitative type of approach[5]. However, IRT is influenced by the different approaches for data collection. In general, there are two types of approaches to collecting data for IRT, including Active Thermography and Passive Thermography[6][7][8]. Active Thermography employs an external stimulus to produce an extreme thermal difference (heating or cooling) between the objects and the environment. These approaches can detect hidden defects in detail, but they assume that auditors are fully aware of positions of potential thermal anomalies. Therefore, active approaches cannot be adopted effectively when auditing a whole district. On the contrary, passive thermography does not rely on man-made stimuli. Passive thermography concentrates on observing thermal patterns based on the temperature values and is influenced by weather and thermal emissivity.

Automated fly-past survey is referred as Unmanned Aircraft System (UAS), known as drones, with mounted thermal cameras. Firstly, UAS is flexible to collect thermal information from different angles and different altitudes.[9] Secondly, UAS not only can capture images horizontally, obliquely, and vertically from different angles around a building, but also can fly at a lower altitude and fly through two buildings to capture fine details. Finally, UAS can reduce time and labor. To date, UAS based IRT has been one of the most popular methods used in energy audits. New products, for example, allow the deployment of dual cameras to capture RGB images and thermal images at the same time

from the same angle and altitude. The main issue is that thermal camera's resolution is not as high as optical camera's resolution resulting in a lower quality 3D model generated by photogrammetry mapping.

Although UAS based IRT can reduce the time and complexity of data collection, and capture detailed images throughout a whole district, there remained serval problems in terms of drone flying configurations and efficiency. Additionally, auditing a single building differed from auditing a group of buildings within a district. It was crucial to investigate the impacts of factors such as camera angle, flight patterns, and pictures overlap when auditing energy of a group of buildings within a district. To explore factors affecting the performance of 3D thermal mapping for energy audits by using Infrared Thermography (IRT) mounted on Unmanned Aircraft Systems (UAS), this study proposed a method for testing different combinations of flying configurations and for comparing the results derived from those different combinations. The comparisons were based on quality and efficiency, and different factors' influences were analyzed. The following sections will present the proposed research method, the results, the discussion and conclusions.

2 Research Method

2.1 Architecture of Research Method

This study has three parts, Data Collection[10]; 3D Mapping; and Data Analysis and Comparison. In the first stage, different drone flying configurations in terms of flight patterns (vertical grid, horizontal grid and mesh grid), camera angles (90 and 45 degrees), and the percentage of image overlap (90% and 85%) were tested over a district. In the second stage, the features of every image were detected and used to reconstruct a 3D model. Due to several well-established commercial 3D reconstruction software programs, this process is effortless to implement. In the last stage, all 3D models based on different flying configurations were ranked. The ranking criteria compares the images rendered from 3D models and terrestrial images captured on site at the same time when flying the drone. The rendered images consist of points so relative points can be projected onto captured images. For thermal models and thermal images, points contain the temperature data, and so do the images. Temperature errors can distinguish the performance of different flying configurations. The workflow is shown in Figure 1. Each stage will be introduced in detail in the following paragraphs.

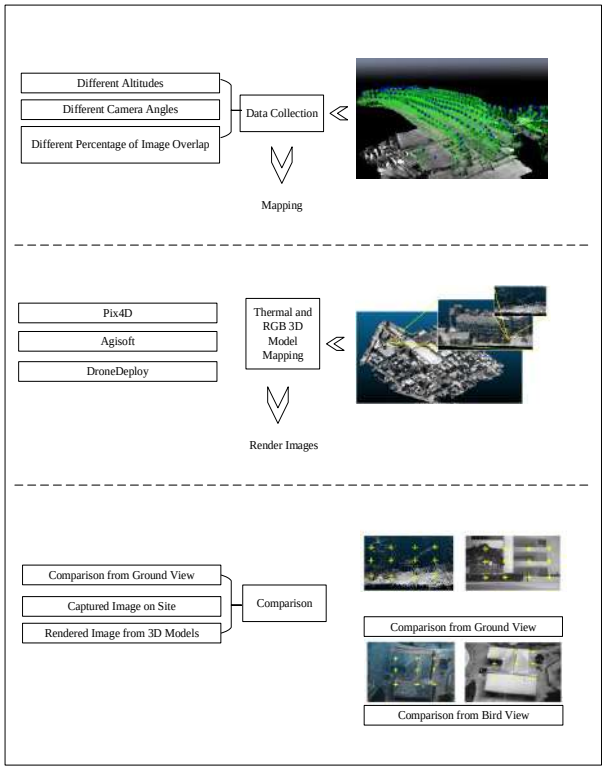

Figure 1. Workflow of research method

2.2 Data Collection

The Unmanned Aircraft System (UAS) used in this study is shown in Figure 2. The UAS consists of three parts: the main body, the data collection system, and the controller. The main body consists of an aircraft and a gimbal. The DJI M600, an industrial level drone, was deployed in this research. Gremsy T3 was the gimbal connecting the camera to the drone. It can horizontally and continuously yaw 360 degrees, has a vertical pitch from positive 90 degrees to negative 135 degrees, and can roll positive and negative 45 degrees. The gimbal can also connect to data collection system. One thermal camera, FLIR DUO Pro R was used in the data collection system. This camera can provide at the same time both a high-resolution featuring thermal image and a high-definition color image in a single integrated package. The data format is known as Radiometric JPEG. This file format contains both thermal and visible data in a single file. The resolutions of visible sensors and thermal sensors are 4000*3000 and 640*512 respectively. An additional benefit of this product is that absolute temperature can be read from its thermal images. The final part of this whole system is the controller. The controller can both remotely operate an aircraft for flight patterns, gimbal for angles, and cameras for data collection.

(1) Gimbal - Connection to DJI M600; (2) Gimbal - Frame for Camera; (3) FLIR DUO Pro R – Visible Lens Barrel; (4) FLIR DUO Pro R – IR Lens Barrel; (5) FLIR DUO Pro R – Electric Wires; (6) FLIR DUO Pro R – Integration Cable; (7) FLIR DUO Pro R – GPS Antenna Cable; (8) FLIR DUO Pro R – USB Cable.

Figure 2. Cameras setup for the deployed unmanned aircraft system

The most significant part in the data collection stage was to test different flying configurations. In this study, different flight patterns (vertical grid, horizontal grid and mesh grid), camera angles (90 and 45degrees), and percentage of image overlap (90% and 85%) were tested.

There are a great number of software programs which can be used for data collection. The available software programs are compared with each other in Table 1. However, not all software can be used to support both a drone systemand a camera system. In this study, DIJ GS Pro were used.

2.3 Visible and Thermal 3D Mapping

Due to the overlaps between two pictures, common feature points in different pictures can match with each other. To find common feature points, two widely used methods, Scale-Invariant Feature Transform (SIFT) and Speeded-up Robust Features (SURF) has been introduced. This process is called finding correspondence. To filter incorrectly matched points, Random Sample Consensus (RANSAC) is responsible for removing the outliers. After enough common feature points obtain their matches, the Location Determination Problem (LDP) can be solved and the positions of points can be determined in space. This technique for reconstructing 3D points from two-dimensional image sequences is called Structure from Motion (SfM)[11]. There are plenty of well-established commercial software programs for 3D reconstruction, including Pix4D, Agisoft, and DroneDeply [6] that implement this approach. In this study, Pix4D was used because of its ability to process both RGB and thermal images and to merge RGB and thermal models

Table 1. Comparison of data collection software

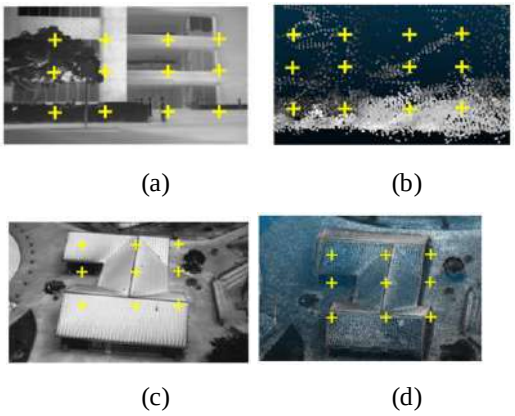
Designed by	Operated on IOS System	Operated on Android System	 Plan Mapping	Circular	Peripherical Mapping	 Waypoint Route	360 Degree Panorama
Pix4D Capture	Yes	Yes	Yes	Yes	No	No	No
DIJ GS Pro	Yes	No	Yes	Yes	No	Yes	No
Drone Deploy	Yes	Yes	Yes	No	No	No	No
Drone Harmony	No	Yes	Yes	Yes	Yes	Yes	No
Hangar360	Yes	No	No	No	No	No	Yes
Drone Blocks	Yes	No	Yes (by coding)	Yes (by coding)	No	Yes (by Coding)	Yes (by Coding)

2.4 Data Analysis and Comparison

After images collected through different flying configurations and processed by mapping, different 3D models with different flying configurations were obtained. In this stage, all constructed 3D models can be tested and ranked to determine which UAS flying configurations are the superior ones to audit energy loss.

In this study, data collected with UAS was compared with data captured by terrestrial thermal camera. Temperature values can change over time, however, each flight took less than 15 minutes, a span of time that does not allow temperature values change dramatically. After each flight, cameras have been immediately utilized as a stationary equipment to capture a thermal image close to

a selected building (less then 12m) facing selected façade and windows. Shown in Figure 3 (a), this picture was captured by thermal camera. Meanwhile, this selected viewing position and the same camera parameters were recorded. These setting then can be used to create a virtual camera with the same viewing position in a given 3D mapping model related to the flight to render an image from the model. Shown in Figure 3 (b), this is a rendered image from the thermal model. In order to measure the performance of mapping, quality of rendered images generated from a 3D mapping model, and captured images from a thermal camera were compared. Every point in (b) had color information representing temperature values. The criterion of comparison was to calculate the differences and errors between points in rendered images, illustrated by yellow crosses in (b), and related pixel in captured images, illustrated by yellow crosses in (a).



(a) (b)

(c) (d)

Figure 3. Cameras setup for unmanned aircraft system

One case of comparison was facing façade and windows shown in Figure 3 between (a) and (b). Another case was facing the roof system. In the second case, capturing extra images on site were not necessary. The images that were captured from drone view could be directly employed, shown in Figure 3 is a captured thermal image (c) and a rendered thermal image (d). The same comparison was also conducted for the second case.

To calculate the differences and errors between two images, two mathematical approaches were used being Mean Squared Error (MSE) and Structural Similarity Measure (SSM). Shown in equation (1) and equation (2).

$$MSE = \frac{1}{mn}\sum_{i=0}^{m-1}\sum_{j=0}^{n-1}[I(i,j) - K(i,j)]^2 \quad (1)$$

$$SSIM(x,y) = \frac{(2\mu_x\mu_y + c_1)(2\sigma_{xy} + c_2)}{(\mu_x^2 + \mu_y^2 + c_1)(\sigma_x^2 + \sigma_y^2 + c_2)} \quad (2)$$

MSE checks difference of every two relative pixels in two images. It squares these differences, sums them up and divides the sum of squares by the total number of pixels in the images. An MSE of value 0 indicates that two pictures are perfectly identical. The greater the value of MSE is, the more errors rendered pictures create. However, MSE simply compares the distance between pixel intensities. There is a need to compare the structural information of images. The SSIM method can perceive changes in small sub-samples, whereas MSE estimates the perceived errors in the entire images. In equation two, (x, y) indicates the $N \times N$ sub-window in each image, and SSIM can be calculated on various windows of an image. The SSIM value can range between -1 and 1, where 1 represents perfect identicality.

3 Case Study

IRT for energy audits usually has a requirement for a minimum indoor and outdoor temperature difference. The required temperature difference between indoor and outdoor for energy audits using IRT should be at least 10 °C (18 °F)[12]. In order to meet this requirement, we conducted our case study on a university campus in Boston, USA. According to the *105 CMR 410.00: Minimum Standards of Fitness for Human Habitation* published by Massachusetts Department of Public Health [13], regulation requires indoor temperatures of at least 64 °F at night and 68 °F during the day from September 15th to June 15th. During the data acquisition for our case study in Boston the outdoor temperature was 30.2 °F at 7:00 AM and 43 °F at 10:00 AM when we conducted the research.

In this case study, we tested 3 different factors, flight patterns, camera angles, and overlap of images. Due to the complexity of this study, we tested vertical grid (parallel to north-south direction), horizontal grid (parallel to east-west direction) and their combination mesh grid in the area for flight patterns factor, 90 degrees (facing the ground) and 45 degrees (to the horizon) for camera angle factor, and 90% and 85% for the overlap of images. Table 2 shows the 8 flight configurations that were implemented in this study

In table 2, Number of calibrated images indicates how many images were calibrated to create 3D mapping. The pictures which were not calibrated and did not match with other images did not contribute to the creation of 3D points and meshes. 2D key points features were extracted from images by using SIFT or SURF as was explained in the research method above. 3D points were matched to 2D key points and indeed contributed to the creation of 3D models. The reprojection error referring to the image distance between a projected point and a measured one was introduced to quantify how closely an estimate of a 3D point recreates the point's true projection.[14]

Table 2. Summary of different flight configuration

Session	Flight Pattern	Camera Angle	Front Overlap	Side Overlap	Number of Calibrated Images	Number of 2D Key points Observations for Bundle Block Adjustment	Number of 3D Points for Bundle Block Adjustment	Mean Reprojection Error [pixels]	Abbreviation
1	Horizontal Grid	45	90	65	505 out of 512 images calibrated (98%)	418410	121473	0.208	45-h
2	Vertical Grid	45	90	65	590 out of 592 images calibrated (99%)	490601	142500	0.209	45-v
3	Complete Mesh Grid	45	90	65	1099 out of 1104 (99%)	935059	274080	0.198	45-com
4	Complete Mesh Grid	45	85	65	884 out of 887 images calibrated (99%)	734397	224810	0.191	45-com-85
5	Horizontal Grid	90	90	65	539 out of 651 images calibrated (82%)	237600	77236	0.205	90-h
6	Vertical Grid	90	90	65	560 out of 644 images calibrated (86%)	214038	70300	0.216	90-v

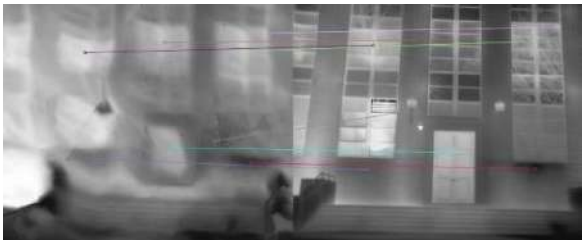
8	Complete Mesh Grid	90	85	65	720 out of 1040 images calibrated (69%)	263227	90663	0.195	90-com-85

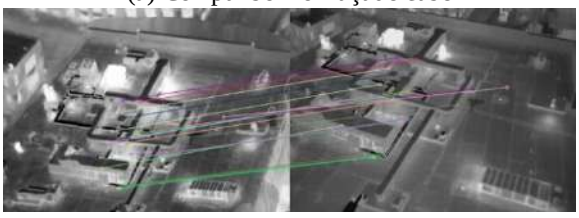
4 Result and Discussion

Two cases for comparison were created for each flying session as demonstrated on Table 2. One was facing doors and windows and the images were captured by a camera from a fixed location on the ground as shown in Figure 4 (a). The left image was a rendered image, and the right one was a camera captured image. Therefore, there was only one scenario for doors and windows.

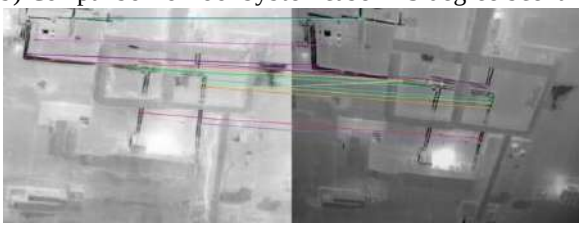
For the other case the flight acquired data facing the roof with 90 degrees and 45 degrees camera angles. The camera captured images were direct bird view images. Two 3D models were reconstructed with all 90-degree images and all 45-degree images, each of those two models produced four rendered images two with 90-degrees and two with 45-degrees by the use of model based virtual cameras. The two 90-degree rendered images from models were compared to a 90-degree camera captured image and the same was done for the 45-degree rendered images from models. Due to the camera angle, the visual perception of the camera captured images was totally different between 90 degrees and 45 degrees. This was also the reason for the cross comparison of both scenarios. The images shown in Figure 4, (b) is for 45 degrees camera, while (c) is for 90 degrees camera. The left ones are rendered images and the right ones are camera captured pictures in both (b) and (c). The rendered images in (b) and (c) are both from a model reconstructed from all 45-degree images. A comparison of two rendered images from a model reconstructed using all 90-degree images with two camera captured images were also conducted, but they are not shown here.



(a) Comparison of façade case



(b) Comparison of roof system case – 45-degree scenario

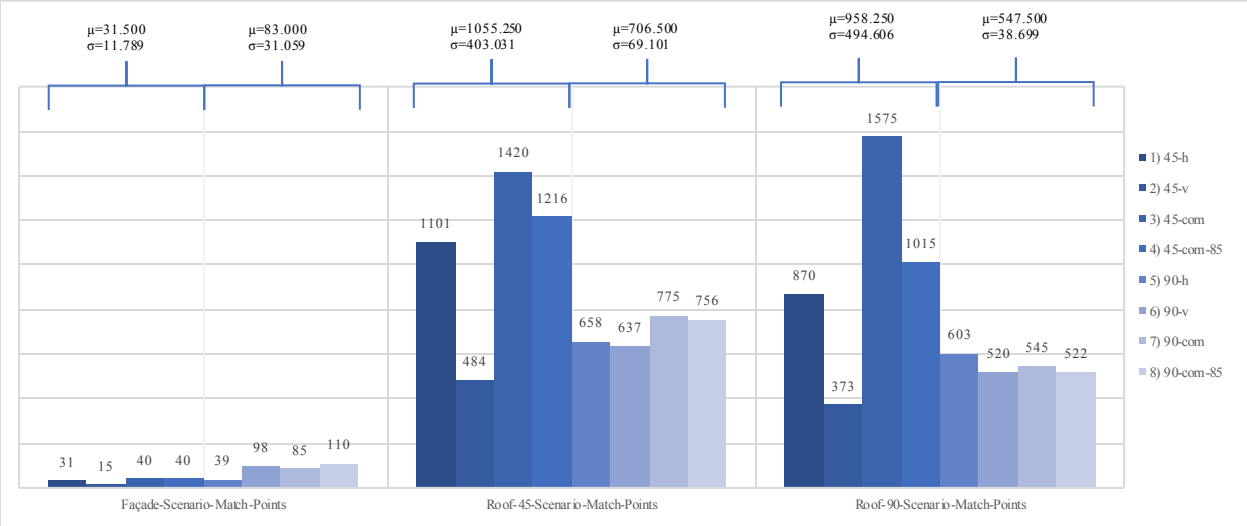


(c) Comparison of roof system case – 90-degree scenario

Figure 4. Illustration of match points between

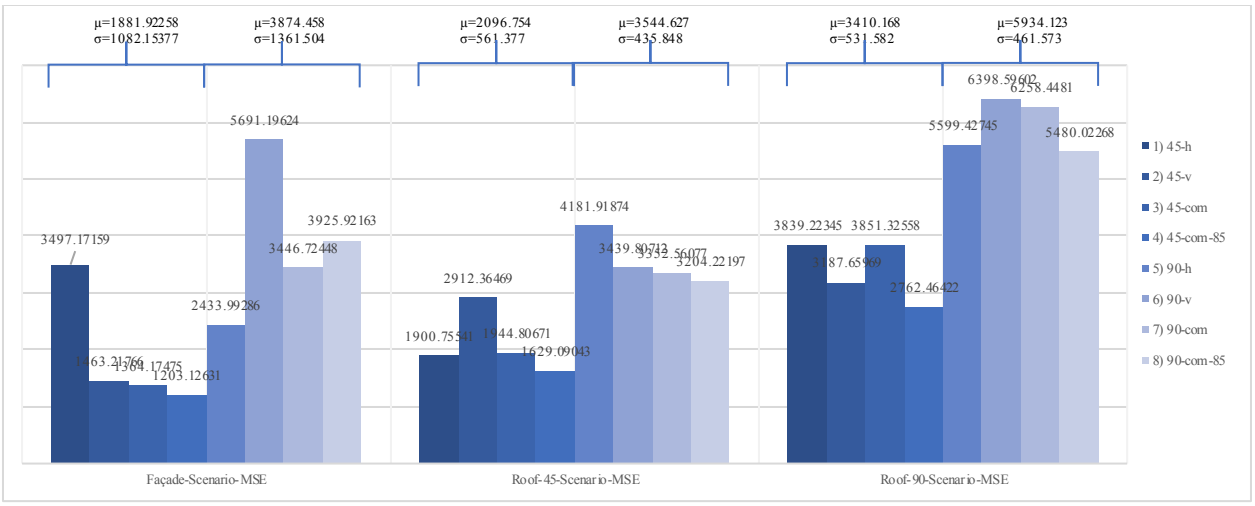
camera captured pictures and rendered pictures

In Figure 4, the solid lines illustrate the match points between rendered images and captured images. Match points, MSE, and SSIM were calculated and plotted in Figure 5. The legend in Figure 5 refer to the *abbreviations* on table 2. Average and standard deviation of flying session 1-4 and flying session 5-8 in different comparisons are calculated and shown on the top bar charts. According to Figure 5 (a), two roof system scenarios created more numbers of match points than door and windows scenario. As for those two roof system scenarios, a model reconstructed by a flight camera angle of 45 degrees can create more numbers of match points in its rendered images than a model generated by a flight camera angle of 90 degrees can in both scenarios. Average numbers of match points in 90-degree and 45-degree rendered images from a model with a flight camera angle of 45 degrees (session 1-4) are 958.250 and 1055.250 calculated based on the captured images taken by a 90-degree camera and on a 45-degree camera respectively, while those numbers are 547.500 and 706.500 in rendered images from a model with a flight camera angle of 90 degrees (session 5-8). More match points indicate that rendered images have a better performance in terms of capturing control points. To test color rendering performance and structure similarity performance, MSE and SSIM are introduced in Figure 5 (b) and (c). According to Figure 5 (b), rendering images from a model with a 90-degree flight camera angle (session 5-8) performed worse than rendering images from a model with a 45-degree flight camera angle (session 1-4) in all scenarios in terms of capturing color information, because they had higher MSE scores. In Figure 5 (b), the session *"45-h"* where the flight camera angle was 45 degree, and the flight pattern was horizontal obtained a rendering image in façade scenario whose MSE was 3497.17159. This abnormal score is bigger than the average score plus standard deviation which should be considered an outlier. In Figure 5 (c), rendered images from a model reconstructed by all images with a 90-degree flight camera angle performed better than rendered images from a model with a 45-degree flight camera angle in both two roof system scenarios because of the higher SSIM scores. However, it was entirely different in scope for façade scenarios. Rendering images from a model with a 45-degree flight camera angle obtained 0.641 for average score of all flight patterns, which is higher than 0.593 average score obtained by rendering images from a model with a 90-degree flight camera angle.

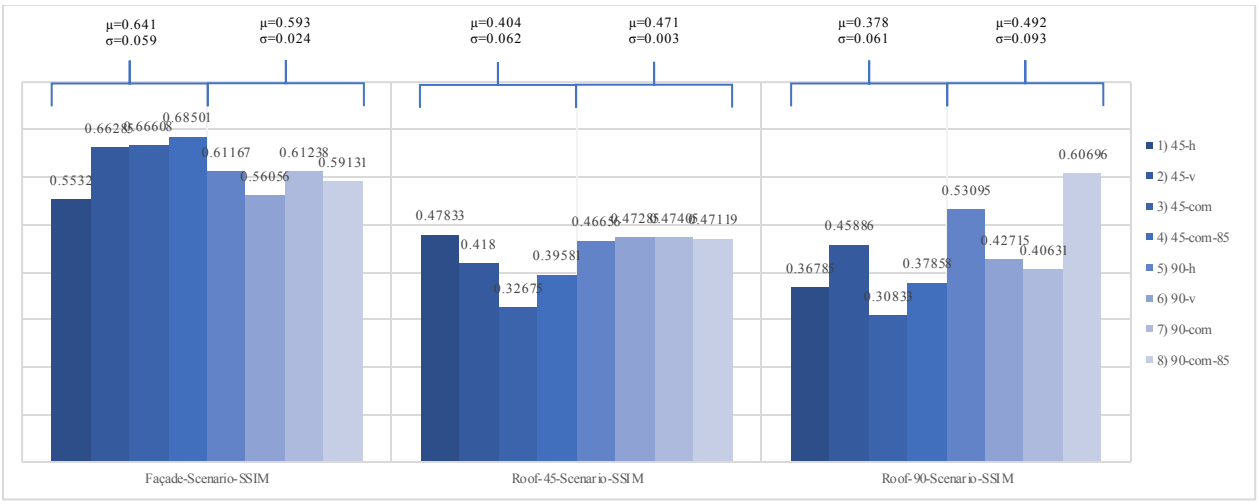


(a) Key points

Figure 5. Statistics of match points, MSE, and SSIM for different flying configurations



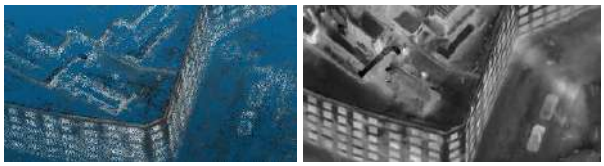
(b) MSE



(c) SSIM

Figure 5. Statistics of match points, MSE, and SSIM for different flying configurations (continued)

Not only can flight angles have an influence on the performance, but also the flight patterns and the image overlaps. According to Figure 5 (b) and (c), mesh grid flight patterns can result in lower MSE and higher SSIM than a monotonous grid which can only have vertical or horizontal lines. However, as for the image overlaps, in this study, higher image overlaps (90 %) not always performed better than lower image overlaps (85%). More thermal images do not contribute to a better reconstruction of a 3D thermal model. Some thermal images cannot be calibrated and matched to each other. Observation in Figure 6 also confirmed this statement. There are holes on the roof system in a point cloud model no matter how much the images overlap. Different types of roof systems have different influences on performance. As the pix4D software manual mentioned, water surfaces, snow, and sand have almost no or little visual content due to its large uniform areas. Roofs of buildings may have versatile color in RGB images but may have monotonous thermal values, which means the color of roofs will be monotonous in thermal images. Those large uniform areas can result in a sparse point cloud model. Shown in Figure 6, there was some equipment on the left roof in Figure 6 (a). Thus, sufficient points could be created. However, less points could be created on the right roof in Figure 6 (a). Figure 6 (b) is a mesh model fitted from a point cloud model.



(a) (b)

Figure 6. Thermal point cloud model and mesh model

5 Conclusions

UAS has been introduced into a great number of research fields. It also has been utilized to capture energy loss from a single building. However, to audit energy loss from a group of buildings in a district and to create a 3D thermal model for infrastructure use are still challenges in terms of the efficiency and performance. Methodologically, different drone flying configurations in terms of flight patterns (vertical grid, horizontal grid and mesh grid), camera angles (90 and 45 degrees), and the percentage of image overlap (90% and 85%) were tested over a group of buildings in a district in this study.

Empirically, a flight camera angle of 90 degrees could capture more details on the roof system, whereas a flight camera angle of 45 degrees is more suitable for capturing details on façades. Also, more images could obtain a perfect 3D model. According to the result in this study, A flight angle of 90 degrees does exceed a flight angle of 45 degrees on roof case, and a flight angle of 45 degrees outperform a flight angle of 90 degrees on façade case in terms of structure similarity performance. As for color rendering, a flight angle of 90 degrees has a disappointing performance in both roof and façade cases. Indeed, mesh flight patterns are suggested over single grid patterns. As for the overlap of images, more thermal images might introduce more outliers. The algorithms can have difficulties in reconstruction. Additionally, no matter how many images are utilized, it is hard to create a 3D thermal model for a flat roof system which has large uniform areas. If both RGB and thermal images can be captured from the same angles and altitude, a detailed 3D model can be created by high resolution RGB images, and thermal textures can then be projected on top of the 3D model. This is the next factor's influence on efficiency and performance 3D Thermal Mapping we plan to explore.

Abstract -

Interest in integrating E-construction in highway construction projects has increased in recent years due to reductions in staffing and resources across Departments of Transportation (DOTs) and initiatives from the Federal Highway Administration (FHWA). Specifically, the addition of e-construction methods offers a boost in efficiency and safety in highway resurfacing jobs. E-ticketing, Paver Mounted Thermal Profiling, and Intelligent Compaction were incorporated on resurfacing projects in the state of Kentucky. Using GPS and GIS technology tied with electronic report-out systems, a fleet tracking system traces haul routes, travel times, and tonnage. The addition of paver mounted thermal profilers that allow for remote monitoring of temperatures, and intelligent compaction offers the ability to monitor roller patterns and track the overall compaction effort. The contribution of this manuscript is to document recent advancements, lessons learned, and evaluate their effectiveness compared to traditional inspection practices. Future work discussed include the possibility of combining these technologies into a singular interface for easier integration into the industry.

Keywords –

E-Construction; E-Ticketing; Paver Mounted Thermal Profiling; Intelligent Compaction

1 Introduction

Ground-breaking technological advancements over the past decades have drastically changed individuals' lives. Today, gadgets such as smart phones, personal computers, and tablets are providing a wide range of services in an economical and efficient manner. Industries around the world have made significant changes to adopt to these technologies to improve efficiency and safety, and reduce operating costs. The highway construction industry in the United States has been slower to adopt technology and thus opportunities to improve efficiency and safety in its operations exist. In addition, the industry is facing staffing reductions both in the field and management levels. The labor force is decreasing partially due to a cultural change of young adults wanting higher education and desiring white-collar jobs. Management staffing is seeing a reduction because people are being pulled by the booming private construction industry. Due to the staffing reductions, DOT personnel are being forced to do more work with fewer resources. A study produced by the National Cooperative Highway Research Program (NCHRP) reported that, "DOTs are managing larger roadway systems with fewer in-house staff than they were 10 years ago. For the 40 DOTs that responded to the survey, between 2000 and 2010 state-managed lane-miles increased by an average of 4.10%, whereas the number of full-time equivalents (FTEs) decreased by 9.68% [1]."

The Federal Highway Administration (FHWA) and Departments of Transportation (DOTs) are looking to incorporate e-Construction practices and advanced technologies into their workforce to improve overall efficiency and reduce workload on the personnel. E-Construction is defined as "The creation, review, approval, distribution, and storage of highway construction documents in a paperless environment [2]." These processes can include electronic submission and approval of documents, and real-time management of documents through electronic devices [2]. E-Construction has been heavily promoted by the FHWA through the Every Day Counts (EDC) model that looks to rapidly deploy proven yet underutilized innovations in the highway construction industry [3]. E-Construction was first promoted in EDC-3 in the year 2013, and since then, many DOTs have collaborated to share their e-Construction practices through webinars and peer exchange reports [2]. The addition of e-Construction and other advanced technologies can help maintain high quality and service in highway construction.

One specific area of the industry that can be drastically improved through the addition of technology is asphalt paving inspections. The collection of delivery tickets, monitoring of pavement temperatures, and

tracking roller operations all fall under this activity, and is typically done by a DOT inspector. This crucial activity that can impact the long term performance of the pavement is often given little attention due to insufficient staffing levels, and the DOT inspectors having to cover multiple projects at once due to the short paving windows. Incorporating technologies such as e-Ticketing, Paver Mounted Thermal Profiling, and Intelligent Compaction can assist the inspectors improve productivity and document project records.

The three technologies discussed herein have been promoted by many DOTs and were recently tested in two pilot projects by the Kentucky Transportation Cabinet. The goal of this manuscript is to document the results, discuss the lessons learned for industry practitioners, and discuss the possibilities of combining these separate technologies into a singular interface for easier use and integration into the industry.

2 Background

Two resurfacing projects in the state of Kentucky were chosen as pilots to evaluate the effectiveness of the technologies. The study was coordinated with the Kentucky Transportation Cabinet (KYTC) District 7's staff to use the technology complimenting the typical duties of the inspectors. Although a typical highway resurfacing job includes many activities such as traffic control, plant operations, milling, paving, striping etc. For simplicity and a better control of the study, the focus is solely on the paving operations which included ticket handling, tracking mat temperatures, and monitoring roller operations. The data collection during the study included ticket receipt and acceptance; tracking theoretical tonnage; monitoring asphalt temperatures behind the paver, in the screed, and in the hopper; and tracking temperatures at breakdown and roller passes. The data collection was completed both through the traditional manner and through the technologies. The traditional manner included collecting data the way that the inspectors would traditionally. Simultaneously, the same data was collected using the technologies that were being tested during the pilots. The results were then compared for accuracy of the technology data, and the time savings that come with incorporating technology.

2.1 Electronic Ticketing (E-Ticketing)

The process of manually collecting delivery tickets from delivery trucks is an outdated practice that exposes the inspectors to many safety hazards. Whether it is walking adjacent to traffic, climbing the side of the trucks to collect the tickets, or working near moving equipment, the inspectors face many safety challenges while conducting this simple task that can easily be computerized. E-ticketing technology exists that can collect the same information electronically allowing for inspections that are safer and more efficient.

E-Ticketing was promoted by the FHWA in the EDC-4 model as an e-Construction method that can be collaborative and mutually beneficial to both the contractor and the DOT [2]. Additionally, the technology was initially successfully incorporated in highway construction by IowaDOT. In 2015, IowaDOT began the transition to have a completely paperless construction management operation to improve efficiency. The agency used GPS and GIS technologies to trace haul routes, report yield tonnages, and record travel times [4]. In 2016, Iowa achieved a major milestone of 100% paperless processes on a construction project [4]. The implementation of e-Ticketing can be a significant time saver, as it can provide a way for the inspectors to track material deliveries remotely from a safe location.

2.2 Paver Mounted Thermal Profiler

Traditionally, highway construction inspectors have used hand-held infrared thermal cameras/guns to ensure proper pavement temperatures and to identify isolated areas in the mats [5]. Paver mounted thermal profilers provide real time tracking of the temperatures of the entire mat. An infrared temperature monitoring system can be installed on the back of the paver capable of providing a continuous record of mat temperatures throughout the project [5].

This technology has been used by DOTs across the country, and Texas was an early adopter. In 2012, TxDOT implemented Pave-IR as a standard test method into its HMA specifications [6]. The current specification requires the contractor to use a "thermal imaging system" as defined in test procedure Tex-244-F in the Standard Specifications for Construction and Maintenance of Highways, Streets, and Bridges [7]. Thermal imaging has also been promoted by the FHWA as a technology to enhance quality control on asphalt pavements [8]. This technology provides a way to track the mat temperatures in real time, on site and remotely, allowing more efficient inspections and the ability to inspect multiple projects concurrently.

2.3 Intelligent Compaction

Intelligent compaction (IC) technology is available to improve quality control during the compaction phase of paving projects. IC rollers are equipped with GPS devices, infrared temperature trackers, accelerometers, and on-board LED screens that display roller movement in real time. These devices track roller movements, temperatures at breakdown, and record the Intelligent Compaction Measurement Values (ICMV) [9]. Currently, two forms of IC rollers are available in the industry. The Original Engineering Manufacture (OEN) is installed

directly from roller vendor's factory, whereas the IC retrofit can be installed on select roller models [9].

From 2008 to 2010, 13 DOTs participated in a FHWA, Transportation Pooled Fund (TPF) study that tested and evaluated IC technologies in multiple field pilots [10]. The results of the study showed that IC can be an effective way to track roller passes, and asphalt surface temperatures [10]. Being able to track the roller passes and temperatures can assist the roller operators to improve uniform compaction of the mat. Additionally, the technology enriches projects records for the DOTs to look at if pavement defects are noticed during the life cycle of the road.

3 Methodology

3.1 E-ticketing

E-ticketing technology works during the construction phase of a project to improve project efficiency and safety by going paperless. For the two pilot projects, EarthWave Technologies based out of Indianapolis, IN were contracted to set up an e-Ticketing system. EarthWave provided GPS transponders for all equipment that was to be used during the projects. All transponders could be tracked on EarthWave's online system called FleetWatcher. Additionally, this interface allowed all parties to view delivery tickets electronically, and view cycle times during operations.

A Geo-Fence called a Static GeoZone around the perimeter of the project site and a smaller Geo-Fence around the paver and haul trucks called a Mobile GeoZone were established by the contractor. When the GPS transponders entered or exited the static GeoZone, the system showed that as the trucks entering or leaving the project site, which could be used to control deliveries and reduce wait times in front of the paver. When the GPS transponders entered or exited the mobile GeoZone, the system showed that as the time at which the load was dumped from the truck into the paver.

Each e-ticket would have the same crucial information that is found on traditional tickets such as: Ticket Number, Ticket Data/Time, Material Name, Cumulative Tons, Net Tons, and Dump Coordinates. All e-Tickets for the project could be accessed on the FleetWatcher website, and in the field through the FleetWatcher app.

Throughout the projects, the traditional tickets were collected by the inspectors, and the ticket information was recorded in the field along with the time it took to retrieve the individual tickets. The same information was then retrieved from FleetWatcher, and the time required for this activity was also recorded. The conventional and the technology information was then compared for data accuracy and time savings.

In addition to measuring the accuracy of the data and time savings, electronic tickets can be used to calculate theoretical tonnages in a more efficient and safe manner. The theoretical tonnage is a crucial calculation that the inspectors perform to estimate the amount of asphalt mix that should be used over a certain paved distance. This value is then compared to the cumulative tons given on the delivery tickets to confirm if the crews are paving according to the specifications, and to ensure that material is not being wasted along the process. The theoretical tonnage calculation is given be Equation 1:

$$Theoretical\ Tonnage(tons) = Mix\ Density\left(\frac{lb.}{sy.in.}\right) \times Pavement\ Thickness(in.) \times \frac{1(sy.)}{9\ (sf.)} \times Pavement\ Width(ft.) \times Pavement\ Length\ (ft.) * \frac{1\ (ton)}{2000(lb.)} \quad (1)$$

In Equation 1, the pavement length is calculated from the dump coordinates on the e-Tickets. To calculate the theoretical tonnage, the distance between a dump location and the starting point, or between two dump locations is estimated using the "measure" tool in Google Earth. This distance is then used in Equation 1, along with the other factors which are found in the specifications to estimate the yield tons for the paved surface. This value can then be compared to the cumulative tons delivered to track project productivity.

3.2 Pave-IR

As mentioned previously, the Pave-IR system provides real time temperature tracking of the entire mat. For the pilots, MOBA Automation installed thermal cameras on the back of the pavers to track the mat temperatures at placement. Unfortunately, due to communication issues between the contractor and the technology vendor, no cameras were placed over the hopper, or the screed to track the temperatures of the dumped load. The installed infrared cameras displayed the mat temperatures in real time on LED screens mounted on the pavers for the crews to look for cold spots and take immediate measures if necessary. Additionally, the thermal recordings of the mat are directly uploaded to a MOBA Cloud, or they are stored on a USB storage drive for remote areas without sufficient cellular signals.

For the study, the mat temperatures at various locations were recorded using a temperature gun periodically throughout the projects. Following project completion, the same thermal recordings were retrieved from the MOBA Cloud, and the manually recorded temperatures were compared to the Pave-IR temperatures to assess the accuracy of the data. This technology allows the inspectors to monitor and inspect paving projects remotely and cover multiple projects at the same time in

an efficient manner. Additionally, this allows the DOTs to review pavement temperatures at a later date if failures are noticed on the road.

3.3 Intelligent Compaction

Prior to the pilot projects, Sitech Solutions were contracted to setup an Intelligent Compaction system for the study. Two breakdown rollers were retrofitted with the Intelligent Compaction technology that could track roller movements, temperatures at breakdowns, and record the ICMV. A LED screen mounted on the roller shows real time tracking of roller passes which can assist the roller operator achieve uniform compaction of the entire mat.

During the pilots, the roller movement and the temperatures at breakdown were tracked periodically by the inspector to ensure proper compaction. The IC system on the roller, recorded the same information electronically and displayed it on Sitech's web-interface called VisionLink. This system displays information such as, temperatures, roller passes, and ICMV on a GIS-based map. Following project completion, manual data and IC data was compared for accuracy. IC provides similar benefits to Pave-IR in that it allows the inspectors to cover multiple projects at once, and it provides continuous project record to review if a failure is noticed in the pavement.

4 Results

4.1 E-ticketing

When comparing the accuracy of the data collected electronically by FleetWatcher to the traditional tickets, it was found that the data aligned perfectly for following categories: Truck Number, Mix Design, Ticket Number, Net Tons, and Cumulative Tons. A small sample of the collected data is shown in Table 1 where the "conventional" data was gathered from physical tickets, and the "technology" data was recorded through FleetWatcher. Although Table 1 shows a small sample of data collected during a single shift of one project, it is representative for all 75 load delivery tickets.

Improving inspector safety was one of the main driving factors behind conducting this study. As mentioned earlier, highway construction inspectors face many hazards while collecting delivery tickets. Activities such as walking adjacent to traffic, climbing the side of dump trucks, and working next to heavy equipment exposes the inspectors to unnecessary risks. The data from the projects shows that the time to acquire the traditional tickets was significantly longer than through FleetWatcher. Additionally, data retrieval through e-ticketing could be done in a safe environment away from the hazards. During this shift, a total of 19 tickets were collected from delivery trucks. It took the inspector approximately 54 minutes to collect the 19 paper tickets. In comparison, the same data was retrieved from FleetWatcher in just 18 minutes. Additionally, the data from FleetWatcher was retrieved in the inspector's truck, which eliminated the hazards from physically collecting paper tickets.

E-Ticketing provides a way to calculate theoretical tonnages in a more safe and efficient manner. It is important to note that the calculated theoretical tons rarely match with the cumulative tons delivered to the project site due to the many errors and uncertainties that are present in construction projects. However, huge differences between the values can indicate that the pavement is too thin, too thick, or material loss along the process. Several theoretical tonnage calculations were performed using the dump coordinates recorded by FleetWatcher, and the information given in the specifications. Table 2 shows the results of the calculations. Many accurate estimations were calculated throughout the study, and the KYTC inspectors assigned to the projects confirmed that the theoretical tonnages calculated followed the trends noticed in the field.

To further investigate differences, a theoretical tonnage was calculated for each load delivery and compared to the values on the ticket. With the

Table 1. Data Alignment, Date: 07/05/2018

corresponding nature of the data, a paired samples t-test will unveil whether there are any statistical differences between the theoretical and actual ticket loads. The results of the paired samples t-test are reported in Table 3. The null hypothesis of a paired samples t-test is that the true mean difference is zero with the alternative hypothesis being that the true mean differences are not zero. The high p-value of 0.768 indicates that the null hypothesis cannot be rejected and that the true mean difference is zero. Practically speaking, there is no significant difference between the theoretical and actual ticket tonnage. Thus, while differences are expected from a variety of error sources, the theoretical tonnage calculation embedded in the e-ticketing software is effective at reporting accurate quantities for these projects.

4.2 Pave-IR

Utilizing Pave-IR proved to be an effective way of tracking pavement temperatures throughout the projects. During the paving operations, it was noticed that the real time display of mat temperatures on the LED screens allowed the crews to quickly patch any cold spots that were noticed. Concerning data accuracy, it was found that the temperatures that were physically collected during the operations using an infrared gun were well aligned with the temperatures recorded using Pave-IR. Figure 1 is a screen shot of the Pave-IR interface that shows a continuous recording of mat temperatures throughout the paving operations. Table 4 provides the field recorded temperatures and the Pave-IR temperatures, and it can be seen that the percent differences between the two methods are almost insignificant. Although the Pave-IR data shown here is a small sample, it is representative of the data collected across the two pilots for the study.

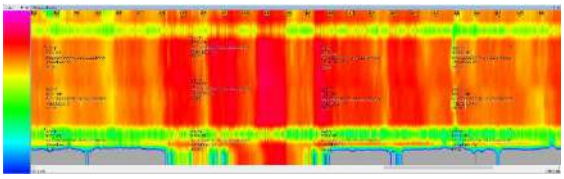

Figure 1. Pave-IR Interface

In addition to data accuracy, retrieving data from Pave-IR was much more efficient and eliminated the need for the inspector to be physically present at the project site. Project records were improved through Pave-IR as well since it provided an electronic cloud storage of the data in comparison to the traditional method where the temperatures were written down in inspector notes.

4.3 Intelligent Compaction

Of the three technologies tested during the study, Intelligent Compaction was the least successful in terms of data accuracy and improving project efficiency. Poor

Table 4. Temperature Alignment, Date: 07/02/2018

Data	Lat.	Long.	Avg. Mat Temp (◦F)	Percent Difference (%)
Conventional	38.403	-84.567	297.33	0.78

communication between the parties lead to no data being collected for one of the pilots. The data that was collected by the IC rollers did not align with the manually recorded data. Figure 2 is a screen shot of the temperature data displayed on VisionLink. It shows that over 95% of the temperatures at breakdown were below 200ºF. Figure 3 shows the manually recorded temperatures at breakdown. It can be seen that the actual temperatures were between 200-250ºF or above 250ºF. The data range on VisionLink was customized to provide a better visual understanding through the screenshot. The average temperature at breakdown captured through IC was approximately 160ºF.

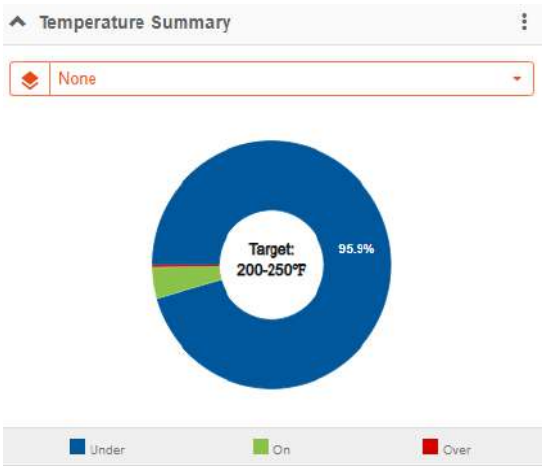

Figure 2. Temperature Summary, VisionLink

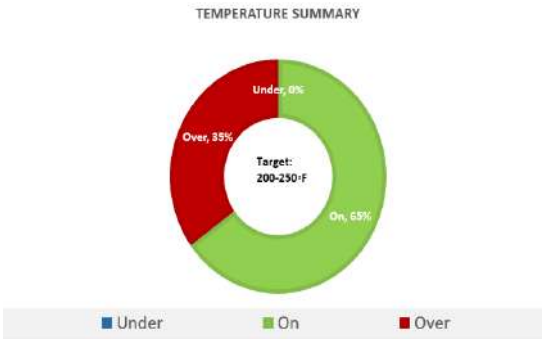

Figure 3. Temperature Summary, Manual

Inconsistent results were also noticed when comparing the roller pass counts between the IC and manually collected data. Figures 4 and 5 respectively show the pass count data as displayed on VisionLink, and the manually recorded pass counts. Similar to the temperatures, the pass counts recorded by IC were also significantly lower than what was noted in the field.

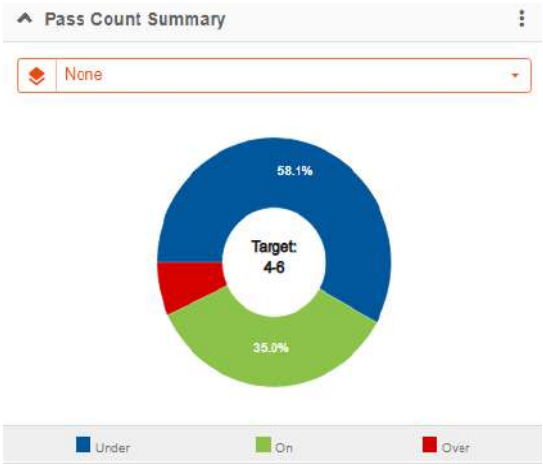

Figure 4. Pass Count Summary, VisionLink

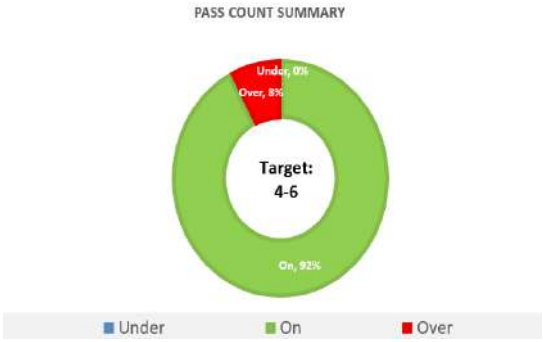

Figure 5. Pass Count Summary, Manual

Although Intelligent Compaction did not perform up to the expectations during this study, it has proved to be useful in other cases. The inconsistent data collected by the technology could have been caused by improper setup of the technology, miscommunication between the parties, and many other uncertainties that are present during construction projects.

5 Lessons Learned

The technologies discussed in this manuscript are still relatively new in the highway construction industry and the case study revealed many important lessons to take away for future use. First thing to note about all three technologies is that the most important step is to ensure that all aspects are setup prior to the project starting. There were many issues encountered throughout the project that showed lack of preparation by both the contractor and the technology vendors.

One major issue encountered with the e-ticketing technology was the setup of the Static GeoZone. As discussed previously, the purpose of this GeoZone was to record the time when the trucks arrived at the project site, in order to reduce wait times. However, the contractor

failed to setup the GeoZone around either of the project sites and therefore no data was recorded in this category. Another crucial issue encountered with e-ticketing was that some of the trucks being used for deliveries did not have GPS transponders installed. Without the GPS transponders, the mobile GeoZone could not be utilized and thus dump times for those trucks were not recorded.

Regarding the paver mounted thermal profiler, the contracts stated that infrared cameras were to be setup on the paver, on top of the hopper, and on top of the screed. However, only the back of the paver cameras were successfully installed for both of the pilots. This was a huge loss for the study because seeing the temperatures in the hopper and screed could be one way to monitor effective workflows and future pavement failures. Further, the technology vendor was unsuccessful in providing access information for the online MOBA interface to the stakeholders prior to project startup, which delayed data analysis.

Finally, Intelligent Compaction had the most issues during the pilot projects. Lack of communication between the parties led to no IC data being collected from one of the pilots. The data that was retrieved was not consistent with the field findings. The contractor played a part in this due to the rushed schedule of the project, and the lack of transparency with the other stakeholders.

In general, most of the issues encountered during this study could have been solved easily through having open communication between the parties. If used properly, these technologies can benefit all stakeholders involved in the projects, but the parties must be willing to collaborate and change their attitudes towards technology to take full advantage of these tools.

6 Future Work

Veta is a standardized software for the use and analysis of Intelligent Compaction and Infrared (IR) technologies. This map-based tool can be used to view and analyze geospatial data that can be imported from IC machines and MOBA, Pave-IR scanners. This software is required in the AASHTO PP81-70 specifications and most DOT IC specifications. Additionally, Veta has been promoted by the pooled fund study TPF-5 (334) "Enhancements to the Intelligent Construction Data Management System (VETA) and Implementation." The goal behind this pooled fund study is to "provide a platform for states to engage in discussions and to share information to assist with moving these technologies to the next levels [11]." The collaboration and funding between 16 DOTs from the pooled fund is continuously enhancing the VETA software for easier implementation into the industry.

Although, this tool provides a great, singular platform to analyze IC and IR data, it has yet to incorporate e-ticketing. Having a fleet tracker and electronic documentation system would allow VETA to be the ideal software for tracking paving projects. Having a singular software that tracks all three technologies, would increase accessibility, and ease of use. The three technologies combined can have a tremendous impact on highway construction projects in the United States by boosting project efficiency and safety of the highway inspectors. Finally, contractors and equipment vendors would be more open to incorporating these technologies if they only have to manage one system rather than three different technologies.

7 Conclusions

According to the comparisons between the manually collected data and the electronic data, the technologies shows great potential in improving the efficiency of paving projects and improving project safety. For e-ticketing, and Pave-IR the results support the accuracy of the data as well as the time savings that come with the incorporation of technology into the work place. Although Intelligent Compaction did not perform up to the expectations for this particular case study, it has been successfully used by other DOTs and has shown great potential in improving project records and efficiency of roller operations.

This manuscript presents the application of three technologies which, if used properly can result in much safer and efficient paving projects. Having a strong and healthy culture of collaborating and partnering would significantly help further implement these technologies in the highway construction industry. E-ticketing can eliminate paper, enhance project records for all stakeholders and maintain safer projects. Pave-IR can increase the life of the pavement by providing instant detection of cold spots during the paving operations and also reducing maintenance costs. Lastly, Intelligent Compaction shows great potential of improving project records, and increasing pavement life by allowing consistent compaction during construction. Combining these technologies into a singular interface where all stakeholders can monitor project progress, and store project records will allow further implementation of technology in highway construction.

As the industry faces personnel reductions and resources, technologies such as the ones discussed here will have to be utilized as they offer a way to maintain quality and service on paving operations.

Abstract –

The development and implementation of risk response strategies contributes to effective risk management processes in construction organizations. Risk response strategies need to be developed and implemented as follows: first, all possible risk responses for each given risk event of a project are identified; next, each risk response is evaluated to determine its effectiveness; then, for each risk event of the project, the optimal risk response is identified and implemented; and finally, the risk events and responses are consistently monitored. The existing literature confirms that there is a lack of research on evaluation criteria for risk responses, making it difficult to determine their effectiveness. This paper presents research that fills this gap by developing a way to evaluate the effectiveness of risk response strategies using a fuzzy rule-based system (FRBS) that consists of three inputs and one output. The inputs of the FRBS are the affordability and the achievability of risk responses and the controllability of risk events; the output is the effectiveness of the risk response. The application of fuzzy ranking methods instead of crisp ranking methods allows the model to mimic three human attitudes towards risk: risk averse, neutral, and risk taking. The proposed model lays the foundation for an automated evaluation of risk response strategies and provides a decision support tool for experts in the field.

Keywords –

Risk management; risk response; fuzzy logic; FRBS

1 Introduction

Risk management is vital for achieving business objectives on construction industry projects. Current trends in the construction industry are towards bigger and more complex projects, which can result in a greater amount of risks and uncertainties [1]. These risks can cause failures in terms of cost overruns, schedule delays, environmental damages, and fatal injuries. In general, risk management processes include identification, qualitative analysis, quantitative analysis, risk response planning, and monitoring and control [2]. First, risk events need to be identified and documented. These risk events should be analyzed by qualitative methods so they can be prioritized based on probability and impact. Next, quantitative risk analysis must be performed to model the combined effects of randomly occurring risk events and to develop a synthesized view of the overall effects of risk events on the project. Then, risk responses should be identified, evaluated, and implemented to mitigate occurrence probability and/or the negative impacts of risk events. Finally, the overall effectiveness of the risk management process needs to be monitored, reviewed, and controlled on a regular basis. The effectiveness of the risk response is the extent to which the risk events' probabilities and/or impacts are reduced as a result of implementing the risk responses.

A large amount of the research on risk management acknowledges the importance of risk response planning [3]. Hillson [4] argues that identifying and analyzing risks and uncertainties is clearly vital for the risk management process, as it is not possible to address risks that are not identified or that are poorly analyzed. Risk response planning is considered an important step for effective risk management; it is a process that is complementary to risk identification and analysis; and without risk response planning, only limited benefits can be had from the risk management process [4]. Risk response strategies need to be developed and implemented as follows: first, all possible risk response strategies for each given risk event of the project are identified. Next, each risk response strategy is evaluated to determine its effectiveness. Then, for each risk event, the optimal risk response strategy is identified and implemented. Finally, the risk events and the response strategies are consistently monitored.

Although some researchers have developed optimization-based methods for selecting an optimal set of risk responses [5], the application of these methods on real projects can be a complex and costly process due to

the effort and amount of data that are required. Moreover, these models account for only a limited number of criteria, namely time, cost, and quality, which can lead to the selection of risk responses that are cost effective but unfeasible in terms of technology, environment, and achievability. Optimization-based approaches have low transparency (i.e., they operate in such a way that it is not easy for others to see what actions are performed) during the process of selecting the optimal set of risk responses. Employing approaches with the ability to address the abovementioned weak points can result in more realistic, applicable, and feasible risk responses—a fuzzy ruled-based system (FRBS) is just such an approach. The existing literature confirms that there is a lack of research on evaluation criteria for risk response strategies, making it difficult to determine their effectiveness. The objectives of this paper are to (1) identify appropriate criteria for evaluating risk responses; (2) develop an FRBS to determine the effectiveness of risk responses; and (3) develop a fuzzy ranking method for selecting the most effective risk responses.

This paper is organized as follows. First, a brief literature review of risk management and risk response planning in construction projects is presented, followed by a discussion about the application of fuzzy logic methods in the risk management process. Second, evaluation criteria for risk responses are identified and an FRBS is developed for determining the effectiveness of risk responses; a fuzzy ranking method is then applied to rank the risk responses based on their effectiveness (determined by the FRBS) on construction projects. Third, a hypothetical example is provided to illustrate the proposed framework. Finally, conclusions are presented and future extensions of the current research are discussed.

2 Overview of Risk Response Evaluation and Selection Approaches

Risk response planning involves reducing the negative impact and probability of occurrence of risk events to ensure project success. Identified risk responses need to be evaluated, and the optimal risk response needs to be implemented for each risk event. Several researchers have developed decision support systems for evaluating and selecting risk responses using different approaches, including the trade-off approach [4, 6, 7], the zonal-based approach [8, 9], mathematical modeling and optimization [5, 3, 10–13], and a combination of these approaches and fuzzy logic [14].

The trade-off approach makes trade-offs between parameters—such as cost, time, and quality—that are either risk event-related or risk response-related in order to evaluate a set of risks. Kujawski [6] makes trade-offs that account for a project's objective requirements and project stakeholders' subjective preferences. Risk responses are selected based on the cost of implementing each risk response compared with the probability of project success when the risk response is implemented. Hillson [4] argues that the effectiveness of proposed risk responses must be assessed based on appropriateness (i.e., the correct level of risk response according to the severity of the risk event, ranging from a crisis response to a "do nothing" response), affordability (i.e., the cost effectiveness of the risk response), achievability (i.e., how realistically achievable or feasible the risk response is, either technically or in terms of a respondent's capability and authority), agreement (i.e., the consensus and commitment of stakeholders), and allocation (i.e., the responsibility of and accountability for implementing the risk response). Qazi et al. [7] develop a model for selecting a set of optimal risk responses by measuring the impacts of different combinations of risk responses on the objective function of a project. In zonal-based approaches, two-dimensional diagrams are applied to assess the regions of the risk responses using one of two common assessment tools: (1) a matrix that features different factors in a two-dimensional diagram and (2) a two-axis graph that maps risk responses based on the values of the two dimensions.

Using an optimization-based approach, Fan et al. [5] suggest a model for assessing the effectiveness of risk responses based on three criteria: risk event controllability, risk response costs, and project characteristics. Kayis et al. [10] employ five heuristic algorithms to minimize the cost of implementation within the constraints of the implementation budget and acceptable risk effects for new product development. Zhang and Fan [11] maximize the sum of estimated risk response effects (i.e., they reduce the expected loss of the risk event) after risk response strategy implementation using a method for selecting risk responses with an integer linear programming (ILP) model. Zhang [12] uses an ILP model that accounts for the cost of implementation and the determined budget for risk responses. Wu et al. [13] propose a multi-objective decision-making model for the selection of risk responses that minimize total expected losses, total expected schedule delays, and total expected quality reduction. An optimization model is used to minimize expected time loss, expected cost loss, and expected quality loss. To calculate the coefficients of the objective function, a fuzzy analytic hierarchy process (FAHP) is employed as a technique to guide the risk analysts [14].

3 Developing the Risk Response Evaluation and Selection Approach

In order to develop the proposed FRBS for the evaluation of risk responses, appropriate evaluation

criteria are identified, which are the inputs of the FRBS. The output of the FRBS is the effectiveness of the risk responses. Based on the output of the FRBS, the risk responses are then ranked using a fuzzy ranking method that allows the model to mimic the three human attitudes towards risk: risk averse, neutral, and risk taking.

3.1 Evaluating Risk Responses: Identifying Inputs and Outputs

This study uses three criteria to evaluate risk responses: affordability of the risk response, achievability of the risk response, and controllability of risk events. These criteria make up the three inputs of the FRBS, and its output is the effectiveness of the risk response strategy. There is a positive correlation between the controllability of a risk event and the effectiveness of its risk response. For example, even if you implement a risk response with high affordability and high achievability, the risk response will not be effective in addressing a risk event with low controllability. Therefore, the FRBS developed for the evaluation of risk responses needs to evaluate both risk events and their identified risk responses in order to identify the most effective risk responses. Subjective system variables (evaluation criteria) are represented by triangular fuzzy membership functions, which are commonly used in engineering applications.

Affordability refers to the cost-effectiveness of risk responses, where the amount of time, effort, and money spent on addressing a risk should not exceed the available resources for implementing risk responses. One way to measure the cost-effectiveness of risk responses is to use the risk reduction leverage (RRL) factor, which can be calculated by converting the impact of the risk event into a monetary value (for example, the cost of delay and/or the cost of negative impacts on quality) [4]. RRL represents the ratio of the increase in risk event exposure to the cost of risk response implementation. RRL can be calculated by dividing the difference between the risk responses' cost impacts before and after implementation by the implementation cost (see Equation (1)) [4].

$$RRL = \frac{(\text{Cost Impact})_{\substack{before \\ response}} - (\text{Cost Impact})_{\substack{after \\ response}}}{\text{Cost of response}} \quad (1)$$

Hillson [4] proposes that responses with high effectiveness in terms of affordability should have RRL values above 20. Responses with medium effectiveness have RRL values ranging from 1 to 20, and RRL values of less than 1 can be labelled as having low effectiveness (i.e., they are ineffective) because their implementation cost is more than what they might save later. Thus, the fuzzy membership functions for affordability are defined as low (less than 1), medium (between 1 and 20), and high (more than 20).

Achievability refers to the feasibility of a risk response in terms of three considerations: the technical complexity of the proposed risk response, the capability of the respondent, and the authority of respondent [4]. According to Fan et al. [5], the complexity of a risk response may stem from technical obstacles, political obstacles, limited access to information, or conflict resolution obstacles. Three fuzzy membership functions of achievability can be defined, namely low, medium, and high achievability.

Miller and Lessard [15] define *controllability* as the likelihood that the probability of occurrence of a risk event can be changed. This criterion describes the nature of the risk situation. Risk events with a low degree of controllability include occurrences such as natural disasters, while risk events with a high degree of controllability are caused by scheduling and budget problems. The latter can be addressed more effectively than the former by implementing an identified risk response [5]. Although the controllability value of a risk event is the same for all of its related risk responses, this criterion can be used to ascertain whether risk responses meet the threshold for effectiveness, which can be determined by risk decision makers. As with affordability and achievability, controllability can be categorized into three fuzzy membership functions, namely low, medium, and high.

3.2 Evaluating Risk Responses Using an FRBS

An FRBS is a methodology for modeling human logical thinking and decision-making. These systems use membership functions and fuzzy rules to make a decision [16]. An FRBS can be developed with either data or expert judgments using one of the few approaches proposed in the literature. Fuzzy c-means (FCM) clustering can be employed when there is access to historical data [17]. Expert judgments can be applied to develop an FRBS when historical data is unavailable [18, 19]. In this paper, the FRBS for the evaluation of risk responses is developed using expert judgments. The membership functions of three inputs and one output are determined based on documented literature using MATLAB® R2018b.

In this paper, a Mamdani fuzzy inference system is used to develop an FRBS for the evaluation of risk responses; by delivering fuzzy outputs, the Mamdani inference system facilitates the use of different defuzzification methods for fuzzy ranking. The membership functions of affordability are determined by RRL values between 0 and 20 as recommended by Hillson [4]. Figure 1 shows the membership functions of affordability.

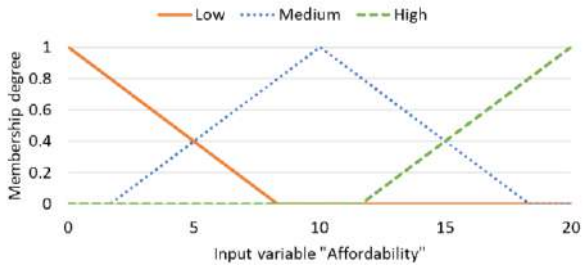

Figure 1. Membership functions of affordability

For the achievability and controllability membership functions, the three linguistic terms *low*, *medium*, and *high* are used, as illustrated in Figure 2 and Figure 3, respectively.

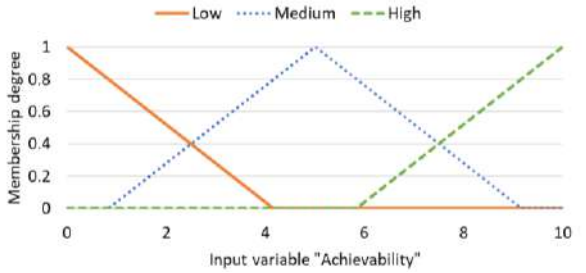

Figure 2. Membership functions of achievability

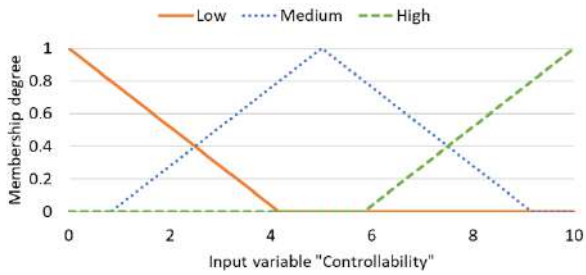

Figure 3. Membership functions of controllability

The membership function of the FRBS output (effectiveness) is also between 0 and 1, as shown in Figure 4.

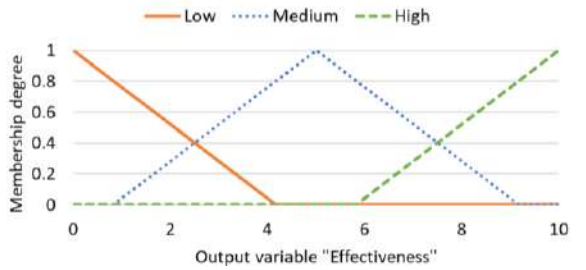

Figure 4. Membership functions of effectiveness

Fuzzy rules are defined as "if-then" rules. In this system, 27 if-then fuzzy rules are defined. Some of these rules are presented in Table 1.

Table 1. Fuzzy rules used in the FRBS

Rule	If			Then
	Affordability	Achievability	Controllability	Effectiveness
1	Low	Low	Low	Low
2	Low	Low	Medium	Low
3	Medium	Medium	Medium	Medium
4	Low	Medium	Medium	Medium
5	High	High	High	High
6	Medium	High	High	High

Figure 5 shows the three-dimensional curve that represents the mapping from inputs to output and the dependency of effectiveness on controllability and affordability.

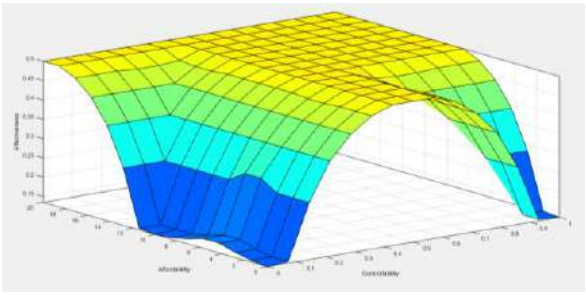

Figure 5. Three-dimensional representation of the proposed FRBS

3.3 Selecting Effective Risk Responses Using the Fuzzy Ranking Method

In the next step, the risk responses need to be ranked based on their effectiveness, so that the most effective risk response can be selected for each risk event. In order to solve decision-making problems, fuzzy ranking methods are commonly used, wherein the evaluation scores (i.e., effectiveness) of decision alternatives (i.e., risk responses) are represented by fuzzy membership functions [20, 21]. There are various fuzzy ranking methods discussed in the literature, the majority of which can be grouped into three categories based on the approaches they use to rank fuzzy numbers. The first category of fuzzy ranking methods includes those methods that rank fuzzy numbers based on their α-cuts at a pre-specified level of α [22]; thus, these methods change the fuzzy ranking problem into an interval ranking problem. The second category of fuzzy ranking methods includes those methods that use fuzzy distance measures to rank fuzzy numbers [23]. The third category

of fuzzy ranking methods includes those that rank the fuzzy numbers based on their defuzzified values [21]; these methods change the fuzzy ranking problem into a simple problem of ranking crisp numbers. The first two categories of fuzzy ranking methods (i.e., α-cut-based methods and fuzzy distance-based methods) usually require that fuzzy numbers be regularly shaped (e.g., triangular or trapezoidal fuzzy numbers) [21]. However, in this paper, the output of the FRBS (i.e., the effectiveness of the risk responses) is an irregularly shaped fuzzy membership function. Therefore, in this paper, the third category of fuzzy ranking methods (i.e., ranking methods based on the defuzzified value) is used to rank risk responses based on their effectiveness. To do this, the results of the FRBS need to be defuzzified. There are various defuzzification methods proposed in the literature; the smallest of maximum (SOM), largest of maximum (LOM), and center of area (COA) methods are commonly used in different engineering applications of fuzzy logic. Figure 6 presents the three aforementioned defuzzification methods implemented on a hypothetical example of risk response effectiveness. Moreover, Figure 6 also shows how different defuzzification methods can result in different defuzzified values for risk response effectiveness.

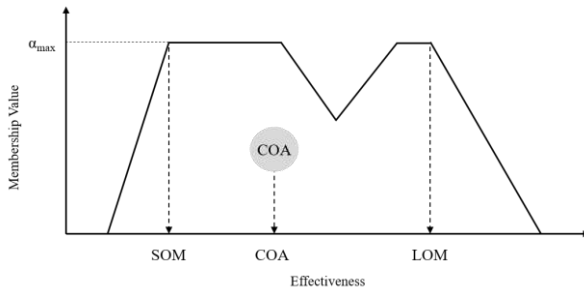

Figure 6. COA, SOM, and LOM defuzzification methods

When ranking risk responses based on the defuzzified value of their effectiveness, the use of different defuzzification methods can mimic different human attitudes towards risk. Ranking risk responses based on the results of the SOM method means that the decision maker considers the smallest maximum value of effectiveness for each risk response and ignores all other possible values for the effectiveness of the risk response (see Figure 6). Thus, ranking risk responses based on the results of the SOM method mimics a risk-averse attitude. In contrast, ranking the risk responses based on the results of the LOM method means that the decision maker considers the largest maximum value of effectiveness for each risk response and ignores all other possible values for the effectiveness of the risk response (see Figure 6). Thus, ranking the risk responses based on the results of the LOM method mimics a risk-taking attitude. The COA, on the other hand, determines the defuzzified value of effectiveness by taking into consideration all possible values of effectiveness for each risk response. Accordingly, ranking risk responses based on the results of the COA method mimics a neutral human attitude towards risk. In this paper, the three aforementioned defuzzification methods (i.e., SOM, LOM, and COA) are used to rank risk responses based on their effectiveness so that all three human attitudes towards risk can be mimicked in the selection of the most effective risk responses.

4 Hypothetical Example

In this section, a hypothetical example is presented to demonstrate how to use the proposed approach to evaluate the effectiveness of risk responses and select the most effective. Assume two risk events: (1) incomplete design and (2) operation interruption due to adverse weather conditions. The first risk event can be addressed by two possible risk responses: (1-1) outsourcing design to subcontractors or (1-2) employing professional design teams. To mitigate the second risk event, two risk responses are possible: (2-1) schedule compression using extra resources or (2-2) considering alternative construction methods, such as using precast materials. A number between 0 and 10 represents achievability (where 10 is high) and another number between 0 and 10 represents controllability (again, 10 is high); these numbers are determined for each risk response by expert judgment. The values for each criterion can be found in Table 2.

Table 2. The input values of each risk response and its related risk event

Risk Event	Risk Response	Affordability (RRL)	Achievability	Controllability
1	1-1	7.00	9.00	6.00
	1-2	12.00	5.00	6.00
2	2-1	7.00	6.00	2.00
	2-2	5.00	3.00	2.00

Since this hypothetical example is presented simply for illustrating the proposed approach, a limited number of risk factors are identified for risk response evaluation. In a real construction case study, a comprehensive list of risk factors such as environmental and safety risk factors may be considered for risk response evaluation. Table 3 shows the effectiveness values, which are based on the information in Table 2. The inputs are imported to the FRBS to evaluate the effectiveness of the risk responses. Crisp numbers representing the effectiveness of the risk responses are then predicted by the FRBS using three defuzzification methods (i.e., SOM, LOM, and COA) as discussed in Section 3.3 and the risk responses are ranked accordingly. Table 3 presents the effectiveness of the risk responses and their rankings for the two risk events.

Table 3. The effectiveness values of each risk response and its related risk event

Risk Response	Effectiveness					
	(SOM)	Rank	(LOM)	Rank	(COA)	Rank
1-1	8.50	1	10.00	1	6.95	1
1-2	4.10	2	6.00	2	5.00	2
2-1	0.00	-	2.00	2	3.74	2
2-2	0.00	-	2.50	1	3.92	1

Table 3 presents the most effective risk response for each of the two risk events as determined by three different defuzzification methods. The effectiveness value determined using the SOM defuzzification method mimics a risk-averse attitude; the LOM defuzzification method mimics a risk-taking attitude; and the COA defuzzification method mimics a neutral attitude towards risk. Although in this case study the rankings of the risk responses are similar for each of the three defuzzification methods, on real construction projects with numerous risk responses, rankings can be different for different defuzzification methods. Since higher effectiveness of risk responses is favorable, in the hypothetical example, risk responses 1-1 and 2-2 should be selected for risk events 1 and 2, respectively. As shown in Table 3, the values of effectiveness for risk responses 2-1 and 2-2 are equal to zero, which indicates neither of these two risk responses should be applied to risk event 2 if the risk response strategy is based on a risk-averse attitude. Moreover, as discussed in Section 3.1, risk responses can be rejected if their effectiveness is less than a threshold value that is determined by the decision maker. For instance, assuming an effectiveness value of 5 as the threshold for the risk responses' effectiveness, both risk responses for the second risk event (i.e., 2-1 and 2-2) are not acceptable in this case study (refer to Table 3). In this situation, new risk responses should be identified for the second risk event or its adverse effects on the project should be accepted.

5 Conclusions and Future Research

This paper presents a methodology for evaluating the effectiveness of identified risk responses by applying an FRBS that has three inputs as evaluation criteria and that produces the effectiveness of risk responses as an output.

The three inputs are the affordability of each risk response, the achievability of each risk response, and the controllability of related risk events. The FRBS uses the estimated crisp values of affordability, achievability, and controllability to evaluate the effectiveness of risk responses according to the rules developed based on experts' opinions. The output, which is a fuzzy set, is used as an input for three different fuzzy ranking methods, one based on SOM, one based on LOM, and one based on COG (COA), to determine the most effective risk response in terms of affordability, achievability, and controllability. Applying an expert-driven FRBS and fuzzy ranking methods can help automate the evaluation of risk response strategies, and this technique delivers an expert-level risk management tool to a non-expert in the field. The contributions of this paper are threefold: first, the appropriate criteria for evaluating risk responses are identified from the literature; second, an FRBS is developed to automate the evaluation of risk responses; and third, the application of different fuzzy ranking methods is proposed to mimic the risk-taking attitude of experts for risk response evaluation.

On construction projects, risk events are often dependent on one another; for example, the risk of precipitation is linked to the risk of excessive soil moisture in earthmoving operations. In order to develop a comprehensive risk response planning tool, interdependencies between different risk events need to be taken into consideration. In future research, the FRBS developed in this paper will be extended to capture these interdependencies and determine the most effective risk responses for each risk event, accounting for all risk events that affect a project throughout its life cycle.

Abstract –

Statistical reports point to the fact that civil infrastructure projects remain hazardous working environments. Despite the implementation of various safety procedures, the frequency and cost of work-related injuries are significant. Improvements in sensor technologies, wireless communication and processing power of computers as well as advancements in machine learning and computer vision are now enabling data-driven systems as effective safety barriers for accident prevention. In recent years, many researchers have studied various methods of leveraging technology to improve safety in civil infrastructure projects. However, previous investigations have not produced a thorough analysis of the practicality of those approaches. While considerable progress has been made in developing methods to improve construction safety, few studies have focused on implementation of data-driven real-time accident prevention systems to effectively minimize risk in the event where other safety measures have failed or been absent. Motivated to facilitate the development of such method, this paper carries out thorough analysis of the field and its trends, identifies research gaps, provides a discussion of recent advancements, and highlights future research directions to help researchers gain an up-to-date overview of the state-of-the-art and navigate through this domain efficiently.

1 Introduction

Around 15% of occupational fatal accidents have occurred on construction sites across Australia, where construction only accounts for 5% of the workforce [1]. In the same year, United States construction fatalities alone amounted to 991 lives lost [2]. In the past decades, research on safety climate and culture, worker-oriented safety, safety management programs, hazard recognition and risk assessment, and applications of information technology in construction safety has led to improvements in overall safety performance [3]. However, the number of fatal and non-fatal accident injuries still remain significantly high in the construction industry.

Recent advancements in machine learning, computer vision, and increased affordability and processing power of advanced technologies have prompted researchers to work towards the development of data-driven accident prevention systems, adding a technology-driven safety layer to construction sites.

Given that safety is an ongoing issue on the construction site, the development of continuous safety monitoring systems has great potential to improve safety risk management. As described by Australia's Work Health and Safety Act (WHS), the risk management process involves identification hazards, assessing risks, controlling risks, and reviewing control measures [4], [5].

This paper provides a review of recent developments of data-driven accident prevention systems designed to improve construction safety. It reveals the trend of technologies and approaches being used, and discusses their potential applications, and identifies future research directions. As such, it can be used as a guide for researchers interested in this particular domain to study an up-to-date account of state-of-the-art research.

2 Review methodology

A methodological approach is employed to conduct a comprehensive review. Scopus was selected as the

database for the search, and the keywords such as construction safety management, machine learning, computer vision, sensors, information and communication technology, building information modeling and so on, were used for the initial search. The returned results are screened based on their title and abstract, and out of 982 documents, 118 were found to be relevant. To ensure a more comprehensive and thorough search, an explorative search was also carried out, leading to an additional 125 documents found, amounting to a database of 243 journal articles in total. Section 3 provides an overview of the selected articles, and critical review of the most relevant papers is carried out in section 4 of this study.

3 Analysis of the domain

The database of the selected papers cover articles published from 2006 to 2018. The number of relevant papers did not exceed 6 before the year 2012. In the past few years, however, the number of publications have risen significantly, due to increased interest in using sensor technologies and vision-based systems, wherein 2018 it nearly doubles to 78 publications. The analysis reveals that the United States, China, and South Korea are the top three countries contributing to the domain. Figure 1 shows the distribution of selected articles by year and country of affiliation.

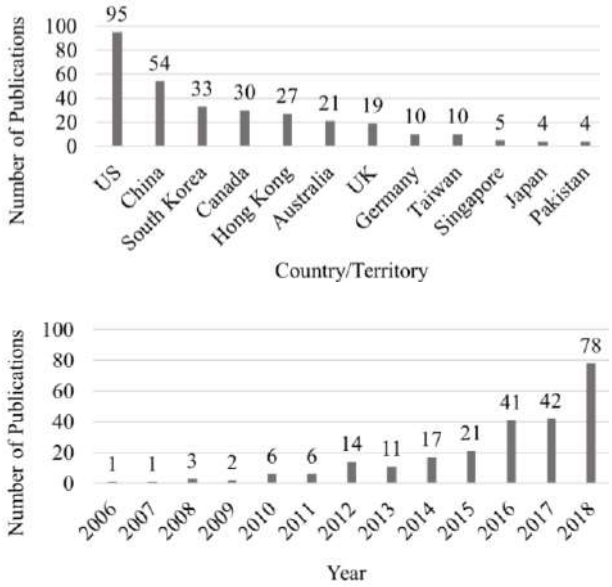

Figure 1. Distribution of articles by publication time, and country of affiliation

Table 1. Journals and the number of corresponding articles

Journal	Number of Appearances
Automation in Construction	93
Advanced Engineering Informatics	23
Journal of Computing in Civil Engineering	21
Journal Of Construction Engineering And Management	17
Safety Science	16
Visualization in Engineering	12
Sensors (Switzerland)	6
Engineering Construction And Architectural Management	4
Journal Of Management In Engineering	4

The selected studies include publications from more than 35 different journals. Table 1 lists the journals publishing more than four papers within the selected list of articles. Not surprisingly, Automation in Construction has contributed the most to this domain, with more than 38% of the papers being published in this journal. Other relevant journals include Advanced Engineering Informatics, Journal of Computing in Civil Engineering, Journal of Construction Engineering and Management, and Safety Sciences, each representing more than 15 papers in the selected database.

Based on the database of selected articles, co-publication of authors are analyzed using Gephi, an open source graph and network analysis software [6]. Figure 2 shows the network of the most prominent scholars, active in the domain.

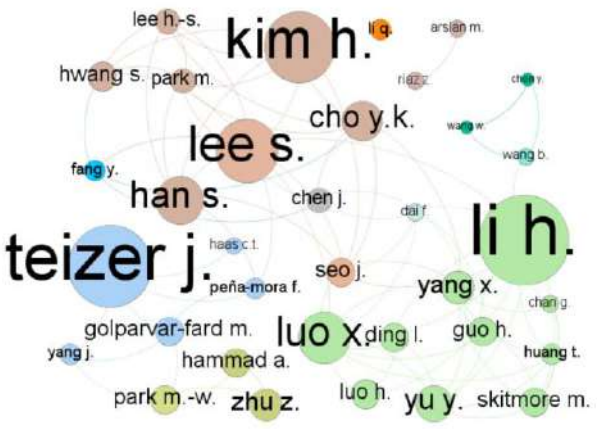

Figure 2. Network of the most influential scholars in the domain

4 Data-driven safety risk management

This section provides an overview of latest developments in data-driven accident prevention systems and discusses their relation to various steps of safety risk management as described by Australia's Work Health and Safety Act (WHS) [4], [7]. The following subsections cover the impact of such systems on identification of hazards, assessing risks, controlling risks and reviewing control measures.

4.1 Hazard identification

Hazard identification is the process of finding entities or situations that have the potential of causing harm. Developing data-driven systems for real-time hazard identification is a crucial step towards intelligent safety management. Three different approaches to hazard identification are discussed in this section. First, an indirect approach, which attempts to identify hazards by analyzing data from the construction site for anomalies that may be suggestive of an existing hazard. Second, identifying hazards as they directly relate to workers' behavior. And the last approach is to monitor the workplace for specific anticipated hazards.

4.1.1 Indirect hazard identification

Considering the dynamic nature of a construction site, regular safety inspections need to be carried out to ensure a hazard-free work environment. However, since inspections are often manually performed, it is not uncommon for newly appeared hazards to remain unidentified for a prolonged period of time, exposing workers of the site to risks of trip, fall, struck by falling objects, electrocution or other accidents. Continuous monitoring of the site can therefore immensely facilitate safety management. An innovative approach to automatically identify hazardous areas has been proposed by Kim et al. [8]. In this study, a real-time tracking system is used to identify potentially hazardous areas by comparing workers' actual path to their optimal routes. Location tracking is performed using an RFID-based Real-Time Location Tracking System (RTLS), where RFID tags are mounted on workers' hardhats. Upon testing the framework in a case study, it was found that 80% of the identified hazards by the system corresponded to real hazards such as material piles, openings, areas with inadequate electric wire protection, and areas with a lack of falling object protection.

Although RFID technology is used in various industries for tracking some entities, the rapidly changing nature of the construction sites and their complexity make effective use of RFID very challenging. RFID requires a direct line of sight for optimum accuracy, which is a condition hard to realize in construction. In addition, it requires installation of multiple tags and receivers which limit its practicality [9].

Ultra-wideband (UWB) is another radio frequency-based technology used for location tracking. UWB uses high-bandwidth radio pulses for communication, which makes it less susceptible to signal interferences. However, it still requires installation and maintenance of multiple tags and receivers [10].

Global Positioning System (GPS) has also been widely used to track workers' trajectories in construction sites in order to improve safety. For instance, Arslan et al. [11] demonstrated a prototype of a GPS-based system for identifying stay points, the intersection of multiple trajectories, and classifying the trajectory into running or walking. Such semantic enrichment of data using various data mining and machine learning techniques helps improve the decision-making process by providing insight on workers' behavior.

Vision-based systems as an alternative to other methods for tracking various entities on construction sites has recently attracted researchers' attention. Although still in early stages of development, vision-based systems have the advantage of not requiring installation of multiple tags, have lower costs, and are easier to maintain.

Park et al. [12] propose a vision-based method that uses videos obtained from ordinary 2D cameras, and employs detection and tracking algorithms in a hybrid system for tracking entities. However, the method is limited to tracking workers across video frames, and is unable to produce trajectories with respect to the workplace.

In another study, Konstantinou et al. [13] developed a framework for obtaining 3D trajectories using multiple camera views. The proposed method uses three sequentially activated matching techniques. The output of a 2D tracking method is first checked using a motion matching technique, followed by a geometry matching, and finally a template matching technique. In any step if a match is found, further checking is terminated, therefore significantly reducing the required computational power.

In a comparative study, Xiao et al. [14] evaluated the performance of a number of 2D vision-based tracking methods employed in the context of construction. Their study showed that although vision-based systems have promising potentials, many challenges such as occlusion, clutter, illumination, and scale variation need to be tackled for practical deployment of such systems.

Another innovative approach for identifying potential hazards based on real-time information obtained from construction site was proposed by Yang et al. [15]. They propose using wearable Inertial Measurement Unit sensors to analyze workers' gait abnormalities to identify potential fall hazards. In their experiment, subjects were asked to walk across a steel beam in a controlled

environment. There were two hazards placed along the beam, a slippery surface, and an obstacle. Upon analysis of data obtained from multiple subjects, it was found that the correlation between collective gait abnormality and presence of a hazard is significant. However, this study was limited to one dimension only. The extension of such method to two or three dimensions by taking advantage of location tracking methods as discussed above would provide valuable information that could be used for effective real-time hazard identification. Moreover, such spatio-temporal data enriched with information about gait pattern, activity, etc. can be used for further analysis.

4.1.2 Behavior-related accident precursors

Construction accidents are often directly related to the worker's behavior. In an investigation of identifying the root causes of accidents, Abdelhamid et al. [16] explained that accidents occur either due to the failure of workers in identifying hazards, workers deciding to proceed despite identification of hazardous condition or workers deciding to act unsafely regardless of work condition.

Real-time safety monitoring systems have great potential to be used as supplementary tools for safety supervision. Workers' disregard of hazards often manifests itself in lack of adequate personal protective equipment usage. Recent advancements in computer vision and machine learning provide powerful tools for object detection using images. For instance, Park et al. [17] used Histogram of Oriented Gradients along with Support Vector Machines to detect human bodies and hardhats, and by matching geometric and spatial relationship of the two, identify cases where the person is not using a hardhat.

Fang et al. [18] developed a method for monitoring appropriate usage of harness, anchoring and hardhats by steeplejacks. In the proposed method, cameras are installed inside the rooms and facing the windows where steeplejacks are to perform the aerial work on exterior walls. They use the Single Shot MultiBox Detector (SSD) algorithm, which uses Convolutional Neural Networks (CNNs), and reported precision and recall rates of higher than 90%.

In a similar study, Fang et al. [19] used Faster R-CNN, and a deep CNN model to identify workers not wearing a safety harness when working at height. Using automated safety inspections, safety managers can be notified of unsafe behaviors, and take appropriate action to mitigate the risks in a timely manner.

A different approach of identifying unsafe behaviors was proposed by Guo et al. [20] whereby they used depth cameras to identify various postures related to unsafe behavior. Various body angles obtained from the skeleton-based posture information are compared to an unsafe behavior database in order to identify postures that are suggestive of unsafe actions, such as jumping over a guardrail or dumping construction waste from higher levels.

Other forms of unsafe behavior leading to hazardous conditions include working under the influence of drugs or alcohol, working under a high level of fatigue or attempting a hazardous task with low relevant skill level. One example is the loss of balance possibly induced by the aforementioned factors. To address this issue, Umer et al. [21] developed a balance monitoring tool that uses wearable Inertia Measurement Units (IMUs) and fuzzy set theory to determine workers' balance performance by taking 20-second tests at different times of the day.

Monitoring physiological condition of workers using Physiological Status Monitors (PSMs) has also been explored [22]. Using these methods, metrics such as heart rate and breathing rate can be monitored, providing valuable information for identifying unsafe working conditions as they arise.

High levels of stress induced by schedule pressure or other factors may cause workers to act unsafely in certain conditions. Therefore, it is essential to provide a work environment, which is free of stress-producing conditions.

4.1.3 Workplace-related accident precursors

Certain hazards can be identified by monitoring the workplace for specific accident precursors. One example is site congestion. Congested working areas are more prone to accidents. Location tracking systems as discussed in section 4.1.1 can enable workplace analysis in terms of congestion. Zhang et al. [23] used GPS sensors attached to workers' hardhats to track their activity while working on cast-in-place concrete columns. The workspaces were then visualized in a BIM platform to identify conflicts among other work-zones or material handling paths.

Environmental factors of the site such as temperature, noise level, and pollutants are important workplace hazards that require constant monitoring. For instance, Riaz et al. [24] have proposed using wireless sensor networks for monitoring workplace temperature conditions, and integrating the system with a BIM platform for enhanced work and safety management.

Temporary structures on construction sites are another aspect requiring a thorough inspection to ensure all safety requirements are met. Safety inspection of scaffolds, for instance, is performed visually by the inspector and is a labor-intensive process. Cho et al. [25] proposed a system for real-time safety monitoring of the structure using strain sensors mounted on the scaffolds. With the aid of Finite Element Method (FEM) analysis, they develop a machine learning model to classify various states of the scaffolds such as over-loading, uneven settlement, and over-turning based on the data

obtained from the strain sensors.

Vision-based systems also have the potential to be used as an effective monitoring method to ensure worksite safety. Kolar et al. [26] explored using transfer learning and CNN-based models for detecting guardrails in images. Furthermore, an improved version of Faster R-CNN can be used for detecting workers and equipment in images of civil infrastructure projects [27].

Often in construction sites, workers are required to perform their task alongside heavy equipment in a shared working area and therefore are exposed to high risk of struck-by accidents. Developing proactive real-time alarm systems are another active area of research. In a recent study, Soltani et al. [28] developed a method, fusing computer vision based systems with real-time location systems to estimate the poses of excavators in three dimensions, using surveillance cameras installed on the construction sites as stereo-cameras.

Understanding task-specific accident precursors, and defining quantitative metrics for evaluation of unsafe behaviors or conditions will facilitate the development of effective real-time monitoring systems.

4.2 Risk Assessment

Assessing risks associated with the identified hazards requires consideration of how severe the consequences are if someone is exposed to the hazard, and how likely it is to occur. Data-driven systems facilitate the process of risk assessment and reduce the bias caused by the subjectivity of the analysis.

The context in which hazards appear and the co-occurrence of various hazards determine the severity and likelihood of risks. For instance, in the case of struck-by accidents, heavy equipment approaching a worker in a congested working area is more likely to cause an accident than one approaching worker spacious area. Similarly, the close proximity of a worker and equipment is more indicative of high risk if the worker is standing in the blind spot of the equipment. Seo et al. [29] developed a method to monitor struck-by accidents using computer vision. They propose using fuzzy inference for determining the safety level, based on risk factors such as congestion and proximity.

Evaluating safety and health risks associated with a given task is another important part of safety management. A number of studies have focused on methods of performing ergonomic analysis in a minimally intrusive way. The rapidly changing and complex nature of construction make reliable ergonomic assessment challenging. To address this issue, researchers have developed data-driven systems to quantitatively perform ergonomic risk analysis [30]. The outcome of such systems can be used to improve safety training, planning, and task design.

For instance, insole pressure sensors have been used to detect and classify awkward working postures. In a study, Nath et al. [31], using accelerometer and gyroscope sensors built-in in smartphones, and machine learning algorithms estimated duration and frequency of various activities. And by doing so evaluated the overexertion risk level associated with the task.

Vision-based systems have also been used to perform ergonomic risk assessment using posture analysis based on body angles. Golabchi et al. [32] proposed a framework for data collection, analysis, and visualization to facilitate ergonomic analysis. Vision-based techniques that utilize CNNs, to estimate 3D skeleton of the subject from 2D images for ergonomic assessment have also been reported.

Risk assessment is a crucial step in safety risk management. Therefore, development of effective automated safety monitoring systems requires the integration of data-driven risk assessment systems into the frameworks.

4.3 Control risks

Controlling risks, once identified and assessed, can be categorized into three levels based on their effectiveness. The most effective level of control is elimination [33]. Real-time safety monitoring systems facilitate elimination control by identifying newly appeared or unidentified hazards and informing safety managers or site supervisors, which will then take the necessary steps to eliminate the risks if applicable.

The second level of control includes substitution of the hazard with a safer alternative, isolating the hazard from people, or reducing the risks through engineering controls [34]. Safety will be enhanced by timely identification of hazards, and notification of the people in charge to take appropriate actions. In addition, real-time safety alarm systems that will notify the workers or equipment operators of danger can be considered as another form of engineering control, driven by data-driven monitoring systems.

The last level of control is aimed at reducing exposure to hazards. This level includes methods such as Personal Protective Equipment (PPE) and administrative controls. Proper usage of PPE is often overlooked on construction sites. Real-time monitoring systems provide a promising solution to continuous supervision of their appropriate utilization. The data obtained from real-time systems can also be used for trend analysis and evaluating safety culture at different work zones or various stages of the project. Thus, facilitating targeted administrative controls, and enhancing safety training quality.

4.4 Safety Control Measures

The last step in the safety risk management process refers to performing hazard identification, risk

assessment and controlling risks repeatedly to ensure appropriate control measures are taken at all times. Data-driven monitoring systems facilitate automation of the process. By continuously monitoring the workplace and workers' conditions, the automated safety risk management systems supplement human supervision to effectively prevent accidents at the construction site.

5 Discussion of Research Gaps

In this study, we have reviewed various aspects of safety risk management that can be improved using data-driven systems. This section identifies a number of research gaps and suggests future research directions.

1. At the current stage, most studies have focused on the development of monitoring systems that collect and process certain types of information from various entities at construction sites (e.g. workers' gait pattern, physiological state, workers' activity, workspace congestion, temperature, etc.). A desirable feature would be a framework for combining information obtained using various methods into an integrated system. The added dimensionality to the data can provide managers with valuable information. For example, a system that is able to detect safety violations can be extended to include more information such as where the violation has occurred, information about the subcontractor, environmental factors at that time (e.g. temperature), and information about the physiological conditions of the workers.
2. Near-miss events are important safety-leading indicators that are often left unreported and undocumented. Although frameworks, which facilitate the process of reporting near-misses and visualizing them through BIM have been proposed [35], the possibility of using real-time monitoring systems to identify and document near-misses automatically has not yet been fully explored.
3. Real-time monitoring systems create enormous amounts of data. Further domain specific studies, including Big Data Engineering and Data Analytics, are required to extract valuable information from data obtained from real-time monitoring systems, and explore their applications to construction safety [36][37].
4. Visualization of information obtained via real-time monitoring systems through BIM platforms can improve analysis, facilitate accessibility, and enhance communication and training. While some studies have explored the integration of wireless sensor networks with BIM [38], solutions that combine vision-based monitoring systems with BIM platforms have not been sufficiently explored.
5. Rapid advancements in the field of computer vision, and an abundance of cameras on construction sites create an exceptional opportunity for vision-based techniques to be used as effective monitoring systems in the industry. However, the majority of vision-based studies have evaluated their proposed algorithms on datasets that are proprietary to that project and are often small in size. Lack of publicly available large datasets for construction safety monitoring that can be used as benchmarks makes performance comparison of various algorithms difficult.
6. Further research in the identification of critical accident precursors as they relate to fall, struck-by, caught in or between, and electrocution, and detailed breakdown of each accident precursor by defining quantitative parameters to be monitored can accelerate the development of automated monitoring systems.

6 Conclusion

Developing sensor-based systems for improving construction safety has recently gained a considerable amount of attention. In particular, vision-based monitoring systems have become an active topic of research in construction. This study has provided an overview of recent advancements in the domain as they relate to safety risk management and mapped the area for future work.

Safety risk management as described by Safe Work Australia {4} includes four steps, identifying hazards, assessing risks, controlling risks, and reviewing control measures. The impact of data-driven systems on each aspect of the process, along with examples of various methods employed by researchers have been discussed. The reviewed studies cover a range of technologies and approaches being used. These include but are not limited to utilization of wireless sensor networks, RFID, UWB, IMUs (accelerometers and gyroscopes), and vision-based techniques for location tracking, gait analysis, object detection, activity recognition, ergonomic assessment, and so on for the development of data-driven accident prevention systems.

Data-driven systems can be used for automated continuous monitoring of construction sites. They can be used to proactively prevent accidents by notifying workers or equipment operators of an incoming hazard. Further, such systems can be used to notify safety managers or site supervisors of unidentified, or newly appeared hazards. As a result, necessary actions can be taken in a timely manner to prevent accidents.

The overview provided in this study can be used as a guide for researchers pursuing research on intelligent accident prevention systems. It is acknowledged that this review study is only limited to construction industry.

Future research effort should examine state-of-the-art techniques and technologies used in other sectors and consider their applicability to tackling construction safety challenges.

Abstract –

Disruptive technologies offer avenues to significantly improve the performance of construction project delivery. While the construction industry is often labeled as conservative and unimaginative with regard to technology adoption, significant strides have been made in recent years – specifically, the use of Building Information Modeling (BIM) for information storage, distribution and communication, as well as Lean construction techniques such as production planning and control (PPC). While the implementation of these innovative technologies and practices individually improve project performance, integrating them together can provide still greater benefits. BIM is certainly useful, but it alone is not a satisfactory answer to the paradox: how does one design and visualize a 3D product in a 2D space? Augmented Reality (AR) is a disruptive technology that can help address this challenge. AR is both an aggregator of information and an information publishing platform which allows users a spectrum of capabilities to 1) passively view displayed information, 2) actively engage and interact with published content, and 3) collaborate with others in real time from remote locations. No extant research effort has comprehensively investigated the opportunities and benefits of the integrated use of AR, BIM, and Lean in the planning process to improve project performance. This paper addresses precisely this research gap. Using insights gained from real-world construction projects, this paper examines the current state of production strategy process (PSP) development – an integral part of PPC, identifies pain-points and opportunities for process re-engineering using AR, and develops an AR-enabled PSP future state.

Augmented Reality; Building Information Modeling; Lean Construction; Production Planning and Control; Production Strategy Process; Takt Time Planning

1 Introduction

The construction industry is poised for significant growth. [1] forecasts that by 2030 the global expenditure on construction and related activities will reach $15.5 trillion. While the construction industry is quintessentially a factor in the prosperity of nations, it is fraught with waste and inefficiencies. Since the 1960s, manufacturing, service, and other industries have steadily and significantly increased their level of productivity, and consequently realized improved quality and better profitability [2]. There are several factors that play into construction's stagnant productivity: its project-based nature prevents the same holistic improvement that a process-based manufactory can achieve; the supply chain in construction is not consistent and is constantly in flux; the industry operates at a high level of complexity; there is a high level of heterogeneity; and construction is subject to the whims of international markets [3]. Per [4], a single instance of rework can cost on average 10% of the total project cost (in the United States). The volume of waste in construction has been estimated at between 25% and 50% of total project cost. This figure stems from inefficient control of labor, materials, interactions between trades, and the site in general.

The information-intensive nature of construction projects is a significant contributor to inefficiencies and losses in the industry. Between $17 billion and $36 billion are lost annually due to omitted information when design documents are translated into construction documents. [5] noted that on average only 55% of work planned and promised to be completed each week was actually completed. Other studies that focus on construction efficiency have documented 25% to 50% waste in coordinating labor and management [6].

In an effort to respond to these issues, significant strides have been made over the past two decades to improve construction planning, collaboration, and integration. These methods include Lean Construction via Production Planning and Control (PPC) and Information and Communication Technologies via Building Information Modeling (BIM).

Both these initiatives are radical in and of themselves,

and their impacts on construction have been far reaching and documented by multiple researchers.

[7] analyzed possible interactions between 24 principles of Lean Construction and 18 BIM functionalities. They identified 54 points of direct interaction, 50 positive and only 4 negative. Their conclusion was that implementing BIM and Lean alongside each other was optimal, as the functionality of BIM improved Lean processes significantly.

[8] contended that traditional delivery systems, like Design-Bid-Build (DBB) preclude proper implementation of these innovative practices, and instead recommended the use of Integrated Project Delivery (IPD). IPD is a construction contracting approach which promotes trust, collaboration, team chemistry, team alignment and maximizes value – key support mechanisms for the implementation of innovation [9]–[11].

Construction leaders have recognized this need for innovation, and have taken measures to transform their operating procedures. These leaders have realized benefits that put them ahead of other competitors in the construction sector – which given the competitive nature of the industry is a distinct advantage [11]. Thus, in order to remain competitive and support further growth, companies must successfully innovate to the point that they differentiate themselves from their peers. Early adopters have already realized benefits and brought the industry along, but must now ask: what comes next? [12].

Researchers argue that disruptive technologies have the potential to significantly improve project performance. One such technology that is currently gaining increasing traction is Augmented Reality (AR).

This paper will explore the new frontier that AR offers to construction companies, and how these firms may best exploit it by leveraging existing innovations (BIM and Lean) in an AR space to improve and innovate PPC, specifically the Production Strategy process (PSP).

2 Research Objectives and Methodology

The principal objective of this paper is to propose a new, AR-Enabled Production Strategy Process (AR-PSP). Our approach to achieving this goal entails the completion of several sub-goals: (1) investigate via literature review and expert interviews the current state of PPC and BIM integration in the industry; (2) identify current challenges and choke points in the current state PPC; (3) identify leverage areas for the integration of AR; and (4) define an AR-Enabled PSP future state. The research tasks and outcomes are described in the remainder of this paper.

3 Background

The notion of innovative production philosophy originates in Japan in the 1950s with the Toyota Production System (TPS) [13]. [14] defines this philosophy as a management philosophy for manufacturing, as well as a method of enhancing corporate vitality which aims to totally eliminate waste and achieve the maximum possible quality with the shortest possible lead time. In the early 1990s, the term ‘Lean’ production was introduced to contrast with ‘mass’ production [15]. The operational prerogative of Lean is the reduction of waste and maximization of value, and as such it has quickly become popular in healthcare, service, administration, production development, and construction [13], [16].

Lean as applied to construction was first discussed by [13]. In 2000, Koskela explained that Lean construction projects should be viewed as production systems, with the output being the built product [17]. This departs from the traditional view, or the transformative view, in which construction production is performed through individual activities that transform inputs (raw materials) into output (built product). Koskela put forth the Transformation/Flow/Value (TFV) theory, which prescribes that construction be viewed as the transformation of resources (raw materials), flow of materials and people, and the creation of value. In this system, construction projects are considered temporary production systems, with three pillars: eliminate waste, collaborate, and optimize the value-added chain [17]. The crucial challenge to construction is the spatial and scheduling coordination of the vested parties and disciplines. As such, innovative PPC methods like Last Planner System and Takt Time planning have come to the fore.

3.1.1 Last Planner™ System

The Last Planner System (LPS) was initially developed by Glenn Ballard and Greg Howell as a PPC system to improve construction predictability and reliability by bringing ‘last planners’ forward in the process [18]. The last planner is the project party who is responsible for the control of operative tasks – typically trade foreman. As such, the LPS involves these foremen with general contractors, architects, and owner’s representatives to bring site knowledge and practical experience to the table, making plans more realistic [19]. LPS decentralizes management tasks and improves cooperative work [20]. There are four chronological phases to LPS, as follows [21]:

1. Master Scheduling is a front-end planning process that produces a schedule describing the work to be carried out over the project duration.
2. Phase Scheduling generates a schedule covering each project phase, such as foundation, structural frame,

overhead, in-walls, or finishing. In a collaborative planning setup, the project team defines these phases and their various activities and uses pull planning to schedule the activities backward from the milestones.
3. Lookahead planning is the first step in production control (i.e., executing the work) and it usually covers a six-week time frame. At this level, activities are broken down into the level of production processes, constraints are identified, operations are designed, and assignments are made ready.
4. Weekly work planning is the most detailed plan in the system, and covers the particulars of work to be performed each week.

3.1.2 Takt Time Planning

The traditional view of construction considers a project as a conglomeration of various tasks and focuses on optimizing the process by which each task transforms its inputs into outputs. The shortcoming of this view is its lack of consideration for the dynamics and interdependencies of construction tasks [22].

[23] stressed the importance of considering space as a resource when planning construction projects. One space planning method that has been previously explored by academicians and professionals is Takt-Time planning. Takt is a German word which means 'beat' or 'rhythm.' It is applied to Lean Production to establish flow [24]. Implementing Takt into processes prevents overproduction, reduces lead times and inventory, stabilizes processes, optimizes workflow, and improves production capacity [25].

Within Lean Construction, 'Takt Time' is the unit of time in which a product must be produced (i.e. supply rate) to match the rate at which the product is needed (i.e., demand rate) [26].

Takt-time planning thus breaks work down into individual, manageable, chunks and determines their demand and supply rates [27]. [28], [26], [29] presented various methodologies to implement takt-time planning in construction. The current study presents a generic framework for implementing Production Strategy through the synthesis of the aforementioned methods with existing practices via industry expertise.

3.1.3 Integration of Last Planner System and Takt Time Planning

As noted by [30], LPS does not presuppose any specific work structure. The authors indicated that work structuring happened before project control – i.e., before lookahead planning could occur. However, location-based work structures like Takt-Time planning have been successfully integrated with LPS. [31] demonstrated the complimentary nature of Takt-Time and LPS, noting that Takt-Time introduces a standard, continuous flow of work that the LPS then is able to control, and LPS allows the flow of work to remain when obstacles emerge and must be adapted to.

[32] added a stage to the LPS: Production Strategy. Its three principal goals are: 1) implementing sequence and flow analyses, 2) defining production areas, and 3) designing production using takt-time principles to achieve stable and predictable construction flows.

Production Strategy is the portion of the PPC which has the highest potential for AR integration given its high volume of information and necessary level of communication and understanding.

3.2 Building Information Modeling

BIM has transformed the traditional paradigm of construction industry from 2D-based drawing information systems to 3D-object based information systems [33], [34]. For more than a decade, BIM has been one of the most important innovation means to approach building design holistically, to enhance communication and collaboration among key stakeholders, to increase productivity, and to improve the overall quality of the final product [35]. BIM's greatest strength is its ability to represent in an accessible way the information needed throughout a project lifecycle, rather than being fragmented [36]. BIM serves as a shared knowledge resource for information about a facility, forming a reliable basis for decisions during its lifecycle from inception to commissioning and beyond [37].

3.3 Augmented Reality

In the context of this research, Augmented Reality (AR) is characterized as both an information aggregator and a data publishing and visualization platform. As such, it allows the user to 1) passively view displayed information, 2) actively engage and interact with published content, and 3) collaborate with others in real time from remote locations [38], [39].

AR's market share is anticipated to reach $63 billion by 2021 and has found application in many domains such as gaming, medical, military, and manufacturing [40]. [41] described AR as the bridge between digital and physical realities; a new information delivery paradigm which permits consideration of both physical and digital information simultaneously. [42] found that AR facilitates a more thorough understanding of project documentation, construction progress, and communication between stakeholders. [3] stated that AR has great potential to improve the scheduling software.

3.4 Cross-Pollination of AR, BIM, and Lean

[38], [42] have developed several frameworks and prototypes that support the integration of BIM and AR

using different platform (i.e., Head Mounted Displays, smartphones, etc.). [43] noted that BIM and AR have a direct relationship with what Koskela defined in 1992 as construction integrated by computer and automatization in construction. [8] highlighted the potential use of AR for collaborative planning to improve predictability and reduce waste. [3] developed a framework and a mobile application, AR4Construction that integrated BIM and AR with Lean Construction methods, particularly Location-Based Management System to support the efficient management of construction works on site. Most existing literature focuses on implementing AR on the construction site. Our research focuses earlier in the project delivery process, and explores opportunities for integrating AR with PPC, such that it is used before construction begins, particularly with the PSP.

4 Production Strategy Process Current State

Before embarking on any process re-engineering effort, it is important to gain a sound understanding of the current state of practice as this will allow those involved in the innovation initiative to develop a shared basis for the improvement [44]. As such, this section describes the five principal steps of the PSP as it currently stands, using the example of an IPD project. The current PSP is illustrated in Figure 1.

Step 0 – Prerequisites

Prior to the Production Strategy, the project team (including last planners) must have set the expectations for the project and identified the major milestones for the project in the Master Scheduling phase. The project team then must divide the project into phases (such as overhead, in-walls, exterior finishes). Each phase should contain a series of activities performed by different trade partners. In the Production Strategy level, the project team works together to develop a production plan for each phase using the following four steps:

Step 1 – Perform Sequence and Flow Analysis

The project team reviews the 2D construction drawings of each phase, identifies repeatable and non-repeatable work, agrees on the linear sequence of construction activities of the corresponding phase, determine flow and non-flow areas, and finally determines the direction of the flow (i.e., work to be performed from North to South, East to West, etc.). The output of this step is a set of 2D construction drawings highlighting the flow and non-flow areas and indicating the direction of the flow for each phase.

Step 2 – Gather Information

The General Contractor (GC) conducts one-on-one interviews with the Trade Partners individually. For each activity within the corresponding phase, the GC provides the last planner of the corresponding trade partner with the 2D construction drawings. The last planner is then asked to use color markers to highlight the 2D drawings and show how much work they can complete in one day based on their ideal crew size. This is referred to as daily production. The last planner uses the direction of the flow identified earlier for the corresponding phase as a reference to identify their daily production. The GC acts as a facilitator. A 2D color-up construction drawing will be created for each activity within this step. Color-up drawings are not quantity takeoffs, as they require the last planner to think about how the work will be performed, by whom, where and in what sequence [26]. The GC then asks the last planner from each trade partner to use the color-up drawings and divide their floor plan into production areas. The production area, also referred to as Takt area, is a collection of individual daily productions. For example, if the last planners are asked to develop one-week takt areas, then each area should include five days' worth of work (assuming conventional schedule), or five daily productions. It should be noted that the precise mechanism of determining takt time is beyond the scope of this research. One week is used as a threshold since it is consistent with the weekly work plan phase of the LPS. The output of this second phase is a set of 2D drawings with production areas for each activity assigned to the corresponding phase.

Step 3 – Develop common areas

The GC collects the individual 2D production areas drawings, overlays them and attempts to identify common areas. The objective is to develop common areas within which the scopes of work of all the different activities are balanced.

Step 4 – Define Production Strategy

Once common areas are determined by the GC, the GC will determine the scope of work for each trade in that area and identify which trade(s) will bottleneck. The objective is to balance workflow such that all trades finish their work in an area within takt time for that area. The workflows are balanced either by adjusting crew size and hours or by adjusting work area. This process should go through multiple iterations to produce a cohesive strategy.

Step 5 – Validate the Production Strategy

The GC circulates the initial production plan to trade partners for feedback, which is collected and used to inform updates and revisions. Once a working plan is agreed upon, it should be documented via a convenient mechanism (e.g., an Excel spreadsheet).

5 Challenges in the Current State and Augmented Reality Opportunities

As is evident from Section 4, PSP is information-dense, lengthy, and iterative. The lynchpin of this process are numerous sets of 2D construction drawings, which are the conventional means of communication

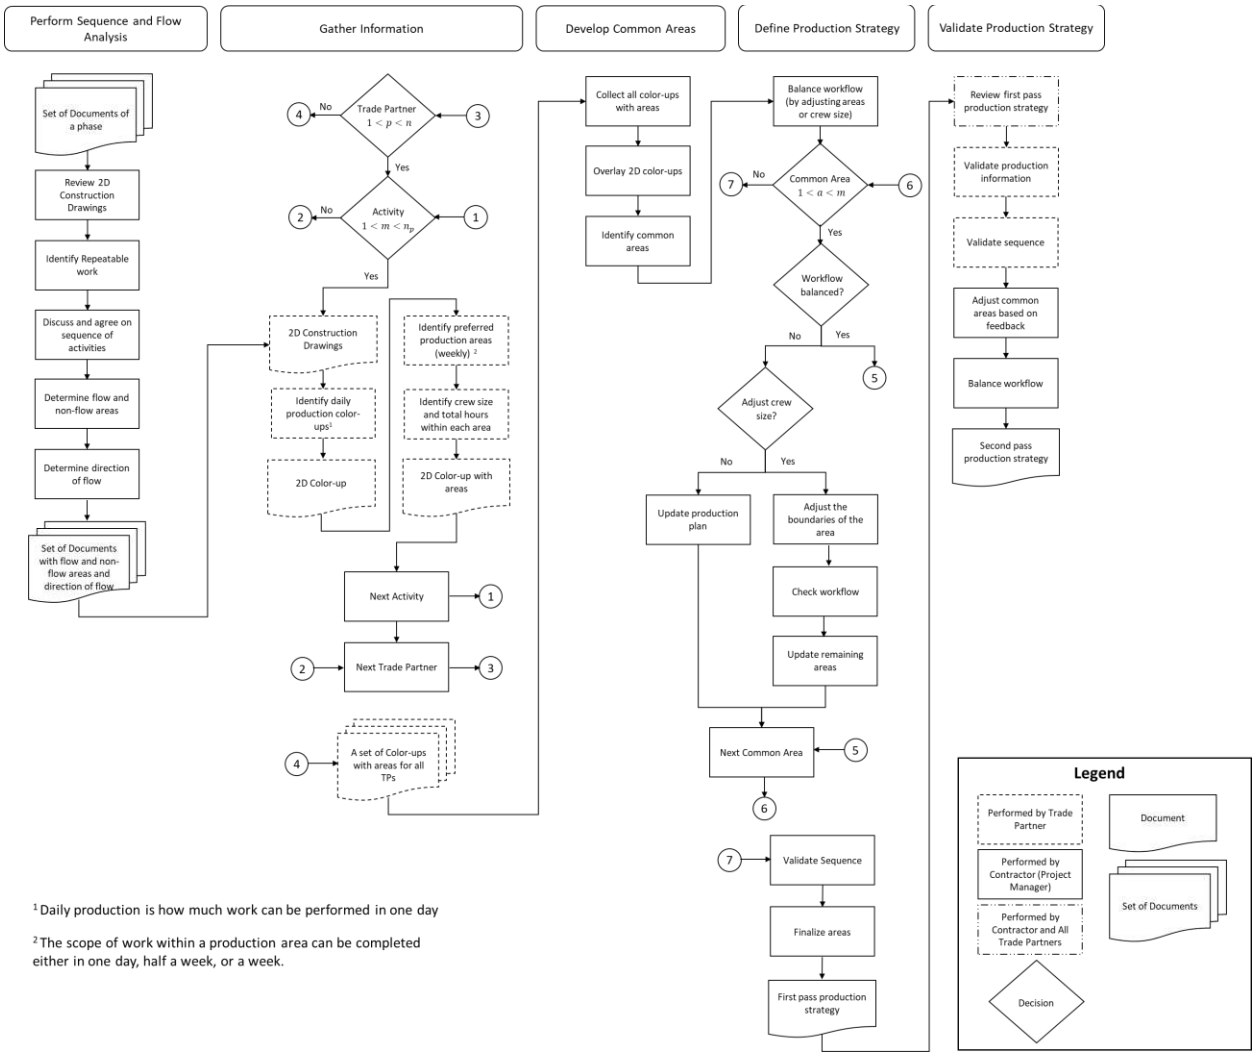

Figure 1. Current state of the production strategy process

between different contracting parties [45]. However, they present an individual view that is subject to individual interpretation [46]. Based on the 2D drawings, a last planner must visualize the built product, which will exist in 3D space. This presents a difficulty, as some information will not correctly translate (e.g., flat pipe vs. inclined pipe). Furthermore, another challenge that pertains to this phase is software diversity (i.e., 2D drawing packages may be prepared in numerous different CAD suites which are incompatible).

During the planning process, there is a lack of centralized information storage – necessary data is often stored in various forms (hard copy, spreadsheets, email chains, etc.) across different devices or locations.

As such, a challenge emerges in making sure last planners fully understand what work they are committing to.

Furthermore, the current process does not effectively consider safety, which should be a perspective from which the plan is validated.

In addition, this process requires project team to be available in the same space.

These challenges result in numerous iterations and mixed coordination of data, which ultimately increases the chances of miscommunications and associated non-valued added effort.

Opportunities to Integrate Augmented Reality:

Using augmented reality as the delivery mechanism for drawings and production information during the planning process has several advantages. First, it allows more advantageous use of BIM, as AR can operate in 3D space. Second, it creates a living single source of information, reducing miscommunication. This allows for an overall improvement in collaboration and communication, permits the last planner a better understanding of scope of work and as a result produces

more reliable commitments, allows for safety analysis in more real space, improves spatial cognition, and allows an iterative tracking system. According to [41] the use of AR eliminates the need to mentally translate two-dimensional information into the three-dimensional world, and elaborate that this improves the ability to absorb and interpret information which leads to better decision making, and tasks being executed faster and more efficiently. A study by [47] noted that AR eases information retrieval for those working in information-intensive environments, and increases the efficiency of the working processes through avoiding information overload. Finally, using AR facilitates standardization of the process to a single governing data point and citation.

6 AR-enabled Production Strategy Process Future State

We envision an AR-enabled PPC process in which the BIM model is used as the guide and chief reference for production strategy development. Thus, BIM is a precursor to implementing AR-PPC. The following five steps define the process by which AR-PPC can be implemented.

Step 1 – Perform Sequence and Flow Analysis

The project team:

1. collectively uses the 3D model as a guide and reference to visualize the corresponding construction phase(s) and its activities
2. interacts with the 3D model and selects repeatable work
3. interacts with the 3D model and collectively develops the sequence of activities and identifies potential safety hazards, thus improving the decision-making process in a collaborative environment
4. interacts with the 3D models and collectively discuss flow and non-flow areas
5. interacts with the 3D models and collectively assess the project and determine the direction of flow.

AR helps project participants from diverse trades better understand each other's scope and flow of work, facilitating better collaborative decision making. The output of this step is saved within the 3D model and accessible at any later point by the project team. This central information repository is more efficient than traditional methods, and provides additional transparency – all participants are provided the same information.

Step 2 – Gather Information

Last planners will be among the project team participants with access to the information generated in Step 1. Integration of BIM and AR allows 3D visualization of the scope of work, and improves visual understanding by providing an interactive solid model of the whole project. Within the augmented environment, the last planner:

1. selects to only visualize their scope of work
2. performs their daily production for the entire phase in a virtual environment, which in addition to generating 3D color-up drawings, will also create quantity takeoffs. The last planner can also investigate the space for any safety problems and adjust their daily production accordingly
3. creates production areas virtually. This allows the last planner to automatically visualize the scope of work within each area, obtain the total quantity of work to be installed, and input production information (such as labor hours, crew size, working days, constraints, etc.). This information can be easily retrieved by the last planner.

Each last planner can create their production areas and save them to the same source, allowing project managers to coordinate and check for trade clashes

Step 3 – Develop Common Areas

The GC retrieves the results of the last planner's work from step 2. Their production areas are overlaid, allowing visual creation of common areas.

Step 4 – Define Production Strategy

The GC, once common areas are developed, retrieves the production information that was input pertinent to each scope of work. This facilitates the performance of workflow balancing in an environment that updates in real-time, improving efficiency. AR thus acts as a decision support tool for the GC as they create the production strategy plan draft.

Step 5 – Validate Production Strategy

Once the first-pass production strategy is complete, the team meets in the augmented environment to review it. This greatly enhances collaboration, as it facilitates meetings that do not require co-location of participants, as well as changes that are visible in real-time to all parties.

The production plan created in AR can be used during project execution to visualize the work to be installed and to track performed work. Project Percent Complete could be then calculated more accurately and effectively.

In summary, AR has the potential to transform the current state of the PSP. It provides a common source of truth which enables a higher level of collaboration among the participants of the PSP when working in the same space or in remote locations. The AR-enabled PSP is a centralized reference that encompasses the different types of information used during the PSP. AR enables the users to interact with the built product in real-time, thereby enhancing visualization, space perception, and decision-making. The technology also allows last planners to identify potential safety hazards during planning and integrate safety more effectively into the production strategy.

7 Future Work

Based on the framework for an AR-enabled PSP that we have defined in this paper, we are developing a proof-of-concept application on a wearable display. Using BIM models from real-world construction projects, we are validating the reengineered future state PSP and the associated benefits.

8 Conclusions

Most literature which was reviewed focuses on the avenues to integrate AR into site operations (visualizing blueprints, safety, etc). However, this paper and research effort considers integrating AR into PPC, and specifically into the Production Strategy Process. A process map was presented which highlights the current state of the practice based on previous research and industry expertise. Challenges which exist in the current method were then presented, and opportunities to address these challenges via AR were explored.

Finally, a conceptual future state of the Production Strategy was described. The principal advantage that AR-enabled PSP has is its centralization of information and increased collaboration over traditional PSP.

Abstract -

This research aims to explore the effectiveness of chatbot system for highly-complex data management. With the growing popularity of mobile devices, the conversational information technology (IT) service, such as chatbot, has permeated into our daily life. Conversation-based systems are now widely utilized for helping the user to access the data they need or control other devices more intuitively. Although lots of systems have been developed for personal assisting, such as Siri, Alexa, and so on, or customer services, seldom of them are used for data management. Therefore, this research will focus on exploring the application of chatbot system for the management of complex data. We used the disaster-related data and a chatbot system developed in the previous work as a case study. A one-year field test was conducted for figuring out the feasibility and effectiveness of chatbot system for data management. After the field test, we found that the number of users of the developed system was doubled within six months. The usage of the system increased approximately 2.5 times with six months. We also found that the users now rely on the chatbot system for their daily tasks. The results reveal that the chatbot system may be a promising direction for highly-complex data management due to its intuitive data accessing process.

Keywords –

Data Management; Conversational System; Chatbot

1 Introduction

Data management has always been a critical issue in the field of engineering. Recently, the fast development of the internet and high computational hardware bring the explosion of digital data. Around 2.5 exabytes of data are created each day in 2012 [1]. Therefore, how to effectively translate those massive amounts of data into the knowledge that can improve the decision-making and performance is essential and worth for detailed research. To deal with the massiveness and diversity of the data, many information technologies were developed within these years. For instance, the Lesson Learn Center proposed by Kang et al. provided all the historical disaster data in Taiwan for decision-makers' reference [2]. Terroso-Saenz et al. proposed an IoT platform for the management of energy data in 2019 [3]. Carmona et al. used the IoT technology in the data collection of the construction site for enhancing the productivity of constructions [4].

Although IT related systems have been developed, the user interface and the data retrieval approach of these systems seem unintuitive and inconvenient for users. Therefore, studies have recently started to focus on developing conversation-based systems [5, 6] by considering user involvement [7]. The Siri, Amazon Alexa, and Google are the most famous examples. Those conversational systems play the role of personal assistant that allows users to check the weather, traffic, email, and so on. Ko and Lin used a chatbot system as a virtual assistant for business card management [8]. Besides personal assisting, such systems are also widely utilized as customer services. For instance, Thomas and Gupta et al. both utilized the chatbot for the customer service for e-business [9, 10]. Despite that chatbots have been developed for different purposes, the application of the chatbot system in complex data management is rarely discussed.

2 Previous research

To explore the feasibility of applying the conversational system on data management, we developed a chatbot, named Ask Diana, for water-related disaster in 2018 [11]. Among different types of data, disaster-related data is one of the most difficult for managing due to its following characteristics [12]:

- large number of producers and consumers of information;
- time sensitivity of the exchanged information;
- various levels of trustworthiness of the information sources;
- lack of common terminology;
- combination of static and streaming data;
- heterogeneous formats, ranging from free text to XML and relational tables.

Ask Diana was designed as a keyword-based chatbot system for disaster data management. It consists of a disaster database, a user-intent understanding mechanism, and a mobile-based user interface (Figure 1). The system allows the disaster-related personnel to access the data they need through directly using inputting keywords. Building on a popular communication platform, LINE, also allows the user to forward the data to others easily.

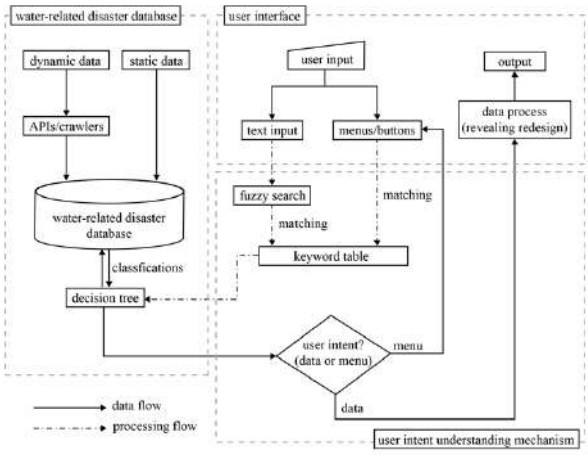

Figure 1. The system structure of Ask Diana [11]

Ask Diana improved data management of disaster data delivery process and allow decision-makers to access real-time disaster data by themselves. During emergency operation period, rapid response is essential. Decision-makers require real-time disaster data to make decisions. However, decision-makers are high-level government officials, who are not the first line operators who operate the disaster response system. Therefore, in real emergency operation process, decision-maker would ask their major supervisors to provide disaster data which required no emergency response personnel's judgement or confirmation. Then, the supervisors would ask emergency operators and their cooperation team to provide disaster data. After cooperation team fulfils the requirement, they would provide disaster data to operators. Operators would then deliver the data to major supervisors. Finally, the major operators would deliver the related information to decision-makers for further decision making. The delivery process is very time-consuming which would usually cost more than one hour. It may somehow make the disaster data hard to deliver in time.

Ask Diana was validated to have higher efficiency in disaster data retrieving through a six-month field test. Ask Diana has an easy user interface to allow user access to real-time disaster data by themselves. Therefore, decision-makers could require disaster data just by click Ask Diana's menu or input simple disaster keywords. Ask Diana would provide feedback in just seconds without long-time latency. The related personnel were thus willing to use Ask Diana for their daily tasks. Three hundred eighty-one users have used Ask Diana for disaster response activities. Twelve thousand seventy-eight using records were collected within six months (Figure 2).

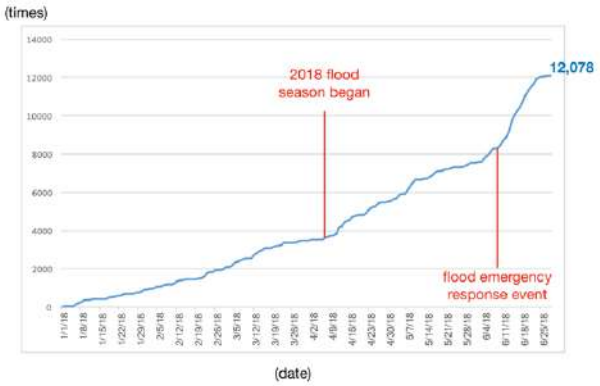

Figure 2. The user records of the field test [11]

3 Research Objectives

This research aims to explore the feasibility of utilizing the chatbot system on data management. A field test of utilizing the developed system into an actual field was conducted. The user's behaviours were all recorded for further analysis. After the field test, the advantages and the shortage of chatbot system for data management would be concluded.

4 Field Test

For feasibly test, we cooperated with the government of Taiwan (Water Hazard Mitigation Center) to have a six-month field test in our previous research. In this research, we extended the duration of the field test to one year for more detailed observation of the user behaviours. The background of the users and the usage of Ask Diana were all recorded for analysis.

Based on the user log, 790 users have added Ask Diana as their Line friend at the end of 2018. The number is doubled within only six months, which represents the

willing to using Ask Diana for their tasks is gradually increasing. Figure 2 illustrates the distribution of the registered user role. Among the 790 users, 95% are disaster response personnel, 2% are system developers, 2% are system managers, and 1% are decision-makers.

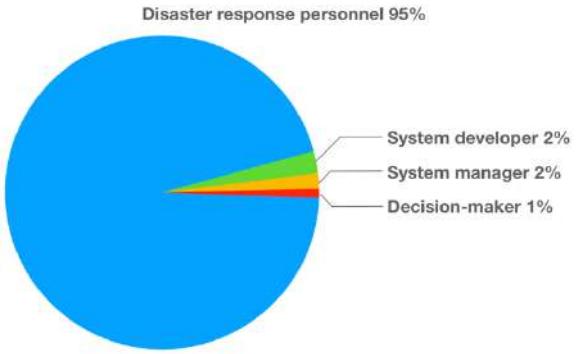

Figure 3. The distribution of the user role

Ask Diana collected totally 31,355 records from actual users within a year (Figure 3). The usage is around 2.5 times increasing compared with the first six months. In Figure 3, we can find that the usage will have a significant rising when major disasters happened.

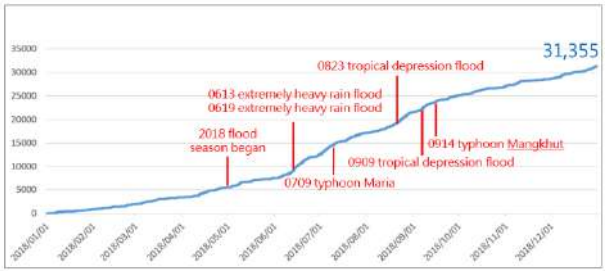

Figure 4. The cumulative usage graph of Ask Diana during Jan. 1st ,2018 to Dec. 31th, 2018

Besides the user logs, we also collected the user feedbacks during the field test. According to those feedbacks, three major comments were concluded:

1. Ask Diana provides an intuitive platform for the user to access data easily and efficiently. With the low threshold operation, the willing of the user to use it for actual disaster response activities were increased.
2. The keyword-based mechanism of Ask Diana did not allow the user to get the data through hierarchical questions. Therefore, they needed to provide Ask Diana with the keyword of the data specifically.
3. The user expected that Ask Diana could have some emotional responses. For example, when the user inputted "Hi Diana, I would like to know the flooding situations now," instead of just providing the flooding information, it will be better if Ask Diana can reply "Taipei is now having serious flooding, please keep your attention at any time!"

5 Conclusions

This research explored the feasibility and effectiveness of the chatbot system in data management. Through a long-term field test on disaster-related data with user feedbacks collected, we found that the chatbot system can have high performance and efficiency in data management, even for highly-complex data. Due to the intuitive operation process of chatbot system, the willing of the user to use such a system can be significantly increased. More discussions can be found in Ask Diana: A Keyword-Based Chatbot System for Water-Related Disaster Management [11]. However, as a chatbot system, the user will expect it to have a more human-like response with emotions. Also, for the complex data, the user may need to retrieve the data through hierarchical queries. In conclusion, the chatbot system can effectively be utilized for data management meanwhile provide an intuitive platform for users to access the data.

6 Acknowledgement

This research was supported by Taiwan's Ministry of Science and Technology (MOST) under contract 107-2119-M-011-002 & 108-2119-M-011-002. Also, Weather Climate and Disaster Research of National Taiwan University (NTU) and Water Resources Agency provided great support and enormous feedbacks in field application and user test. Prof. Yun-Cheng Tsai of NTU assistance in developing the system and conducting user tests.

Abstract –

Unmanned Air Vehicles (UAVs) are increasingly used and have many potential applications in the architecture, engineering, and construction (AEC) industry. UAVs are now commonly controlled manually with an experienced survey engineer in field operation, but UAVs can also fly autonomously with the support of localization technologies such as simultaneous localization and mapping (SLAM). Autonomous flying of UAVs can reduce human effort and minimize human error. However, it requires careful flight path planning, active environment sensing, and effective obstacle avoidance techniques, especially where the built environment is complex and space is tight. Currently, algorithms flight path planning, object detection and obstacle avoidance are developed based on testing that involves actual Survey UAVs; this is not only time consuming but also expensive and hazardous in the sense that it may damage hardware and injury ground personnel if error-induced crashes occur. This paper presents a hardware-in-the-loop simulator which can simulate the behavior of a drone and generate synthetic images from the scene as datasets, detect and verify as-built MEP objects with a trained neural network, and generate point cloud data for validating as-designed BIM model with as-built BIM model in the future. The system architecture, operations, and performance of the developed simulator are discussed, followed by an illustrative example.

Keywords –

Automation; Flight Path Planning; Robotic Perception; Simulation; UAV

1 Introduction

Surveying using terrestrial laser scanners has been common practice in the AEC industry. Meanwhile, building information modeling [1] (BIM) has been increasingly required by both public and private sectors as a part of any building and infrastructure developments. As the more recent a design is, the higher level of details its digital 3D model will contain, and as-designed BIM models need to be validated against their as-built counterparts. For example, mechanical, electrical and plumbing (MEP) inspection of a tunnel traditionally requires inspectors to go inside the tunnel and use a terrestrial laser scanner to inspect and confirm coherence with the as-designed BIM model. This method normally requires much manpower, making it inefficient, time-consuming and risky. Some civil structures like tunnels and wastewater treatment plants can have hazardous volatile organic chemicals (VOCs) [2] which can lead to cancer and other medical problems. For another example, to conduct a bridge inspection, expensive high-energy laser scanners and a helicopter are often required. UAVs equipped with cameras, Lidar and/or other detection equipment are promising alternatives as they can collect point cloud data [3] and photogrammetry images [4] and generate 3D models for inspection and visualization.

Testing a physical survey UAV in a real-world environment can be dangerous, expensive and time-consuming. On April 28, 2017, the US Federal Aviation Administration (FAA) released a very detailed report on drone crash tests. The 107-page report was a joint research involving 23 academic institutions working together with the FAA with the aim to understand the risk and hazards (including possible injuries) of the system failure of a UAV. The objective is based on the FAA's research addressing seven questions: (1) What are the hazard severity criteria for a UAV collision (e.g. weight and kinetic energy)? (2) What is the severity of a UAV collision with aircraft on the ground? (3) What is the severity of a UAV collision with property on the ground? (4) What is the severity of a UAV collision with a person on the ground? (5) What are the characteristics of a UAV where it will not be a risk to an aircraft or person/property on the ground? (6) Can the severity of a UAV collision

with an aircraft or person/property on the ground be characterized into UAV categories and what would those categories look like? (7) How can UAV be designed so as to minimize the potential damage done during a collision? [5] In the study of human injuries due to loss of control of a UAV, Section 2.4.4 (Payload Loss Injury Applications) and Section 2.4.5 (Fire Injury Applications) of the report are the most relevant to our research interest: indoor UAV scanning application. In an indoor environment under the condition with no magnetic and wind interference, yet with low lighting and weak GPS signals, a UAV can still be prone to crashes even when the operator is an experienced pilot. Energy sources such as Lithium Polymer battery or Nitromethane mixed with methanol [6] (depending on the overall payload of the vehicle) may ignite upon ground collision, which poses danger to the ground operator. In addition, a survey UAV that carries high precision laser scanners, cameras, and/or various control and processing units on board are too expensive to be damaged. Even a single failure can result in a devastating crash. Therefore, designing a virtual environment close to the real environment for UAV simulation and training before testing a physical UAV on site is proposed in this framework.

Many simulators have been established in the fields of robotic research, computer vision, gaming technology. The UE4 [7] engine, for example, is considered a leading game engine among others such as Unity to provide many resources such as AAA-level realistic virtual environment, through its state-of-the-art shader and the recently improved ray tracing rendering technique. These photorealistic virtual environments can be used as a source for generating images for neural network training, such as training a convolutional neural network to detect objects. However, simulators like UE4 or Unity [8], despite the shader rich feature that they support, lack features such as predefined sensors models provided in the (robotics operating system) ROS [9] simulator.

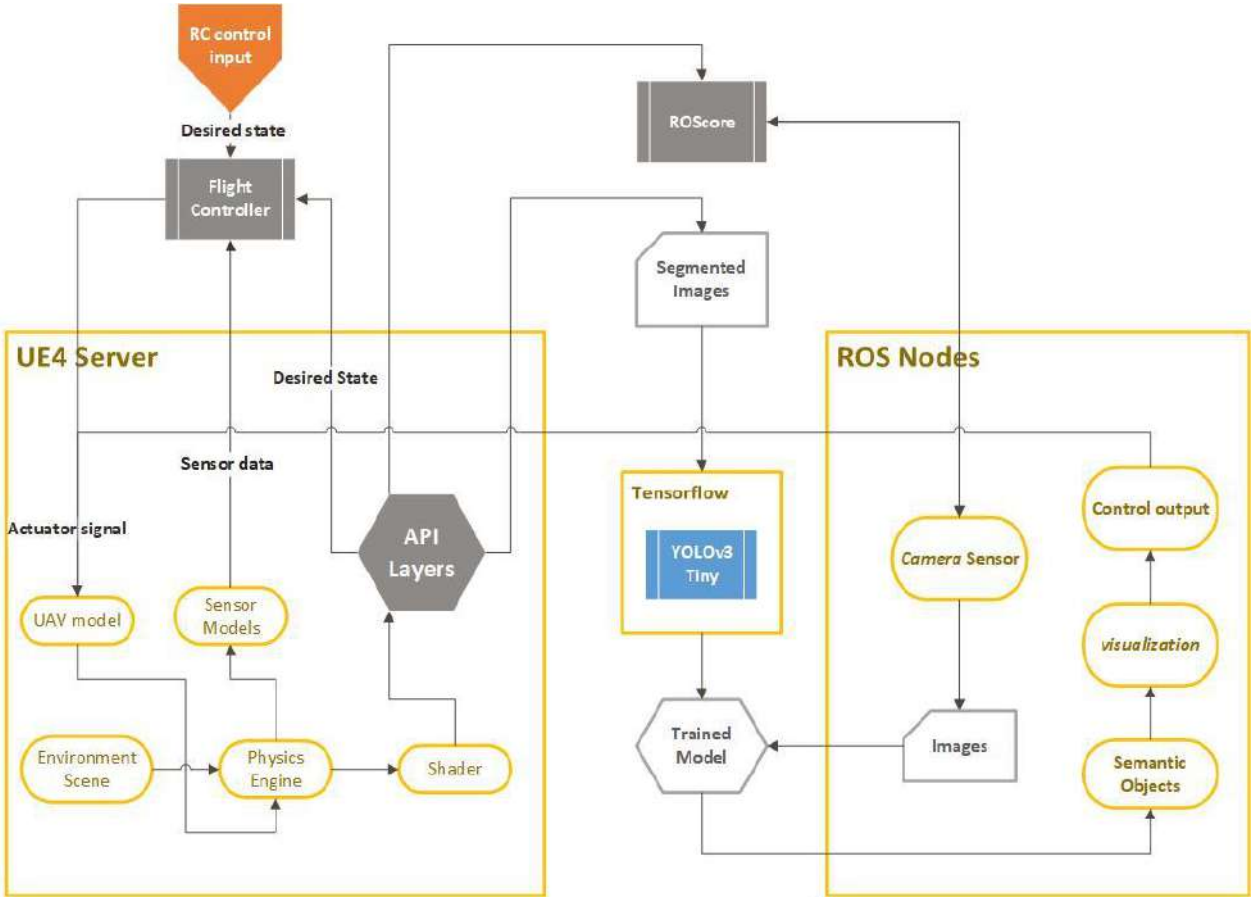

Figure 1. The developed framework for UAV planning using hardware-in-the-loop simulation and BIM technology

Section 2 illustrates the developed framework for UAV planning using hardware-in-the-loop simulation and BIM technology, which contains the following three major parts:

1. The creation of a high-fidelity simulation environment with MEP pipes models and connected flight controller in hardware-in-the-loop [10] mode.

2. The creation of ROS nodes that link the virtual Lidar from ROS to UE4 simulator and generate point cloud data and obstacle avoidance.

3. The creation of a perception system by training of a YOLO v3 [11] object detection neural network with pictures of MEP models.

Implementation details and results of these three parts will be presented separately in the followings.

2 Proposed Framework for UAV Planning Using Hardware-in-the-Loop Simulation and BIM

The proposed framework (as shown in Figure 1) starts where a radio control signal is passed from a radio controller to the virtual flight control module, which drives an actuator on the UAV. Gravity and weather information from the environment will then be sent to the physics engine to simulate the kinematics and return pose information of the UAV. The image API will then acquire high-fidelity images from the scene and compose a directory for neural network training, for the purpose of object detection. The ROS API layer will receive the vehicle pose and location information and via each ROS node for simultaneous localization and mapping, and trajectory planning.

2.1 Simulation Environment Setup

A MEP scene is focused in this study due to the complexity in geometry. The scene, which contains common MEP components such as pipes, elbows and supports, is generated in realistic visual effect using the UE4 engine. This virtual environment consists of MEP pipelines, both having similar object settings and made with appropriated UV to make it realistic. A virtual quadcopter is also created as an avatar to simulate a physical UAV with a weight of 3 kg. A physical flight controller is installed in hardware-in-the-loop mode, and we use a physical 9-channel radio controller which is plug in our server USB port to control the virtual quadcopter within the scene. The simulated environment is shown in Figure 2.

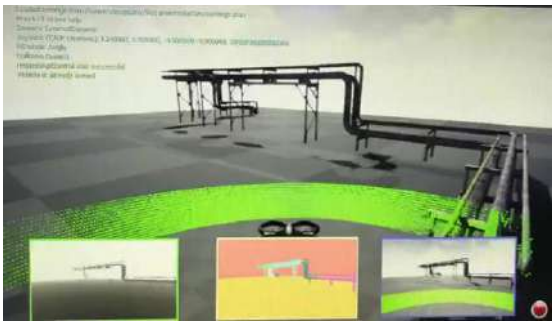

Figure 2. The simulation environment

2.2 Hardware-in-the-Loop simulation with Pixhawk Flight Controller

Hardware-in-the-loop simulation is a type of real-time simulation that are commonly used to test complex embedded system [12]. Figure 3 illustrated the relationship between the flight controller hardware and to the developed simulator.

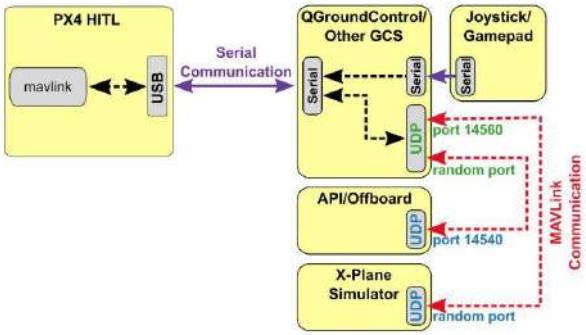

Figure 3. Connection between Pixhawk 4 and the developed simulator

Pixhawk 4 [13] is connected to the USB port of a server. Through the UDP port of the simulation engine, the flight controller can establish communication with the simulator and interact with the built-in physics sub-engine to send actuator signals, pass environment data (e.g. gravity, wind, atmospheric pressure, etc.), and update the real gyro and accelerometer sensors onboard the flight controller. In this way, the simulated environment can behave as close to the real environment as possible.

2.3 Training of an Object Detection Neural Network with YOLO v3 Tiny

The simulator has a Python API so that it can connect with Keras [14], a high-level deep learning

Python middleware that runs on top of Tensorflow [15], which we use for the neural network training (of xxx). There are numerous deep learning-based object detection architectures. YOLO (You Only Look Once) v3 Tiny [16] is used in this research because it is 100 times faster than Fast R-CNN [17] and it is a very small model, comprising only 9 convolutional layers, which is ideal where computational power is limited, such as what is available on the Nvidia TX2 [18] embedded unit. Darknet [19] is used as a trained deep architecture with trained YOLO weights. The training process consist of the following four steps.

1. Create a dataset which includes image classes of MEP models such as pipes, valves, industrial air conditioning units, fittings, water heating, etc. 2000 images are used as training set for each class.

2. Tag images via Visual Object Tagging Tool.

3. Batch and subdivision, using an input resolution of (416 x 416) with a batch of 64 and a subdivision of 3. (Note: values were chosen based on the maximum result achieved without CUDA [20] error.)

4. Train a model, weights will be given for every 100 epochs in Darknet. The result is shown in Table 1.

Table 1.

Input Resolution	416 x 416
Weights	YOLO v3-tiny-VM.cfg
Iterations	50,000
Average Loss	0.2103
Average IoU (%)	47.18%
mAP	62.39%

Finally, we will test the result of training by connecting this object detection network with our simulator via the Python API. MEP pipes are detected in the simulator as the simulated UAV flies, detects objects of interest, and marks their locations in the simulated scene in the virtual environment, as shown in Figure 4.

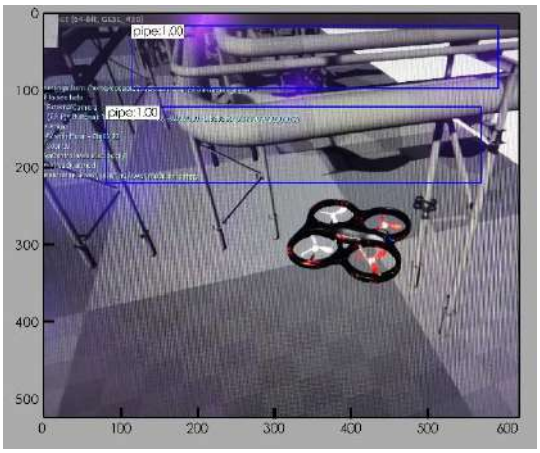

Figure 4. Detection with YOLO v3 Tiny

2.4 Generate Virtual Lidar Data with ROS and UE4

The virtual Lidar in the UE4 engine requires the implementation of two technologies: (1) ray tracing within the UE4 engine to have the visual effect of a laser beam, and (2) construction of virtual sensors within ROS via ROSbridge to publish the defined Lidar sensor reading from ROS to the listening port of the UE4 engine.

The parameters of the virtual Lidar in the simulator are configured in the same way as the RS-Lidar 32 with 32-channel laser, 640K points per second, +/- 15-degree FOV (vertical) and 360-degree FOV (horizontal). [21] The green line indicates the laser beam is generated, as shown in Figure 5 and Figure 6.

The acquired point cloud data will need to change the camera projection matrix with a Build Projection Matrix function, which computes a 4x4 matrix using FOV, width, height and near plane.

Figure 5. Virtual Lidar in the simulator

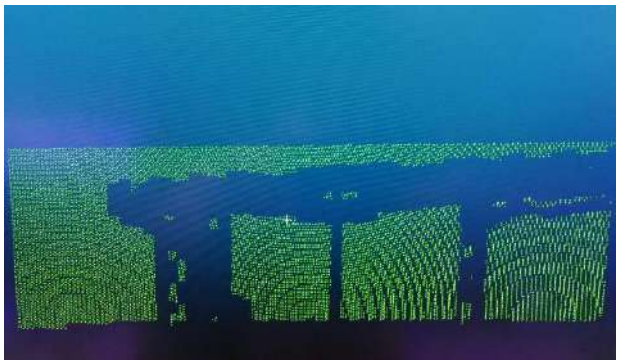

Figure 6. Point cloud visualization

3 Implementation and results

The proposed survey UAV is implemented with a DJI F350 chassis and a Nvidia TX2 embedded unit. The Nvidia Jetson TX2 features a Nvidia Denver dual-core and an ARM Cortex-A57 quad-core. TX2 also carries a 256-core Nvidia Pascal GPU with 8GB of RAM. The power consumption is only 7.5 watts. A stereo camera is incorporated for running a visual simultaneous localization and mapping (SLAM) [22] algorithm for the purpose of localization and obstacle avoidance. A 32-channel Lidar is also mounted on the system to generate some point cloud data. A Pixhawk flight controller with radio receiver is installed along with four electronic speed controllers and corresponding RC rotors. A 9-channel radio controller is used to control the UAV. The total weight of the system is approximately 3 kilograms with a 20K mAh Lithium Polymer battery.

Figure 6. UAV implementation

The stereo camera is a global shutter camera, which does not have an onboard IMU. It is calibrated using a checkerboard (shown in Figure 7) to calculate the intrinsic and extrinsic camera parameters with Pinhole model. With the calibrated stereo camera, we flew the UAV with a VINS SLAM algorithm running in TX2, and a circular trajectory is generated. The trajectory is visualized in Rviz as shown in Figure 8 and Figure 9.

Figure 7. Stereo Camera Calibration

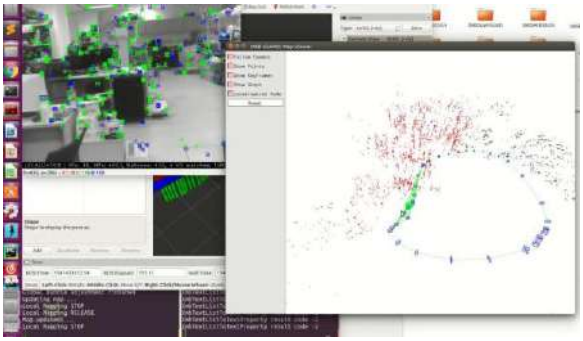

Figure 8. ORB SLAM in Rviz

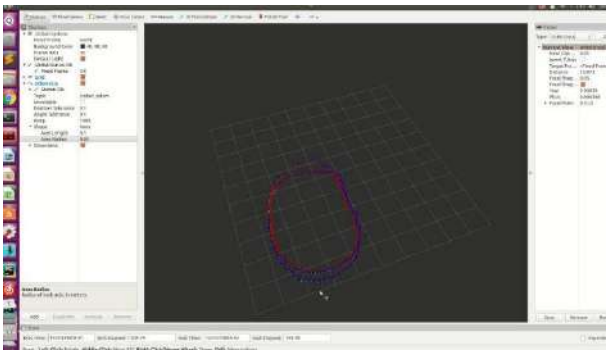

Figure 9. Trajectory in simulator

We also load the AirLib library from our simulator and deployed it on the TX2. The simulator uses the MavLinkCom component, which is a proxy architecture where a connection to the Pixhawk flight controller can be achieved via a serial or UDP port. The Pixhawk flight controller will send messages via MavLink, which allows the controller to be connected to the serial port of QGroundControl (QGC) [23]. We can control the UAV as a client to run on the TX2 meanwhile have it connected to our server with virtual simulation environment.

Running the VINS stereo algorithm along with the YOLO v3 Tiny object detection neural network gives a high load of computation. Usage statistics show that VINS uses roughly 60% of the processing power in the TX2.

4 Conclusion and Future Work

This paper presents a hardware-in-the-loop simulation, which can simulate the behavior of a UAV, generate synthetic images from the scene as datasets, detect and verify as-built MEP objects with a trained YOLO v3 neural network, and generate point cloud data for future as-designed BIM and as-built BIM validation. This demonstrates an effective way of testing the behavior of a UAV prior to live demo flight and blazes a trail toward implementing AI-based robotic inspectors in the AEC industry. Moreover, the capability of generating virtual point clouds in the simulation engine provides a low-cost way for verifying the trajectory of a survey UAV before actual UAV-based scanning takes place. This can simulate any missing point cloud region in the environment constructed with an as-designed BIM model.

The developed framework will be improved in the future. In particular, (1) the proposed framework has not been tested in a real industrial environment with MEP piping installed for field detection. Future tests at a plant room site with MEP components will be conducted. (2) A better stereo camera with IMU will be installed to give the VINs' SLAM performance a boost, potentially resulting in better localization and mapping. (3) A trajectory planning module will be developed on the system and further tested its stability with a motion capture system.

Abstract -

Safety improvement in construction remains a high priority due to the significant rate of accidents compared to other industries. Despite the ongoing multitude of safety studies and policy recommendations concerning the high rate of injuries and casualties in construction, the extent of damage sustained is still significant. Major research studies in construction safety are focused on identifying conditions and causal factors leading to near misses, incidents, and accidents. This paper aims to provide a review of such literature in construction safety from social and individual perspectives. Three major categories of construction safety factors, i.e., social, physiological, and cognitive factors, are synthesized, and the main findings in each category are presented. Implications of the findings are further discussed to guide the research and practice in construction safety management.

Keywords –

Construction; Safety; Social Factors; Physiological Factors; Cognitive Factors

1 Introduction

Improvement of safety in construction sites remains a vital concern due to the high rate of accidents compared to other industries [1, 2]. In addition to the high rate of injuries and casualties in construction industry, the complex and unpredictable nature of work is adding to the importance of safety improvement for construction sites [3]. Construction workplace safety has been extensively studied [4], and human unsafe behaviour and error were recognized as some of the direct causes of accidents [5-7]. Many research studies in construction safety are focused on identifying conditions and causal factors leading to near misses, incidents, and accidents, which in this paper will be classified to aid construction industry with the aim of improving safety. This paper provides a review of such literature in construction safety, aiming to clarify reasons leading to an unsafe act, from social and individual perspectives.

Through a systematic review of the literature, aiming to clarify reasons leading to an unsafe act, three major categories have been considered and studied in this research. Due to the connection and collaboration among workers and other construction personnel in construction sites, social factors have been viewed as one of the major categories to identify attributes related to accident occurrence. Furthermore, due to the demanding nature of construction work and the rough environment of its working place, physiological conditions of individuals are another set of factors discussed in this paper. In addition to social and physiological factors, cognition has been considered as another category of factors in construction safety, which relates to the way workers perceive information, think and decide. Therefore, the construction industry can benefit from a systematic review of social, physiological, and cognitive factors that have not been presented in the current body of knowledge.

In the following sections, a literature search for construction safety is presented and significant social, physiological, and cognitive factors extracted from the literature are discussed. Afterward, some discussions on the implications of findings in addition to the challenges and opportunities are presented.

2 Literature Search

In the search of representative factors influencing construction safety in each major category (i.e., social, physiological, and cognitive), keywords have been chosen based on the number of published papers. The number of the literature linked to each keyword was counted in order to see a distribution of the literature in each major categories. Figure 1 shows the number of the literature that appeared relevant to the subject in six different publishers (i.e., ASCE, Elsevier, Taylor and Francis, Springer, IEEE, American Psychological Association). These factors were reviewed in this paper to give readers a broader view while supporting the majority of research in construction safety.

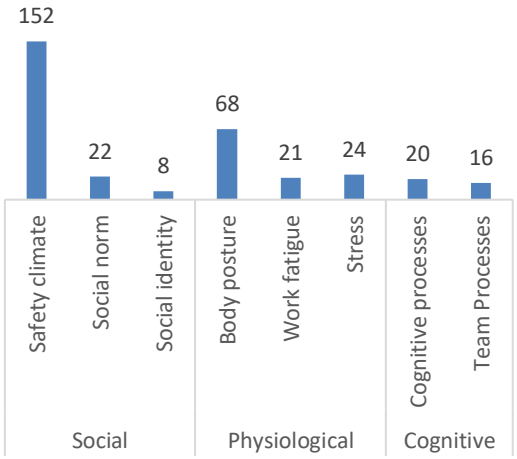

Figure 1. Distribution of the literature in each major categories of factor affecting construction safety

3 Social Factors

Safety in construction sites is not only related to the isolated act of workers, but also the social interactions resulted from the collaboration and communication among workers in such a dynamic environment. Therefore, investigating workers' safety behaviours from a social point of view has attracted researchers' attention. The following section will briefly present safety climate and social norm and identity as the social aspects of workers' safety behaviours.

3.1 Safety climate

Safety climate is defined as a subordinate of organizational climate and management commitment to safety, which determines workers' view toward safety in their workplace [8]. Safety climate has been considered as an effective component in the safe behaviour of construction workers [9] and is considered to have a higher impact on improving safety when compared to factors associated with workers experience (e.g., it is more practical to improve management commitments to safety instead of recruiting workers with more work experience) [10]. Therefore, understanding the factors contributing to the safety climate will have a positive outcome through the safe conduct of work in construction sites.

For measuring safety climate, Zohar in 1980 established an eight-factor model and concluded that a change in management attitudes and increased commitment are essential for safety in industrial workplaces [8]. In 1986, Brown & Holmes established a three-factor structure on an American sample of production workers for assessing safety climate [11]. Following the research conducted by Zohar [8] and Brown & Holmes [11], Dedobbeler & Blend [12] presented a two-factor model by using data on nine nonresidential construction sites in Baltimore, MD. The two selected factors for measuring safety climate were (a) management's commitment to safety and (b) workers' involvement in safety with the overall emphasis on management and workers' participation in safety matters.

Core components of safety climate approach have been identified as (a) safety priority, (b) safety supervision, training, and communication, (c) safety involvement, and (d) safety rules and procedures [13].

In addition to the identified factors in safety climate, the impact of five specific safety climate factors (i.e., safety management systems and procedures, management's commitment, safety attitudes, workmate influence, and employees involvement), and four other factors associated with workers' experience were investigated. The results indicated the higher impact of safety climate factors on improving safety when compared to workers' experience factors [10].

3.2 Social norm and social identity

The other social factor that has been considerably studied in the literature is the effect of social norms and social identities on workers' safety behaviour. This is due to the importance of social influence on construction worker's safety behaviour. [14] demonstrated the effect of social influence by adopting a virtual reality system in a hazardous situation. Social norm driven from co-workers and managers influences workers' safety behaviour and could be responsible for workers' unsafe act [15].

In social context, social identity theory explains that people categorize themselves and others into different social groups with specific group members' behaviour [16]. When a specific group identity is salient in an individual's mind, that person considers herself or himself as a representative of the group and is eager to align with group norms, which would affect her or his behaviour [17]. Choi et al. studied the role of social norm and social identity on construction workers' safety, and the chosen group identity included trade, workgroup, union, project, and company [18]. The results showed the strong influence that group norms have on personal standards since trade identity and workgroup identity were more prominent in construction workers' mind, as they identified themselves a representative of trade and workgroup. Consequently, workers' safety behaviour is more likely to be influenced by trade and workgroup norms. Project identity, however, was identified as the least relevant group among the construction workers. Therefore, workers' safety behaviour is not strongly affected under project managers' influence. The findings indicate that improvement in the project identity could enhance the relationship that the perceived management

norms have on workers' safety behaviour.

In [19] the effect of different cultural backgrounds and organizational structures on achievement from [18] was investigated. United States, Korea, and Saudi Arabia were chosen to study the impact of social norms (i.e., perceived management norms, perceived workgroup norms) and project identity on construction workers' safety behaviours in different settings. The results showed the lessening effect that project identity has on the relationship between social norms and safety behaviour in the U.S. and Korea. However, Saudi Arabia with a direct hiring system that leads to a strong project identity did not show an effective impact that project identity and social norms could have on safety behaviour (the reason recognized as the project manager did not show enough strictness to influence workers' safety behaviours).

In [20] the effects of three different safety management interventions on workers' safety behaviour along with three different site risks were investigated. The three safety management interventions, i.e., stricter management feedback, more frequent management feedback, and fostering workers' project identification were found effective for reducing incident rate. Based on the results, improving workers' project identification in moderate-risk site condition was recommended as the best policy as their risk acceptance would be aligned with their perceived management norms rather than workgroup norms. Also, in the low-risk site condition, rigorous management feedback is needed to see the improving results of other interventions.

4 Physiological Factor

Construction work is a physically demanding job, and a considerable number of workers go beyond the accepted and safe physiological level for manual work [21]. In addition to the physical demands of the work, workers' physical status can affect the safety and productivity in the work setting. Therefore, measuring and monitoring workers' physiological status can provide valuable information for safety in construction. Three major physiological aspects of construction workers, i.e., body posture, work fatigue, and stress, are identified from the literature and will be discussed in detail below [22-28].

Implementing new technologies for monitoring workers' unsafe actions and providing instructions on conducting safe activities have been suggested by Bernold and Guler [29]. For collecting data on workers' physical status, Lee et al. [30] investigated the applicability of wearable sensors on roofing crews. Data were collected during and after work hours for measuring heart rate, energy expenditure, metabolic equivalent, and sleep efficiency aiming to observe workers' physiological status and well-being. This study confirmed the feasibility of using wearable sensors for construction safety and individual health monitoring and management.

4.1 Body posture

Excessive physically demanding work such as manual material handling tasks in construction activities could lead to musculoskeletal injuries [31], which is a risk to workers' safety and health. To identify and locate unsafe postures of workers, Cheng et al. [32] presented an automatic remote monitoring approach focusing on bending postures. Different physical status such as heart rate and bending angle recorded using physical status monitoring (PSM) tools (BioHarness BT 1 and Equivital EQ-01) were synchronized with ultra-wideband (UWB) signal to give the accurate time and locations of unhealthy bending postures. Moreover, PSM tools were validated to be an effective tool for unobtrusive and remote monitoring and control tool to manage workers' health and safety [33].

4.2 Work fatigue

Analysing sleep deprivation and fatigue among construction workers showed the 8.9% increase in the risk of having an accident [34], and the construction industry needs to avoid fatigue especially for workers in higher risk that need priority in training and monitoring. In general, crewmembers are more prone to physical fatigue than machine operators and they routinely exceed acceptable levels of energy expenditure, oxygen consumption, and heart rate [35]. Among different occupation of crewmembers, Chang et al. [26] investigated work fatigue and physiological symptoms in order to identify occupations in need of more attention regarding health and safety. The scaffolders, steel fixers, and form workers were categorized as the most physically-demanding work groups, and scaffolders experienced the highest average heart rate during work hours. Furthermore, Techera et al. in [36] investigated a fatigue predictor model and showed that predictors vary by trades in a construction setting.

4.3 Stress

Job stress has been recognized as a risk factor in different industries that affect workers' health and safety [37-39]. Finance, inadequate personal time, and the nature of work have been recognized as the main source of daily stressors among construction workers [40]. Construction environment with a dynamic setting, complicated ongoing tasks, and various threatening hazards, shakes workers' stress level and their behaviour toward safety. Goldenhar et al.'s paper [41] investigated

the relationship between different job stressors (job-task demands, organizational stressors, and physical/chemical hazards and protection from them) and near misses among construction workers. Moreover, Leung et al. [42] conducted research to identify the relationship between job stressors (safety equipment, supervisor support, co-worker support, job control, and job certainty), physical stress (i.e., biological reactions), psychological stress (i.e., traumatizing experience), safety behaviour, and accident. The result showed that (1) having a job certainty, co-worker support, and safety equipment would result in decreased physical stress; (2) the level of psychological stress is predicted by supervisor support and lack of job certainty; (3) safety behaviour would be achieved by supervisor support and minimum physical stress; and (4) accidents could be prevented by safety behaviour.

5 Cognitive Factors

Understanding the way construction workers perceive information and decide to take a specific action is undoubtedly a critical way of discovering why an unsafe act has been chosen and how information collected by workers can affect their decisions. In this section, critical cognitive factors in the literature are discussed to better understand workers' cognition and its impact on safety in construction sites.

5.1 Cognitive processes

Knowing human error as the most frequent cause of accidents [5-7], different cognitive models in high-risk industries (e.g., nuclear plants [43], aviation [44], and mining [45]) have been developed to describe human cognition. For construction worker's unsafe behaviour, Fang et al. [46] proposed a cognitive model that contains stages of a construction worker cognitive process while encountering with a potential hazard, namely obtaining information, understanding information, perceiving responses, selecting response, and taking action.

As described in [5], an unsafe behaviour could be derived from a failure at any stage of cognition. In a construction setting, limitations in worker's senses due to unfavourable site conditions (e.g., loud noise or obstructed views) could prevent a worker from observing the hazards and consequently result in a failure in obtaining information [46]. Also, workers' lack of attention could prevent a worker from identifying an incident that leads to an accident [47]. Certain eye movements can represent the state of worker's attention and therefore be used to predict human error [48]. Furthermore, workers' selected response is likely to be influenced by the high production and coordination pressure rather than safe conduct of the job [46].

5.2 Team Processes

Team process is an essential factor for construction safety since a team can stop errors from happening and manage a situation that affects safety. The relationship between team members could help workers with learning and adopting safety behaviours. Moreover, from a resiliency perspective, the team recognizes, collaborates, and adjusts to unplanned events and manages to stabilize the situation [49]. Teamwork as a component of a team performance includes cognition, attitude, and behaviour leading to the dynamic processes of performance [50]. Team cognition is a cognitive activity happening at a team level and not individually [51], which has different dimensions, namely team mental model, transactive memory, group learning, shared team situation awareness, and strategic consensus [52]. Compatible environment, anticipation to balance workload, and instant information are essential for a team's cognition, performance, and safety in construction [49].

6 Concluding Remarks

This study presented significant factors affecting construction safety through a review of the literature in this realm from social, physiological, and cognitive viewpoints. Three major categories of construction safety factors, i.e., social, physiological, and cognitive factors, were synthesized to guide the research and practice in construction safety management.

It was identified that improvement in safety behaviours in construction site can be achieved by improving management commitment and engagement in safety programs. The study also presented that improving safety climate is more effective than paying attention to the individual's work experience. In a work setting, workers' safety behaviour is more likely influenced by the trade and workgroup norms rather than the project norm. Improving project identity to increase project managers' influence on workers' safety behaviour would be a solution to align workers safety behaviour with project manager attitude.

With high volume of manual and physical work in a construction, monitoring workers physical factors such as bending angle, heart rate, energy expenditure, and oxygen consumption can help manage and control workers physical status during working hours. Eliminating job stressors (i.e., safety equipment, supervisor support, co-worker support, job control, and job certainty) is another way of improving workers safety behaviour.

Studying individual cognition and team cognition is instrumental in understanding the reasons in taking an unsafe act. Different stages of cognition are important since a failure in any stage could lead to an accident.

Providing appropriate circumstances in favour of accurate cognition is essential to eliminate accidents.

Abstract -

With the emergence of 3D technologies in a recent decade, BIM software makes it easy to detect those conflicts in the early stage of a project. Clash detection in BIM software is now a common task. Among those conflicts found by BIM software, however, a relatively high percentage belongs to 'pseudo conflicts'—which are permissible or tolerable, but BIM software does not reveal this information. Thus, currently BIM managers have to manually inspect every detected conflict to classify the type of conflict. Some researchers urged an automated process to facilitate this laborious process. This study implemented both a rule-based reasoning system and machine learning classifiers to help classify those BIM-detected conflicts. Preliminary testing results indicate that machine learning algorithms can achieve comparable results to a traditional rule-based system, but with much less costs and energy in developing.

Keywords –

Clash detection, Machine learning, Rule-based reasoning, BIM

1 Introduction

Generally, engineering designs are constructed and compiled by engineers of different professions, such as those in construction, structural engineering, and mechanical, electrical, and plumbing (MEP). Therefore, conflicts between different design disciplines are inevitable [1, 2]. Design conflicts are errors in which building components overlap in a certain space when various design plans are being compiled. Minor design conflicts often induce rework and cost increases, whereas severe conflicts may cause change orders, resulting in cost overruns, delays, and labour safety issues. Therefore, project performance will be substantially affected if design conflicts are not properly mitigated. [3].

The emergence of building information modelling (BIM) software in recent years has simplified design clash detection, with conflict or interference checking being basic functions of BIM software programs. Because resolving design conflicts is critical to project performance, combined with the popularity of BIM software, building codes in many countries have mandated the enforcement of clash detection in public projects [1]. For example, in the United Kingdom, a design team is mandated to perform clash detection every 1 to 2 weeks to ensure that engineering designs are fully coordinated and free of conflicts, thus reducing the likelihood of design changes occurring.

However, a discussion of effective methods to mitigate design conflicts and the use of BIM to assist in decision-making has been neglected in the literature [3]. Due to the existence of numerous engineering interfaces in a single project, BIM software can often easily detect hundreds of clashes, even for small-scale projects. BIM managers thus must examine and analyse each conflict manually. Some researchers have stated that although BIM software programs have excellent clash detection functions, the classification of detected clashes is still difficult, time-consuming, and costly, and thus an automated classification method is urgently required [1].

Because classifying clash types requires the input of experts with vast knowledge and experience, conventionally a rule-based expert system is often used for automated process development. However, rule acquisition when developing an expert system is time-consuming and laborious, and its prediction performance is usually limited by the number of rules. By contrast, supervised learning (i.e., machine learning) only requires the collection of sufficient cases and appropriate feature manipulation to quickly obtain required results. Furthermore, its accuracy increases continuously as the number of cases increases.

This study used the structural and MEP models of a construction project as an example, and implemented

three automated processes to classify those conflicts detected by BIM software using rule-based expert system, individual classifiers of supervised learning, and multiple classifiers of ensemble learning, respectively. Their performances in terms of predictive accuracy were then compared and evaluated. The results showed that the accuracy of the rule-based expert system was approximately 58% while 92% and 94% were acquired using individual classifiers and ensemble learning, respectively. This indicated that machine learning algorithms can achieve comparable results to a traditional rule-based system regarding conflict classification, but with much less costs and energy in developing.

2 Related Work

2.1 Spatial clashes

Wu [4] divided spatial conflicts into four categories: design conflicts, construction conflicts, damage conflicts, and congestion. Design conflict refers to spatial overlap between building components when different design teams develop their own designs. Wu also found that the existence of numerous interfaces among construction project participants is the main source of design conflicts. Researchers in another participatory action research project in the United Kingdom introduced a collaborative environment in a jointly designed large-scale, multistory construction project, and assisted the designers in avoiding design conflicts. However, more than 400 conflicts were still observed between the structural model and the MEP model [1]. The study revealed that although collaboration can decrease design conflicts, clash detection still remains a necessary process.

In summary, design collaboration does not prevent all conflicts; thus, clash detection and resolution are still necessary. Although most BIM software provide clash detection, classifying and resolving those detected clashes remain manual and difficult. The UK study [1] found that after performing clash detection, BIM managers need to classify types of those detected clashes, namely: (1) errors, which must be resolved; (2) pseudo clashes, which are permissible and does not require to be resolved; 3) deliberate clashes; and (4) duplicate clashes. Due to the considerable number of engineering interfaces, BIM software will produce substantial clash detection results, even for small-scale projects. BIM managers must go through the above-mentioned manual process. Since this process is highly mechanized, time-consuming, and costly, an automated classification method is urgently required; otherwise, the benefits of clash detection provided by BIM software will be reduced due to information overload [1]. Concluding remarks in those studies illustrated the necessity and importance of this study.

2.2 Machine learning in civil engineering

Machine learning is a computer science related to how machines can learn in a similar manner to humans. In machine learning, the process of human learning and adjustment is transferred to machines. According to whether or not the answers are provided during the training, machine learning has been usually identified as two categories: (1) Supervised learning：During training, answers (labels) are supplied to a question to provide the machine with the ability to recognize errors. This study applied this approach to train and test those classifiers; and (2) Unsupervised learning：No answers are provided to a question during training process; thus, the machine must find the answer itself. The expected results from this learning method are usually less accurate than those in supervised learning.

Machine learning has widely been used in numerous studies on civil engineering applications, such as for monitoring construction progress using 4D BIM, performing regulatory inspections using BIM, reconstructing 3D models using computer vision, and using static images to monitor constructability [5].

The development of machine learning algorithms involves five basic steps [6]: (1) Obtaining data required for training, analysing and selecting the features related to problem solving. (2) Choosing a performance metric. (3) Choosing a classifier and optimization algorithm (4) Evaluating the performance of the model; and (5) Tuning the algorithm. Once learning is completed, estimations can be performed by inputting new data into the algorithm. In most problem-solving tasks, the classifiers can be either linear or nonlinear models. The most common linear model is the linear regression model while non-linear models include the decision trees, k nearest neighbors (k-NN), support vector machine (SVM), and deep learning. However, due to problems having different domain-specific characteristics, it is nearly impossible for a single classifier to work well across all scenarios [7]. Besides, the performance may be dependent on the training and testing data, especially when the number of samples is not large enough. Therefore, it is highly suggested to compare the performance of different classifiers and select the best model for the domain problem.

Since the problem of identifying clash types in this study belongs a classification problem in machine learning, this study used non-linear models to implement individual classifiers and ensemble learning models.

3 Methodology

To evaluate the performance of the rule-based reasoning and machine learning algorithms on classification of clash types, this study developed a process of research methodology as shown in Figure 1. Section 3.1 and 3.2 describes the collection of clash cases and how we labelled the clash type by human experts. Section 3.3 introduced the implementation of the rule-based system, followed by Section 3.4 and 3.5 which detailed the training of single classifiers and multiple classifiers, respectively. Section 4 then provides the results of prediction by different methods using the testing dataset as well as the evaluation of their performance in terms of prediction accuracy。

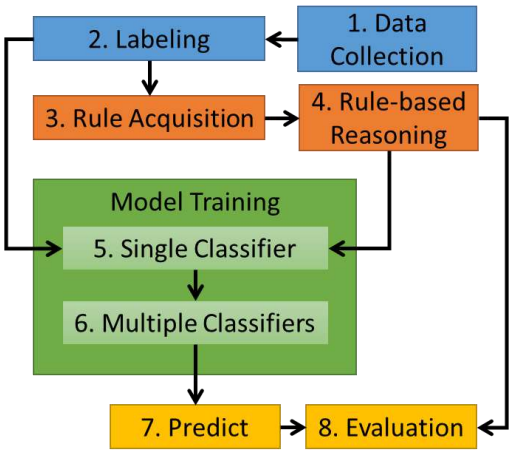

Figure 1. Process of research methodology

3.1 Data Collection

This study used a large shopping mall with nine floors above ground and four floors underground as a sample case. Three floors of the structure were extracted, and Autodesk Navisworks was employed for clash detection. To reduce the load of subsequent labelling process, this study only selected water supply pipelines within the MEP model against the structural model for clash detection. Figure 2 shows the clash detection report for models on the sixth floor . The table at the top shows the total number of clashes while the following table lists all details of each clash, including grid location, clash point, distance, and information about the two clashed items (e.g., item ID, layer, item name, and item type). In addition, two image icons are available. The image can also be viewed by clicking on the icon (Figure 3). Table 1 shows the statistics of the entire clash detection report including 415 structural clashes against flow segments such as pipes and fittings.

Figure 2. Illustration of the clash detection report produced by Autodesk Navisworks 2017

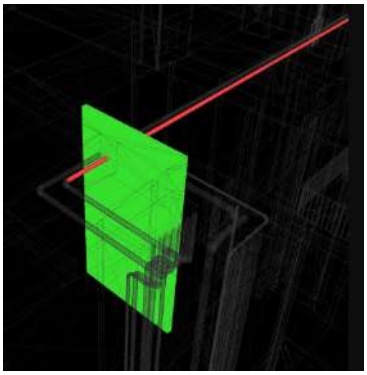

Figure 3. The snapshot of a clash produced by Autodesk Navisworks 2017

Table 1. Statistics of the clash detection report

	Pipes	Fittings	Total
Framings	153	25	178
Walls	155	68	223
Columns	1	1	2
Landings	12	0	12
Total	321	94	415

3.2 Labeling the Clash Types

After completing the clash detection report, the research team integrated the HTML-based clash report into a spreadsheet. Two senior engineers with experience in clash resolution were requested to classify the clash types. A column with a drop-down menu in the spreadsheet was provided for the experts to carry out labelling (Figure 4). This spreadsheet contains all the information in the clash detect report of Figure 2, including a hyperlink to view the clash image, as shown in Figure 3. The drop-down menu consists of four

options with intuitive common vocabulary: severe clashes, negligible clashes, legal interventions, and unknown. These four options were mapped to the four categories suggested in the literature: errors, pseudo clashes, deliberate clashes, and unknown, respectively. The research team also provided the experts with 2D CADs and 3D models of the building for their references.

The labeling process took approximately 10 days. Table 2 shows the summary of results by the two experts. After a detailed comparison was undertaken, 89 clashes were labelled with different answers by the two experts, accounting for approximately 20% of the total number of clashes. Therefore, the remaining 326 cases were used for subsequent analysis.

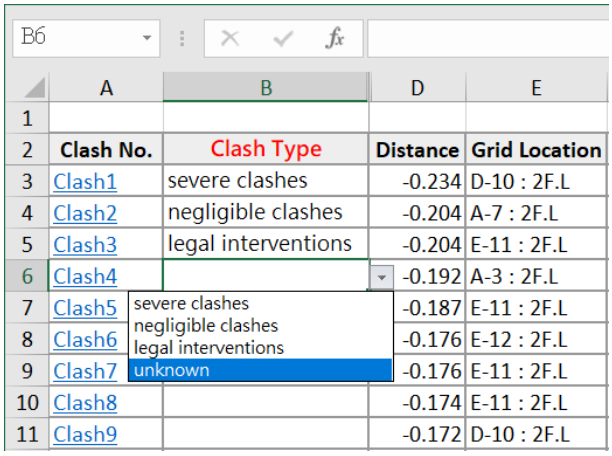

Figure 4. Spreadsheet-based clash detection report for labelling by human experts

Table 2. Statistics of training and testing data

Clash Type	Expert #	Expert #2
Serious clashes	159	208
Neglectable clashes	0	0
Legal intervenes	174	148
Unknown	82	59
Total	415	415

3.3 Rule-based reasoning

After obtaining the labelling results from the experts, the research team acquired 4 rules of clash type classification rules by interviewing the two experts as follows:

1. Beam rule: If the structural component of a clash is a beam, then the clash type is either a severe clash (i.e., error) or negligible clash (i.e., pseudo clash). Severe clashes located near two ends of the beam can affect structural safety, whereas negligible clashes do not affect structural safety but require perforation processing.
2. Column rule: If the structural component of a clash is a column, then the clash type must be a severe clash (i.e., an error).
3. Slab rule: If the structural component of a clash is a slab, then the clash type must be a legal intervention (i.e., a deliberate clash).
4. Wall rule: If the structural component of a clash is a wall and a load-bearing wall, the clash type must be a severe clash (i.e., an error); otherwise, it is a negligible clash.

Some rules involve complex spatial operations or require other supporting information to be processed. For example, the identification of clash position and wall type is required for Beam and Wall rules, respectively. The limited information provided in the report did not allow for corresponding calculations. Therefore, under a conservative consideration, this study simplified the aforementioned Beam and Wall rules as follows:

1. Simplified beam rule: If the structural component of a clash is a beam, then the clash type is a severe clash (i.e. errors).
2. Simplified wall rule: If the structural component of a clash is a wall, then the clash type is unknown.

Numbers in parentheses in Table 3 represent the numbers of clashes that are consistent with expert classification results. Because the simplified rule tends to be conservative, the prediction accuracy rate will be lower, especially for the Wall rule, which had an accuracy rate of only 15%, resulting in an overall classification accuracy of less than 60% (189/326).

A further modification was made to the Wall rule: “If the structural component of a clash is a wall, then the clash type is negligible (i.e., a deliberate clash).” This increases the overall accuracy rates to 87% (283/326). However, this modification may carry a potential risk of mis-classification

Table 3. Results of rule-based reasoning using simplified rules

Clash Type	Simp. beam rule	Column rule	Slab rule	Simp. wall rule	Total
Serious clashes	174 (154)	2 (2)			176 (156)
Neglectable clashes			12 (12)		12 (12)
Unknown				138 (21)	138 (21)
Accuracy	0.89	1.00	1.00	0.15	0.58

3.4 Feature selection and pre-processing for machine learning

As described in the literature review, the first step in developing a machine learning algorithm involves selecting features that are relevant to problem solving. In addition, because the development tool used in this study (i.e., scikit-learn) can only process numerical data, the nominal or text features must be coded as numerical features. Table 4 shows the selection and manipulation of each feature that we used for training machine learning algorithms. Among them, numerical features such as "Distance", "Floor-1", and "Floor-2" remain unchanged; "Clash Point" is the coordinate with a mixture of numbers and text and is separated into three numerical features, namely "Clash Point_x", "Clash Point_y", and "Clash Point_z"; As for "ItemType-1" and "ItemType-2", which are nominal features, one-hot encoding is performed separately, thus deriving six features as shown in Table 4.

In addition, to test whether the results of rule-based reasoning (see Section 3.3) contribute to the improvement of the prediction accuracy of the machine learning algorithm, another feature "Rule-Tag" was also added to label the result of the rule-based reasoning. Since this feature is nominal, one-hot encoding is also performed before the training process.

Table 4. Summary of feature selection and pre-processing

Original Feature	Data Type	Example Value	Revised Feature
Distance	numeric	-0.234	unchanged
Floor-1	numeric	2	unchanged
Floor-2	numeric	2	unchanged
Clash Point	text	x:-7370, y:-1171, z:24	Clash Point_x Clash Point_y Clash Point_z
ItemType-1	nominal	Pipes	{Pipes, Fittings}
ItemType-2	nominal	Framings	{Framings, Walls, Slabs, Columns}

3.5 Modeling by machine learning classifiers

The research team adopted a free software machine learning library, scikit-learn, as the implementation environment, which provides a rich set of tools for classification, regression and clustering using machine learning algorithms such as decision trees, SVM, k-NN, random forests, gradient boosting, k-means and DBSCAN. Researchers suggested that no single classifier can work well across all scenarios. Therefore, this study implemented three common single non-linear classifiers and three multiple classifiers of ensemble learning. We will evaluate the performances of those different classifiers later in Section 4.

Table 5 summarizes the manipulation of training classifiers by this study. In order to test and evaluate classifier performances, the research team randomly selected 30% of the entire 326 cases as testing dataset, i.e. 98 cases, while the rest of cases is further split into training and validation datasets with a proportion of 4:1 when applying k-fold cross-validation (k=5). For classifiers like kNN, SVM, Voting, the features of training dataset were standardized before the training process.

Table 5. Summary of machine learning manipulations

Measures	Description
Data splitting	7:3 (228 cases for training; 98 cases for testing)
Performance metric	Confusion matrix
Classifiers	Decision Tree, SVM, kNN, Voting, Bagging, Random Forest
Evaluation	k-fold cross-validation (k=5)

3.5.1 Single classifiers

1. Decision Tree

First, the research team implemented a classifier using decision tree algorithm with a maximum tree depth of 6 and a criterion of Gini impurity. Figure 5 shows its learning curves with the best f1-score of 0.92. Both the training and validation curves converge at a high prediction accuracy indicating the classifier doesn't under-fit the real situation. However, two curves converge with a large gap indicating the model may suffer from over-fitting.

2. K Nearest Neighbors (k-NN)

Next, a classifier using k-NN algorithm with 3 neighbors and a uniform weight. Figure 6 shows its learning curves with the best f1-score of 0.90. Both curves in Figure 6 also converge at a high prediction accuracy with a small gap indicating the classifier doesn't suffer from under-fitting, but a bit from over-fitting.

3. Support Vector Machine (SVM)

The last single classifier implemented in this study is using SVM algorithm with 1.0 penalty and a linear kernel. Figure 7 shows its learning curves with the best

f1-score of 0.90. Although the curves do not converge well as the previous two classifiers, its high prediction accuracy and small gap still indicate the classifier doesn't suffer from high variance nor high bias.

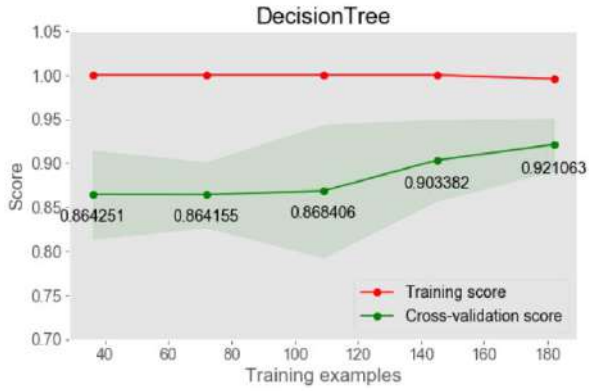

Figure 5. The learning curves of the classifier of a decision tree with a maximum depth of 6

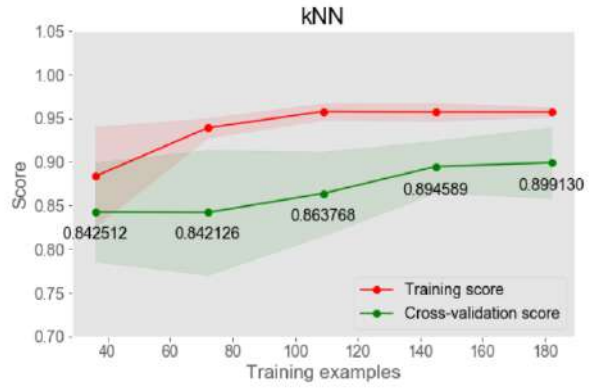

Figure 6. The learning curves of a k-NN classifier with 3 neighbors and a uniform weight

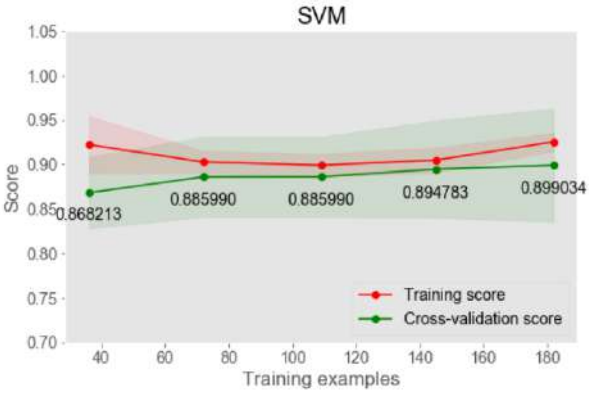

Figure 7. The learning curves of a SVM classifier with 1.0 penalty and a linear kernel

3.5.2 Multiple classifiers by ensemble learning

All single classifiers implemented previously have performed well in terms of prediction accuracy so the research team then moved forward to build up a set of classifiers following the principles of ensemble learning. The benefit of ensemble methods is to combine different classifiers into a multiple classifier that can often have a better predictive performance than each individual classifier alone. Those multiple classifiers implemented by this study include Voting classifier, Bagging classifier, and Random Forest classifier.

1. Voting

The first implemented ensemble learning algorithm is the Voting classifier, which combined three individual classifiers implemented previously, namely, a decision tree classifier, a k-NN classifier, and a SVM classifier, with a soft voting weight of 5:1:1, respectively.

Figure 8 shows its learning curves where both training and validation curves converge with a small gap at the best f1-score of 0.94 indicating the classifier doesn't suffer from under-fitting, but slightly over-fits.

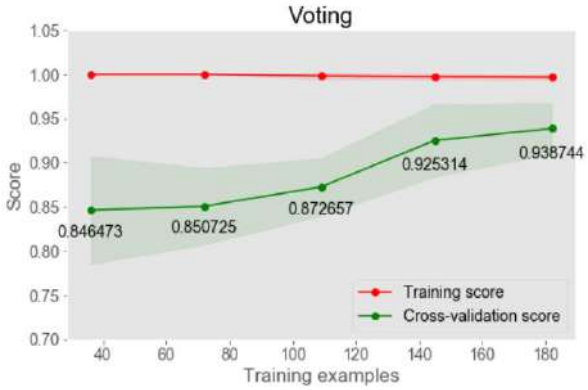

Figure 8. The learning curves of a Voting classifier combining a decision tree, k-NN, and SVM classifiers

2. Bagging

The research team then implement a Bagging classifier with 100 default estimators, where are decision tree classifiers. The learning curves shown in Figure 9 indicate that the classifier has gained a higher prediction accuracy (0.96) than any of previous classifiers. The convergence of both training and validation curves also indicates this classifier does not over-fit nor under-fit.

3. Random Forest

Finally, the research team implemented the commonest ensemble learning classifier, Random Forest,

with also 100 default estimators, or the decision trees. Figure 10 shows its learning curves with a very similar shape with the Bagging classifier.

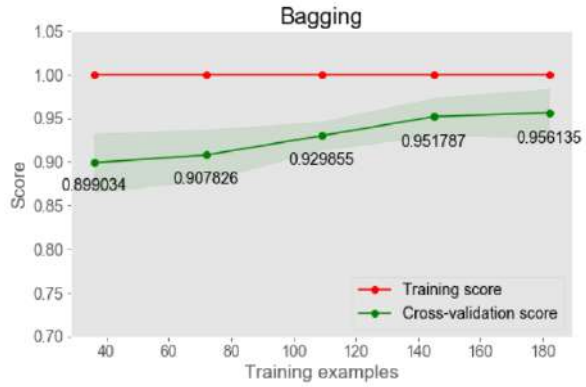

Figure 9. The learning curves of a Bagging classifier with 100 decision tree classifiers

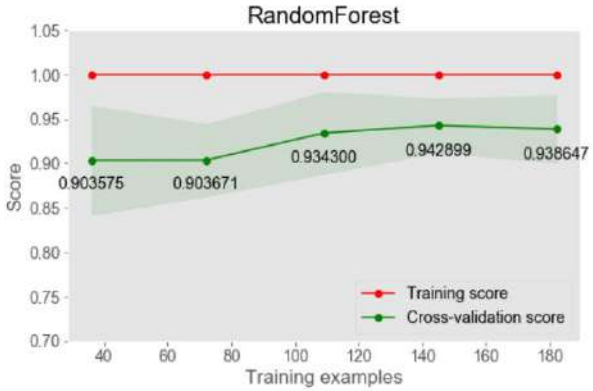

Figure 10. The learning curves of a Random Forest classifier with 100 decision tree classifiers

4 Results and Evaluation

In this section, the testing dataset of 98 cases is used to test the performance of those trained classifiers. The confusion matrix is adopted for the evaluation, which reports the counts of the true positive, true negative, false positive, and false negative predictions of a classifier, as shown in Figure 11. Three rates derived from the confusion matrix are recorded as the performance metric against all trained classifiers, including precision, recall, and f1-score, which are defined as in formulas (1), (2), and (3).

Besides those quantitative measurements, feature importance suggested by each classifier is also addressed to reveal which features explain more about the prediction results than others. Only the decision tree classifier and Bagging classifier are selected for evaluation.

		Predicted labels	
		True Positives (TP)	False Negatives (FN)
Actual labels		False Positives (FP)	True Negatives (TN)

Figure 11. The confusion matrix used to evaluate the performance of the trained classifiers

$$Precision = \frac{TP}{TP + FP} \quad (1)$$

$$Recall = \frac{TP}{TP + FN} \quad (2)$$

$$f1 - score = 2 * \frac{Precision * Recall}{TPrecision + Recall} \quad (3)$$

4.1 Results

Table 6 illustrate the testing results of 98 cases against the decision tree classifier with 6 levels. The average f1-score is 0.92 indicating a good predictive accuracy. Table 7 show the testing results of the bagging classifier with 100 decision trees. The average f1-score reaches an even better predictive accuracy of 0.94. Compared with the classification accuracy obtained by the rule-based reasoning, both classifiers can produce a much better predictive performance.

Table 6. Performance matrix of the decision tree classifier

	precision	recall	f1-score
Deliberate clashes	1	1	1.00
Errors	0.89	0.95	0.92
Unknown	0.78	0.58	0.67
Average	0.93	0.93	0.92

Table 7. Performance matrix of the Bagging classifier

	precision	recall	f1-score
Deliberate clashes	0.98	1.00	0.99
Errors	0.93	0.95	0.94
Unknown	0.80	0.67	0.73
Average	0.94	0.94	0.94

4.2 Evaluation

According to the confusion matrix of the decision tree classifier shown in Figure 12, none actual “errors” is classified as deliberate clashes or pseudo clashes, which provides a conservative prediction with a lower risk. In addition, the classifier filters out 42 “noises” (in

this case, deliberate clashes), accounting for 43% of all clashes from the original clash report, remaining only 57% to be inspected by human. Similarly, none actual "errors" is mis-classified by the Bagging classifier. The classifier also filters out 43% of clashes from the original clash report.

Figure 13 lists the top 6 features that have the higher importance to contribute the prediction results. Item type-1 "Framing" is the most discriminative feature in the dataset, which aligns with the result of rule-based reasoning in Section 3.3. Likewise, the feature importance suggested by the Bagging classifier presents a similar distribution to that by the decision tree classifier.

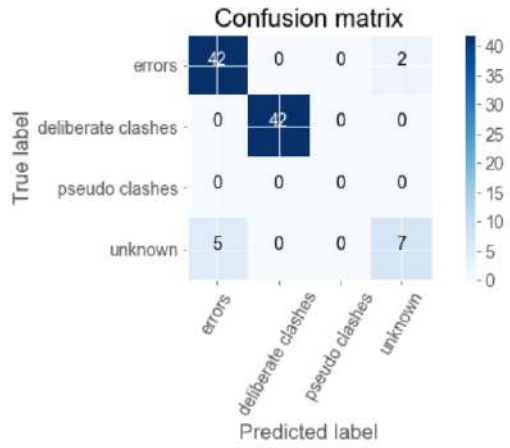

Figure 12. The confusion matrix of the decision tree classifier

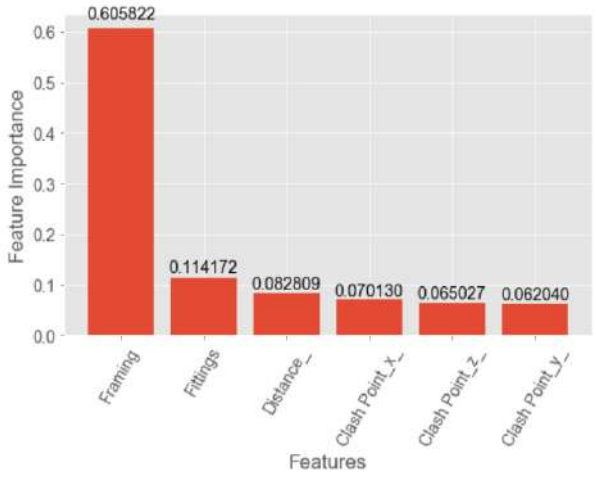

Figure 13. Feature importance suggested by the decision tree classifier

5 Conclusions

This study developed a tiny rule-based reasoning system to classify those conflicts detected by BIM software, which obtained a predictive accuracy of 58%. Then, both individual machine learning classifiers and multiple classifiers were also implemented to perform the same task. Preliminary testing results showed that both the decision tree classifier and 3 ensemble learning classifiers can obtain a much better predictive accuracy than the rule-based version.

However, the current model and its predictive performance can only be applied to this setting since the dataset used to train and test the machine learning classifiers only contains clashes between structural components and piping components. The dataset needs to be extended to include other MEP components, such as ducts, conduits, fire alarm devices, or lighting devices. Besides, most classifiers built in this paper have an over-fitting issue according to their learning curves. This could also be resulted from a relatively small number of training cases in our dataset. This limitation originates from that fact that labeling the dataset highly relied on human experts' experiences and labor work. All the mentioned issues remain to be solved in the future.

Abstract -

The retrieval of as-is information for existing buildings is a prerequisite for effectively operating facilities, through the creation or updating of Building/Asset Information Models (BIM/AIM), or Digital Twins. At present, many studies focus on the capture of geometry for the modelling of primary components, overlooking the fact that many recurring actions need to be conducted on assets inside buildings. Furthermore, highly accurate survey techniques like laser scanning need long offsite processing for object recognition. Performing such process on site would dramatically impact efficiency and also prevent the need to revisit the site in the case of insufficient/incomplete data.

In this paper, an Augmented Reality (AR) system is proposed enabling inventory, information retrieval and information update directly on-site. It would reduce post-processing work and avoid loss of information and unreliability of data. The system has a Head-Mounted Display (HMD) AR interface that lets the technician interact hands-free with the real world and digital information contained in the BIM/AIM. A trained Deep Learning Neural Network operates the automatic recognition of objects in the field of view of the user and their placement into the digital BIM. In this paper, two uses cases are described: one is the inventory of small assets inside buildings to populate a BIM/AIM, and the second is the retrieval of relevant information from the AIM to support maintenance operations. Partial development and feasibility tests of the first use case applied to fire extinguishers, have been carried out to assess the feasibility and value of this system.

Augmented Reality, Building survey, Inventory, BIM, Facility Management.

1 Introduction

One of the biggest challenges in the construction industry today is information management both in the construction phase and in the operational phase [1, 2].

In fact, the retrieval of specific data during the lifecycle of buildings represents a high cost for all the stakeholders involved in this field [3, 4]. Today, facility maintenance contractors are paid to survey existing buildings in order to capture the as-built/as-is status. In these cases, owners would pay twice, once for the construction contractor to complete the documents at the end of construction and again for the maintenance contractor survey [1]. Moreover, as far as existing buildings are concerned, information is often not available nor updated, although data mirroring the current state (i.e. digital twin) are needed for further action. As a result, a building survey is usually necessary. A number of techniques and technologies are now in use, including EDM (Electronic Distance Measurement), GPS (Global Positioning System), 3D Laser scanner [5]. However, each of the aforementioned technologies requires further post processing of data in order to provide its interpretation. This may also require further site visits to acquire supplementary data.

Another aspect to take into consideration is how the information is stored after being collected. Since BIM is becoming an industry standard, Facility Management (FM) is expected to be based on information contained in an Asset Information model (AIM) populated from the BIM model. Information collected through a BIM process and stored in a BIM/AIM could be beneficial for a variety of FM practices: such as commissioning and closeout, quality control and assurance, energy management, maintenance and repair, and space management [6]. Furthermore, data modelling is often conducted manually. The automatic detection of objects types and the related automatic creation of the digital objects

would improve process efficiency and data reliability.

For the reasons stated above the objectives of this research are as follows:

- to decrease post-processing efforts thanks to the automation of some processes and smart human intervention on site;
- to reduce the time necessary to gather any piece of information;
- to collect data in in a BIM model by creating standard BIM objects with linked data including all information necessary for further operations.

The core innovation proposed in this research lays in the integration of several hardware and software innovations into one system architecture: Neural Networks, Mixed Reality (MR) and BIM. The proposed system develops efficient human-machine collaboration, employing MR as a powerful medium between the human, (cloud) computing facilities and the BIM data.

2 Literature review

In recent years there have been increasing efforts towards the automation of survey procedures. Technologies such as Laser Scanning and photogrammetry are very accurate but they also collect a vast amount of raw data that need to be interpreted. Solutions for semi-automatic survey of the environment have already been pursued:

- The Bonanni et al. [7] combine a robot, which employs a SLAM (Simultaneous Localization and Mapping) module for building up the map of the environment, and human input to provide spatial hints about entities of interest that must be included into the map. Solutions of this type still demand a lot of effort and long time to detect all the objects since the operator has to manually detect the object and enter its features.
- Adan et al. [8] resent a coloured 3D laser scanned point clouds algorithm that allows the location of doors. This system integrates the analysis of both geometry and colour provided by a calibrated set of 3D laser scanner and colour camera with the aim of detecting, localizing and sizing doors.
- The method proposed by Quintana et al. [9] regards a system for the detection of 'small components' in coloured point clouds acquired by a 3D laser scanner.
- Lu et al. [10] propose a recognition system composed of sub-systems for: (1) object recognition, based on a new neuro-fuzzy framework; (2) material recognition, based on image classification procedures and the trained texture library; (3) IFC BIM object generation, that automatically transforms recognized objects with materials information into complete BIM objects in IFC.

These studies focus on the automatic interpretation of collected data. Anyway, they still require post processing effort, such as the Adan [8] and the Quintana [9] studies, or they are way too complex to be effective during on site procedures, like the Bonanni's one.

As far as the support given by MR in maintenance operations is concerned some early experiments have already demonstrated the possibilities provided by the display of information on site. The numerous advantages in the use of MR towards the entire lifecycle of building is well described by Riexinger et al. [12]. Both this article and the one by Fonnet et al. [13] demonstrate the convenience in displaying information on site through holograms so as to help during the refurbishment of buildings. Practically, Ammari et al. [11] developed a system capable of showing holograms thanks to Augmented Reality (AR) and image tracking. The system is composed of a IFC XML database that makes it possible to display separated pieces of information if necessary. Hugo et al. [14] used Revit for the geometric and appearance features and Dynamo for a query of data transferred to Unity in XML format. Then they developed the MR environment in Unity and finally deployed into the Hololens a first attempt of holographic projection of a building three dimensions model at a small scale. Finally, Kopsida and Brilakis [15] present an evaluation of different methods that could be implemented for a marker-less mobile BIM -based AR solution for inspections. In conclusion they state that there are no efficient mobile AR solutions for on-site inspections and that other methods for marker-less AR, even if already introduced, have not yet been tested on construction sites.

As for the use of Neural Network (NN) and Augmented Reality together, Baek et al. [16] proposed a NN-based method for indoor localization. Their work is also motivated by the need to provide relevant information in FM applications.

While these works demonstrate the growing interest of the AEC industry in MR, many issues have still to be addressed: the proper scale of the visualization of building components in situ; accurate localization of the operator inside the building so as to automatically display relevant information; recognizing building assets without specific markers (visual markers or RFID tags); and providing an effective interface between MR headsets and BIM data.

In this paper we propose an architecture that combines some of the aforementioned techniques to allow operators effectively survey buildings for maintenance applications, with MR interface to the

BIM/AIM model, and automatic object detection supported by NN.

A significant challenge to the delivery of such system is the development of an effective approach to indoor user localization.

3 System Architecture

The system architecture supports both use cases previously defined and it can be divided into two main environments as shown in Figure 1:

- The Mixed Reality (MR) environment which is where the digital copies of the real objects are developed and/or manipulated while on siteThis includes an object recognition application (paragraph 5.2).
- The real environment which is represented by the building and the assets object of the survey, the operator and its whole equipment. The real environment is the place where the holograms are displayed and overlapped to it.

The MR environment is composed of the following components:

- BIM environment used to develop the initial building model. This digital twin of the real building will be enriched with the data from the survey.
- The MR environment, which is represented by the software Unity, that allows to develop applications for the MR tool. The scene inside Unity includes the building model imported and all the components necessary to make operations and have interactions between reality and digital information.
- The real environment on the other hand comprises the following elements:
- Microsoft Hololens which is the head-mounted display chosen to show the MR environment on site and to act as an interface between the digital world and the real world (operator and environment).
- On-site operator who is doing the survey wearing the Hololens.
- Neural Computer Stick-Movidius which is a neural computer stick that is specially designed for working with neural networks. In order to make the entire system usable on site the images are processed by this tool, as opposed to rely on cloud computation.
- Embedded PC- Raspberry which works as an interface between the Hololens and the Movidius, and as a hardware support for the latter.

The Hololens application created in Unity performs the following tasks:

1. it keeps track of the position of the gaze (the

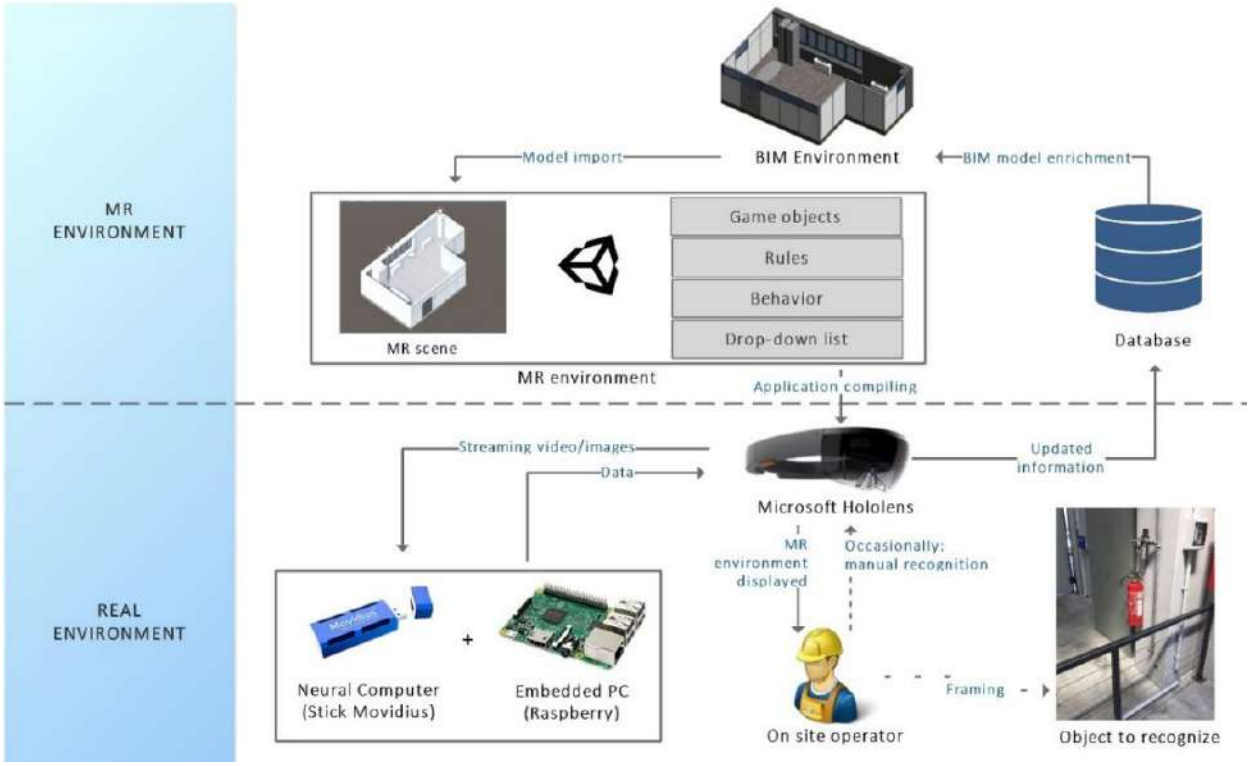

Figure 1. System architecture

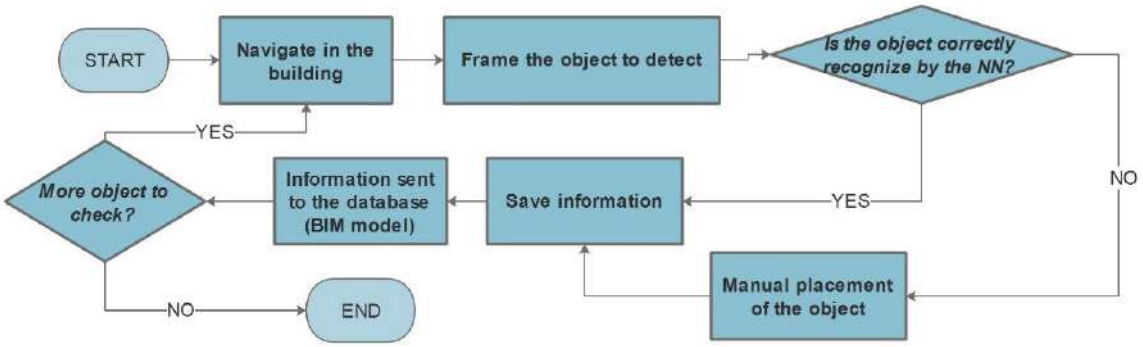

Figure 2. Assets inventory procedure

point the operator is looking at);
2. it sends the streaming video (or images) to the embedded pc;
3. it reads the information provided by the neural network;
4. it acts as interface for the user to manipulate digital objects, their placement in the BIM model.

4 Use cases

The previously explained architecture is specifically thought to be used in two different use cases: the inventory of secondary building assets ; and the support of maintenance operation through asset recognition and retrieval of information concerning selected objects.
These two use cases are discussed in the following paragraphs.

4.1 Assets inventory

The inventory is a costly operation [2] since it requires a large amount of money and thousands of man-hours for creating/updating information [3, 4] necessary for operating buildings. The system proposed aims to reach a certain level of automation in the process of data collection, especially compared to current inventory procedures that still require long post-processing [8].
For these reasons, the first use case aims to improve the efficiency of survey procedures as well as to lead to the automatic enrichment of BIM models.
The procedure proposed (Figure 2) with this system considers an operator wearing the MR head-mounted display and walking into the building for the first time. Once any asset (secondary component) to detect is framed by the MR device the image is sent in real time to the neural network which is trained to recognize a specific category of objects. The neural network sends back the label associated with the image (as an outcome of the recognition) and the coordinates of the position of the object (assessed from the drawing of a bounding box containing the element). These data allow the application to choose a specific object, among a predefined library, and to place it, as a hologram, into the real environment. In the case of incorrect or missing identification, the operator has still the possibility of manually placing the object, as a hologram, into the real world. All the data about the detected objects and their positions are transferred into a NoSQL Database so as to be available for future operations.
The procedure just explained will enable the operator to check real time the collected data and to modify them if necessary while on site. This will reduce the possibility of errors or of losing. AR will represent a valuable means to display the gathered information so as to interact with them on site. The operator and the application proposed will work in parallel leading to a higher efficiency in contrast with current methods where there is a prevalence of man-machine working in series. This use case has been partially developed as explained in section 5.

4.2 Maintenance operation support

The architecture proposed can also be valuable to support maintenance operations. Buildings contain a series of assets that need maintenance and which are subjected to regular inspection. Correct and immediate localization of objects requires time and it involves a greater possibility of error in complex buildings.
With the objects recognition system the procedure starts with the inspector walking around the facility with the head-mounted display. The application in the device sends continuously in real time the video of what the operator sees to the embedded system. Once the operator frames a component of interest, a pre-trained neural network in the embedded system performs an identification. The application

automatically shows the hologram of the object identified, with all its components, and asks for the information to additional show as holograms (e.g. procedures, check-lists, user manuals, usage data). The technician has the possibility to check information needed and to fill in forms at the end of operations. The information entered in the application is transferred to the FM database so as they can be consulted in case of further maintenance operations.

On one hand this procedure will ensure better performance on site, thanks to the possibility to show larger amounts of information on a digital device and directly related to the object. This will save time used to retrieve the useful information. On the other hand, the real time updating of data reduces the time necessary to fill in the database with this information and support the operators in preventing data loss. Furthermore the automatic localization on site is highly beneficial in case of buildings where the operator is working for the first time, or to avoid manual errors (e.g. wrong floor selection). Finally, this system would definitely provide support with new personnel since the MR allows to show detailed step-by-step procedures directly in their field of view.

5 Preliminary development

5.1 From BIM to Unity

Information from the BIM model necessary to create the proper MR scene. First, the geometry of the building is required to allow an accurate positioning of the secondary components. Secondly, component definition, parameters and details are needed to improve the accuracy of the location data. For instance, an object fire extinguisher has to be placed on wall surfaces, thus walls need to be sufficiently detailed. Materials too could be practical as it would make the vision more pleasant and realistic and it would help the operator in identifying surfaces and components.
In order to upload the BIM model into the Unity project the method chosen was to use the *.fbx* format. Importing such file directly into Unity without any other operation results in a loss of graphical information, so it is fundamental to do a second passage through 3D Studio Max so as to re-assign materials to objects. However, with this first method, non-graphical object information is not showed in Unity. The recognition system for inventory requires the geometry more than these non-graphical parameters. However, for the second use case, object parameters are necessary in order to update or consult data during operations. For this reason, further studies will be conducted on a new method to import non-graphical along with graphical object information, possibly by deploying a COBIe or IFC data parser.

Figure 3. Secondary element recognition embedded system

5.2 Recognition application

The recognition application will be developed in Unity, using the programming language C#. This application will carry out the following tasks:

1. to read and interpret the data about the position of the operator in the building, and therefore in its digital twin;
2. to send the streaming video to the embedded system;
3. to read the data from the recognition process (bounding box coordinates and object type);
4. to identify among a predefined library of objects the object type that matches the recognition response;
5. to locate the object in the right position according to the bounding box coordinates provided in the recognition response, the depth dimension provided by the mesh (that Hololens automatically does because the fire extinguisher owns a behavior for its positioning on walls);
6. to provide the possibility of modifying the object type or its position manually;
7. to provide the possibility of adding objects manually.

Tests on the insertion of doors and windows in the MR environment have been carried out.

5.3 Streaming video and data transfer Hololens – embedded system

The purpose of this system was to have the whole process performed on site. From the sending of the first piece of information, the video, up to the positioning inside the digital building of the

components, in the form of hologram, everything is carried out on site and real time (Figure 3). The communication protocol supporting the information flow for the recognition process from the Hololens to the embedded pc is defined as follows. In order to let the Hololens communicate with the Raspberry, a custom protocol over TCP/UDP is employed. This communication works through a local network and it is able to transfer both streaming video and data deriving from the recognition.

5.4 Neural Network

The recognition of small objects takes place by means of trained neural networks. The objectives of this recognition process are to identify the right type of object (e.g. fire extinguisher size), and locate it accurately within the frame ;

Several types of neural networks exist and the YOLO is the one chosen for this project, for the following reasons [17, 18]:

- the speed which is 45 frames per second; this means streaming video can be processed in real-time, with negligible latency of a few milliseconds.
- the one-step method for classification and localization of objects;
- the simultaneous prediction of multiple bounding boxes;
- the simultaneous prediction of multiple label confidence score;
- it is an open source solution.

In this project, a pre-trained YOLO is used. With this kind of neural networks, it is possible to re-train the last level of the network to detect the object of interest. The network needs a dataset of images to learn how to recognize the object of interest. The dataset features are explained in the following sub-section.

5.4.1 Dataset creation

The dataset to train the network to recognize a specific object should have specific features. With the aim of identifying only the right object, i.e. a fire extinguisher, the dataset will include at least one image for every existing type of fire extinguishers, so as to be able to recognize the fire extinguisher no matter the external appearance. As the dataset must include thousands of pictures, it will be made up of both original pictures and graphically re-edited photos as suggested by studies on dataset creation [19]. The process of editing the original photos is performed with the help of an augmentor software program available online.

The creation of the dataset involves labelling all the images, both with the bounding box around the object to be recognized and with the label assigned to it. YOLO requires a .txt file for each image with a line declaring the class and the bounding box coordinates (X,Y of the center and width and length).

The first goal was to recognize the object but next steps will handle the recognition of different fire extinguisher type. For this purpose, the distinctive components of the fire extinguisher need to be recognized separately. For instance, the pressure gauge helps in the identification of the extinguishing agent, the horn too is helpful in defying the type.

5.4.2 Neural Network training

A first training has been carried out using a tiny YOLOv2 pretrained with the COCO dataset.
YOLO requires some files to start training which are [17, 18]:

- total number of action classes (1 for our case);
- text file with the path to all frames which we want to train;
- text file with names of all action classes (fire extinguisher);
- the path to save trained weight files;
- a configuration file with all layers of YOLO architecture (described in Figure 2).
- pre-trained convolutional weights.

The value of filters in the configuration file of YOLO (.cfg file) for the second last layer is not arbitrary and depends on the total number of classes. The number of filters can be given by: filters=5*(5+number of classes). In order to start training the original .cfg file, the structure must be modified in its following features:

- batch=64, this means we will be using 64 images for every training step;
- subdivision=8, the batch will be divided by 8;
- classes=1, the number of categories we want to detect;
- filters=30, from the previous formula;

Figure 4. Training image type

Figure 5. Drawing the bounding box and labelling the object

- learning rate=0.001, advised by the developer of YOLO in order to avoid false minimum point.

After the training session, the new *.cfg* and weights files are created. The network automatically creates two groups of images, the former to train the network and the latter to test and validate it.

6 Tests and Results

First tests have been made about the training of the Neural Network. All these tests have been carried out on a computer in this preliminary phase.
The YOLO tiny v2 chosen has been trained with three different datasets in order to check if there was any improvement in the detection of fire extinguisher.
The three datasets are composed as follows:

- DATASET 1 (D1) =300 images, 75 (25%) original taken inside the Engineering Faculty premises (Polytechnic University of Marche), 225 (75%) obtained through the augmentation process;
- D1 added to DATASET 2 (D2) = 200 images, 50 (25%) original downloaded from Flickr (only images of fire extinguisher meeting the requirements expressed in the paragraph 5.4.1), 150 (75%) obtained with dataset augmentation;
- D1 and D2 added to DATASET 3 (D3) = 200 images, 50 (25%) original taken inside the Economic and Science Faculties (Polytechnic University of Marche), 150 (75%) come from the augmentation process.

For every dataset the images were divided into two groups, one for the training and one for the test, with the following splits: first dataset (D1) 260 training images and 40 testing images, second dataset (D1+D2) 429 training images and 71 testing images, third dataset (D1+D2+D3) 590 training images and 110 testing images. The kind of chosen images was similar for all the photos, close-up and with the object entire and placed in the center (Figure 4). In the test performed we worked using Visual Object Tagging

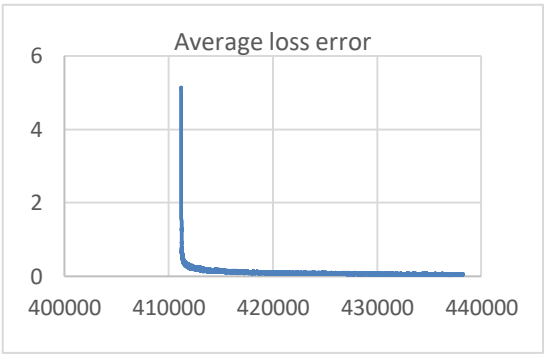

Figure 6. Decreasing of average loss error training 2

Tool for the manual drawing of the bounding box and for the assignment of the label (Figure 5).
The output of this process was a series of .txt file (one for every picture) containing the coordinates of the boxes and the category label (fire extinguisher in this case).
With the first dataset the training was stopped after 22100 iteration. For every training the choice of the weights was done extracting the indicators every 1000 iteration and then choosing the best one in the no longer decreasing area of the average loss error (Figure 6). The reached mean average precision (mAP) was 60,23% in the first case.
The second training counts 86700 iterations and in this case the mAP was 61,54%.
In the final training the number of iterations reached 26900 with a mAP of 62,81%.
The validation tests have been conducted for each of the three training sessions with the third training dataset of 110 photos. The results are displayed in Table 1. The percentage of fire extinguisher identified started from 38% and reached 45% with the latest training. the precision improved too because while in the first case 26 false positives occurred, in the latest case the number decreased to 14.

Table 1. Training results

	TR 1	TR 2	TR 3
N° of recognized fire extinguisher	42	44	50
N° of multiplied bounding box for one fire extinguisher	26	16	14

7 Conclusion and next steps

This research aims to provide a support to FM operations during the building lifecycle. The system proposed combines three different technologies: the AR, the BIM data model and Deep Learning, all in one embedded solution for on-site use. The two use cases described could improve their efficiency thanks to the

effective Human-Computer Interaction (HCI). First feasibility tests have been conducted related to the training of Neural Network and the recognition through the AR device. Further steps will be developed, starting from the increase of the number of images in the dataset so as to achieve a higher precision in the recognition process. Furthermore, after having reached a higher level of precision the new datasets will be developed for the recognition of precise type of fire extinguisher. Next steps will include also the full development of the AR interface and tests in a real environment.

Abstract –

Managing digital information in construction is commonly described through Building Information Modelling (BIM), which advocates seamless chains of information, increased coordination between different actors and a life-cycle perspective on information management. However, low adoption outside the design phase entails that handling information in production is in many cases manual and paper-based, which increases vulnerability for upstream errors materialising downstream in production. Furthermore, issues with interoperability surround many areas when managing digital information. For industrialised house-builders, the transmitter and receiver of information are in many cases integrated within the same company or based on long-term collaboration. This affects their ability to manage information and utilise design information, which implies that their strategy for digital information management (DIM) might benefit from being addressed differently compared to more traditional BIM-based approaches. In this paper, we describe and discuss an implemented DIM-solution at an industrialised house-builder in order to address the benefits and challenges with DIM when managing information from design to production. The results imply that in order for several different functions within the company to reap benefits, a customised DIM-solution adapted after the company's specific needs is a well-suited approach forward to avoid sacrificing functionality when utilising design information.

1 Introduction

Utilisation of design information is crucial for planning and execution in production. The sequential nature in which a construction process is carried out poses however challenges for the continuity of the information flow, partly because different phases can be divided over longevity of time but also distributed amongst various actors with different responsibilities. Further complexity is added when these phases are carried out in a sprint-like manner where the previous ends as the sequent begin [1].

Paper-based documentation (e.g. printed drawings) constitutes the main container for generated design information during production. However, with the digital evolution, questions regarding its suitability as a main source to manage the amount of information generated during design has been raised [2]. Paper-based information is surrounded with limitation in regards to its lack of flexibility, meaning that changing prerequisites are difficult to address in production, partly due to information flowing unilaterally from design to production and rarely vice versa. Effects thereof can lead to vulnerability downstream in production when errors, or rather the rationale behind errors generated in design, are difficult to assess, and iterative bi-directional communication between design and production is rarely supported [3]. Most commonly, proposed solutions stress the importance of Building Information Modelling (BIM) to advocate seamless information management. BIM has for a long time been discussed as a solution to obtain information traceability and to minimise information losses over a building's life-cycle. However, there has been a concentration on the use of BIM during the design phase and less focus on BIM use during production [4]. In recent years, critical voices regarding BIM has also been raised, where the utopia of BIM as it is addressed today is being questioned [5]. Among identified challenges, interoperability stands out, both in its

occurrence found in literature and with various frameworks containing proposed solutions [6]. Commonly, open and globally standardised schemas such as Industry Foundation Classes (IFC) serves as the backbone to resolve issues linked to interoperability. There are however differences between construction companies in terms of their capability to handle information in a standardised way which could be connected to their level of industrialisation. In this paper, we discuss how industrialisation affects the need to conform to traditional BIM-approaches to resolve e.g. interoperability.

Increased industrialisation can be obtained by integrating otherwise sub-contracted activities into a controlled concept or moving value-adding activities upstream in the value chain (e.g. by moving on-site production to an off-site setting) [7]. This increases the use of pre-engineered solutions with standardised work procedures [8]. In a study, Johnsson [9] mapped core capabilities at four different case companies with various production strategies regarding pre-engineering, i.e., different levels of industrialisation. Companies with a full product offer (i.e. delivering turnkey buildings) and higher levels of pre-engineering exhibited core capabilities in areas wider spread along the construction value chain in comparison with more traditional project-based construction companies. This aligns well with the notion that industrialised house-builders tend to own or control a larger portion of the value chain, reaping the benefits of repetitiveness from pre-engineering and standardisation in several phases of construction.

It is argued that the benefits with BIM should be far greater within industrialised house-building in comparison with traditional construction [10]. Regardless of if this is true or false, when applying the lens of BIM as a tool for coordination and communication of digital information between different actors, this statement at least needs diversification to be adapted for the specific context of industrialised house-building [11]. Value chain control, pre-engineering of products and standardisation of work procedures, positively affects the possibility to manage information and presents an opportunity to assess information in a controlled environment [12] with less need for actors coordination. This is essential, as it implies that handling digital building information could benefit from being addressed differently compared to a more traditional BIM-approach. The software solutions and the work procedures determining how information is managed could be unique and tailored in that sense that they are adapted to the specific needs and circumstances visible at each company rather than there being a one-size-fits-all solution readily available off the shelf. It might also imply that challenges with managing digital building information are different within industrialised house-building compared to traditional construction. Furthermore, focusing on the notion of BIM, a single unified definition does not exist and the concept has different meanings depending on the situation or application. To avoid preconceptions, it was therefore in this paper deemed useful to broaden the perspective and address how information is being managed between design and production more generally.

The area of information management (IM) [13] describes how information is acquired from its sources to a format that can be distributed to those needing it until its disposal to an archive or to a trash bin. Although IM stems from the development of information technology as a managerial field of how organisations, for example, should get the best use of storage formats, ranging from early technology like punch cards and magnetic tapes to today's cloud services, it can still be of value to have a subfield named digital information management (DIM). In this subfield, we would specifically focus on IM based on digital technology. For construction, this would include BIM-tools with links that work as a glue [14] by enabling automation functionalities between different software. In this way, a sort of tailored interoperability between different IT-systems can be enabled, for communicating information between domains, such as design and production within construction companies. In this paper interoperability with BIM is exemplified in the specific context of industrialised house-building, but addressed using DIM.

There is a shortage of studies demonstrating the interplay between IT systems and work procedures linked to IM in construction, as well as studies reporting on the benefits and challenges of the tool implementations.

The purpose of this research is twofold, firstly to, through a case study approach, describe digital information management between design and production at an industrialised house-builder. This is exemplified through structures for information utilisation, a DIM-solution for linking software used in design and production, and how different departments have adapted their work procedures after implementing a DIM-solution. Secondly, the purpose is to discuss benefits and challenges with digital information management, from a perspective of flexibility in managing information and rigidity imposed by a digital solution. With the standpoint that flexibility and rigidity are opposing properties when managing information.

2 Research approach

This study was conducted as a single case study at an industrialised house-builder during the spring and fall of 2018. The research was explorative in the sense that no clearly demarcated research questions were set prior to

the study other than focusing on exploring digital information management between design and production. This influenced the course of the study, as gathered input guided the direction along the way. The main method for collecting data was through semi-structured interviews with representative persons with different insights into how information is managed and handled between design and production. The interviewees consisted of the project manager for implementing the DIM-solution at the case company; the head of the design department; an employee at the pre-production department with particular insights in the structures and systems within the DIM-solution; and finally, an employee from the production department with responsibility over integrating and managing the control system for machinery used in production. As a supplement to interviews, archival material, participation in a workshop, observations, and observed demonstrations by operators were used to collect data. In total, four interviews were conducted which lasted from circa 45 minutes to 1 hour and 30 minutes. Questions posed during interviews were mainly specific since facts rather than opinions were of interest. The first author transcribed the interviews verbatim. Since facts in regards to an already existing IT-solution was in focus, little regards were focused at interpreting the responses collected during the interviews and no thematic analysis were performed. The workshop was recorded with image and audio. Findings gathered from workshop notes as well as from reviewing the recording was later discussed in a separate meeting with key participants (said meeting was recorded and transcribed) and used to formulate a process map of the information flow from design to production. The process map was iterated back and forth until the case company deemed it representative for their process of managing information. Although the process map itself is excluded as a result from this paper, due to its size and level of detail, experiences thereof were used to compliment the interviews in the case description.

Determining the choice of case company was important for the purpose of the study. The case company, CC, is one of the leading actors on the Swedish market for industrialised house-building. CC offers customisation in each building project, not relying on a catalogue of pre-engineered buildings whilst maintaining a high level of standardisation in their work procedures for designing and producing buildings. CC regularly competes in tendering against construction companies which applies traditional building design processes and on-site production which means that narrowing the customer segmentation would affect CC's market position adversely. Mitigating the effects of adapting to customer requirements puts stress on how information must be managed in order to maintain efficient production. How CC balances pre-engineering, standardisation, and customisation whilst simultaneously controlling the construction value chain are therefore significant characteristics for this study.

In order to give a broad perspective on the many aspects which together forms contemporary experience on DIM within industrialised house-building, the case description has been allowed to take up the major part of this paper. The scarcity of published work with a similar focus or approach to describe information management between design and production for industrialised house-builders is also a reason for why this structure was deemed relevant.

3 Case CC

CC produces multi-family dwellings consisting of wooden-frame modules. They enter the construction process as early on as possible and takes full responsibility from the entrance to a completed building. The modules are manufactured off-site, elements, i.e. walls and slabs, are primarily based on pre-engineered components but the modules they form and the module's interrelated composition in a completed building are unique for each project.

Within CC, sales, design, purchasing, logistics, pre-production, factory-set production, and on-site assembly are all integrated departments. Their design process bears many resemblances with a more traditional construction design process in that different actors, e.g. architects, HVAC engineers, and structural engineers, both in-house and procured, has to be coordinated for each project due to the high level of customisation. The isolated tasks needed to be performed in order to complete a building design are however the same or very similar for each individual project. The pre-production department operates in midst of design and production, with a role to serve as a bridge between these two. Their main assignment is to feed information to production in the corresponding production sequence, acting as a funnel and a filter so that the right information gets delivered at the right time to production. In production, there are different production lines for elements which are later combined into modules, sequent work (i.e. electricity, HVAC, mounting etc.) is carried out by a skilled workforce in a one-piece takted flow. In conjunction with starting up a new production facility, CC initiated a project to digitally integrate their information management systems (DIM-solution) and exchanging printed paper drawings for a Manufacturing Execution System (MES) to display information in production. Previously, CC relied on physical deliveries of drawings and documentation used in production. The sheer size of their new production facility together with an aim for a decrease in takt-time rendered this approach infeasible.

The overarching aim with implementing a DIM-

solution was to reduce the amount of time passed from the point information was needed in production to when it could be retrieved, i.e. a solution primarily focusing on the needs of the operators in production. However, in order to facilitate utilisation of design information and obtain a broader perspective on DIM, work efforts and changes affecting many departments at CC were needed. In lieu of a strict top-down or bottom-up process, an interplay between adapting to the current way of working whilst simultaneously adapting this so it fits in a digital environment rendered CC to have more of a middle-out approach. Instead of buying an off-the-shelf software solution, CC decided to customise the solution on their own by integrating new and existing software. The implemented DIM-solution was mainly aimed at providing the factory-set production lines with digital information but derived functionality for supporting functions, such as purchasing and logistics, was also obtained.

The work procedures related to how information is managed and the system solution are interrelated with each other. DIM at CC is not fully automated, meaning that workers interact and adapt to the procedures stipulated by the system solution. It is therefore of importance to describe how work procedures are affected as well as describing the DIM-solution itself. This research did not partake in the actual development of any solutions, and at the time of this study, the DIM-project was in a start-up phase, meaning that functionality existed and was, for the most part, implemented but still in a run-in period.

3.1 Information structures for information utilisation

In order to utilise digital information generated during design, three separate but related information structures were identified during the course of this study.

3.1.1 Article-based information

In order to determine what articles (e.g. boards, studs, insulation etc.) are needed in production within a digital system, building information had to be broken down and sorted in an article database with a standardised nomenclature. At this stage, this is only done for information linked to elements such as slabs and different types of walls. The DIM-solution is prepared however to handle information related to e.g. installations (HVAC, electrical etc.) furnishing etc. Communicating defined article objects forms a vital part for information utilisation since it enables article identification along the entire information chain for different functions and departments. With information on an article level, customised bills-of-material (BOM) can be formed, readable to both man and machine. In this case, a BOM contains information about every article that together forms each element. This includes studs, noggins, boards, etc. with related metadata such as dimensions and type of material, but also relations between articles, elements, modules, levels, and buildings.

3.1.2 Sequence-based information

The second key aspect for utilising digital information was to incorporate the production sequence, hence attending to the aspect of in which order work procedures should be performed and when information is needed, thus enabling detailed planning and scheduling. The factory production sequence is ruled by the assembly sequence on the construction site. The key to deducting a corresponding factory production sequence is to work backward from building orientation onsite by modules to component assembly in elements production. This is possible as production is executed with a one-piece takted flow, meaning that production work is organised following one line of modules through the factory. Slabs follow the module sequence so that two slabs, forming the floor and ceiling of a module are completed prior to module assembly. The various types of walls used to enclose a module (inner, outer, apartment separating) facilitate that production of wall elements can be optimised so that as many similar walls are produced as a long wall segment, which later can be separated into different wall elements.

3.1.3 Operational-based information

After incorporating information in a sequence, the next step is to further enrich the data with information on work procedures and instructions on how they should be performed. Descriptions of standardised work procedures are communicated through Standardised Operation Sheets (SOS). The SOS documents describe in a step-by-step fashion accompanied with images what, how and why an operation should be performed. The idea of developing SOS is to enrich the knowledge of production by the use of experience. The novel approach is to link this information on parts level by incorporating it with the BOM, which entails a digital representation of what work procedure should be performed on an article. This is done automatically during design due to each article being defined and based on where a specific article is located in the element. When linking a particular work procedure to a particular article, detailed planning and resource allocation in production are enabled.

By addressing these structures and incorporating them into a DIM-solution, the ability to combine and digitally incorporate several functions and departments within the value chain enables a wide variety of information utilisation.

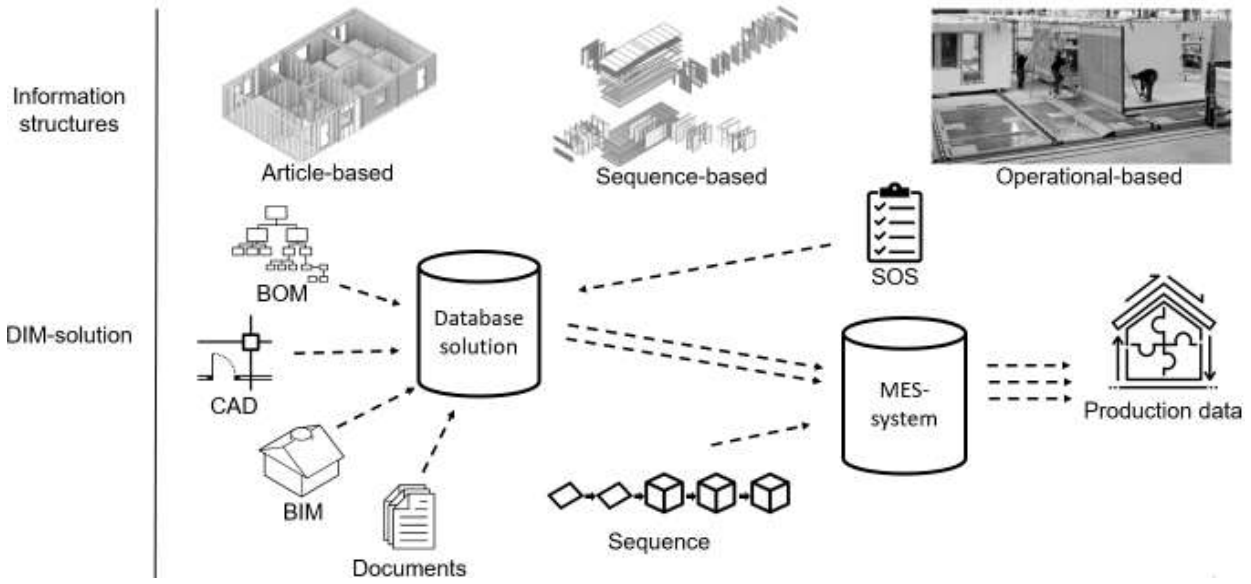

Figure 1. Illustration of information structures and DIM-solution

3.2 DIM-solution at CC

No suitable off-the-shelf IT-solution to accommodate presented needs at CC were found. Placed amidst between manufacturing and construction, CC's demands for a software solution for managing information are specific. Adapting to a proprietary solution had also in this case been associated with risk since a number of related systems would have had to change at once to make them interoperable with each other. Building design is performed using two different software applications. One of which is a BIM-software adapted for supporting element and module design within industrialised house-building, and one CAD-software for designing module features, e.g. kitchen layouts, wardrobes, etc. The latter is currently used for 2D-drawing. In production, an MES was introduced to track and document production data as the material is converted to finished modules along the production lines, as well as distributing the relevant information to the operators at each work-station. Their solution was to customise a database solution (DS) to operate as a link and a translator between the CAD/BIM-software's used in the design and the MES used in production. This was needed since interoperability between these is lacking. Functionality for digitally supporting sequence planning, as previously explained, was added as well. Figure 1 illustrates the different information structures as well as a schematic outline of the DIM-solution. The figure is illustrative in that sense that its purpose is to assist the reader by complementing the text provided in this paper rather than the other way around. As prime input to enable information utilisation, DS takes the bill-of-material (BOM) in a spreadsheet format from the BIM-software. Once imported into DS, a hierarchical structure is formed with parent-child relations for parts into elements, elements into modules, modules into floors and floors into buildings. Apart from structuring material, links to drawings from both CAD-software as well as additional documentation relevant for the project are created in DS. Models from the 2D-CAD-software lack possibility to trace each object on an article level, the generated drawings are however being funnelled through the database solution. In this case, the DIM-solution serves as an intermediary step to avoid printing drawings on paper. The generated links are semi-dynamic, meaning that it requires that the name and location of each file are syntactically correct in order with a standardised nomenclature and file system structure. The links are imported according to the right production sequence by the MES together with necessary additional documentation e.g. SOS, room data sheets etc. In this case, the MES is serving as a document manager for production, supplying production data in the right sequence to work station operators.

3.3 Impacts on work procedures

Implementing a DIM-solution affects how the workforce manages information, however, depending on the level of abstraction, the overarching process before and after the implementation of a DIM-solution has remained basically the same, albeit the processes are adapted to fit in a digital environment. These differences are highlighted in the following section, the headlines marked in bold are presented in a chronological (from a project perspective) order and an attempt to clarify the

utilisation of the DIM-solution between the different departments step-by-step has been made.

Design: As previously stated, building design follows a rigorously monitored and standardised process. In implementing the DIM-solution, the design department´s work procedures are adapted so that it affects where information is retrieved and in what form it is received and delivered, previously printed documents are now managed digitally. Templates for modules and parts from pre-engineered rules and dimensions generate information in relation to CAD and BIM-tools.

Pre-production: The most notable changes in work procedures is visible at the pre-production unit. Previously, upon completed building design, pre-production used to receive design information digitally from the design department and print, e.g. drawings and material lists on paper. A vital and time-consuming task was to sort and order drawings and documentation in sequence for production. As production is based on standardised work-procedures and split up on multiple stations, the number of drawings needed can be quite considerable. A single floor element can require around six different drawings to mediate all views necessary for each layer and work-operation. Apart from printing drawings and necessary additional information, pre-production also used to audit element drawings in search of non-frequent occurring articles, which are parts for structural rigidity, e.g. lifting posts. This operation was important to enable a high pace in production where time to review drawings in detail is limited. This was done by manually marking on the drawings to clarify for the right recipients in production. In time for production, pre-production previously physically delivered drawings and additional information to the logistics department. For pre-production, the tedious task of manually printing and auditing drawings for non-frequent occurring articles could be removed due to the DIM-solution. The objects formerly marked manually on drawings are now listed objects in a parts database. Manually sorting drawings in sequence and physically delivering drawings and enclosed documentation is also rationalised. The imposed change is first and foremost time saving (at least for pre-production), but since a manual audit of drawings can be considered error-prone in comparison with an automated solution, the quality and precision has also been positively affected. On the other hand, the time-consuming task of auditing drawings also served as an extra opportunity to detect errors made in design which are better off being discovered prior to, rather than during, on-going production.

Logistics and purchasing: Pre-production's main point of delivery is the logistics department, they receive information that they use to prepare and supply workstations with material. The material is cut-to-fit and kitted in the corresponding production sequence. Enhanced overview over the production sequence provided by the DIM-solution enables logistic preparations to be more on par with the flow of the production lines.

Purchasing takes place during an extended period in parallel with design, pre-production and almost up until production. The level on which the DIM-solution can be utilised is related to the overall progress in the project. Early on, prior to detailed design, purchase might need analogue documents (e.g. printed drawings or lists) and as information gets entered in the system, the possibility to utilise DIM increases. Previously, various articles e.g. timber used for studs and noggins and plaster boards was bought in bulk based on visual inspection of the stock. This ad-hoc approach to purchasing was made redundant when article based information was made available through a DIM-solution. The ability to retrieve tailored bills-of-material sorted by production sequence enables purchasing of smaller batches with the right material delivered more in sync with production.

Production: Just prior to production detailed planning and dividing of specific tasks on different operators working on the production lines take place. This could previously be done explicitly through markings on drawings. For production, the main difference after implementing a DIM-solution is related to how information is received and read. Where paper drawings previously were used, there is now monitors and portable display devices to communicate all information required for them to carry out their work. Through the monitors, linked documentation describing for example how the current work task is to be performed (SOS-sheet) and functionality to support reporting errors or deviations is also available. Detailed production planning previously performed by marking on a physical drawing are now performed by balancing the required operations with available operators aided by time studies for work operations in a spreadsheet distributed to all operators.

4 Discussion

Production in a one-piece takted flow requires that there is detailed knowledge on *what* needs to be done, *when* it should be done, and *how* a specific work procedure should be executed in order for production to run smoothly. DIM does not add the possibility of answering these questions, at CC these questions were already addressed prior to extending DIM. Adapting to how information should be managed digitally rather suggests that these questions need to continue being addressed in order for production to work properly. This is highlighted when assessing how element information is managed in relation to module information. The latter is not yet detailed enough to obtain the same level of

information utilisation, as individual objects cannot be queried within the system. This hinders, for example, purchasing from extracting information with the resolution needed to purchase off a customised BOM.

For CC, the opening of a new production plant spurred the initiative to rethink how information was managed and distributed from design to production. As side effects rather than their main objective, digitally integrating the systems for managing information enabled added functionality. Both in terms of ability to log production data for quality control and analysis, as well as a possibility to perform production simulations to verify constructability or to optimise resource allocation in the production line to name a few examples.

Different challenges exist which span over a wide range of perspectives. Moving information from humans to computers in an existing organisation requires workers to adapt to new procedures and routines. Enforcing a new system upon a workforce is, therefore, a considerable aspect to handle. Furthermore, a digital system exhibits less inertia when comparing it to managing paper-based information. In this case, inertia can be seen as the momentum needed to send or receive information between two entities (i.e. from computer to human, computer to computer, or human to human). This entails a following responsiveness when sending and retrieving information which presents itself as both part of the solution as well as an associated risk. In cementing a confined digital solution, the flexibility enabled by a skilled workforce, possible to adapt to whatever problem is presented, was decreased. Changed prerequisites which previously could be managed ad-hoc now requires implementation (adding of new functionality) in a system in order for the function as a whole to be maintained. The same responsiveness also implies that errors entering the system quickly spreads and affects both vertically and horizontally within the organisation. At CC, the DIM-solution is still dependent on a manual step being performed between design and pre-production, namely exporting and importing the BOM from the BIM-software to DS. The remaining steps are automated, provided that information is placed and named correctly. A side effect from this manual step is that some inertia is introduced to the system. In a practical sense, this means that information is compiled and audited by the design department before being pushed into DS instead of being pulled on demand by pre-production. To further the understanding of what role inertia plays in a digital IT-system is an interesting aspect for future studies. Balancing this inertia could serve as a strategy to mitigate risks associated with responsiveness in a semi-automated system for managing information where there is an interplay between a system, and the work-force operating the system.

At CC, a trade-off between the DIM-solution's flexibility and information quality was visible. This means that the enrichment (e.g. increased use of metadata to enable purchasing) and precision of information (e.g. reduced dependency on manual auditing) increased. Although no time studies have been conducted, by rationalising the time-consuming step with printing, auditing and physically delivering drawings in pre-production, there are also implications that the total expenditure of time for managing information has decreased. These preliminary benefits are achieved at the expense of increased rigidity in how information must be managed. Albeit these results are preliminary and this single case cannot be used to generalise, it is a noteworthy aspect that risks and constraints associated with managing information digitally needs to be assessed and weighed against the benefits rather than digitalisation being an end in itself.

At CC, the DIM-solution was tailored, meaning that CC avoided adapting to an off-the-shelf proprietary software solution and thus managed to better adapt their DIM-solution after the organisation rather than the other way around. This could be very important for already existing organisations striving towards digitising their information management and where a top-down process could be associated with risk since it might affect several parts of the organisation simultaneously. For industrialised house-building, it is reasonable to argue that adaptations and tailoring of DIM so it fits the existing organisation is required. In part, because they depend on technology-intensive manufacturing equipment to support automation in production to a higher degree than in comparison with traditional construction. Nailing portals, robots, and conveyors which are utilised in production are delivered from a wide range of suppliers and interoperability is not guaranteed. Machinery used in production is also often delivered as unique products to each customer due to spatial- or requirements adaptations at each industrialised house-builder, which makes reusing solutions for DIM between different industrialised house-builders complex. At CC, introducing an MES sorted out the interoperability between machinery in production. However, in order to broaden the perspective and better utilise design information to establish links between production, design and support functions such as logistics and pre-production, a tailored DIM-solution was required to avoid sacrificing functionality. The authors have not encountered such a solution readily available off-the-shelf, addressing similar needs as those presented at CC.

Owning or controlling the value chain [9] alleviates the threshold for successfully implementing a solution with a broader perspective on information management, spanning for instance over several departments within an organisation as exemplified in this paper with information being managed between design and

production. The system also encompasses a digital bi-directional link between design and production in comparison with the usual mono-directional link between different trades [1]. Results imply that utilising BIM-data for information management in the specific context of industrialised house-building could benefit from being addressed with a strategy adopted for the unique traits visible for these companies. Value chain control, or ownership, minimises the need for adapting to commonly proposed strategies to obtain system interoperability, such as open format schemas (IFC). This encompasses a wider solution space with the ability to choose optimal software solutions for each sub-department, not needing to worry about systems interoperability to the same extent since this could more easily be tailored alongside the solution itself.

5 Conclusion

This paper focuses on the (digital) information management between design and production in industrialised house-building. A case company was studied to describe and discuss benefits and challenges with implementation of a solution for digital information management (DIM). The main conclusions from this study are:

- Characteristics visible in industrialised house-building, such as value chain control and the possibility to standardise work procedures, affects how information can be managed compared to traditional construction.
- Effects thereof imply that a tailored solution, adapted for the specific company, as opposed to an off-the-shelf proprietary solution could be a viable way forward to extend information utilisation.

Abstract –

Product platforms have proven to be an effective means for many industries, seeking to achieve front end variety based on back end commonality. Modular design with standardised interfaces, enabling reuse of components in derivative products over time, has been a success factor for i.e. automotive industry and other types of industries operating in a modify-to-order or configure-to-order supply chain. For construction companies who operate in an engineer-to-order, or even design-to-order supply chain, extensive and changing customer requirements must be managed and full product standardisation could, therefore, affect a company's market offer adversely depending on its market segmentation. In previous research, one key finding is that construction companies tending to a wider market segment could focus on standardising processes rather than products. Furthermore, previous research highlight the notion of process platforms as a subset within product family design, albeit, little research focus has been given to process platforms for construction companies. In this study, two construction companies are studied with the aim to describe their means for enabling a flexible product offer whilst maintaining a platform strategy. Findings shows that both companies have process platforms with explicit and implicit relations to product realisation and that standardised processes are a vital part in offering end product flexibility whilst maintaining a platform strategy. This study identifies the need for additional research to elaborate and generalise the relation between process platforms and product flexibility, and implies that theory linked to product platforms need to be developed in order to incorporate construction companies where full product standardisation is in conflict with their production strategy.

Industrialised house-building; Process platform; Process standardisation; Platform strategy

1 Introduction

Industrialisation in construction has gained attention and traction from both academia and construction companies [1]. By moving value-adding activities upstream in the construction value chain, through pre-engineering and off-site construction, a trade-off between flexibility and productivity can be evaluated and used to target specific customer segments [2]. An orientation towards increased industrialisation is often, for the Swedish market, motivated in research through low productivity for the construction industry in comparison with more traditional manufacturing industries [3] and therefore often proposed approaches have been suggested by glancing towards the same successful strategies which has been applicable for traditional manufacturing, e.g. automotive industry. Applicability of lean principles for industrialised house-building [4], [5] or adoption of product platforms has been among notable examples of such strategies, where the latter forms the basis for this paper.

A widely used description of a product platform is presented by Robertson & Ulrich [6] which defines it as *'the collection of assets that are shared by a set of products'* and that these assets can be divided into *components*, *processes*, *knowledge* and *people and relationship*. In essence, product platforms strive to offer customers products which exhibit front-end variety based on back-end commonalities, by altering the process of product development. The leap is from the development of unique one-off products to platforms where a family containing several variants shares some common assets. Through modularisation, i.e. dividing products into modules or chunks containing related components and standardising interfaces between these, the automotive industry has been and remain to be successful [7]. Jiao et al. [8] presented '*a holistic view of product family design and development'* based on axiomatic design [9] in which several platforms in between different domains accounts for all fundamental issues related to product realisation from a client perspective (front-end) to the entire supply chain (back-end). In related work, Jiao et al. [10] define

a process platform in a generic hierarchical structure as the combination of machining- and assembly operations required in combination with a corresponding product structure (raw material, parts, and subassemblies) to formalise an end product. Most of the subsequent studies including process platforms have adopted this view on its relation to explicit product realisation [11]–[13]. However, it is the authors' standpoint that a formally defined solution space for product realisation requires confined boundaries for the product definition, which is contradictive for construction companies which offer product flexibility through open design processes.

In a multiple case study by Johnsson [14], empirical findings were used to suggest that mainly companies *'who integrate the supply chain towards a specific market segment benefit fully from the platform concept'*, i.e. companies with a higher degree of product standardisation. Companies with a wider scope of customer segmentation could, whilst maintaining a platform strategy, focus on standardising processes rather than products. It is important to distinguish between two different types of processes and how they are being used in this paper, those with explicit or implicit relation to product realisation.

- **Explicit processes:** Machining operations, assembly operations, raw material treatment with direct connection to product realisation [10]
- **Implicit processes:** An umbrella-term for processes which indirectly aides product realisation, e.g. open design work, setup/preparation in production or following routines when managing information.

The purpose of this study is twofold, firstly to describe platforms at two construction companies with production strategies aimed at enabling flexible products. Secondly to discuss, whether the theoretical notion of process platforms, found in literature today, are applicable for house-builders where full product standardisation conflicts with their production strategy.

2 Related research

2.1 Distinguished characteristics of different construction companies

Construction companies can be differentiated according to their level of industrialisation, which partly depends on their use of pre-engineered solutions [14] and production methods [2]. A different but related take is the dividing on companies depending on how they manage their supply chain [15]. As buildings are rarely pre-produced and kept in stock based on a forecast, and product realisation often requires an engineering design phase to adapt to regulations or spatial conditions, the predominant production strategy for construction can be characterised as engineer-to-order [14]. Johnsson (ibid.) elaborates on this and distinguishes between different production strategies within the engineer-to-order context depending on the level of pre-engineering in the design phase. Engineer-to-stock represents a fully predefined product and design-to-order offers product flexibility through an open design process. Adapt-to-order is a middle ground between these two. This determines in what stage the customer enters where a fully defined engineer-to-stock-solution entails later client entrance.

There are various contextual interpretations available for the specifics related to the construction industry on this matter. Winch [16] proposes concept-to-order and design-to-order to distinguish between the difference visible between two standard forms of procurement, namely design-build (CTO) and design-bid-build (DTO). Segerstedt & Olofsson [15] differentiates between different production strategies based on the level of completed specifications upon client entrance, where building systems within engineer-to-order bases the pre-set specifications on current building codes and local regulations, leading to high flexibility in the end product. When buildings instead are completely specified upon client entrance, all that is left is for the client to select a variant. Regardless of terminology, the different strategies can be linked to the level of pre-engineering applied in product definition and realisation.

2.2 Platform use in construction

In this paper, platform use can be interpreted as an agreed upon strategy applied by a company, to gather, distribute and reuse pre-engineered solutions and standardised processes as well as actively working with managing, maintaining and utilising said solutions and processes. A prerequisite is that product or component pre-definition exists to some degree within the platform.

Applied to construction, the majority of studies available on platform development have inherited their product orientation from traditional manufacturing, focusing on either confining or defining the product within boundaries set by a product platform. Veenstra et al. [17] introduce a methodology for developing product platforms in the specific context of house-building in which a framework for defining a module based product architecture is presented. Jensen et al. [18], [19] similarly approach the construction industry by modularising the building system. In their work, different module variations with standardised interfaces and parameterised variables, i.e. length, width etc., produce an allowed solution space in which the product can be designed through a configurator.

In a case study, Bonev et al. [20] applies the holistic approach to product family design as suggested by Jiao

et al. [8] on a precast manufacturer and noted the interrelationship between reuse and commonality along the entire value chain. Furthermore, they highlight product platform deployment as a mean to retain flexibility whilst moving towards mass customisation, but argue simultaneously that a higher degree of predefinition during the engineering phase is inevitable for platform benefits. Thuesen et al. [21] made a study on success factors from a German housing platform and highlighted the importance of continuous learning, repetition, and standardisation through *'[…] long-term incremental and systematic innovation with a clear separation between the continuous development of and the production based on the platform'*. Standardisation of different house types available for the customer was particularly stressed.

construction company. The platforms are described as the collection of blueprints with technical solutions and documents or procedural descriptions aimed at guiding the design and production phases. Lessing [1] reinterprets the traditional platform concept and separates for industrialised house-builders between a technical platform and a process platform. Figure 1 depicts how the continuous interplay between both platforms are used to support a stream of projects as well as how experience is continuously fed back to each platform.

Even though no empirical data is presented to verify or in practice identify his exemplified process platform, it is proposed to contain processes beyond assembly operations or raw material treatment, i.e. beyond explicit product realisation. In his licentiate thesis, the process platform consists of modules where ICT (Information

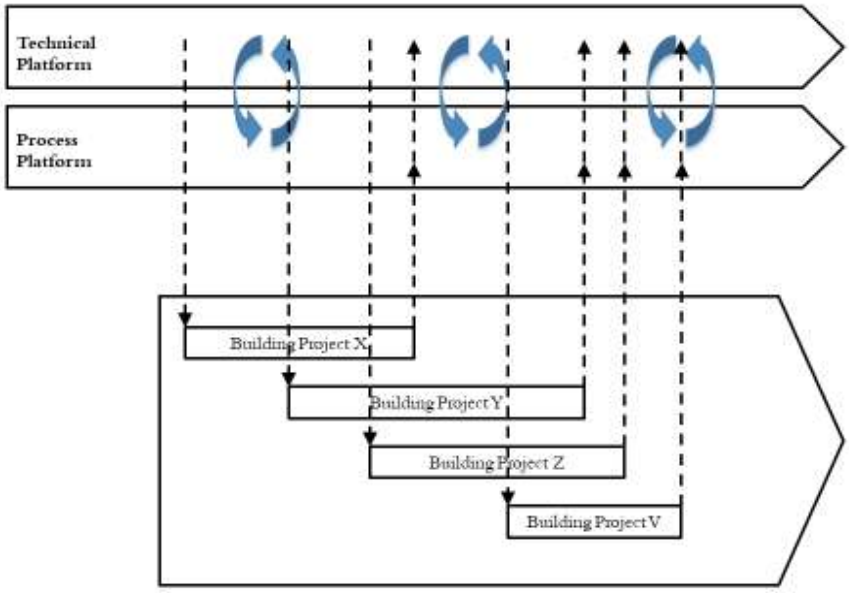

Figure 1. Process model for industrialised house building [1]

Jansson et al. [22] acknowledge the specific conditions visible for ETO construction companies in terms of managing the balance between commonalities and distinctiveness. Jansson et al. (ibid.) propose a platform model with support methods to manage distinctive project parameters. That case study identified all product platform assets described by Robertson and Ulrich [6], but the presented support methods for implicit product realisation focuses mainly on the design phase.

According to Styhre & Gluch [23], the platform serves as an object to facilitate knowledge sharing and accumulation. This knowledge management perspective on platforms is presented through a case study in a large

and Communication Technology), team collaboration and routines for integrating logistics for a reliable flow of material are some examples. In reviewing these platform-related studies applied for construction, the production process and its interrelatedness to a defined product are of essence when process platforms are addressed. Many elude the flexibility required or desired by certain actors in terms of their ability to adapt their end product after customer requirements, and there is a scarcity of studies which elaborates on how the process platform mediate end product flexibility.

3 Research approach

To meet the purpose addressed in this paper, two companies have been studied. The research was grounded in a literature review on process platforms and platform use in construction where the literature review highlighted the gap in the reviewed body of previous research which motivated the purpose of the study.

To collect empirical data, two different methods were used; interviews and study of archival material. Interviews were conducted with a representative person of each company who has insight and responsibility for the use and development of platforms. Each interview lasted approximately one hour and questions posed were mostly concise, focusing on facts linked to each company's product offer and platforms rather than opinions. Interviews were semi-structured, where follow-up questions were posed for clarity when deemed appropriate. Interviews were recorded and later transcribed verbatim for the analysis. Both authors participated during both interviews and were later responsible for transcribing one interview each. The archival material consisted of access to one of the participating company's (Alpha) intranet, where all documentation in regards to their platform is stored.

The descriptions of each company provided in the following section of this paper are based on empirical data and the idea is to provide insights into what kind of strategy each company applies, i.e. what their product offer is, as well as information regarding their platforms with particular focus on their process platforms. The empirical data was also used to identify explicit and implicit processes according to the definitions previously provided in this paper.

4 Companies Alpha and Beta

Two different companies has been examined, Alpha and Beta. Alpha is a Swedish multinational construction company that has construction projects in all main areas, including residential buildings, commercial buildings, roads, bridges, tunnels and more. The company is among the top biggest construction companies in Sweden and they are organised in regions as separated divisions all over the country.

Beta is an industrialised house-builder who uses modular technique to produce multi-family dwellings for the Swedish market. The company is mid-sized, family owned and an important actor on the market for multi-family dwellings as well as one of the leading actors applying industrialised methods in production.

Both companies apply industrialised methods to various degrees with the common traits that they both have adopted a platform strategy and they both gain a competitive advantage in offering product flexibility to their customers, albeit to various degrees in comparison to one and another.

4.1 Alpha

Alpha is what can be considered as a traditional construction company. They do both general contracts, turnkey contracts and project developments starting with a concept. Alphas main selling point is that they can develop and produce almost any kind of structure that the client has in mind. Alpha has almost no repetition of projects. In offering this variety, it is difficult to define Alpha as a single entity. This study is limited to the part of Alpha affiliated with design and production of multi-family dwellings.

4.1.1 Strategy

Alpha's main production strategy is either concept-to-order or design-to-order depending on contractual agreements (design-build respectively design-bid-build) [16].

For concept-to-order, Alpha can either procure an architect or do design in-house, depending on the client's wishes. Structural design is often performed in-house by Alpha's engineers, often in concrete or steel as Alpha is more experienced with these materials. Remaining disciplines, e.g. HVAC engineering is often procured. The construction process follows a traditional flow with tendering, design and construction. The projects are treated like small companies within the company. The design and engineering department work with several projects at one time. Construction is either done completely on-site or in combination with prefabricated walls or slabs produced off-site. Each project usually procures multiple subcontractors to work at the construction site.

Alpha previously offered a platform-based concept containing multi-family dwellings with a high degree of pre-engineering. Late adaptation to customer requirements and an inability to reduce production costs rendered the business unsuccessful and the project was cancelled. Alpha now has an affiliated subsidiary that offers platform-based engineer-to-stock concepts for housing.

To offer a very flexible product in a resource effective way, Alpha operates two main platforms on different abstraction levels. MP (Managing Platform), for managing a full project life-cycle from tendering to the maintenance phase, and CP (Construction Platform), for the design and construction phase.

4.1.2 Process platform

The main difference between the two used platforms is that the MP (Managing Platform) contains only support for the process of pursuing and controlling a project, while the CP (Construction platform) contains both

support for the design process and the technical solutions and decisions. Both platforms are easily accessible for all employees on the intranet home page.

The MP is used for all projects regardless of size and type, and supports the process of pursuing a project, but has no connection to technical components at all. The MP is divided into two parts, where the first part is aimed for upper management and is the same for all divisions. The second part is aimed at site managers downwards to all the white-collar worker positions and is division specific. The MP consists of mostly different kind of text documents, checklists, time planning sheets, and descriptions. It is organised around the different phases, specifying all the required activities, whose responsibility it is to realise them, comments, and supporting materials.

During the engineering process, the MP defines standardised steps mostly consisting of meetings where limits and responsibilities for the project are to be decided. There are many templates for meeting agendas, how the organisation and positions in the project should be set up, when and how important economic decisions should be made, what risks to consider and when to consider them, and how the engineering phase should support a later safe work environment in production. For the production phase, the MP is focused on quality control, what to consider in different situations, how and what to check to ensure that the projects are running well, and make sure laws, certifications and standards are followed.

The CP consists of descriptions, checklists, drawings, films and documents for both the design phase and construction phase. For the design phase, the CP consists of a collection of conceptual technical solutions. For each technical solution, there is a document describing the components and what to consider for each of them, and advice on how to avoid risks and mistakes that will lead to a lower quality product. Some of the advice is more conceptual, while some are detailed with given values or solutions. The conceptual technical solutions for different parts of a building are referred to as "standard construction parts", and most technical solutions prescribed by engineers are variations of these. There are ready made-drawings of standard construction parts complete with text for production that can be imported to a project drawing.

The design process is supported by the CP where there are predefined concept solutions that can either be used as they are or tweaked to fit the current project. These predefined concepts act as a base for the engineers to work from, but they are free to create their own solutions if it better fits their project. The CP also contains a great number of documents describing what is important to consider and why for different parts and concepts of a building, on both higher abstraction levels like the layers in a wall, and more concrete ones like the required measurements for garages. The designer also has access to documents that describe risks with different options and what can be considered to minimise these.

The CP has a dedicated chapter for standardised productions methods, that contains pictures, drawings, documents, links to manufacturers and instructional films. There are links between the standard construction parts and their corresponding standard construction method. For each construction method there are lists of prerequisites, "tips and tricks" from other employees, possibilities and risks described. The production methods described give room for adaptations to the project and describe how to create a quality structure rather than a specific one.

4.2 Beta

Beta integrates sales, design, manufacturing and on-site assembly within the firm as different departments and takes full client responsibility from client entrance to a finished building. Modules are manufactured off-site in one of two production plants and shipped to the construction site where they are assembled together. Both production plants have different production lines for wall elements and slabs which are later combined into modules; sequent work (i.e. electricity, HVAC, mounting etc.) is carried out by a skilled workforce in a one-piece takted flow.

Beta has a technical product related platform consisting of templates in their CAD-software with predefined technical solutions for e.g. planar elements or joints between two elements. Complementing the technical platform, there is linked related information for product realisation such as assembly operations, checklists etc. which forms a part of their process platform.

4.2.1 Strategy

Beta competes regularly for tenders with traditional contractors within their product offer, and balances between platform standardisation and product flexibility as one of their competitive advantages. Beta produces multi-family dwellings (tenancy and condominiums), hotels and student housing, but no single-family houses or row houses. Element standardisation from a parts library within a technical platform forms their basis for enabling off-site production in a factory setting. Repetitiveness in production must be high enough to enable specific workstations for each particular operation to be performed. This is especially important for the structural system forming the modules, i.e. wall elements and slabs. Each section of the production line is designed for a particular operational procedure, e.g. mounting layers of plasterboards, insulating etc. This can be done manually by a skilled workforce or fully automated by

machines, depending on where in the line or in what factory the operation takes place.

On the sequent volume line, after elements have been assembled to modules, work-tasks vary more according to the specifics of each module. Even though planar elements are highly standardised between different projects, compositional combinations of different modules are customised for each project. In that sense, the modules are not standardised objects, apart from in a few pre-defined concepts aimed at e.g. student housing which can be offered to clients. In doing so, Beta fulfils customer needs and requirements by offering product flexibility in regard to floor layout or module features. This requires a somewhat traditional design process where both in-house (e.g. structural engineers) and procured personnel (e.g. HVAC engineers) collaborate.

Beta operates mainly with an adapt-to-order engineering strategy based on their level of predefinition in their structural building system, which can be used to configure unique modules. The level of platform adaptation varies between and within different projects where certain project related subparts, e.g. a detached but adjacent building for laundry could be engineered design-to-order in accordance with an open design process based on customer requirements together with current norms and standards. Engineer-to-stock solutions, as in the case with conceptualised solutions for student housing exists as well.

Beta has *'preferred solutions'* in different aspects of defining or realising a building in which they know, based on experience, what works well and what doesn't. In operating a platform strategy, there are some *'non-negotiable'* limitations for product flexibility at Beta, i.e. the thickness on a slab separating two storeys, affecting the structural system.

4.2.2 Process platform

To alleviate the constraints inflicted by product standardisation in the technical platform, Beta has a process platform. Standardised processes for product realisation are mainly communicated through Standard Operating Sheets (SOS), but they could be any type of documentation which successfully can be used to illustrate how a certain task should be carried out, e.g. through a checklist. The collection of documentation capturing these standardised processes constitute the basis for Beta's process platform. Some SOS explain explicitly how to conduct a specific task, for example through a step by step guide with associated images, which are needed to perform a specific work operation.

There is however a large number of standardised processes which has no explicit connection to a specific product, these can instead have implicit relations to the realisation of a product. This can be exemplified by describing Beta's design process, which is aided by a tailored software system for visual planning. The broken-down processes needed to carry out a building design is to a large extent standardised and rigorously monitored in a system as the design progresses. What documentation or activity is required, who should deliver or perform it, when should it be delivered or performed and who is the recipient. These are formalised questions which are gradually being answered during the design process. The majority of all sub-processes in the design process are the same in each project, regardless of which building project is in focus.

There are also standardised processes for different departments at Beta, including supporting functions such as sales, logistics, and purchasing. The process of drafting a standardised process is in itself a standardised process, which is firmly grounded within the collegial community as they are regularly formed and updated.

The complete collection of process documentation for all departments is stored on a server in which the head of each department has the responsibility to update and maintain its own processes. According to the company respondent on the managerial level, both the technical platform and the process platform are equally important. Though that may be a view not entirely shared between everybody at Beta, it gives an insight into the perceived value of working with standardisation on both product and process level.

5 Analysis and discussion

The limited amount of empirical data collected should be assessed alongside the sparsely explored subject in focus of this research. Being a study with a qualitative analysis, the purpose is not to claim generalisability, but rather to provide insights into the subject at focus by providing experiences from these two construction companies. The possibility to access and study archival material in form of documentation of Alpha's process platform was a strength for the validity of the findings. It provided an additional perspective on the platform description by enabling the authors to examine the content and structure for themselves. On the other side, those insights could not be used to draw any conclusions regarding how the platform is actually implemented in projects. The access was however important to avoid misinterpretations during and after the interview, as the platform concept as discussed in research literature, was quite unfamiliar to the respondent at Alpha. No such clearly compiled documentation was available for the authors at case company Beta, where the respondent on the other hand is very knowledgeable in the field of product platforms from both a practical and a theoretical perspective.

Platforms at Alpha differs from the more traditional notion of product platforms mainly aimed at

manufacturing industries in that it contains fewer defined products and more processes. The concept of e.g. product family development is not aimed or well suited for describing platform use in a company like Alpha. According to Jiao et al. [8], the concept even implies a make-to-order or assemble-to-order production strategy. Alpha strives however towards increasing platform utilisation in which appropriate theoretical models could be useful.

At Beta, platform use is already firmly grounded within the company, and considering their level of component pre-engineering in their structural system and their production method, both a technical platform and a process platform forms a vital part of their knowledge base. Nevertheless, their use of open design processes to accommodate customer needs outside the boundaries of their platforms on a project basis is not sufficiently represented within the reviewed frame of platform-related theory.

At both companies, processes not explicitly related to the realisation of a specific product were identified. More than so, these were a formalised part of each company's platform. Probably most companies have formalised and standardised processes which could be argued to have an implicit relation to realising products, regardless of production strategy or type of business, for that matter. The question is how the theoretical notion of product platforms should incorporate or account for this? This study does not answer that question, but the results suggest that standardising processes with implicit relations to product realisation could be an important aspect of enabling product flexibility whilst maintaining a platform strategy. Product platforms is a strategy originally intended for businesses with fewer open design processes on a project basis compared to the companies Alpha and Beta. This suggests that theoretical frameworks, which accurately address these aspects, needs to be developed to fit within the existing body of platform-related theory.

At both companies, we saw both an interplay between a technical platform and a process platform as well as how parts from both platforms fed the stream of ongoing projects. This interplay was for instance manifested at Alpha when links between a pre-engineered part (e.g. a wall element) and associated documentation (e.g. checklists etc.) were established. At Beta the same interplay could be seen through the link between a pre-engineered part and the collection of associated SOS. A proposed update to the process model presented by Lessing [1] is that the process platform, not just the technical platform, is feeding each project. This is specifically highlighted and presented in Figure 2. The revised figure does not deepen the insights regarding the actual interplay between a technical and a process platform but it stresses the process platform's role in individual projects as important.

The platform model proposed by Jansson et al. [22] could also be used to incorporate findings presented in this paper, the implicit processes are arguably acting as support methods in product realisation at the two case companies. However, as a platform model, it too lacks the required granularity needed to depict how pre-engineered solutions and standardised processes actually interplay with each other and fit together within the

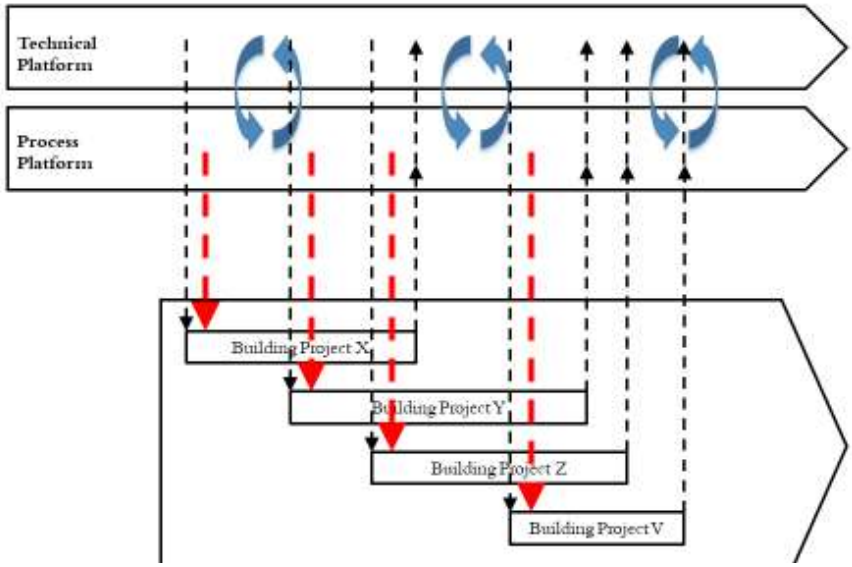

Figure 2. Process model for industrialised house building, revised from [1]

platform. Therefore, further studies are needed to elaborate on this interplay and provide data to identify what mechanisms are put to use within the platform as all subsets within a platform work together to offer flexibility whilst maintaining benefits from applying a platform strategy. An updated platform model should differentiate between mechanisms which are completely or partially dependent on open design processes from those mechanisms which are needed to handle pre-engineered solutions as this study suggest that this level of granularity is needed to establish the relevant processes, implicit and explicit, needed to accommodate product flexibility. Then it can be further developed and concretised to form the basis for a platform strategy better suited to companies like particularly Alpha.

Abstract –

Kinetic facades are dynamic building surfaces that manage light, ventilation, energy, or information. The programming of Kinetic facades require a vast technical expertise of building systems, materials and computer devices and constant alteration of models to examine till the desire purpose of the kinetic façade is achieved. There heavy dependence alterations to physical scale models to understand the systems performance. This paper focuses on a building a mechanical building skin that adjust to the sun path to harness solar energy while shading the building and considering unpredictable weather changes which is an inspiration from biomimicry architecture concepts derived from how leaves react to sunlight in nature rather the conventional fixed photovoltaic panels. Using rhino grasshopper plugin we design and find geometric forms representing panels that can optimally harness sunlight at different times of the day without disrupting sunlight from accessing the interior space though a radiation analysis that measures kilowatt hours per meter squared (Khpm2). The collection changes in panel elements of the façade in various position, orientation generated from Rhino grasshopper are then compiled into a sequence through unreal engines animation tool that can be triggered to move in relation to another object and function in the virtual world which simulates the animation of the system in relation to the suns position and intensity which becomes a virtual animated model. This animated virtual model created in the game engine can constantly be edited to improve performance through immersive experiential design and alterations of the forms generated in grasshopper. The task of simulating and designing models that are performance based is challenging and requires constant Adjustments. We explore the possibility of using a virtual reality model as a potential alternative for physical simulation models that require constant alterations to reach the desired design properties for complex kinetic motion facade.

Keywords –

Kinetic system, performance-based design, digital simulations, design considerations, simulation.

1 Introduction

Building facades perform various function such as such as ventilation, daylight management, interior providing convenience for users, energy saving and information display.

Recently, there has been an increase in the interest of users and designers in Kinetic facades as a solution to problems that arise in the buildings and cities. Technology has played an important role in innovation and increased performance of Kinetic facades to respond to climatic problems that could not be solved by the conventional static façade.

Computational simulation tools and 3D modelling grant designers the ability to creatively simulate and experiment on various forms, structures and materials, while considering environmental factors such as climate and use real time-data to design building skins that are intelligently perform required task such as improved daylighting, shading, displaying aesthetic information, and movement as required.

Kinetic facades combine mechanical electrical and often sensor devices into the building skin that creates the behavior of the building.

To achieve the desired results for kinetic façade design there various design decisions that need to be made from conceptualization to maintenance of the façade. As kinetic facades are complicated based on the task they are required to perform. Early decisions need to be explicit and precise as mistakes made from the early stages further get complicated in later stages of the design process and can lead to facades that perform below the required performance standard intended by the designer.[1]

Even though there has been a constant development of computational simulation and 3d modeling tools there are still limitations that hinder the creative expression and

innovation of kinetic facades such as motion simulation and user convenience experience. Previous researches conducted on Kinetic façade design presents that most users create physical scale models in early design stages to experiment and analyze design concepts and ideas. This can be a tedious process as physical models need to be constantly altered to achieve the desired result.

Virtual reality technology is a possible solution to test and analyze the performance of Kinetic models. Recently Game engines have be used to create various architectural projects and have become a pivotal tool for communication in the Architectural engineering construction (AEC) Industry. Functions such as real time rendering, lighting, shading, collision detection and animation are important for rapid prototyping and interaction of digital models that are dynamic in nature which allows users to make more efficient and accelerated decisions that could not be made through the means of physical models. Although Game engines are a beneficial tool for rapid prototyping of kinetic models, as a standalone game engines cannot perform required measurement of performance required. The required performance and expected behavior need to based on the modelling and climatic that are compatible with real world data

2 Background and Related Research

There has been a substantial amount of research concerning the geometric forms, technology, and fabrication of with little research allocated to the motion. A composition of multiple elements of a kinetic façade have to create a pattern that can remain in constant motion to achieve the required expected motion behavior.

It is not enough to see architecture or interpret it based on drawings; the experience of a built environment reveals the collection of all design decisions. Virtual reality has the potential to provide the AEC professional with the ability to experience the project designs before they are built. With benefits such as immersion and interaction that can be achieved at a higher level in virtual models than physical models. A research conducted by Siitonen used and compared a walk-through VR and an endoscope-photographing model method, and verified which one was better in manipulation, lighting and spatial reasoning capacity through visual observation of outcomes and interviews with participants with VR the most accepted tool. [2]

Game engines have a physics that is based on physical systems to provide approximate simulation, such as rigid body dynamics (including collision detection) that is important to the scope of this paper to simulate the motion of the geometry.

Dynamic animation in game engines allow the simulation of various assets in the game individually as required. They can act collectively or based on individual object oriented animations that collectively become a system patterned of motion.

Adaptive façade design aim at creating strategies for designing facades to respond to environmental conditions, various factors are to be considered but in this paper we focus on motion that can optimized to create shading for the building and harness sunlight at the same time. Adaptable architecture is described for the first time by Frei Otto as a system that is able to change of shape, location, utilization, or spaciousness.[3] The lighting and shading system of game engines allow the user to immersive experience kinetic with a high degree of realism.

Based on the typology classification by F. Otto Mechanical movements can always be reduced to basic types of movement: Rotation, Translation and a combination of the two. [4] Rotation was the selected motion to analyse in this paper.

For kinetic facades, the main considerations in delivering viable plans are automating and active arrangement with comprehension of kinematics, development of recreation, dependability and toughness are the keys to fruitful execution of kinetic elements in structures. These components are concurred by the greater part of the planners and designers when managing dynamic facades. Essentially, the behaviour of the simulation and kinetic motion patterns and what capability of the mechanical essential as the understanding will impact the expected execution of the kinetic facades.

In moving in the direction of utilizing the style and productivity of game engine shading functions, we asked "what can be a data generated comparable base to the virtual model? Furthermore, "What aspects of kinetic motion can be studies in a virtual model?" which presented the required tools for this research as Rhino grasshopper and unreal engine 4.

3 Methodology

3.1 Approach

The proposed experimental process of modelling and simulation considers two main factors that are important in the design for the scape of this research.

1. The optimization of the kinetic faced based on climatic data especially illuminance annual daylight of the interior space
2. Visualization of the kinetic system’s motion in virtual reality with special concentration on day light intensity and shading from the façade design which can be an immersive experience in virtual reality.

There are limitations to the function animation of geometry in game engine virtual spacey based on real world data. So in this paper we consider a simple vertical upward and downward motion of the building cladding to provide sunlight and shading to the interior space as required. Absolute prediction and mimicry of the behavior of kinetic motion of facades that can be applied to real world buildings in a game engine simulation is a challenge and most likely an ineffective method at the current time so the scope of this paper is limited to conceptual design decisions using the combination of data generated from an optimized model and animation functionality of VR game engines to create innovative design concepts and solutions. As seen in figure 1.

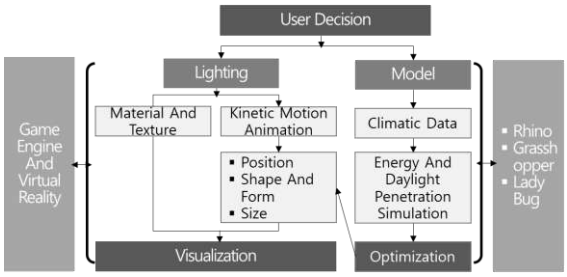

Figure 1. Overall Flow of Research

3.2 Kinetic façade optimization

The performance of the kinetic façade was measure using Ladybug grasshopper plugin. The cladding is a simple hanging cladding at the bottom and top of the curtain wall that shades the building as it rotates upwards and downwards. Both claddings rotated as a mirror of the cladding. Computing for multiple levels presented inconclusive results. So the simulation was conducted for a single floor. Four simulations where conducted in relation to motion. The Climatic data was real world data of Incheon, South Korea downloaded from an open source.

1. The Static mesh averaged 626.5 kWh/m2 and the annual daylight was concentrated around the windows of the space.
2. Introducing the cladding without any rotation the annual daylight averaged 783.9 kWh/m2 and the lighting concentration was even all across the space due to the replacement of windows with a curtain wall.
3. At rotation motion of 15 degrees of the cladding the annual daylight averaged 506.8 kWh/m2 and the lighting concentration was most concentrated at the rear end of the space.
4. At rotation motion of 20 degrees of the cladding the annual daylight averaged 469.9 kWh/m2 and the lighting concentration was generally dimmer than previous iterations.

Further simulations presented results that were either to bright or too Dim, which presented the acceptable range of rotation motion of the cladding to be from 0 degrees to 20 degrees. The annual daylight simulation was programed using the ladybug plugin as show in figure 2.

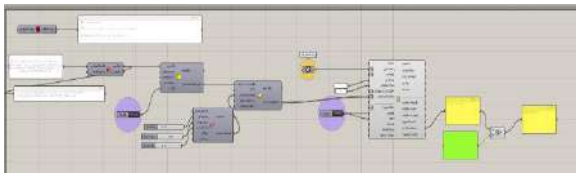

Figure 2. Ladybug grasshopper simulation using real world climatic data

3.3 Game Engine Animation system

The animation of the kinetic system in the game engine was created using a visual language system called blueprinting. The entire movement was controlled by the blueprint which remain constant through the entire simulation excluding the angle of rotation that needed to be changed after every run of the animation as seen in figure 3. Considering that the motion was purpose was to provide insight into the motion of the cladding, the simulation was ran at different the animation speeds and durations that are easily customizable after each animation run. Every cladding had its own animation blueprint which made the animation of every element independent and made it possible to run the animation of any single geometry possible when required

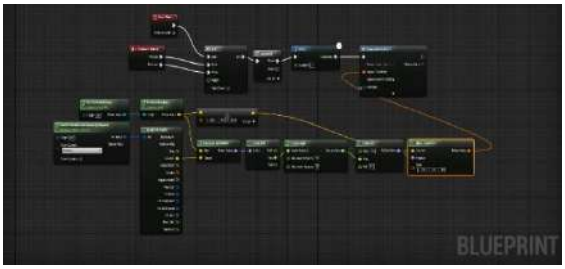

Figure 3. Rotation animation blueprint

3.4 Virtual Reality Experience

Through Virtual reality executables we were able to experience the lighting, shading and motion in immersive VR as seen in figure 4. And shading created by the kinetic motion of the cladding in real world scale and as a small scale model. Through virtual reality controls, aspects of the kinetic façade were edited or turned off to help the user understand how other movements can be changed. A limitation of this process was the complexity of the workflow that made it difficult to make changes to

the virtual simulation in real time.

Figure 4. Immersive VR experience of the Kinetic façade motion

4 Results and Assessment

The results of this proposed workflow that incorporates Rhino as a simulation tool and unreal engine as an immersive VR game toll presented the following results as seen in figure 5.

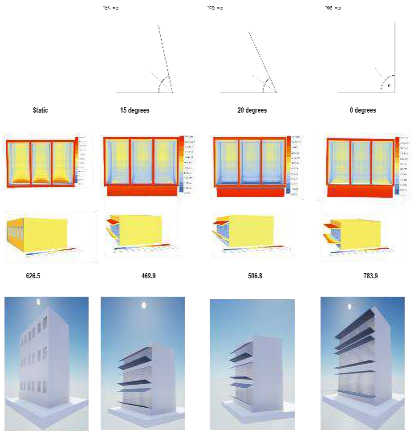

Figure 5. Results comparing the data and model of the Daylight simulation and Game VR motion

1. The game engine lighting and shading were consistent with performance simulation models which makes light and shading studies through the VR game engine effective and convenient.
2. The dynamic nature of the motion of the kinetics elements changed the level of lighting intensity in both the performance model and virtual space thereby altering the comfort of the space.
3. The Immersive animation conveyed the experience of the performance simulation explicitly compared to a third person view of the 3D model

5 Discussion and conclusion

The behavior if the kinetic of the kinetic motion that was required in this paper was simulated using a real world data compatible simulation tool which is an important as designers of kinetic structure must consider performance

The potential for game engine VR to be a toll for modelling complicated kinetic structures is possible but requires the user to have an in depth understanding of game engines or VR software which can make the process of integrating such method of modelling kinetic systems apprehensible for constant use.

VR game engines are potentially alternative modelling tools as any errors or mistakes enquired during the performance simulation in Rhino grasshopper were adjusted and re integrated into the animation blueprint which would have been a more complicated and tedious task in a physical model

We acknowledge that this research is basic in and simplified in in the demonstration of the convergence of performance based model and virtual models. Our Further research intends to address more complicated geometry, structures, mechanics and materialism

The proposed process can be an important way forward for designers to innovative create kinetic modes that perform based on real world data in a convenient workflow.

Abstract -

Today, with the development of technology, various buildings can be constructed in the field of architecture, and the size and complexity of construction are increasing, and the life cycle of buildings is also increasing. As a result, the importance of technology and systems that can maintain and manage not only old buildings but also newly constructed complex buildings is emphasized in modern society. Therefore, in this study, we propose a methodology to improve the efficiency of utilizing MR in the visible aspect of the maintenance of buildings and try to find a way to improve the efficiency of the actual worker by verifying the feasibility of the methodology. The information obtained from the BIM model was uploaded to the MR device, confirming its effectiveness in terms of visibility. We have developed an add-in that can complement the interoperability problems such as data exchange and uploading through the data that can be obtained through the current limited BIM model. By integrating it with other technologies such as artificial intelligence in the future, It is expected that we will be able to fill in deficiencies other than the problems of visualization presented.

Maintenance; BIM(Building Information Modeling); MR(Mixed Reality); Efficiency

1 Introduction

1.1 Research Background and Purpose

The shape of architecture has changed according to the trend of the times. In the modern era, buildings were widely distributed in internationalist style, and buildings built at that time are still continuing and aging. Also, with the development of technology today, various buildings can be built in the field of architecture, and the size and complexity of construction are increasing, and the life cycle of buildings is also increasing. As a result, the importance of technology and systems that can maintain and manage not only old buildings but also newly constructed complex buildings is emphasized in modern society.

Considering the safety performance of the building at the time of construction, maintenance and maintenance of the building, maintenance and replacement of the structure during the lifecycle of the building, and improvement of the performance are performed according to the aging of the structural materials. Building Information Modeling (BIM) has been introduced to manage such a series of work efficiently, so that it can cover all phases of design - construction - maintenance. Based on the information generated through BIM model, Facility Management System, FMS) as basic data. In other words, when creating the BIM model, the information necessary for maintenance should also be input to the BIM model as attribute information. Based on the information, the FIM can be utilized actively. In spite of this technology, however, it is still difficult to establish a complete link between BIM information and FMS. Therefore, in the maintenance stage, it is based on the existing 2D drawings. Especially, when the lifecycle of construction materials is confirmed, BIM information is utilized for intuitive visualization. It depends on human eyes and 2D drawings.

In recent years, 'Microsoft' in the United States has introduced Mixed Reality (AR), which is a mixture of augmented reality (AR) that adds virtual information based on reality and augmented virtuality (AV) , MR) devices have been developed for 'Hololens' HMD (Head Mounted Display). In the field of construction, it is used as a tool to visualize parts that are difficult to understand in drawings and to help constructors understand them. Therefore, this study suggests a methodology that can improve the efficiency of utilizing the existing ineffective method in the maintenance of buildings, especially MR, in terms of visual aspect, and by verifying the feasibility of the methodology, I want to find a way to do that.

1.2 Scope and method of research

This study is a basic study to find a methodology for efficient operation using MR devices in the field of building maintenance. Therefore, this study limited the MEP(Mechanical Electrical and Plumbing) area in terms of visualization, which was especially difficult even in the inefficient way that has been done with the existing drawings in the maintenance process of the buildings. The flow of research is shown in Figure 1.

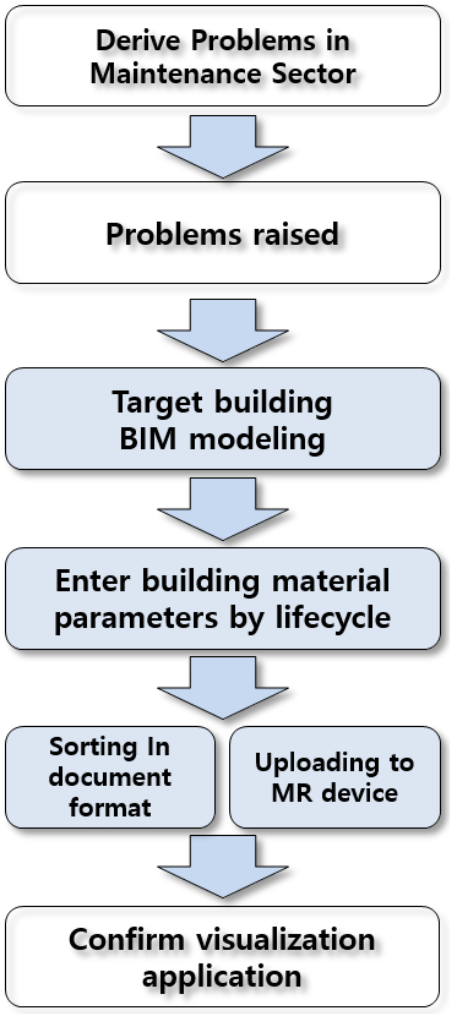

Figure 1. Flow of Study

First, the verification target building for method validation is modeled using BIM tool. After inputting attribute information such as life cycle to the completed MEP model, coloring is performed on the material in the BIM model so that efficient visualization can be performed by filtering according to the information required for maintenance. At the same time, data sorting is performed to increase the efficiency of actual workers by using information of materials according to attribute information. After the work as a BIM tool is completed, the BIM model is uploaded to the MR device and the verification step is performed in an actual 1:1 size AR model.

2 Background and Related Research

In Korea, since the approval of the use of buildings since 2013, the maintenance management system of existing buildings, which was maintained only by the unilateral intention of the owner or manager, is supplemented, and periodic maintenance and inspection of collective structures and multi-use building. Maintenance and inspection system of buildings is being implemented. [1] In the Building Act before the revision in 2012, owners or managers of buildings were legally required to maintain and manage buildings, land, and building facilities. However, the willingness of the relevant authorities to supervise and supervise the maintenance of such buildings was weak, the contents of the management check items are unclear, the maintenance reporting time and the report maker are not clear due to the use and size of the building, and the overall control system is lacking. [2] Since the current buildings are approved by the law, they are maintained and managed only by the unilateral will and intention of the owner and the manager. In the process of using after the completion, there is no specific regulation for the maintenance of the building, but it has not fulfilled the role of protection. [3]

In the United States, each state or city is operated as a form of each ordinance. Especially, evaluation items and criteria for the specific performance of the building are developed and maintained for the purpose of improving the specific performance of the building.

In the UK, maintenance and management are being carried out to build a healthy and comfortable residential complex based on HQI (Housing Quality Indicators) and to improve the quality of the residential level. This provides comprehensive and specific performance evaluation criteria by providing information on performance certification and standard setting related to residential buildings.

In Japan, the Architectural Standard Law, which introduces concrete and strengthened regular reporting systems at the government level, has been amended to take a more active attitude toward maintenance. As such, internationally, maintenance-related systems are approaching from a broad perspective, such as environment, energy, performance evaluation, and urban environment, from a futuristic point of view. However, in each country, improvement is being made in terms of the system by laws and regulations.

Through a series of efforts, the BIM technology

mentioned above is introduced to process the data generated during the construction process at once and utilize it throughout the life cycle of the building. However, this is also due to the various information required by various software functions, and several owners of BIM data are created, but there is a lack of a single integrated information system. [4] Even if the integrated BIM model is constructed to manage all information, there is still a lack of research on visualization of work such as supplementing and replacing aged building components in the maintenance field.

MR technology has been applied as a means to overcome the problems of visualization and has already been widely used in the field of architecture. 'MIDASI'T introduced a display house using VR (Virtual Reality) equipment and introduced a virtual reality in the field of architecture. The company called 'Urbanbase' developed the interior application using AR to maximize the visual effect thereby increasing the satisfaction of actual users. In addition, 'Hololens for Sketchup Viewer', developed by 'Trimble', improves the efficiency of work by showing MR parts to the contractor not only in MEP field but also in difficulties. However, there is not yet a methodology and research that utilize this in the maintenance field.

Figure 2. VR Display House from 'MIDASIT'(vr.midasitonline.com)

Figure 3. AR Interior System from 'Urbanbase'(https://urbanbase.com)

3 Target building analysis and BIM modeling

In this study, the building is one of the lectures within Kyungpook National University located in Daegu, Korea. The outline of the building is shown in Table 1 below.

Table 1. The Outline of Target Building

Type	Straight Type
Height	14.6 m
Each Floor Area	1278.5 ㎡
Floor	4
Long side/ Short side	70000mm/18800mm

This building is a building that has been over 20 years old since its completion and is in need of maintenance but not properly maintained. In particular, although the remodeling has been carried out twice in the past, there is no work to supplement the performance of the building such as elevator installation, rooftop solar panel installation, and structural aspects. Autodesk's Revit 2017 was selected as a tool to make this target building a BIM model. Revit is a BIM modeling tool that not only provides basic modeling but also has an embedded energy performance analysis program that can be used in many aspects of building performance in terms of maintenance.

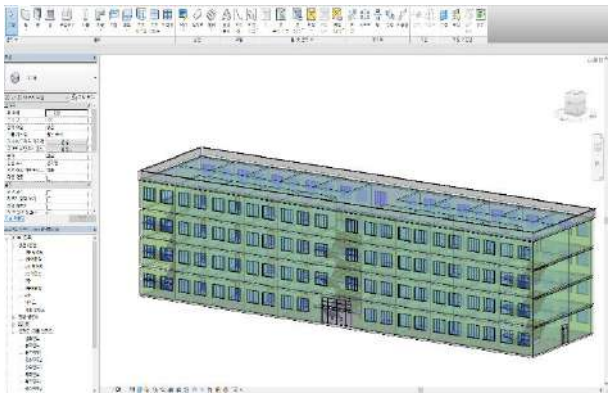

Figure 4. BIM Model of Target Building

The modeling level is defined as LOD 100 based on document E202TM-2008 and AIA Document G203TM-2013 document considering the level of visualization of the target object only in view of maintenance rather than accurate numerical information. In this document, LOD is used in combination with 'Level of Detail' and 'Level

of Development'. However, in order to prevent confusion, this study used 'LOD Development'. Contents are shown in the following Table 2. [5]

Table 2. Contents of LOD(Level of Development)

LOD	Contents
LOD 100 Conceptual	The type, volume, and type of mass are defined at the level of the planning task, and the area, height, volume, position, and orientation of the entire building are set.
L0D 200 Approximate Geometry	Space program, space plan and spatial relation are defined and main architectural general system is determined as conceptualized planning stage. The rough floor area, coverage ratio, floor area ratio, floor height, number of floors, main structure, envelope structure, facility system, etc. are planned
L0D 300 Precise Geometry	The LOD 200 is a step in which the outline of the building process is determined. The building system including the specific facility elements is determined, and all the building elements are modeled.
L0D 400 Fabrication	The size, shape, quantity, etc. of all systems determined as modeling steps for actual construction are modeled. All the elements related to construction, fabrication, and assembly are modeled, such as materials, structures, equipment, piping, and wiring.
LOD 500 As Built	The LOD 500 model is a completion model. The modeling data is the same as the actual building, and includes the entire maintenance/operation.

In this study, MEP, which is an architectural material to be confirmed in this study, is modeled only in the pipes(Plumbing) so that it can be visually and clearly seen at the same LOD level as the same BIM tool, and detailed piping is omitted and three main piping models are modeled.

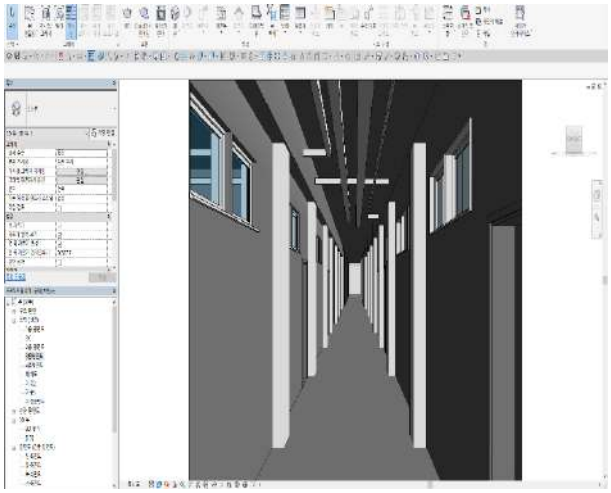

Figure 5. MEP(main pipes) Modeling by BIM

4 Experiment

The detailed experimental scenarios are as follows.

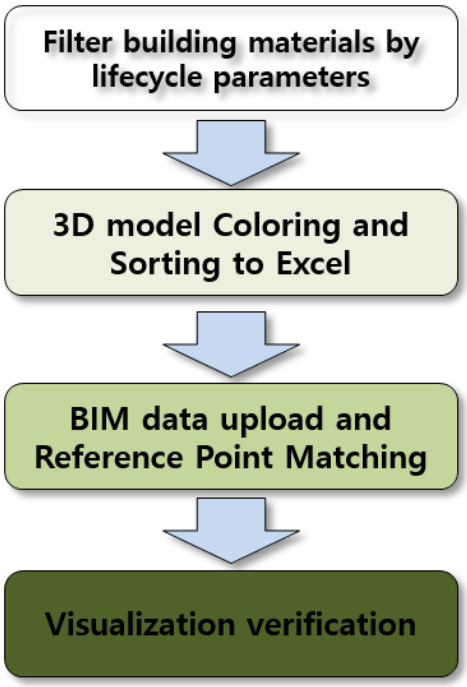

Figure 6. Experimental Scenario

In order to investigate the degree of deterioration of the main piping in Kyungpook National University 's

maintenance lecture, we firstly input the life cycle information of each pipe as a parameter in BIM. Also, the degree of replacement according to input parameters was filtered with different colors.

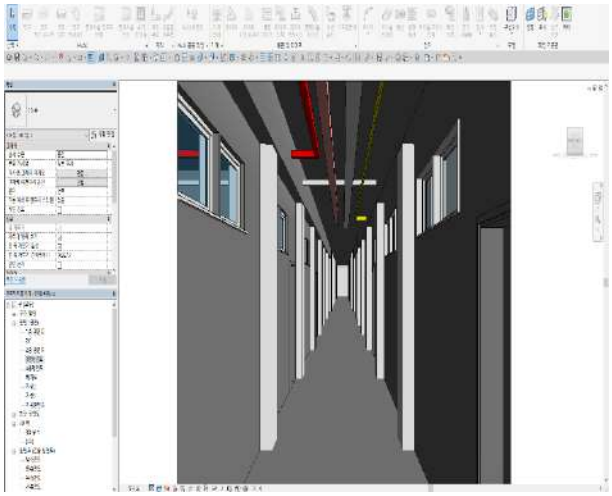

Figure 7. Coloring each Pipes by Life Cycle Parameter

In Revit, you can extract the filtered data using the input parameters according to the desired modeling material. Figure 7 shows data obtained by sorting the coloring data of the piping according to the life cycle into an Excel file.

29	E02-MEP-Pipe04	E02-2	25 year	1990's		
30	E02-MEP-Pipe04	E02-2	25 year	1990's		

Figure 8. Sorting from BIM Parameter Data

When the modeling work using the BIM tool is finished, the BIM data is uploaded to the MR device Hololens. The experiment was carried out using 'BIM Holoview' which is a program to link BIM with Hololens. From the BIM Holoview homepage, create the user ID and upload the BIM model. After logging in with the same user ID in Hololens, you can view the uploaded BIM model as Viewer.

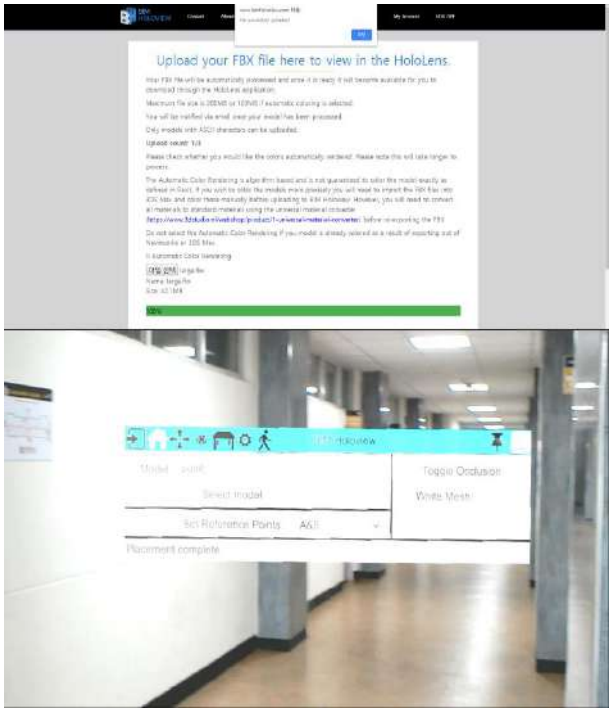

Figure 9. Uploading BIM Data to BIM Holoview

The operation of Hololens is simple. Speech recognition is possible and you can use a remote controller, but the function of clicking on the computer mouse is called 'Air Tap'. You can select it according to the point of sight by hitting your finger on Hololens screen. Another function is 'Bloom' which makes the windows on the screen disappear.

Figure 10. Gestures for Hololens(https://www.microsoft.com/en-us/hololens/)

Figure 11. Control the Hololens

A In this study, BIM data did not include any information other than life cycle parameters other than basic building information. BIM model can have location information and can contain a lot of information such as other energy performance, Time Data (meaning 4D), and Cost Estimate (meaning 5D).

However, as mentioned above, due to the limitation of interoperability in information exchange, only the data required in this study is omitted.

In this case, since the location data is not input, the Reference Point matching the existing BIM data should be prioritized with the Reference Point of the building on the actual Hololens.

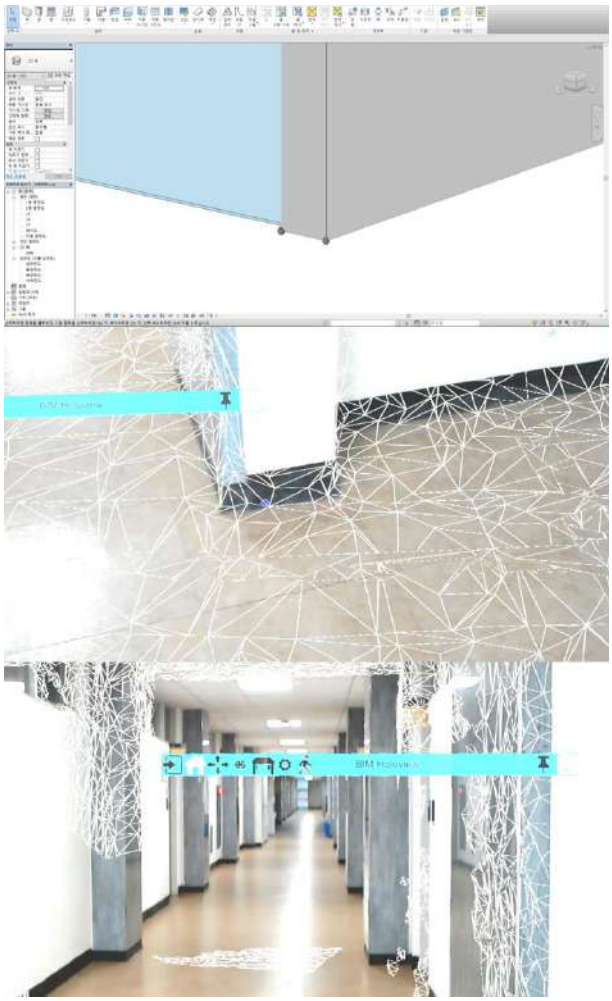

Figure 12. Matching the Reference Point

Then, the verification of the visualization to the MR device was performed based on the sorted Excel data.

5 Discussion

As described in Chapter 4, the BIM model in Hololens was viewed through the Viewer. In addition, the results of the coloring of the piping life cycle as a parameter were also confirmed.

However, the object information in the BIM model, that is, the wall as a wall-specific object and the slab as a slab-specific object, can not be recognized.

Hololens, which is the MR device used in this study, recognizes the wall and space itself in the MR device itself, but the object information of the BIM data disappears in the exporting process and does not reach the step of selecting or modifying the wall in the MR. However, it shows almost 100% synchronous rate, and it is confirmed that MEP which is the target of this study

can be utilized in the maintenance field through the model fitted according to the reference point, and that it is an efficient visualization methodology.

Figure 13. Verification of BIM-MEP model visualization through MR device

6 Conclusion

This study suggests a methodology to increase the efficiency between work during the maintenance and repair process according to the aging of the MEP in the maintenance stage of the building. Especially, it is a method to improve the work efficiency of the actual worker.

Based on the BIM model filtered through the BIM model, the method using the MR device was proposed. The model generated by BIM contains a lot of basic data and can manipulate the parameters to contain more data. However, at present technology level, there is a limit to bring all the data of BIM into MR device.

However, this study shows that it is possible to upload the location information of the desired material and the filtered data according to the life cycle to the MR device. Based on these results, it was confirmed that colorized materials were observed according to the life cycle. And compared to the method of replacing and repairing by relying on the existing 2D drawings, it was able to grasp the exact position, and it was possible to locate the piping of the MEP which was mainly installed in the ceiling duct, And confirmed the possibility of reducing manpower.

In the maintenance stage, the replacement and maintenance of the obsolete materials, which were limited in this study, are part of the maintenance and maintenance in various aspects is needed. If add-in is developed that can complement interoperability issues such as data exchange and uploading through the data obtained through the current limited BIM model, it will be possible to maintain and manage the performance of various buildings such as energy and safety. And it is expected that it will be able to fill deficiencies other than the problems of visualization presented in this study through fusion with various technologies such as artificial intelligence in the future.

Abstract –

It is known that process simulation is a feasible solution to deal with real-world complexities and problems. Civil infrastructure in particular, is a complex system that can benefit from process simulation. This paper provides a critical overview of different simulation modelling paradigms used in construction to achieve better system performance. Three simulation paradigms of agent based modelling, discrete events simulation, and system dynamics are reviewed and their different applications, specifically in civil infrastructure are discussed. The paper then discusses the hybrid paradigms of agent based modelling with system dynamics, and agent based modelling with discrete event simulation, and how hybrid approaches have better capabilities to model complex problems occurring in civil infrastructure. Such modelling approaches, therefore, will improve overall efficiency of construction production.

Keywords –

Construction project planning, Infrastructure sector; Integrated and combined models; productivity and efficiency; Supply chain management

1 Introduction

When prototyping or experimenting with a civil infrastructure system is expensive or impossible, modelling is the best way of solving real world problems, which gives the privilege of optimizing systems prior to implementation [1]. Modelling includes the abstraction process, which is mapping a problem from the real world to its model in the world of models, analyzing and optimizing the problem, then mapping it back to the real system [2]. There are three levels of abstraction, based on the range of problems that are efficiently addressed with simulation modelling, High Abstraction "macro level", Middle abstraction "meso level", Low Abstraction "micro level". Table 1 generates a better understanding of the abstraction level concept and different modelling schema used for each abstraction. Considering an example, macro level traffic and transportation models may not consider individual vehicles or packets. Supply chains are being modeled at very different abstraction levels and they could be placed anywhere in middle to high abstraction range. Problems at the top of Table 1 are typically approached in terms of aggregate values, global feedbacks, trends, etc. Individual elements such as people, parts, products, vehicles, animals, houses are never considered there. Thus, considering how different modelling approaches correspond to abstraction; System dynamics dealing with aggregates is located at the highest abstraction level. Discrete event modelling is used at low to middle abstraction. As for agent based modelling, this approach is being used across all abstraction levels [2, 3]. Agents may model objects of very diverse nature and scale: at the micro level agents may be pedestrians or cars or robots, at the middle level they can be customers, at the macro level they can be competing companies.

The purpose of this paper is to discuss different simulation paradigms in civil infrastructure by focusing on Agent Based Modelling (ABM), Discrete Events Simulation (DES), and System Dynamics (SD). Furthermore, different applications of these approaches along with related advantages/disadvantages are presented. After that, the paper discusses Hybrid paradigms and enhanced modelling performance that can be achieved when combining more than one paradigm. A focus will be on Hybrid ABM-SD, and Hybrid ABM-DES. The paper concludes that agent based modelling is not a substitution to the other modelling paradigms, but a useful add-on that can be combined with system dynamics and discrete event simulation to achieve better results.

Table 1. Paradigms corresponding to different abstraction levels, and applications related to different abstraction level

Abstraction Level	Applications of Simulation modeling (Some of)	Paradigms
High Abstraction/ Macro level/ Strategic Level/ Less details	• Market Place & Competition • Population Dynamics • Manpower & Personnel • Ecosystems • Health Economics	ABM & SD
Medium Abstraction/ Meso level/ Tactical Level/ Medium details	• R&D project Management • Supply Chain • Waste Management • Transportation • Electrical Power Grid • Call Center • Emergency department	ABM & DES
Low Abstraction/ Micro level/ Operational Level/ More details	• Pedestrian movement • Warehouses • Factory floor • Automotive Control System • Computer Hardware	ABM & DES

2 Literature Review of Different Simulation Modelling

2.1 Agent Based Modelling (ABM)

ABM is a computer simulation technique that allows the examination of how system rules, and patterns emerge from the behaviours of individual agents [4]. There is no universally accepted definition for ABM, the primary reason is that researchers in literature are still arguing and discussing what kind of properties an object should have to earn to be called an "Agent" [2]. One of the widely accepted definitions provided by Wooldridge and Jennings, 'A self-contained program capable of controlling its own decision-making and acting based on its perception of its environment, in pursuit of one or more objectives' [5]. Nasirian, et al. [6] explain that Agent-based simulation is basically a model in which dynamic processes of agent interactions are simulated repeatedly over time as in SD, discrete event and other types of conventional simulations. An Agent Based simulation mostly consists of more than one agent interacting, that's why it is often called a multi-agent system, MAS, [7]. Agent- based models, ABMs or MASs, consist of a set of agents characterized by attributes, and interact with each other through the definition of pre-set rules in a given environment [8]. Agents produce output behaviour according to their interaction with each other and their environment and also by following their rules. Many scholars have tried to introduce properties for agents in ABM, [9] defines three properties for agents to be: Cooperative, Learning and Autonomous, and that every agent should possess two of three at least [10]. Pro- and re-activeness, spatial awareness, ability to learn, social ability, "intellect", etc. as described in [7] are some of the many properties of ABM. Aside from the different properties that define Agents, an important feature that distinguishes Agent Based Models from SD or DE is that they are essentially decentralized [2]; there is no such place in AB model where the dynamics of the system could be defined. Instead, the modeler defines behaviour at individual level, and the global behaviour emerges as a result of the many individuals interacting, each following its own behaviour rule, living together in some environment and communicating with each other and with the

environment [2]. The complexity of the ABM system arises from the interactions between different agents [11]. The main objective of the ABM simulation is to track the interactions of the agents in their artificial environment and understand processes through which global patterns emerge [12]. The number of applications to which ABM can be applied are endless due to its distributed and flexible computational power [13]. ABM is a suitable tool to describe the behaviour of complex systems as it serves a 'bottom-up' approach to seize the interactions between individual agents, recognizes each entity as heterogeneous rather than identical, and allows the agents to dynamically evolve and adapt [4]. Extremely complex behaviours can arise from repetitive and competitive interactions between agents enabled to be accounted by the computational power of computers [14]. And thus, ABM is progressively seen in more natural science and engineering purposes, though specific construction applications are more limited. Most recently, Son, et al. [15] have reviewed the use of ABM in construction research and noted its ability to deal with emergent behaviour in complex systems and the advantage that ABM might have over more reductionist approaches. Sawhney, et al. [16] reviewed the use of ABM in answering questions within complex construction systems. They conclude that by combining ABM with more traditional discrete event approaches, these systems can consider human factors that impact the construction site. The traditional approach adopted in studying and understanding construction models has been defined as a "central control" approach, in which the construction plan and schedule are created in advance based on defined resource and constraints [16].

2.2 Discrete Events Simulation (DES)

Discrete Events modelling origins back to 1960s by Geoffrey Gordon, who developed the existing idea of GPSS and brought about its IBM implementations [17]. Entities in DE are passive objects that represent people, parts, documents, they can be delayed, processed, seized and release resources, split, combined, etc. [18], defined the DE methodology as ''the modelling of a system as it evolves over time by a representation in which the state variables change only at a countable number of points in time''. Pidd [19], defined DE simulation as "An instant of time at which a significant state change occurs in the system". Simulation entities can be defined as the elements of the system being modeled and individually identified and processed [20]. Moreover, flow entities and resource entities need to be distinguished in simulation [21]. Flow entities, are usually referred to as (customer entity or temporary entity) and pass through a sequence of activities in a process, and interact with the resource entities (server entities or permanent entities). In contrast with resource entities, flow entities are identical to one another, in a sense that no physical attributes are required to define and distinguish them [22]. A flow entity only carries a time cell to track their arrival times, waiting times, and departure times at activities. The "transaction-flow world view" often provides the basis for discrete-event simulation. In this simulation view, a system is visualized as consisting of discrete units of traffic that move/flow from point to point in the system while competing with each other for the use of scarce resources. The units of traffic are sometimes called Transactions, giving rise to the phrase "transaction flow" [23]." Plentiful systems fit the previous description, which include many manufacturing, material handling, transportation, health care, civil, natural resource, communication, defense, and information processing systems, and queuing systems in general. A discrete-event simulation is one in which the state of a model changes at only a discrete, but possibly random, set of simulated time points. Two or more traffic units often have to be manipulated at one and the same time point. Such "simultaneous" movement of traffic at a time point is achieved by manipulating units of traffic serially at that time point. This often leads to logical complexities in discrete-event simulation because it raises questions about the order in which two or more units of traffic are to be manipulated at one time point. Discrete-event simulation has been recognized as a very useful technique to be taught to tertiary engineering students for the quantitative analysis of operations and processes that take place during the life cycle of a constructed facility [24, 25]. Construction planning is the most crucial, knowledge-intensive, ill-structured, and challenging phase in the project development cycle due to the complicated, interactive, and dynamic nature of construction processes [26, 27]. DES provides support to construction planning by predicting the future state of a real construction system following the creation of a computer model of the real system based on real life statistics and operations [28]. Simulation models for typical construction systems have been delivered as electronic realistic prototypes for engineers to experiment on, which eventually will lead to productive, efficient, and economical field operations.

2.3 System Dynamics (SD)

Developed in the early 1950s by an electrical engineer, Jay W, Forrester, defined System Dynamics as "the study of information-feedback characteristics of industrial activity to show how organizational structure, amplification (in policies), and time delays (in decisions and actions) interact to influence the success of the enterprise" [27]. Since then, definitions and applications

of System Dynamics have been widely studied both in literature and in practical life. Mathematically, a System Dynamics model is a system of differential equations [2]; it is a methodology to understand a specific, predefined- problem or complex problems that include changes over time through multiple feedback loops. System Dynamics uses feedback loops, stocks and flows to model the behavior of complex systems over time [29]. In real world, stocks are a representation of different processes such as, people, money, knowledge, material, etc. Also, real world processes interactions are represented by the flows between the different stocks, and the information that determines the values of the flows [2]. Specifically, feedback loops are closed chains of cause and effect links in which information about the result of actions is fed back to generate further action [30]. To describe the System Dynamics behavior accurately, it should be highlighted that the system is rising from two fundamental types of feedback loops; Negative loops showing goal-seeking behavior and represented with minus sign, and positive feedback loops, represented as plus sign, having the tendency to strengthen their input, leading to exponential growth or decay [31]. A positive feedback loop generates evolution or progression, not equilibrium as in a negative feedback loop [32]. System Dynamics abstracts from single events and entities and takes a comprehensive view concentrating on policies. To method an SD problem, one has to describe the system behavior as a number of interacting feedback loops, balancing or reinforcing. Once the feedback loop are structured and identified, they are translated to what is called stock-flow diagrams to enable simulations [31]. It is important to highlight that large-scale construction projects are extremely complex, highly dynamic, have multiple feedbacks and nonlinear relationships, and require both hard and soft data [31].That explains why System Dynamics can fulfill certain modelling requirements, especially for large-scale construction models. In general, the strength of SD lies in its ability to account for nonlinearity in dynamics, feedbacks and time delays [14], and thus, System Dynamics has been a widely successful tool applied to issues ranging from social, industrial and environmental to project management systems [33]. In construction management, System Dynamics is a widely used modelling tool; however, SD developments in the construction field focus on the characteristics of the traditional construction, or separate sub-systems [30]. A first simple SD model for general project management is developed by [32]. This model then modified for managing different project phases.

3 Analysis of Different Hybrid Paradigms

3.1 Hybrid ABM-SD Simulation

SD and ABM are two simulation methods used to investigate nonlinear social and socio-economic systems [29]. SD has difficulties in many situations and ABM might help to cope with these problems [34]. However, this does not mean that SD is a poorer methodology than ABM, most likely the field of SD is more mature than ABM, which is still in its infancy [35]. Schieritz and Milling [7] presented a comparison between ABM and SD characteristics and found some similarities between the two models. Both of them have the same aim, which is to search for principles underlying the dynamics of complex systems [11]. Lorenz and Jost [36] argued that combining two methodologies helps to be closer to reality as they can synchronize best-fit methods of different methodologies. Schieritz and Milling [7] showed that combining SD and ABM offers the strength of the two methodologies. Adding to that, they believe this combination reduces complexity of the model from the beginning. A hybrid paradigm approach has the advantage of allowing complex problems to be represented more naturally, which improve efficiency and enhance better communication with the simulation project developers [37]. Hybrid simulation involves the use of multiple simulation paradigms, and is becoming an increasingly common approach to modelling modern, complex systems [38]. ABM and SD are among the most important simulation methods available [34]. The idea of creating hybrid models consisting of ABM and SD has been started in the late 1990s. An integration of the two concepts can be successful when it allows for the combination of properties that are otherwise proprietary to a single concept [7]. To fruitfully design a hybrid ABM-SD model; firstly, the framework for this hybrid simulation has to be proposed. This aids construction modelers to combine ABM and SD to benefit the strengths of the two methodologies [29]. It is necessary to define whether a single simulation method or a hybrid ABM-SD simulation approach is needed to model the problem from the beginning, as every simulation method has limited capabilities. The selection of the simulation method replies on the problem type. One should determine the problem can be simulated by one of the ABM or SD, or a hybrid simulation approach is needed [29]. The next step is to define the modelling hierarchy “a top-bottom as in SD, or Bottom –up as in ABM”. Prior to defining the hierarchy, an important note should be highlighted; despite the growing interest in hybrid simulation, little guidance exists for modelers regarding the nature and variety of hybrid models [38]. They proposed three types of hybrid ABM-SD simulation classification including Integrated, Interfaced and Sequential. The

integrated class incorporates feedbacks between ABM and SD representing a continuous process. It means within the Interfaced class may be run in parallel where their outputs are combined as required to represent the desired output as a function of time. In the Sequential class, ABM or SD has to be run first and its output will then be fed to the next. And thus, to determine the hierarchy of the model, for the integrated class of hybrid simulation, SD and ABM can be in a higher or lower level in comparison to each other [38]. However, the SD model is in a higher level in comparison to ABM for the sequential class of hybrid simulation. The next step is to define Information flow path, which the created information passes from one model to another, SD to ABM or vice versa. Nasirzadeh, et al. [29] suggested that the defined path of information flow can be determined based on the purpose of modelling. For example, there is a mutual IFP between SD and ABM models for the integrated class of simulation. The following step is to determine the simulation type based on the modelling purpose. In the case that there is not any connection between ABM and SD models, an interfaced class will be selected. However, if there is an interaction between the two, an integrated or sequential class would be selected. In the case that the interaction is mutual, an integrated class is used. When this interaction is not mutual, a sequential class is used. The last step is to define the Interface variable; which is to determine what should be exchanged between SD and ABM. The variables whose values are changed or influenced by variables of the other model and the variables which influence the values of variables of other models during hybrid simulation are named as 'interface variables'. The interface variables pass data from one model to another in the integrated and sequential classes of hybrid simulation and act as a gate for the transition of data between the two models. So that, SD and ABM exchange data through running time of the hybrid model.

3.2 Hybrid DES-ABM Simulation Modelling

DES is widely accepted in the construction simulation literature as the default approach for modelling construction. Humans, machineries and organizations are modeled in ABM and activities and project environment modeled using DES. The agents' decisions are dependent on the variables in the DES simulation. DES is very established in construction simulation and can be easily adapted to allow interaction with an ABM model. The hybrid framework consists of discrete event simulation as the core, but heterogeneous, interactive and intelligent (able to make decisions) agents replace traditional entities and resources [37]. Many DES models can become more representative of the real world if entities are agents with the ability to adapt to changes in the model. Instead of using the simulation approaches individually, a hybrid DES-ABM simulation proposes framework to integrate unlimited behavioral activities, such as considerations in safety behavioral into construction activity planning. [37]. With further investigation into the relationships of the two modeling paradigms, in DES model, individual entities already exist; those entities can naturally become agents. The DES entities are however described as passive objects and the rules that drive the system are concentrated in the flowchart blocks. Hybrid DES-ABM is described as the process from the entity's viewpoint, thus decentralize "some of" the rules. Goh, et al. [37] describes the hybrid model in a simple manner as; the first component of the hybrid model is an ABM-DES model that analyzes a system in an individual level [39]. This component therefore produces data for the existing base case system, as well as, for systems to test strategic planning scenarios. The second component is the intelligent DES workflow-based that takes as inputs the incident data that is generated from the base case and scenarios. The DES model then combines the time-based input data, and compares the KPIs between the simulated scenarios [39].

4 Conclusion

Prior work has utilised different simulation approaches to model civil infrastructure processes [40, 41]. This paper reviews such simulation approaches. Some simulation techniques such as ABM allow the examination of how systems behave, and patterns emerge from the behaviours of individual agents. ABM is a suitable tool to describe the behaviour of complex systems as it serves a 'bottom-up' approach to seize the interactions between individual agents, recognizes each entity as heterogeneous rather than identical, and allows the agents to dynamically evolve and adapt. Researchers have reported on ABM's ability to deal with developing behaviour in complex construction systems and the advantage that ABM have over other approaches.

DES on the other hand, provides entities that are passive objects and represent people, parts, and documents. Entities can be delayed, processed, seized and released, split, and combined. DES provides support to construction planning by predicting the future state of a real construction system following the creation of a computer model based on statistics and operations. Applications of System Dynamics have been widely studied both in literature and in practical life. The strength of SD lies in its ability to account for nonlinearity in dynamics, feedback and time delays. Thus, SD has been a widely successful tool applied to large scale and complex construction projects. To sum

up, Table 2 shows advantages and disadvantages of using individual modelling paradigms.

Table 2. Comparision of Advantages and Disadvantages between the individual modeling approaches, DES, ABM, and SD

	DES	ABM	SD
Advantages	Easier to create a DES model	Absence of existing elements to be used, provides more flexibility to the modelers to model any scenario in any way they like Understanding the model logic is quite easier as the state-charts do not require simulation modelling knowledge to be understood	Ability to account for nonlinearity in dynamics, feedbacks and time delays
Disadvantages	Output elements had to be added to the model to improve the model performance Understanding the model logic can be difficult	Models are harder to create because no existing and built-in blocks can be used	Difficult in heterogeneous environments As the structure of the system tends to be fixed in SD, it is impossible to use it to study systems which tend to evolve through time

Moreover, the paper focuses on the hybrid modelling paradigms and resultant enhanced applications that can be achieved. The paper findings confirm that better modelling performance can be achieved using hybrid paradigms. A hybrid approach has the advantage of allowing complex problems to be represented more naturally, which improves efficiency and enhances modelling robustness. Hybrid simulation involves the use of multiple simulation paradigms, and is becoming an increasingly common approach to model modern and complex systems.

Abstract -

Site layout planning (SLP) is categorized as a non-deterministic polynomial time (NP) hard or complete class problem. Inefficient SLP can lead to congestion, safety conflicts and productivity reductions. Significant attention to the problem is evident in the field of construction management. A number of optimization routines and mathematical models are suggested in past research to reduce costs associated with improper layouts. However, such models are seldom adopted on real-life projects, where SLP is primarily carried out based on heuristics. The two significant inhibitors to the adoption of sophisticated approaches identified in this study are; lack of realism in the mathematical models and the significant effort involved in setting up the model for each construction site. These two inhibitors tend to reflect as reluctance on the part of the project teams to adopt SLP models. In the present study, the first inhibitor is addressed by incorporating realism into the mathematical model for SLP. The SLP is formulated as an optimization problem involving the reduction of transportation cost on construction site with associated constraints. Realism to the optimization model was brought through the modelled travel distances utilizing Building Information Modelling (BIM). Genetic Algorithm (GA) was used to optimize the objective function. The combined model thus incorporates all the site constraints in terms of travel paths as captured in the BIM model thus bringing in more realism into the SLP modelling. This work is preliminary work in developing a fully automated SLP process where the second inhibitor would also be addressed.

Keywords -

Site Layout Planning; Optimization; Building Information Modelling; Genetic Algorithm

1 Introduction

Research to address the problem of layout planning also exists in sectors like manufacturing, electronics, computer science and information technology and construction. The objectives to achieve and the constraints encountered are unique to the Architecture, Engineering and Construction (AEC) industry. The layout planning for a construction project starts at the initial phase of the project. The objectives during this phase are not limited to the identification of potential locations to accommodate temporary facilities (TFs) [1], finalizing the routes for vehicular movement [2] and selection of equipment [3]. Intertwined tasks brings more complexity to be handled while planning layouts for construction sites [4]. There exist literature where researchers have tried modelling SLP as a mathematical problem. Mathematical models too possessed the complexity and were referred to NP-Hard [5] and NP-Complete [6] class problems. Despite enormous research in the domain of layout planning, the AEC industry utilizes heuristics of the experienced stakeholders on the project for the purpose of SLP. Sometime the drawbacks of layout through experiential learning come to forth in the form of site congestion, restricted access, unnecessary vehicle movement, multiple handling of material etc. The mathematical approach existing in literature provides a segmental solution to the layout problem and lacks in capturing the realism of a construction site [7], [8]. Although the studies in the domain of layout planning have focused on developing a varied approach to tackle different objectives [7] and comparing the algorithms, adopted in the domain for the solution search [6]. This research in contrast presents an effort to understand the inhibitors to the adoption of existing mathematical models and approach. An evolution in the mathematical approach is also evident to make mathematical models closer to real site scenario; from discrete space layout planning problem to continuous space optimization [3] and from

adopting rectilinear distances, to generating actual paths for planning layout [9]. This research effort is focused on the latter and is a distinguish approach as it involves modelling of paths rather generating it algorithmically.

The existing research presents the adoption of BIM and simulation-based methods to benefit the SLP process through optimization approach. The approach established in this research presents a simple and dissimilar method by utilizing BIM, to bring realism to the mathematical model for SLP. The actual paths modelled for SLP to represent the manoeuvring paths of vehicles and the site personnel replaces the Euclidean and the Manhattan distances considered in existing literature. A test case is also demonstrated with an objective to minimize the transportation cost of material on construction site. The domain of layout planning for construction site has shown significant advancement and the approach developed in this study conform to the recent advancements in the area.

2 Site Layout Planning

The task of allocating space to TFs, material, site personnel and equipment can be referred as 'Site layout planning'. During the task, ensuring optimal usage of the available space is among the prime objectives to the stakeholders involved [10]. The task is part of the front-end planning of a construction project and has close interaction with other processes like scheduling, equipment selection and supply management [3]. The existing research in the domain has attempted the problem in ways like static site layout [11], dynamic site layout [12] and phase based site layout [9]. There have been attempts to model the site space utilizing girds, discrete site spaces and continuous site space [13]. These approaches of representing site space present the peers' desire to model construction scenario close to reality. The methods presented in the existing research have utilized different ways to map the site distances. Some studies have considered the Euclidean and Manhattan distances to replicate the site movements of vehicles and site personnel [14]. The depiction of rectilinear distances on the site may help in mathematical modelling of the construction site but are of no good as the resulted output of these models also lead to sub-optimal solutions. Although there exist rich literary resources to plan site layout efficiently, the construction site layout planning is attempted by the responsible stakeholders utilizing heuristics and the experiential learning gained over the years. The employed approach to layout planning sometimes leads to sub-optimal layouts for the construction site resulting in congestion, multiple handling of material and a rise in safety concerns. The adoption of available optimization routines and mathematical models is still not profound in the AEC industry and the reason can be contributed to the lack of representing actuality in the approach [15]. BIM and computer simulation has marked applicability for SLP and offered help to the planners to plan close to reality. There have been advancements in the mathematical modelling for site layout planning and the adoption of fuzzy sets to incorporate uncertainty has also been employed. Some studies have highlighted the interaction of SLP with the other planning process in very recent years [16], [17].

2.1 Advancements in Research of SLP

Mathematical models for layout planning exist from a long period, formulated as a single objective to optimize [18] and sometime multi-objectives are transformed to a single objective by assigning appropriate weights to individual objectives [19]. The literature has an intensive focus towards optimizing the sum of weighted distance represented as $\sum w*d$ [20]. The primary focus of the existing studies has been on smooth interaction between the facilities on construction site [21]. It is also a shift observed from macro-level planning for the site to micro-level planning, leaving the problem of site utilization partially addressed. The concern towards other objectives has also captured the interest of the construction management researchers. The objectives of the layout problems are both qualitative and quantitative. The factors like safety are addressed in layout optimization in both ways [20]. To address the objectives in an efficient manner that were unaddressed due to the uncertainties involved were approached through the simulation technique integrated with optimization [22]. A few BIM based approaches for layout optimization of the construction site are also evident in the studies of recent past. The shape of a temporary facility is one parameter that can affect the site layout decisions. The area of site locations have a tendency of getting changed as the progress of construction moves forward. There exist research to generate a freeform geometry of the locations and its transformation [23]. Studies have presented a necessity to have 'shortest paths' [23] on construction site and a few have highlighted to have 'actual paths' in consideration [9]. The utilization of BIM for planning site layouts collaboratively is another application of BIM integrated with Augmented Reality (AR). The research presented the users' behavior when subjected to AR enabled platform for planning SLP [24]. The concepts of BIM help in providing the required level of realism to the virtual model by leveraging it with the information. There are few studies highlighting the requirement of BIM for rule based checking system for planning site layouts. The rule based checking is to identify conflicts with the design of the permanent facility [10]. Apart from adopting BIM, the four

dimensional (4D) planning is also proposed in existing studies to replicate realistic site planning. These cases of 4D planning comprises of a three dimensional (3D) model integrated with the schedule of a construction project, and based on the generated 4D visualization of construction activities the SLP is carried out [8]. Moreover, to BIM, simulation and visualization aids; there exist efforts of researchers in the domain to generate paths on construction site for mobile cranes [25] and site personnel but sometime the computer generated paths may also be found infeasible to adopt.

The presented approach in this research combines the existing approach of SLP i.e. mathematical optimization and BIM. The BIM module of the study can be an add-on to the existing optimization models bringing them closer to the reality of the construction site.

3 BIM based Framework for SLP

The apparent utilization of BIM in the AEC industry has simplified the tasks of quantity take-off, detecting and resolving clashes, progress monitoring, asset management etc. This research highlights the potential of BIM for SLP. The BIM model of a hypothetical construction site has been developed and is detailed to a required level of detail (LOD). The LOD 300 model presented in Figure 3 is found apt for implementing the conceptual framework of this study. This detailed model acted as a supplement to the mathematical optimization module presented in section 3.1. The developed approach is depicted in Figure 1.

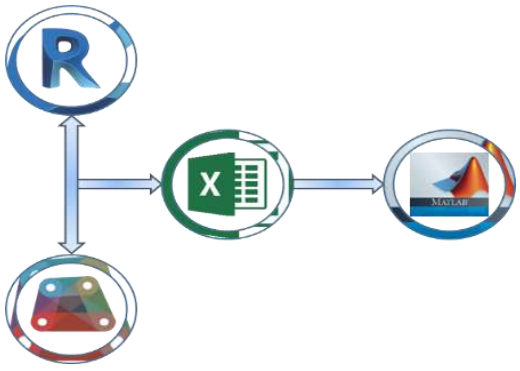

Figure 1. Interoperability Offered by BIM

The modelled site comprises of a reinforced concrete framed structure with isolated footings and a site area of 12385.42 square meters (sq.m.). The main structure has been divided into four quadrants marked in Figure 2.

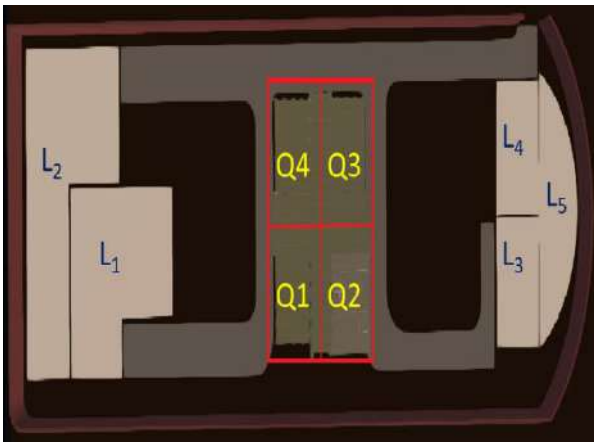

Figure 2. Top View of the Modelled Site

The locations to accommodate TFs, marked as L_1...L_5 in Figure 2 are identified and this represents a case of discrete SLP. It is assumed that the route planning for the construction site is in place and the movement of the vehicles for supporting construction is restricted to the planned paths. During the preparation of the 3D model for the main structure, the paths are modelled to the desired precision. The LOD 300 provided flexibility to takeoff the quantity with high accuracy through Dynamo 2.0, an add-in to Autodesk Revit.

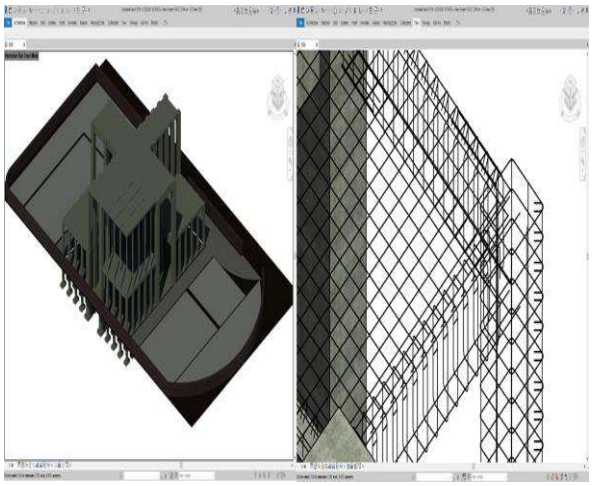

Figure 3. Construction Site Model (LOD 300)

The whole construction site elements are mapped utilizing the visual programming interface of the Dynamo. Figure 4 shows the mapped routes on the construction site joining the locations for temporary facilities and the quadrants of the main structure.

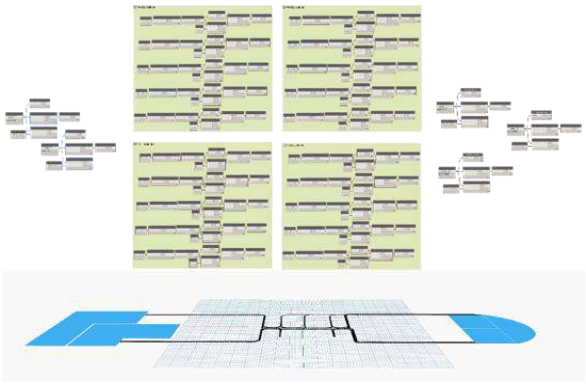

Figure 4. Dynamo Workspace and Preview

The length of the planned routes is extracted from the model and stored in location-distance (LD) matrix as shown in Table 1. The LD matrix is one input for the mathematical optimization module presented in this research.

The quantity takeoff for the required material (M) has been extracted for each quadrant (Q) utilizing Dynamo. The materials required for the modelled framed structure and its respective quantity is tabulated in Table 2. The muck quantity is taken as an approximate of 1.5 times the quantity of concrete required for the isolated footings. The quantities generated by Dynamo are in different SI units and are brought to a common measurement unit by required arithmetic operations.

Table 1. Location to Quadrant Distance

Quadrant / Location	Q1	Q2	Q3	Q4
	Distance in Meters			
L_1	175.8	215.6	220.5	176.7
L_2	186.7	228.1	227.3	166.4
L_3	204.0	164.2	163.1	206.6
L_4	243.5	199.5	195.2	239.2
L_5	242.2	201.0	153.1	210.7

The materials for which the quantity takeoff has been executed are Reinforcement Steel (M_1), Concrete (M_2), Pre-Engineered Steel Sections (M_3), Excavated Muck (M_4) and Shuttering Formwork (M_5). Data from five construction sites of similar area and are at an initial project phase have been acquired to identify the equipment requirement and the cost of operating the equipment. Table 3 highlights the equipment running cost and the maximum carrying capacity per trip.

Table 2. Quantity Takeoff from BIM Model

M \ Q		Q1	Q2	Q3	Q4
M_1	m^3	3.1	3.1	3.1	3.1
M_2	m^3	405.5	405.5	405.5	405.5
M_3	m^3	0.0	91.2	0.0	0.0
M_4	m^3	1459.8	1458.7	1458.2	1459.8
M_5	m^2	1900.2	1897.3	1894.1	1900.2

The trips are calculated utilizing the derived quantities and converting into an appropriate unit. The conversion has been done for M_1, M_2, M_3 and M_4 using the density of material as 7850 kg/m^3 [26], 2400 kg/m^3 [27], 7700 kg/m^3 [28] and 2000 kg/m^3 [29] respectively. The quantity of M_5 is transformed by adopting a value from the industry of 11.3 kg/m^2. The trips required for transporting the entire material to the construction site is shown in Table 4, and is calculated adopting the operable capacity of the appropriate equipment.

Table 3. Data from Field

Equipment	Rated Capacity	Operable Capacity	Cost Unit per Trip of Unit Meter
Transit Mixer	6 m^3	5 m^3	100
Mobile Crane	16 T	16 T	100
Dumping Truck	35 T	32 T	100

Table 4. Required Number of Trips

Material	Q1 Trips	Q2 Trips	Q3 Trips	Q4 Trips
M_1	2.0	2.0	2.0	2.0
M_2	82.0	82.0	82.0	82.0
M_3	0.0	44.0	0.0	0.0
M_4	92.0	92.0	92.0	92.0
M_5	2.0	2.0	2.0	2.0

The transit mixer is found suitable for material M_2 and likewise M_1, M_3 and M_5 are expected to be hauled by a mobile crane. The material M_4 is required to be transported from the execution site to a location for storage by a dumping truck. The excavated soil is stored for backfilling once the planned footings are installed.

Table 5. Transportation Cost Matrix

M \ Q	Q1	Q2	Q3	Q4
M_1	200.0	200.0	200.0	200.0
M_2	8200.0	8200.0	8200.0	8200.0
M_3	0.0	4400.0	0.0	0.0
M_4	9200.0	9200.0	9200.0	9200.0
M_5	200.0	200.0	200.0	200.0

The trip matrix and the cost unit matrix provided the transportation cost unit for materials (TCM) which is another input to the optimization module of this study. The TCM matrix is presented in Table 5. The TCM matrix is the product of cost unit per trip of equipment and the number of trips required to transport the material to the quadrants.

Once the inputs for the mathematical module are acquired, the SLP optimization approach is formulated. The approach adopted is developed to identify the position for storing the materials before transporting to the quadrants along with an objective of minimizing the transportation cost of the materials.

3.1 GA based Optimization for SLP

The adoption of GA for layout optimization is evident in the existing literature. The algorithm follows the criteria 'survival of the fittest' of natural evolution. This study adopts the algorithm to optimize the cost function formulated in equation 1.

$$\text{Min} \sum_{L=1}^{5}\sum_{M=1}^{5}\sum_{Q=1}^{4} \mathbf{C_{MQ}D_{LQ}X_{ML}} \qquad (1)$$

The objective function represents the transportation cost of materials from locations to the quadrants of the proposed main facility. The term C_{MQ} is the cost of transporting material (M) to quadrant (Q), D_{LQ} is the distance between the location (L) and the quadrant (Q) and X_{ML} represents the decision variable depicting the location of material 'M' at location 'L'. The decision variable is chosen as a Boolean variable, limiting its value to 0 or 1.

This research presents a case of constrained optimization where the above-mentioned cost function is minimized subjected to the constraints presented in equation 2 and 3.

$$\sum_{L=1}^{5} \mathbf{X_{ML}} = 1 \qquad \text{Where, } \{M=1,2,\ldots5\} \qquad (2)$$

$$\sum_{M=1}^{5} \mathbf{X}_{ML} = 1 \qquad \text{Where, } \{L=1,2,\ldots5\} \qquad (3)$$

The formulated constraints represent a case of an equal area site layout problem [30]. Here the locations are assumed to accommodate any temporary facility for storing material, irrespective of the area requirement. The constraint in equation 2 limits the allocation of one material to only one location and in equation 3 the restriction is upon the location to accommodate only one material.

This case of constrained optimization is dealt utilizing GA, and MATLAB® is used for running the algorithm. GA requires encoding of the desired parameter, and in this research, the binary encoding is employed. The working of GA starts with initializing a population, followed by performing operations and once the stopping criteria are met, GA provides the optimal value of the fitness function.

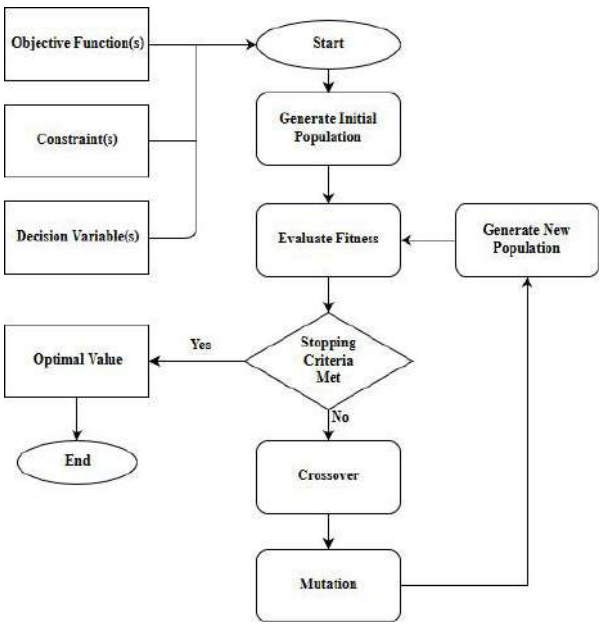

Figure 5. Adopted GA Flow Process

The results from GA are obtained at the parameter values [14] presented in Table 6. A minimum of ten trials are executed for every combination. The optimal results obtained from each combination are presented in Figure 6, Figure 7 and Figure 8.

Table 6. GA Parameters

Item	**Minimum**	**Intermediate**	**Maximum**
Initial Population	100	100	100
Crossover Rate	0.3	0.5	0.8
Mutation Rate	0.01	0.1	0.3

This study has not focused upon tuning up the GA parameters for achieving the optimal or the near-optimal results.

4 Results and Discussion

With the growing demand of BIM for AEC and being mandated on a number of construction projects, it could be anticipated that BIM models would exist for the projects in the near future. The present framework will mandate the creation of material flow paths in BIM models. The depiction of paths on the site model provided a clear view of the vehicular movement anticipated to happen on the modelled site. Whereas manoeuvring on the planned path is expected for safe site conditions, this exercise is expected to enhance safety on construction sites. The adoption of BIM has penetrated in the AEC industry for all phases of construction, but a few studies have highlighted its adoption for SLP. The present study details out the task of integrating BIM into the SLP process. The optimization model supplemented with realistic data of the site could result in better and realistic solutions.

The adoption of GA in this research is an outcome of the existing literature focused on evolutionary algorithm based SLP. The comparative analysis of GA with other evolutionary algorithms and some deterministic algorithms showed the suitability of GA for SLP. The results obtained from all three combinations of parameter set are presented in Figure 6, Figure 7 and Figure 8. The results show the variation in the convergence due to the parameter variation and in this study the ten trials with each parameter set provided an opportunity to understand the concept of near optimality.

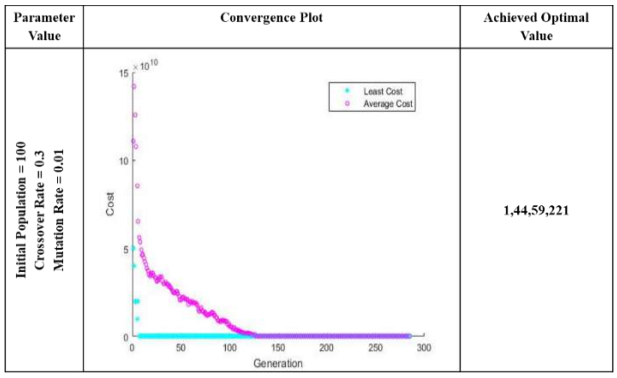

Figure 6. Convergence Plot at Crossover=0.3 and Mutation=0.01

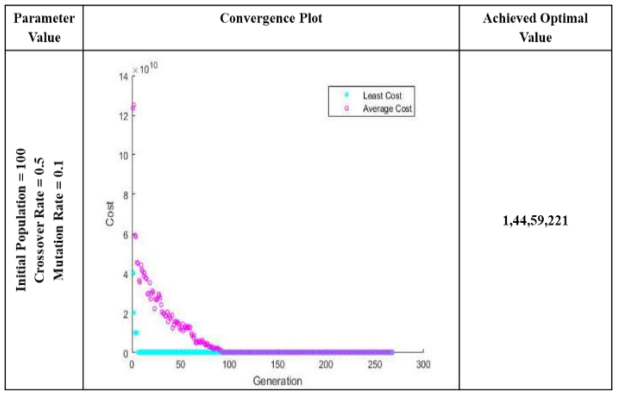

Figure 7. Convergence Plot at Crossover=0.5 and Mutation=0.1

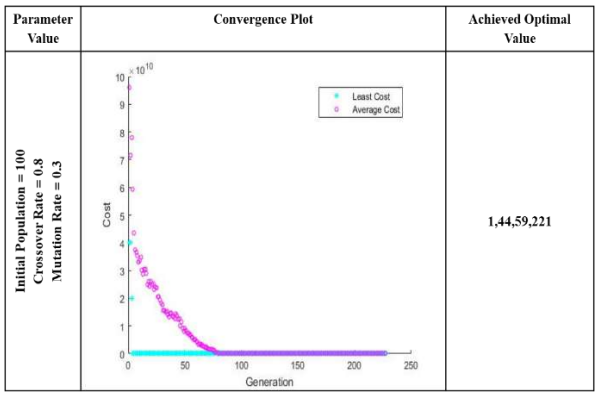

Figure 8. Convergence Plot at Crossover=0.8 and Mutation=0.3

The observation of the convergence plot revealed the effect of the tuned GA parameters and the difference in the plots is easily identifiable. The crossover rate and the mutation rate in Figure 6 reveal the delayed convergence in comparison to other plots in Figure 7 and Figure 8. Whereas the plot in Figure 7 depicts the early convergence due to a high mutation and crossover

in comparison to the mutation rate of 0.01 and crossover of 0.3, adopted as the minimum rate in this study. The convergence plot in Figure 8 also justifies the parameter values of GA by representing a mixed convergence i.e. uneven and early due to high crossover and mutation.

Ten trials with each combination allowed the researchers to verify no premature convergence of GA. The optimal value of cost resulted out to be 1,44,59,221 cost unit. The interpretation of the resulted GA output is presented in Table 7.

Table 7. GA Result Interpretation

Optimal Position	Interpretation	Achieved Optimal Cost Unit
$\begin{bmatrix} \mathbf{0} & \mathbf{1} & \mathbf{0} & \mathbf{0} & \mathbf{0} \\ \mathbf{1} & \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{1} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{1} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{1} \end{bmatrix}$	M_2 at L_1 M_1 at L_2 M_4 at L_3 M_3 at L_4 M_5 at L_5	1,44,59,221

5 Limitation and Future Scope

The study is focused to bring the realism of the construction site to the mathematical approach for SLP. Close integration of BIM with mathematical optimization for the purpose of layout planning has been presented. The study is still under process and is supposed to bring more complexities to the formulation by including multi-objectives and constraints to be solved. The case of discrete layout can also be made continuous. A comparative study of Euclidean distances and the actual travel paths will also add to the understanding and will bring up the necessity of the presented approach. The parameter value optimization presented here is in brief, and further study may include adaptive parameters for GA. Simulation integrated optimization based studies are also expected to help the planners for SLP in an efficient way.

6 Conclusion

There have been attempts to make the process of SLP efficient. The past research optimization routines have received limited adoption in the AEC industry and this research highlights some of the inhibitors to the adoption. This study is an attempt to supplement the existing models with the realism of the construction site. It has been found that the technological advancements like BIM have the potential to promote the existing models by bringing actuality of the site to the mathematical models. In an attempt to do so, the researchers here have modelled a mathematical optimization problem and have presented a framework to integrate it with the available BIM tools. The interaction of the tools resulted in an optimal solution to the formulated problem of transportation on a construction site. The study presented the applicability of GA with this new approach of capturing site realism and thus have strengthened the existing literature of SLP on the other hand.

Abstract –
Autonomous inspection of roads is gaining interest to improve the efficiency of road repair and maintenance. In this paper we will be showing the potential for using Hyper Spectral Cameras, HSC, to identify road defects. The key idea of this paper is that cracks in the road show the interior material of road pavement which have different chemical composition from the surface materials due to surface wear. Material changes of the road surface give rise to a spectral signature that can be easily detected in HSC images. This condition facilitates the detection of cracks and potholes, which can be difficult if working in the visible spectrum domain only. We report on experiments with a HSC to identify the road material changes and their association to cracks and potholes. A new metric is devised to measure the amount of metal oxides and associate its absence to the appearance of cracks. The metric is shown to be more discriminative than previous indicators in the literature.

Keywords –
Road crack detection; Pavement defect inspection; Hyperspectral Imaging; Autonomous road inspection.

1 Introduction

Detection of road cracks from images is difficult since cracks are dark, only have few features and hard to distinguish from road texture [1]. As a result, state of art road crack detection systems suffer from low recall and high false positive rates as reported by [2] [3]. Hyper Spectral Cameras, HSC, are considered in this paper in search for more discriminative clues for crack detection. HSC are used to measure typically spectral range of 350nm-2500nm which contains spectra beyond the human vision range (400nm-700nm). Hyperspectral imaging, though relatively expensive and developed mainly for satellite and scientific imaging, is now becoming affordable and can be exploited for city road monitoring. HSC can be used to identify changes of surface materials if it has a unique spectral signature. Our interest is to exploit HSC fitted on drones for road and infrastructure surface inspection to detect cracks and anomalies.

Hyperspectral imaging, HSI, has been used previously to classify road conditions from satellite images [4] [5] [6] [7] [8]. The research was intended to classify road conditions in general and the spatial resolution cannot detect road cracks or defects. Only few papers considered the detection of pavement cracks based on hyperspectral data [1] [9] [10]. In such case HSC were fitted on drones of low altitude flights to have higher spatial resolutions to enable observing cracks. The previous studies considered using descriptors of the spectrum such as the VIS2 (intensity difference between 830nm and 490nm-showing metal oxide content) and Short Wave Infra-Red, SWIR (Intensity difference between 2120nm and 2340 showing hydrocarbon content). The metrics measure the rise and decay of spectral response curve at the wavelength regions for metal oxides and hydrocarbon which usually characterizes road conditions. These metrics have also been linked [11] to the Pavement Condition Index, PCI, (A standard metric by ASTM D6433 and D5340, used to indicate the condition of road pavement and ranges 0-100) and is usually computed using visual surveys [5].

In this paper, a new spectral descriptor is proposed to describe the spectra of road pavement and, in particular, assist the search for cracks. New roads are mainly composed from minerals and hydrocarbons, while deteriorated roads show more metal oxides on their surfaces [5]. The regions sensitive to both metal oxides and minerals are shown in Figure 1. The hypothesis of this paper is that cracks have a different chemical composition as shown schematically in Figure 2 and therefore, present a unique spectral response. That response can be used to distinguish cracks from un-cracked road surface material. A novel metric is proposed to measure the content of metal oxides from the spectra and associate its depletion to the appearance of road anomalies or cracks.

This paper is structured as follows: The next section outlines the relevant work in road condition analysis using hyper-spectral imaging, then, the new algorithm is described in detail in section 3. The experiments and results on real road conditions are described and discussed in section 4, whilst conclusions are drawn in section 5.

2 Related Work

Hyper-Spectral Imaging, HSI has been used in space and satellite cameras for remote sensing and analysis of natural resources and several other forestry and agricultural applications [12]. Some applications have used HSI as a tool for detecting forgery in art work [13]. It have also been used for art work authentication and for crack detection in paintings [14]. There is currently an increasing interest in the application of HSC with UAV to monitor the conditions of city roads, see [12] for a review of UAV based sensors. A simple UAV system was described in [15] for application in forestry and agriculture.

Several basic problems are still inherent in the use of HSI and infra-red imagery. One is the need to measure the illumination colour, online rather than with a single measurement before using the sensor as is the current practice [16]. Another basic problem is blurred edges [12], since it severely affect the measurements due to spectral aberrations on edges and several studies have focused on de-blurring edges [17] [18].

Spectral mixing also occurs since one pixel of a satellite camera may represent more than five metres of different materials on earth. Hyperspectral un-mixing is useful for satellite images since it can improve the resolution and show different material contents. This effect is less significant when the camera is used at close range to surfaces. Hyperspectral images have been processed by super-resolution systems through different successful methods and reported to improve the spatial detection of target in typical 4 m resolution satellite images. [19] However, the issue of compromise between the spatial and spectral scale in hyperspectral imaging is critical and was the subject of extensive research in remote sensing [6] [20]. Table 1 summarizes the major works in the literature and their significant features. The table shows three categories of research namely: basic problems, physics-based solutions and pure learning approaches.

2.1. Physics-based approaches

Several spectral descriptors were developed in spectral and spatial domains for the classification and object detection in hyperspectral images [9] [18] [20] [21]. Approaches to associate the spectra of roads monitored from satellite with road conditions in general (not for crack detection) have been reported in [4] [10] . The simplest spectral descriptors were devised to measure the rise and decay of spectral response curves for road materials in the full spectral range of typical HSC that is (400nm-2500nm).

The spectral descriptors are known as VIS2 and SWIR ratios [10]. The ratios were used as metrics for a material with the following definition [8]:

$$VIS2_{Difference} = I_{\lambda=830nm} - I_{\lambda=490nm} \quad (1)$$

$$VIS2_{Ratio} = \frac{I_{\lambda=830nm}}{I_{\lambda=490nm}} \quad (2)$$

where I is the intensity of light and (lambda)is the wavelength in nanometer, nm. The ratio SWIR is defined as:

$$SWIR = I_{\lambda=2120nm} - I_{\lambda=2340nm} \quad (3)$$

It should be noted that the metric VIS2 is termed as a ratio in the literature, while it is mathematically a difference. Therefore, we preferred to define it as two metrics, namely the difference and the ratio.

The frequency domain has been exploited to derive spectral metrics. A spectral similarity measure was suggested [22] using the magnitude values of the first few low-frequency components for spectral signature. Harmonic analysis was also used to describe the spectral reflectance and recognize objects [23].

The design of a spectral descriptor requires a compromise between accuracy and simplicity. It seems that a precise descriptor is required, which is easy to compute and encapsulates all the precious information obtained from the camera spectra. This was highlighted in [6] where they discussed whether Hyperspectral imaging with huge number of spectral bands is really required rather than using a limited number of bands, in a multi-spectral imaging fashion, at a much reduced cost.

2.2 Pure learning approaches

Deep learning and convolutional neural networks have been used in a purely learning approach to identify features in both spectral and spatial domains. Classification from a training set, such as the work reported by [24] [25]. The work in this category is interesting, especially for unsupervised classification, since there is a limited set of labelled data for training in general. It is also challenging due to the huge computational complexity of deep learning added to the

complexity of the spectral cube typical for HSI [26]. Feature mining had also been reported to learn discriminative features from datasets through feature selection and reduction methods [27].

3 The New Descriptor

A typical response curve from HSC is shown in Figure 1; the camera used is working in the Visible and Near Infra-Red, VNIR spectral range. That means the spectral range that can be of interest for road material change detection, and hence cracks, is the range showing metal and iron oxide in particular. The response in the VNIR range changes significantly for road based on age and wear as reported in several studies (e.g., [6] [8] [28]).

The main idea is explained schematically in Figure 2. The crack shows the internal pavement material which is different in composition from the road surface due to surface wear. The surface usually reflects light similar to metal oxides because of gravel pigments and loss of the bonding asphalt rich in hydrocarbon and oil.

In the previous work, only the intensity at two spectral bands was used to derive the VIS2 ratio. The new descriptor relies on the observation from Figure 3, that the slope is different between cracks and normal surfaces in the range 450-550nm. In this paper, the approximate line that represents the spectrum in the region between 450nm and 550nm is found. The slope, S, of a line is computed using the least squares method in the range [450nm - 550nm]. The angle of the line from the horizontal axis is then fond through the following equation:

$$\phi = \arctan(S) \qquad (4)$$

The reason to select the range (450nm-550nm) is that it is representing the change of metal oxides in response. It is observed in Figure 4 of the spectral response that this particular region is almost straight without curves. This justification is proved empirically through the experiments.

There is an assumption that the surfaces are clean because the spectral response depends on the surface condition. Fortunately, the weather in the UK is often rainy, which increases the probability that road surfaces will be clean from dust and other metal oxides that may impair the crack detection. The application for road inspection also requires low sensitivity to illumination colour because in real outdoor situations, the illumination colour will continually change. This issue will not be covered here and we will rely on measuring the illumination with the standard grey patch before measurement with the assumption that illumination is not changing after the calibration.

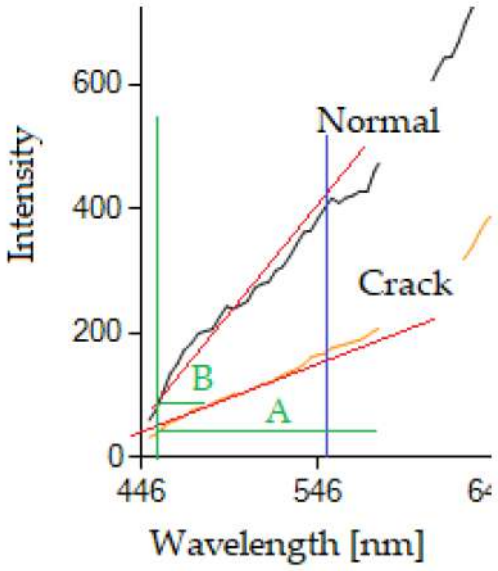

Figure 3: Method of computing the angle ϕ from spectral response.

4 Results

The hyperspectral camera used in this study is a Cubert (model S185) measuring in the range (450nm-950nm) across 125 channels and fitted with a lens of 23 mm focal length. The total image size is 1000*1000 pixels. With the optical system used, one pixel represent (0.5 * 0.5) mm area at one metre depth. The spectral range of the camera enables the measurement of the metal oxides sensitive spectra as shown in Figure 1.

Several experiments were conducted using the camera to view real cracks in paved roads and 3 sample

results are shown in Figure 4. The location of cracks are known in these experiments and both 'normal surface' and 'crack' pixels were randomly selected from identified areas. The images are shown on the left-hand side of Figure 4 and two square windows marked in the image, one for normal road surface and another for a crack region. The right-hand side curve shows the spectral response of both normal surface and crack reflection. The area used to capture the spectrum is fixed during this experiment to one pixel size.

It can be observed in Figure 4, that the crack reflection is less than the reflection from normal surface. It can also be observed that the slope of the spectrum in 450nm-550nm range is radically different from normal to crack surfaces. The angle - was computed using Equation 4, and shown in Figure 5 for regions of both cracks and normal surfaces for comparison.

It can be observed that the slope angle is lower for the crack regions than the surface regions of the pavements in most of the cases. The histograms of this angle computed for cracks and normal surfaces have very little overlap as shown in the right-hand side of Figure 5. However, for any given sample, the angle of slope of crack is always lower than that of road surface. This implies that a single threshold can be used to discriminate cracks from normal surfaces.

The VIS2 ratio was computed for the same sample set and is shown in Figure 6 as a ratio (Equation 2). The VIS2 difference (Equation 1) is also computed and shown in Figure 7. It is observed that the histograms are almost 80 % overlapping in Figures 6 and 7 compared to less than 20 % overlap in Figure 5.

5 Conclusions

Hyperspectral imaging is exploited in this paper to discover the defects and anomalies in road pavement. HSC has the potential to be useful for revealing the defects in infrastructure by observing the changes in spectral reflectance caused by different materials. A new metric was used in this study as an indicator for the change of material and was shown to be a good indicator representing the change of metal oxides in the spectral region 450nm-550nm. The angle of slope of the spectral line in this region, is shown to be better than the VIS2 metric. The angle of the slope utilizes more information from the spectral response than the previous VIS2 indicator. Exploiting more spectral information is good to improve the clues used to find material changes and hence associate this with cracks and potholes and even normal wear of the road surface. This finding may allow

Abstract –

This paper aims to propose an approach to inferring relevant BIM objects using techniques for recognition of design attributes and calculation of visual similarity using a deep convolutional neural network. Main objective is a visual-input based modelling approach to the automated building and interior design, and this paper represents a preliminary yet critical part of the process. While designing a building, it is important to consider requirements such strong constraints (e.g. regulations, a request for proposal) as well as relatively weak and qualitative constraints such as preference style of clients or users, design trend and etc. Building Information Modeling (BIM) enables to execute to check and review a building design according to the constraints. Until now there is no research that has focused on relatively qualitative and "soft" constraints such as preference or design trend. As a part of research on design supporting system for such "soft" constraints, this paper focuses on training deep learning models that recognize design attributes of BIM object, calculate visual similarity with other objects, and for visual-input based auto-modeling on BIM using the models. A deep convolutional neural network is utilized to extract a visual feature of the 3D object. The input data type for extracting feature data is a 2D rendering image of an object with a specific view and option. The target object is a chair. The feature data is used as input to training models inferring design attributes such as design style, seating capacity and sub-type of a chair and also calculating the visual similarity between objects. This models plays an important role of visual-input based automated modelling system.

Automated Modeling, Building Information Modeling (BIM); Design Attributes; Visual data; Visual similarity;

1 Introduction

In general, design problems have been known as "wicked problem [1]" that means ill-defined problem including complex and various requirement [2]. In particular, while designing a building, requirements include strong constraints such building permit regulations, a request for proposal (RFP) as well as relatively weak and qualitative constraints such as preference style of clients or users, design trend and etc.

Building Information Modeling (BIM) enables a computer to understand a building design model and execute to check and review and simulate the digital model with consideration of the above constraints [3]. Until now the researches have focused on relatively quantitative constraints (e.g. energy simulation [4], quantity take-off [5] and etc.), or strong constraints (e.g. rule-checking [6], in particular, indoor circulation [7] and space program [8]). It is true that consideration of such constraints is important as increasing the size of buildings [9] and changing standards of building performance.

In a high level of detailed design phase such as interiors, however, the relatively qualitative and "soft" constraints such as preference or design trend need to be considered as well. Nevertheless, research focusing on "soft" constraints using BIM has not been studied so far. As a part of research on design supporting system for such "soft" constraints, the ultimate goal of this study is to propose a BIM-based design approach using a deep learning model that can understand the design. The approach targets the visual representation of building design references, among other media representing such constraints. Traditionally, visual representation has been the role of important sources to analysis and understand architectural design [10].

As a preliminary study for the implementation of this approach, this paper explores the ways to combine deep learning-based model understanding design reference image or picture with BIM-based design. The scope of this paper is on training deep learning models that recognize design attributes of BIM object, calculate

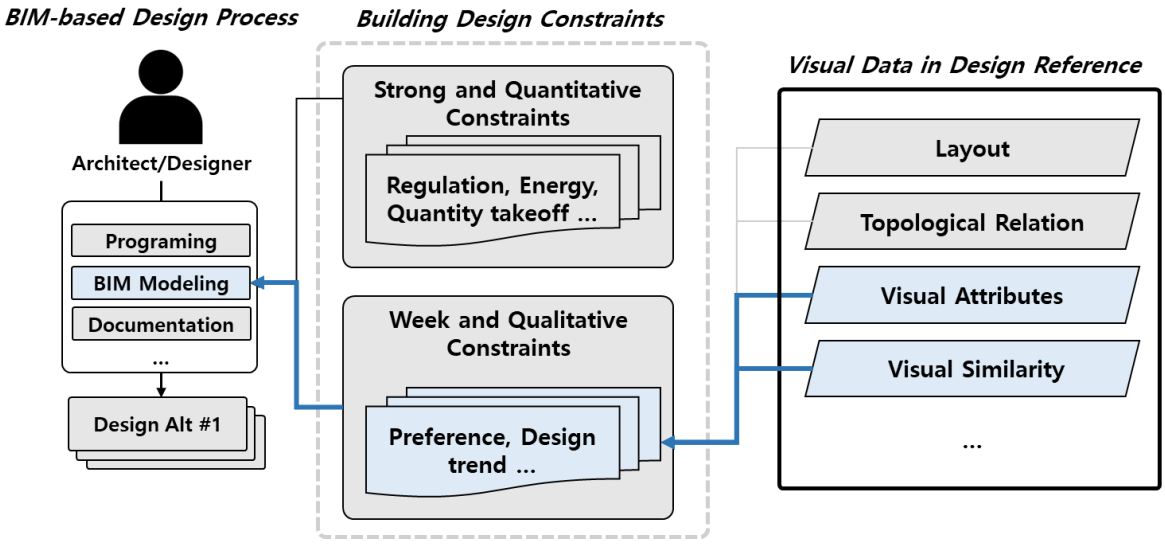

Figure 1. The scope of this paper for visual-input based modelling approach

visual similarity with other objects, and propose an approach to visual-input based auto-modeling on BIM using the models (Figure 1).

For training such intelligent models, this paper utilizes a deep convolutional neural network (CNN) model that showed the successful performance of understanding general object [11], context [12]and even design attributes of interior design object [13] on visual data. The pre-trained CNN model (VGGnet [14]) is used to extract visual feature map data from 2D rendering image of a design object. The feature map data is used as input data to train models recognizing design attributes of chair object (e.g. design style, seating capacity and sub-type). The results of recognition are used to query BIM object in BIM library as a semantic annotation. The feature map data is also used to calculate the visual similarity between objects for the similarity-based query.

2 Background

2.1 Reusing Design Objects in BIM-based Design Process

While solving design problems such as architectural, interior design and etc, the strategy based on generating possible design alternatives is generally adopted [15]. Since it is difficult to make a clear and explicit definition of the problem (“wicked problem”) [16] architects and designers compare, analyze and test the alternatives to reach a satisfactory answer.

Building information modeling (BIM) provides the advantages of rapidly generating design alternatives, evaluating and analyzing them. BIM supports the model-oriented design process, enabling integrated and automatic design tasks about as drawing, simulation, various review processes, and visualization with BIM model and related applications. BIM is derived from the idea that a building is considered as a spatial composition of the spatial composition of a set of parts [17]. In other words, determining which design elements will be utilized and how to combine them is an important process for BIM-based architectural design.

The Search accuracy of traditional keyword-based retrieval models, such as Boolean model, vector space model, or probabilistic model, has been often problematic because of the semantic ambiguity of terminologies in BIM documents and queries. The semantic ambiguity in BIM documents can be alleviated by using a domain ontology. As compared to the traditional metadata retrieval of BIM models, Ge Gao et. al. [18] present a way to search into the content of BIM models, which contains more information. It provides a way to customize their requirement specifically. Both accurate numerical value search and text search is supported A survey of the state of the art is beyond the scope of this paper. Instead, this section briefly reviews the most related studies associated with our work.

2.2 Deep Convolutional Neural Network for Extracting Visual Feature

Deep convolutional neural networks (CNN) is known as the most powerful method to extract a visual feature from pixel data of image [11]. For the feature extraction, stacked convolution filters and pooling filters are used

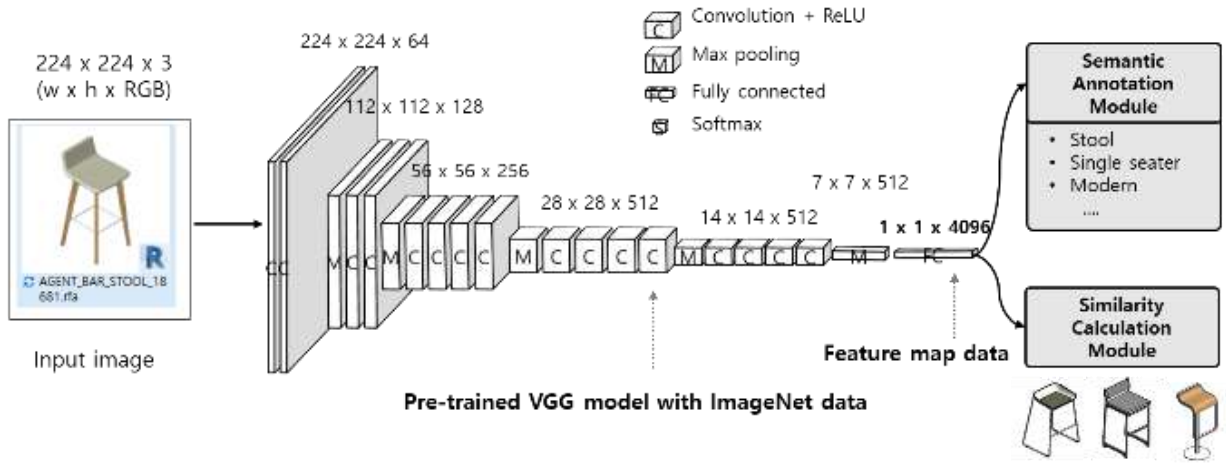

Figure 2. Extraction and utilization of feature map data to get semantic annotation and calculate similarity using VGG model [14]

(Figure 2.). These filters have a specific (n x n) size and are used to screen key pixel data as you scroll through the image to extract a simpler abstracted 'feature map'. The input images are converted to multi-dimensional vector values representing complex elements, such as points, lines, faces, shapes, color, and sizes. These feature map data can be used to train multi-class inference models with softmax algorithm [19] or support vector machine [20] and to find a visual similar one with the Euclidean distance or cosine angle distance [21]. A good model can extract meaningful visual feature. Such good models (e.g. VGG pre-trained with ImageNet [14]) and frameworks (e.g. Tensorflow [22]) are open to the public. The pre-trained model can be directly used to extract features of other images. In this paper, we utilize the pre-trained VGG model to extract visual feature data of BIM object.

3 Methodology

3.1 Approach

This paper proposes an approach to recommend a relevant collection of design objects using visual information from BIM objects. A collection of design objects means a set of objects that a user needs in the context of a particular design process. Metadata, geometry data, and topological relational data can be used when sorting a set of objects in the BIM library, but in this study, semantic annotation information and visual similarity information are only treated. The information of annotation is semantic string information that can be obtained from the shape. For example, when an image of a chair is given, string information such as category, sub-type, functional feature (e.g. armrests, backrest, wheel and etc.), the seating capacity, and even design styles can be inferred. The visual similarity means a degree of visual similarity between the shape of a target object and a shape of the others.

In this paper, the feature map data derived from 2D rendering image of BIM object is used to get semantic annotation and visual similarity information. To get 2D rendering images of BIM object, we develop the image generating module using rendering engine and API of BIM Tool. These images are input into the deep convolutional neural networks model [11] and the feature map data is generated. We utilize VGGnet [14] model that previously trained the ImageNet dataset as feature map extractor. It has been proven that the pre-trained model very well extracts important feature map of the image, and showed the high accuracy (93.2%) of image classification task with at ILSVRC challenge [14].

The feature map data are used as an input in two modules: 1) Semantic annotation module, 2) Similarity between objects calculation module. 2D images of objects are collected through the API of the BIM tool. The inference of semantic annotation information is executed using the softmax algorithm with, and the calculation of visual similarity is done using the Cosine angle distance. Through these two modules, the collection of related and visually similar objects can be recommended.

3.2 Extraction of Visual Feature from Object using CNN

In this study, the feature map data extracted from the 2D image is utilized as visual feature data of the 3D object. CNN model can extract the feature map data that means the abstraction of pixel data that is considered important in the image among the 3 channel (RGB color)

pixel data of the input2D image. We extract the featured 4096-dimensional vector value, using the VGG model pre-trained with ImageNet dataset. Images of 3D objects for input into the model are generated by the rendering engine of the BIM software. We collect the BIM object from public BIM object library such as BIMObject [23], Revitcity [24] and NBS National BIM Library [25]. We developed plug-ins using API to automatically generate such images from consistent and accurate view angles with specific rendering option. In this paper, two different views are used: 1) front view and 2) view of horizontal 45 degrees with vertical 60 degrees. There are no shadows but only shading and realistic color with line stroke. The results of extracted feature maps can be saved as an ASCII file, so the feature map data is stored in an external database or in property field of the BIM object. The feature is used for inferring the semantic information of the object and calculating visual similarity. Sections 3.3 and 3.4 describe methodology and calculatation results using feature map data, respectively.

3.3 Inferring Semantics Information of Object

We train the model inferring semantics information of BIM object using the softmax algorithm [26]. The softmax algorithm is the most popular function for inferring labeling of data. Softmax function takes an N-dimensional vector of real numbers and transforms it into a vector of a real number in the range (0,1). The outputs are marginal probabilities and therefore can be used for multiple-class classification.

The target object is a chair and the scope of semantic information includes a sub-type, seating capacity, a design style. There are other many design related attributes, but we adopt some attributes proposed by Kim et al [13]. The sub-type means conceptual and qualitative classification criteria according to function or shape. This paper covers a normal chair, stool, sofa and office chair. Seating capacity means how many seaters a chair has and this is seen as a quantitative property. The design style is a very qualitative feature that can be perceived differently according to culture, period, region and people. Therefore, this paper cover causal, classic and modern that can be seen as the simple and rough classification criteria of design style.

We use BIM seating object images that are generated from the BIM tool as well as real chair product images that are collected from the catalog. Finally, 250 images per class were collected, 20% of which are utilized for validating and 80% for training. Training model for the design style was conducted with only three detailed classes, so 750 images were utilized. While the others have four detailed classes, so 1000 images were utilized. Training is executed on the Tensorflow framework [22] that is the most useful to train machine learning model. Table 1 shows the results training of models. The accuracy of models training design style and sub-type is closed to 85%. On the other hand, the accuracy of model training seating capacity is relatively lower than others (closed to 75%).

Table 1. The results of training models to recognize design attributes of a chair object

Model	Class	Images	Training Accuracy
Seating capacity	Single 2-seaters 3-seaters 4-seaters	1000	75.2%
Design style	Casual Classic Modern	750	86.2%
Sub-type	Chair Sofa Stool Office chair	1000	85.1%

3.4 Calculating visual feature similarity with Cosine Angle Distance

The similarity is calculated through the cosine distance with vector feature maps. The cosine distance is the cosine value of the angle between two vectors, which the value is bound on the interval (-1~1). The correlation of distribution between random vectors may tend to get closer to zero as the dimensions of space increases. Therefore, the even small value of similarity become significant with growing dimension. Given two vectors of visual feature map, VF_a and VF_b on the n-dimensional space, and cosine similarity, $\cos(\theta)$, is represented as;

$$\cos(\theta) = \frac{\sum_{i=1}^{n} VF_{a,i} \times VF_{b,i}}{\sqrt{\sum_{i=1}^{n} VF_{a,i}{}^2} \times \sqrt{\sum_{i=1}^{n} VF_{b,i}{}^2}} \quad (1)$$

The resulting similarity ranges from −1 meaning exactly opposite, to 1 meaning exactly the same or a very similar one and with 0 indicating orthogonality (decorrelation). The feature map data is the positive number, so practical similarity value ranges from 0 to 1. Table 2 shows the examples of calculation of similarity between chair objects and the inferred semantic annotations. The target object is a famous stool and the

Table 2. The examples of inferring semantic annotation and calculating similarities between target and inputs objects using feature map data and cosine distance

	Target	Input #1	Input #2	Input #3	Input #4	Input #5
Image						Similarity	-	88.9%	81.0%	66.6%	58.1%	51.6%
Seating capacity	Single	Single	Single	Single	Single	2-seaters
Sub-type	Stool	Stool	Stool	Chair	Stool	Sofa
Design style	Modern	Modern	Casual	Casual	Casual	Modern

input #1 is the same one, but slightly different sizes and width. The similarity between the above two is calculated as 88.9%. The input #2 is another stool with different color and detailed design (punched hole). The similarity between target and input #2 is calculated as 81.0% lower than the previous value. Input #3, 5 is not stool, but normal chair and sofa, respectively, and the similarity values are lower than 70%. The input #4 is a round stool, but the similarity value is relatively lower that the values of other stool.

4 Conclusion

As a preliminary study for the implementation of this approach, this paper explores the ways to combine deep learning-based model understanding design reference image or picture with BIM-based design. The scope of this paper is on training deep learning models that recognize design attributes of BIM object, calculate visual similarity with other objects, and propose an approach to visual-input based auto-modeling on BIM using the models. For training such intelligent models, this paper utilizes a deep convolutional neural network (CNN) model that showed the successful performance of understanding general object [11], context [12]and even design attributes of interior design object [13] on visual data. The pre-trained CNN model (VGGnet [14]) is used to extract visual feature map data from 2D rendering image of a design object. The feature map data is used as input data to train models recognizing design attributes of chair object (e.g. design style, seating capacity and sub-type). The results of recognition are used to query BIM object in BIM library as a semantic annotation. The feature map data is also used to calculate the visual similarity between objects for similarity-based query. This models plays an important role of visual-input based automated modelling system.

Abstract –

The construction industry is one of the most hazardous industries suffering from a high on-site accident rate. A lot of safety hazards result from dynamic activities of construction workers and equipment. Therefore, tracking the location and motion of workers and equipment as well as identifying the interaction between them are crucial to preventing safety hazards on construction sites. Currently, with the extensive installation of surveillance cameras, computer vision techniques can be applied to process the videos and images captured on construction sites, which can be used to monitor site safety and to identify potential hazards. With the aim to predict and prevent the safety hazards among workers and equipment, this paper proposes a methodology to monitor and analyse the interaction between workers and equipment by detecting their locations and trajectories and identifying the danger zones using computer vision and deep learning techniques. First, workers and construction equipment are automatically located from cameras and classified by a deep region-based convolutional neural network (R-CNN) model. Then, the location and classification results are further processed by another CNN-based model to obtain trajectories of those objects. Based on the detection and trajectories, the spatial-temporal relationship between workers and equipment is analysed, from which the danger zones for the workers are identified and the corresponding safety alarms are generated. Experiments are conducted to demonstrate the capability of the proposed methodology for accurately identifying and predicting safety hazards among construction workers and equipment, which can contribute to the safety conditions on construction sites.

Computer vision; Construction site safety; Convolutional neural network (CNN); Deep learning; Object detection; Spatial-temporal relationship; Trajectory tracking.

1 Introduction

The construction industry is one of the most hazardous industries suffering from a high on-site accident rate. Between 2013 and 2017 in Hong Kong, the construction industry has reported the highest fatality rate among 11 industry sections in every year [1]. In particular, striking against or struck by moving objects has been ranked the top 3 highest number of industrial injuries out of 23 accident types [1]. These figures reflect that the construction industry has been significantly hazardous. Specifically, the dynamic characteristic of the construction site activities such as the movement of construction workers and equipment is one of the major causes for construction safety accidents, such as injury of workers due to the surrounding equipment. Therefore, monitoring the interaction among workers and equipment is essential to predict and prevent safety hazards on construction sites.

Currently, construction safety monitoring mainly relies on observing the real-time site conditions manually through on-site surveillance cameras. Early alerts of potential hazards are judged based on previous experiences and provided based on observations from the cameras. Such manual approaches are labor-intensive and error-prone considering the difficulty of monitoring through multiple cameras simultaneously. Human fatigue could lead to the ignorance of potential hazards, such as workers unconsciously approaching heavy equipment. Furthermore, the alerts based on personal experiences can be subjective or belated, leading to severe consequences. Therefore, a method capable of

automatically monitoring and predicting safety issues on construction sites is desired to reduce the resources and to improve the efficiency for safety monitoring.

Computer vision techniques are adopted to automatically process images or videos to assist with various human activities. In addition, deep learning techniques have been widely applied to facilitate computer vision tasks and achieved promising performance. The objective of this study is to automatically predict the safety hazards among construction workers and equipment through analyzing spatial-temporal interaction among workers and equipment using computer vision and deep learning techniques. In the rest of the paper, related works are reviewed in Section 2 and the proposed methodology is introduced in Section 3. Experiments and results are elaborated in Section 4, followed by conclusions and future work in Section 5.

2 Related Work

Previous studies for construction safety monitoring were reviewed. In particular, computer vision-based techniques for construction safety monitoring were categorized by [2] into three aspects.

The first category is object detection. Some researches detected workers and equipment by background subtraction algorithm [3], Histograms of Oriented Gradients (HOG) descriptor with Support Vector Machine (SVM) classifier [4], and Scale-Invariant Feature Transform (SIFT) [5]. The approach of SIFT in [5] segmented a wide range of objects on images covering workers, different kinds of equipment and materials. More recently, Fang et al. [6] used a region-based CNN framework named Faster R-CNN to detect workers standing on scaffolds. A deep CNN then classified whether workers are wearing safety belts. Those without safety belt appropriately harnessed were identified to prevent any fall from height. Adoption of deep learning was shown to achieve promising detection accuracy [6].

The second group of techniques is object tracking. Some studies adopted detection-based tracking method, where by definition newly detected objects either initialize new tracks or are mapped to existing tracks for identity maintenance over certain duration. The DeepSORT developed by [7] is a detection-based tracking model. Zhu et al. [8] used SIFT to extract visual features for detecting workers and equipment. Kalman Filter was then used to predict future movement with respect to past measurement. Another study by [9] detected workers and equipment based on HOG features, while their movement were tracked with Particle Filter. For construction site monitoring, deep learning has not been fully studied for target detection in many detection-based tracking approaches.

The third cluster is action recognition. For example, Ding et al. [10] combined CNN with Long-Short-Term-Memory (LSTM) to identify unsafe actions of workers, such as climbing ladders with hand-carry objects, backward-facing or reaching far. While safety hazards of workers were effectively identified, their method only captured single worker and multi-object analysis was not considered. On the other hand, Soltani et al. [11] used background subtraction to estimate posture of an excavator by individually detecting each of its three skeleton parts including dipper, boom and body. Although knowing the operating state of construction equipment would allow safety monitoring nearby, the influence of the equipment on the surrounding objects was not studied [11].

Overall, in terms of automated safety monitoring with computer vision techniques, previous studies focused on different parts accounting for the safety issues separately, such as identifying working status of construction equipment or tracking the movement of workers. There is a lack of an integrated analysis of the spatial-temporal interaction among workers and equipment considering the potential influences from different aspects. A robust mechanism that analyzes the spatial-temporal interaction among workers and equipment is desired for automated and real-time monitoring of on-site safety.

3 Methodology

In this study, an integrated approach is proposed for predicting safety hazards among construction workers and equipment using computer vision and deep learning techniques. The proposed approach involves three parts, as shown in Figure 1. First, images are extracted from videos, and construction workers and equipment in video frames are extracted by the detection model. Then, the detection results are imported into the second part. For construction equipment, the danger zone is identified

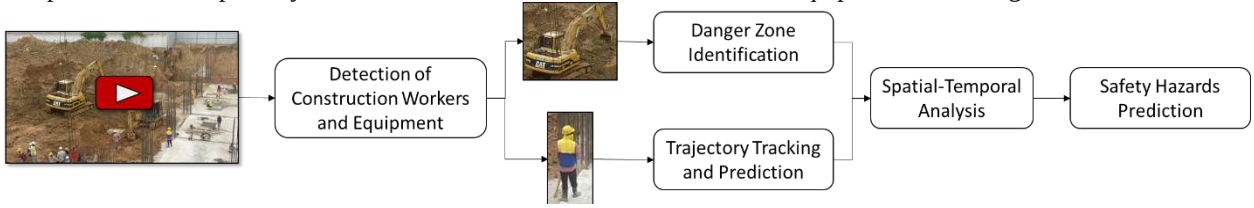

Figure 1. Overall workflow for predicting the safety hazards among construction workers and equipment

while for construction workers, the trajectory is tracked and predicted. By combining the identified danger zone and predicted trajectory, the spatial-temporal relationship among construction workers and equipment is analyzed. In the end, safety hazards are predicted based on the spatial-temporal relationship analysis.

3.1 Equipment and Worker Detection

The detection of equipment and workers are realized through Faster R-CNN, in view of its higher accuracy demonstrated by previous studies [12,13]. The architecture of Faster R-CNN includes (1) backbone network to extract image features; (2) region proposal generate (RPN) network for generating region of interest (ROI), and (3) classification network for producing class scores and bounding boxes for objects. Details of each part are introduced as follows.

3.1.1 Backbone Network

The backbone of the Faster R-CNN is used for feature extraction through a stack of convolution, activation, and max pooling layers. After pre-processing, each image is fed into the network as a three-dimensional array representing the pixel values on the RGB channels. In the beginning, a certain number of filters are assigned with random weights as initialization. During convolution, each filter slide across the input volume and the dot product between the filter and the corresponding image patch convolved is calculated and added with a bias value to obtain the convolution result. To add non-linearity to the network, the convolution result is fed into an activation function, for which rectified linear units (ReLU) is used in this study. After activation, max pooling is performed to reduce the dimension of feature maps by selecting the maximum value from each image patch covered by the filter and use the maximum value as the new feature value. Through setting the max pooling filter size and stride, the dimension of feature maps is down-sampled by a factor of 2 each time, such that the computational cost is reduced. A stack of convolution, ReLU and max pooling layers are performed to generate the feature maps, which are then fed into the RPN network for generating candidate ROIs (i.e. the potential regions with objects). As training the model from scratch is time-consuming and requires a large number of images, transfer learning is applied in this study as the low-level features of objects such as edges and corners are transferable among different datasets. Specifically, the weight of a model namely VGG16, which is pre-trained on another large dataset, is utilized to initialize the backbone network. The model is then fine-tuned with our dataset of construction equipment and workers such that high-level features (i.e. the characteristics of equipment and workers) are learned in the applied model.

3.1.2 RPN Network

The generated feature maps from the backbone network are passed through the RPN network which consists of a convolutional layer and a ReLU layer. The results are then fed into two parallel layers for label classification and bounding box regression. The class labels include foreground and background, indicating whether an object is contained in the region or not while the bounding box regression layer is used for refining the location of bounding boxes. In the beginning, a number of small windows, named anchors, with different sizes and aspect ratios are designed at each pixel location such that multi-scale features can be extracted. During the training, the class scores and the four coordinates of each bounding box are predicted for each anchor, after which the loss for both class scores and coordinates are computed. The number of anchors is reduced by non-maximum suppression (NMS) based on the foreground scores.

3.1.3 Classification Network

After obtaining the potential ROIs from the RPN, the regions on the feature maps corresponding to the ROIs are extracted through a crop pooling method. The extracted regions of the feature maps are reshaped and fed into the classification network, where two parallel layers are used for predicting the class labels with probability of each class and bounding boxes with more accurate locations. There are 7 classes included in this study including 5 types of equipment, the worker and the background. In the end, the loss of the predicted classes and the bounding boxes are computed based on the ground truth labels. The model weights are then updated by back-propagation during training process.

The layers of the three networks are combined together and the weights are trained in an end-to-end manner. After training the model on our dataset, the model is capable of detecting construction equipment and workers accurately during inference using the optimal trained weights.

3.2 Worker Trajectory Tracking

For trajectory tracking and prediction, the DeepSORT framework proposed by Wojke et al. [7] is used as our baseline because it demonstrated robustness of identity preservation upon arbitrary duration of occlusion. As a detection-based tracking framework, the worker detection results at a frame either initialize new tracks or are mapped to the most similar identities being tracked. Kalman Filter is used to predict future position of the target for position proximity matching. Apart from position constraint, identity assignment of the set of new detection also considers appearance similarity against the targets being tracked. Readers are referred to the original

publication for more detailed mathematical formulation of DeepSORT.

There are several parameters in DeepSORT that define its track management mechanism. Two of them are highlighted since their values are adapted to our site analytics. 'Lambda' controls the relative influence of position and appearance constraints in identity matching. For our analysis, Lambda is set as 0.5 for a complementary effect among these two factors. On one hand, construction sites tend to be crowded such that many workers may walk very close to others. Position proximity alone may make identity matching inaccurate when there are many candidates near a target. On the other hand, construction workers tend to have very similar appearance when wearing reflective vest and safety helmet, such that appearance may not explicitly distinguish multiple worker. Therefore, a balanced reliance among these two aspects is granted.

Another parameter 'Max_age' is set to be 200 frames in our study. This means that unique identity of a disappeared worker is remembered for 200 consecutive frames, during which it can be retrieved upon reappearance of the target. A long memory increases the computational burden for handling many targets, while a short memory leads to discontinuous trajectory history and subsequently inaccurate prediction of future trajectory. A 200-frames memory is considered reasonable for obtaining trajectory history. Acquiring complete trajectory history would support the prediction of future trajectory.

3.3 Worker Trajectory Prediction

Trajectory prediction for workers is based on the inference output from Kalman Filter used in DeepSORT. The translation of the 'foot' position of a target is considered, since it represents the area on which he/she walks. Therefore, the bottom center coordinate of a box is obtained by relating the corner coordinates with the width and height of a box. Since Kalman Filter only infers target movement at next timestamp, a mechanism is proposed to predict movement in a longer future. In particular, the future position of the 'foot' of a target (x_2, y_2) is linearly extrapolated with respect to its current position (x_1, y_1) and velocity:

$$x_2 = x_1 + (\alpha_x * \dot{x}) \quad (1)$$

$$y_2 = y_1 + (\alpha_y * \dot{y}) \quad (2)$$

where $\dot{x}$ and $\dot{y}$ are velocities along individual direction output by Kalman Filter, α_x and α_y are number of future frames for position prediction.

With the current and future positions, $P = (x_1, y_1)$ and $P' = (x_2, y_2)$, respectively, the predicted trajectory of a target is defined to be the directed line segment PP' pointing from P to P'. On the image plane, this trajectory line is represented by a linear equation, while the coordinates of P and P' define its boundary. An assumption is that targets tend to produce smooth motion within the inference period, like standing still or walking constantly with current velocities $\dot{x}$ and $\dot{y}$.

3.4 Definition of Danger Zone

When a construction equipment (e.g. excavator) is in its working state, there is an activity region around the construction equipment. There is a high potential of safety hazards when workers or other construction machines enter this activity region. In this study, this kind of activity region is defined as a danger zone.

For an excavator, the exact danger zone could be defined as a located circle in a real construction site, which is an ellipses when projected to 2-D images, based on danger parameters including the position (pos) of the excavator, the lengths (l), working directions (d) and ranges (r) of arms, the size (s) of its body, and other factors (o). An exact danger zone (edz) is defined in Equation (3)

$$edz = f(pos, l, d, r, s, o) \quad (3)$$

On a construction site with a working schedule for on-site machines, most danger parameters of a construction machine are deterministic during a certain time interval, such as the lengths, working directions and ranges of arms, and the size of the construction equipment. On the other hand, the location of the excavator is obtained from the bounding box coordinates through the equipment and worker detection model, as introduced in Section 3.1. With those danger parameters, the size of the danger zone around an excavator could be determined.

3.5 Spatial-Temporal Analysis

Safety status of each worker is categorized into 3 types, based on the geometric relationship between the predicted trajectory and danger zone. As shown in Figure 2, 'Normal' is marked if the starting point of a trajectory (current position) is outside any danger zone while the predicted trajectory does not touch any danger zone (e.g. T1, T6). 'Danger Now' is marked as long as the start point lies within a danger zone (e.g. T2, T3). 'Potential Danger' is marked if the start point is outside any danger zone while the predicted trajectory intercepts a danger zone at least once (e.g. T4, T5, T7).

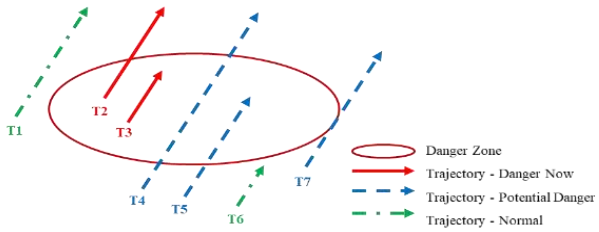

Figure 2. Examples of categorizing safety statuses based on predicted trajectory of a worker

The mathematical relationship between an ellipse and a straight line is derived to check for interception. Equation (4) and Equation (5) show the general forms of an ellipse and an infinite straight line on x-y plane respectively, while Figure 3 summarizes the notation of all related symbols.

$$\frac{(x-x_c)^2}{{r_x}^2}+\frac{(y-y_c)^2}{{r_y}^2}=1 \quad (4)$$

$$y=\frac{y_2-y_1}{x_2-x_1}*x+y_0 \quad (5)$$

$$\text{where, } y_0=y_1-\left(\frac{y_2-y_1}{x_2-x_1}\right)x_1 \quad (6)$$

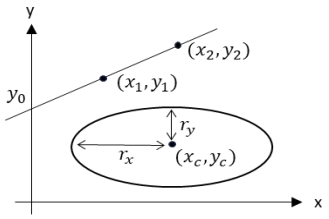

Figure 3. Notation for general representation of ellipse and straight line

A danger zone is centered at (x_c, y_c) with radiuses r_x and r_y. As for the predicted trajectory of a worker, an infinite straight line is defined by the current position as (x_1, y_1) and future position as (x_2, y_2). To find the intercept(s) between an ellipse and a straight line, Equation (4) and Equation (5) are solved simultaneously for x and y. After substitution, a quadratic equation is obtained, as shown in Equation (7).

$$Ax^2+Bx+C=0 \quad (7)$$

$$A=\frac{1}{{r_x}^2}+\frac{m^2}{{r_y}^2} \quad (8)$$

$$B=-\frac{2x_c}{{r_x}^2}+\frac{2m(y_0-y_c)}{{r_y}^2} \quad (9)$$

$$C=\frac{{x_c}^2}{{r_x}^2}+\frac{(c-y_c)^2}{{r_y}^2}-1 \quad (10)$$

$$m=\frac{y_2-y_1}{x_2-x_1} \quad (11)$$

The solution(s) to Equation (7), if any, correspond to the x-coordinate(s) at which the straight line intercepts the ellipse. The expression in Equation (12) is used to check whether interception exist. If $\Delta \geq 0$, the line either passes through the ellipse at two distinct points, or touches the ellipse at one point. In this case, Equation (13) provides the corresponding intercepted x-coordinate(s). If $\Delta < 0$, the line is always outside the ellipse.

$$\Delta=B^2-4AC \quad (12)$$

$$x^+=\frac{-B+\sqrt{\Delta}}{2A} \; and \; x^-=\frac{-B-\sqrt{\Delta}}{2A} \quad (13)$$

The key consideration when checking interception is that each trajectory is a definite segment spanning from the current to future position of the target. It is possible that the interception point(s) is/are outside the definite segment which is only a portion of its associated infinite line. Therefore, an additional condition is imposed to check whether the definite segment intercepts the ellipse. Table 1 illustrates the decision logic. In case of no interception at all, 'Normal' is assigned to a target (e.g. T1 in Figure 2). Otherwise, if the current position lies between the intercepted points, it lies within the danger zone and 'Danger Now' is assigned (e.g. T2, T3 in Figure 2). If the current position lies outside the zone while at least one of the intercepted point(s) is within the definite segment, the trajectory passes through the zone and 'Potential Danger' is assigned (e.g. T4, T5, T7 in Figure 2). Otherwise, the trajectory does not enter the zone at all and 'Normal' is assigned (e.g. T6 in Figure 2).

Table 1. Algorithm for assigning safety status based on worker trajectory and danger zone

If $\Delta < 0$:
Assign '*Normal*'
Else:
If $x_1 \in [x^-, x^+]$:
Assign '*Danger Now*'
Else if $x^- \in [x_1, x_2]$ or $x^+ \in [x_1, x_2]$:
Assign '*Potential Danger*'
Else:
Assign '*Normal*'

4 Experiments and Results

Experiments are performed to demonstrate the capability of the proposed methodology for automatically predicting safety hazards on construction sites through the analysis of spatial-temporal relationship between construction workers and equipment based on the captured images and videos from surveillance cameras. The spatial-temporal relationship is analysed based on two inputs: (1) the danger zone obtained from the detected location of the construction equipment and other

parameters, and (2) the predicted worker trajectory based on the historical trajectory records.

4.1 Experiment Dataset

Several videos captured from surveillance cameras on construction sites are collected and images are extracted from those videos. 2410 images containing 5 types of construction equipment (i.e. dump trucks, excavators, loaders, mixer trucks, and rollers) and construction workers are extracted and each image is annotated with ground truth labels and bounding boxes. 90% of the images are used for model training and validation while 10% are for model testing. In the end, the methodology is also applied on a new construction site video to demonstrate the real-time prediction of the hazards.

4.2 Experiment Implementation

The danger parameters of a construction equipment are assumed to be known in the experiment. Based on this assumption, the size of the danger zone around a construction equipment such as excavator is pre-defined. Then, the exact danger zones on a construction site are determined with the result of equipment detection, and the identified danger zones are used for spatial-temporal analysis.

Firstly, the architecture of the model for construction worker and equipment detection, as introduced in Section 3.1, is constructed using Pytorch, which is a common platform for implementing deep learning models. The model is trained using the annotated images for 40 epochs and the training loss is plotted to monitor the learning progress of the model. The model is evaluated using average precision (AP) for each class and the mean AP (mAP) for all the classes.

As for the worker trajectory prediction introduced in Section 3.3, α_x and α_y are both set to be 60 frames, such that for each target his/her position after 60 frames is inferred. This is a reasonable period because it predicts the target movement in the next 2 seconds, if considering a typical video with 30 frames per seconds. For safety monitoring on construction sites, 2-second movement prediction would allow identification of potential hazards.

4.3 Experiment Results and Analysis

The results include two parts – (1) the accuracy of equipment and worker detection; (2) the prediction results of safety hazard based on the analysis of spatial-temporal relationship among workers and equipment.

4.3.1 Accuracy of the detection model

The accuracy of the Faster R-CNN model on the testing dataset is summarized in Table 2. The model achieved high detection accuracy for both workers and construction equipment. The AP values of all the classes achieved at least 85% and even exceed 95% for most classes except for dump trucks, rollers and workers. With a mAP of 92.55%, the model is demonstrated to be promising for detecting workers and equipment accurately on the construction site.

Table 2. Accuracy of worker and equipment detection

Class Name	AP (%)	mAP (%)
Dump truck	85.12	
Excavator	95.94	
Loader	96.19	
Mixer truck	97.73	
Roller	86.91	
Worker	93.40	
		92.55

Nevertheless, as shown in Figure 4, the detection model tended to miss the excavator when its arm was not hanged horizontally, and those workers squatting or carrying objects. These cases could be attributed to our limited training dataset, which may not have covered a variety of view angles or human gesture. An enriched dataset would further enhance the detection accuracy.

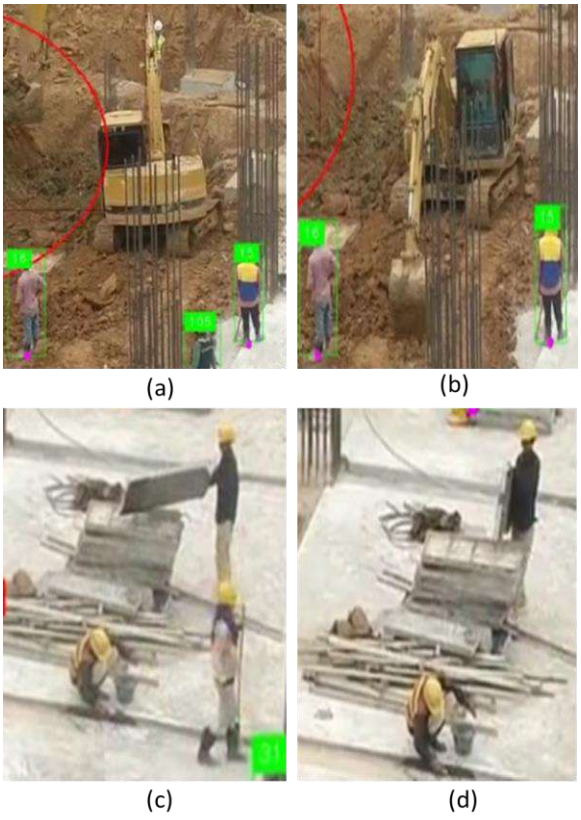

Figure 4. Examples of incorrect detection of equipment and workers

4.3.2 Accuracy of the spatial-temporal analysis

The detection model was applied on a construction site video to detect the equipment and workers. Trajectories of workers were also tracked and predicted. Danger zones were then defined to monitor safety statuses of workers based on spatial-temporal relationship among their trajectories and the danger zones. As shown in Figure 5, an ellipse around the excavator bounded a danger zone. In addition, historical trajectories of workers were displayed in purple, while their predicted trajectories after 60 frames were visualized as blue arrows. Safety statuses were then assigned to individual worker, based on the mathematical formulation in Section 3.5. Different safety statuses were categorized by colorized bounding boxes.

Figure 5. Examples of identified danger zones and different safety statuses of workers

The accuracy of assigning safety statuses is evaluated by Average Precision of Status (AP_{status}), as defined by Equation (14).

$$AP_{status} = \frac{TS}{TP} \tag{14}$$

where TS counts the number of workers assigned with true safety status, TP counts the number of detected workers as true positives from the detection model. In our experiment, assignment of safety statuses achieved an 87.45% AP_{status}. This suggests that our framework accurately revealed the safety status of individual worker against the danger zones. For example, in Figure 5, worker number 15 was alerted in red with 'danger now' since he lied within the danger zone, while worker number 16 was labelled in blue as 'potential danger' since he was about to enter the danger zone.

Nevertheless, dangerous conditions were sometimes not identified. As shown in Figure 6, red alerts were not issued even when workers 15 and 16 stood close to the excavator, possibly because the equipment was not detected and hence no danger zone was defined. Moreover, blue alert was not issued to the worker walking towards the operating area of excavator, possibly because he was occluded by other objects. These cases reflect that the accuracy of assigning safety status heavily relies on the performance of equipment and worker detection. The spatial-temporal analysis would be further supported with a more robust detection model and an enriched training dataset.

Figure 6. Examples of incorrect prediction of safety statuses

5 Conclusion and Future Work

Construction industry is reported to be the most hazardous with a high rate of accidents on construction site. There are various dynamic activities on construction sites such as the operation of various construction equipment and the movement of workers. The interaction between construction workers and equipment is one important reason resulting in on-site safety hazards. Therefore, to avoid potential safety hazards, it is necessary to monitor the working status of construction workers and equipment, and analyse the spatial-temporal interactions between them. Currently, on-site conditions are monitored and analysed manually from the surveillance cameras, which is labour-intensive and error-prone. Furthermore, the alerts for safety hazards may be subjective and belated, leading to severe consequences.

In this study, an integrated approach based on computer vision and deep learning techniques is proposed to predict safety hazards on construction site

through the spatial-temporal analysis of construction workers and equipment. Specifically, Faster R-CNN is first applied to detect construction workers and equipment from surveillance videos. Based on the detection results, danger zones of the construction equipment are identified while worker trajectories are tracked and predicted as well. Finally, the spatial-temporal interaction between the danger zone and the predicted worker trajectory is analysed, based on which the potential hazards are predicted and corresponding alerts are issued.

Experiments are performed with videos captured from surveillance cameras on construction sites to validate the capability of the proposed methodology. The detection model obtained high accuracy on detecting workers and equipment, with a mAP of 92.55% and AP values above 95% for most classes. As for the spatial-temporal analysis, the precision of assigning safety statuses to workers achieved 87.45%, based on which the safety hazard alerts are provided. The experiment results demonstrated that the proposed approach is capable of automatically predicting potential safety hazards through detecting construction workers and equipment, identifying danger zones, tracking and predicting worker trajectories, and analysing spatial-temporal interactions on construction sites. Even though there are still some negative examples in experiments, the overall experiment results demonstrate promising performance of the proposed integrated approach for predicting safety hazards among construction workers and equipment on construction sites. Future work will focus on exploring better methods to obtain danger zones around construction equipment and to improve the performance of the proposed approach.

Abstract -

Indoor environment monitor and control are important aspects of reducing building energy consumption and maintaining occupants' visual and thermal comforts. Previous research showed that the lots of buildings were not able to provide designed service level in the daily operation and the feedback from occupants showed that the predetermined service level sometimes did not match occupants' desire. However, most of existing buildings and residential buildings did not have building management systems that can systematically monitor the indoor environment, collect occupants' feedback, and fine-tune built-in control logic when the occupants' needs could not be met. An easy-to-build and easy-to-use build management system can help researchers, engineers, and occupants themselves to identify the issue.

The goal of this study was to develop a building management platform with the functions of indoor environment data collection (temperature, relative humidity, solar radiation, etc.), remote control (air conditioner, window, shading), occupants' feedback collection (set point, status of building components, etc.), and user interface for retrieving the data and modifying control logic. The platform was developed using Arduino-based and Raspberry Pi-based microcontroller board, low-cost sensors, 3D printing technology, and cloud computing technology. The stored data can serve for personal behavior/comfort analysis, components efficiency analysis, and advanced control logic development. This last part of this paper demonstrated the ability of the developed platform and exhibited the potential application. In the end, we provided further discussion about the potential challenges we might face when developing building management systems in other existing spaces/buildings.

Keywords –

Building Management Platform; Cloud Computing; Low-Cost Devices

1 Introduction

A considerable portion of energy consumptions in buildings are from satisfying occupant' needs and providing human-beings a better life. Researchers try to reduce the energy usages by setting up efficient automated control algorithms for building components such as lighting, shading, heating ventilation and air conditioning (HVAC) system using strategies. However, these newly developed control algorithms may sometimes cause displeased indoor environments since sometimes the algorithms were set too high or too low in an attempt to save more energy and occupants might have different thermal preferences. When occupants took the business on their own and took unexpected actions to control the indoor environment manually, it may result in interfering the designed energy-saving strategies and goals. For example, the HVAC system might experience a startup peak caused by occupants setting the set point too low during the cool down process from the initial state.

To overcome these issues, researchers are paying more and more attention to occupants' behavior and their reactions to automated control recently. One particular challenge of collecting occupants' feedback, is that most of the existing buildings do not have built-in building automation and management system. While the concept, some companies have been promoting intelligent building energy management systems for years[1], the market has not fully accepted these products because of its price and the installation labor works. For most of the prototypes in existence now, the installation and the system integration task are a laborious, ad-hoc process. Adding each new device/features into the building or zone requires a great deal of work. After getting the orders, the engineers must research that targeted buildings' characteristics, operation, protocols of existing devices in the buildings, determining how to integrate new components into the existing system, where to install, how to configure it and how to interface with it. On the other hand, the cost is usually one of the priorities for people when investing in a new system. An easy-to-build and easy-to-use building management system can help

researchers, engineers and occupants themselves identify the issue.

The goal of this research is to develop a building management platform in an existing space with the functions of indoor environment data collection (temperature, relative humidity, solar radiation, etc.), remote control (air conditioner, window, shading), occupants' feedback collection (set point, equipment status, etc.), and user interface for retrieving the data and deploying control logic interface.

2 Literature Review

Human's lifestyle is constantly changing along with the development of technology. In Teichroew [2]'s paper from 1971, they already started to talk about the importance of home automation. Murata [3] introduced a system that can control home computer, television, audio and video entertainment with verbal commands. Ryan [4] designed a system using cordless humidity sensors and temperature sensor to control the heater remotely by occupants. The smart building concept has become very more popular recently. Lots of researchers have started to investigate how to improve the energy efficiency of buildings and how to improve the indoor environment we live in.

To run a smart building systematically, a building management system (BMS) or a building energy management system (BEMS) is essential. Without a good building management system, it is hard for the building manager to find out the issues, for the devices to communicate with each other, and for occupants to provide feedback. Not to say, it would be very challenging for engineers to deploy newly developed control logic and to add new technology into an existing system. Building management system has been installed in more and more newly constructed buildings, especially after some researchers have pointed out that its potential for energy saving.

Rotger-Griful et al. [5] present a multi-modal building energy management system for capturing residential demand response. They set a testbed where they collected indoor environment data from sensors and power meters in order to analyze the occupant's demand response. According to the study, the energy saving potential of a building to be 7.4 MWh/year. Macarulla et al. [6] present the procedure of implementing a predictive control strategy in a commercial BEMS for boilers in buildings based on a neural network that turned on the boiler each day at the optimum time, according to the surrounding environment, to achieve thermal comfort levels at the beginning of the working day. The results showed that the implementation of predictive control in a BEMS for building boilers could reduce the energy required to heat the building by around 20% without compromising the user's comfort. However, as the introduction section points out, it is especially tricky for existing building/space regarding system integration and cost.

Low-cost developmental systems such as Arduino and Raspberry Pi are widely used for developing prototypes of smart building applications [7] since it is capable of serving as a data acquisition system and is also capable of being a controller [8].

Data collecting and monitoring is the core of a building energy management system, and lots of advanced control algorithms are relying on accurate and reliable data sources. Researchers tried to cut the cost of data collecting. Li et al. [9] developed a low-cost real-time data logger with PM sensor, an Arduino Nano ATmega328, and an XBee radio to measure particulate matter. Habibi et al. [10] developed a smart system prototype based on Arduino microcontroller which can obtain and monitor environmental data (light, sound pressure/mic, temperature, and humidity) in real-time. Jin [11] developed a similar system to monitor IEQ. Rajalingam and Malathi [12] used an Arduino system as a smart controller for home power management. Lovett et al. [13] present an approach minimized the cost of sensing by inferred performance metric (e.g., high CO2 levels may indicate poor ventilation). They designed a process for grouping sensor sets to capture energy events in buildings. While these techniques are being widely studies, the accuracy and reliability of these low-cost sensors have not thoroughly been studied.

Research communities and companies started from developing systems and interfaces that allow the occupants to control lighting, shading, and HVAC system remotely. Gill et al. [14] developed a home automation system based on ZigBee to control lighting system and radiator. Occupants can control the lights and the radiator through any device supporting Wi-Fi and Java. Piyare et al. [15] developed a Bluetooth based home automation on a Symbian OS mobile phone for controlling lamps remotely. Al-Ali et al. [16] developed a JAVA based home automation interface that can control lighting, fan, and oven through a local web page. Later on, the research scope was extended. Advanced automated control by analyzing sensors' feedback was studied and implemented. Kuo et al. [17] developed an automatic shading control system using photometer, 3D-printing component, and support vector machine algorithm for learning an individual's lighting preference. Cheng et al. [18] developed a satisfaction based Q-learning system which integrated lighting and blind control by gathering occupants' feedback. Tang et al. [19] used smartphone and light sensors to perform daylight harvesting while maintaining occupant desired light color. Compared to the original control mode, the power savings were up to 54.7%. Fewer studies were published

about the HVAC system since the system is generally more complicated, but it had huge energy saving potential. Rashid et al. [20] retrofitted the functionality of the HVAC system by using the existing distributed heating/cooling infrastructure in buildings to provide a low-cost centralized command and control mechanism namely. The paper targeted buildings in developing countries that lack the necessary infrastructure of a traditional HVAC system. The result showed it could save approximately 45% of the total energy consumption of the air conditioner (AC) on a day.

From reviewing past studies, we can find that the benefits brought by building management system are valuable. More and more researchers started to develop a low-cost smart control and monitor system and building management system for existing buildings. However, the integration of protocols from different appliances and different manufacturers has not been discussed. In the past, we usually control each component separately. While more and more studied indicated – HVAC system, lighting system, shading system, and window system are related and should be considered together in order to achieve [21].

Moreover, the impact of occupants' inputs and feedback were skimmed. This paper aims to address some of the issues mentioned and to present an overview of an integrated building management system that can facilitate further research about occupants behavior and advanced control.

3 Methodology

This section described the system we developed and the method we used to overcome the existing conditions. This system was specifically designed for the test space described in next session. The design plan was carried out according to the current situation and the characteristics of existing building components (HVAC system, lighting system, and shading system).

3.1 System Structure

Figure1 showed the overall system structure which included four groups: the user interface, the cloud platform, the processing units, and the sensors and controllers.

There were two types of front-end components in the structure, environmental sensors, and controlled objects. Sensors collected environmental conditions that helped the controllers to provide appropriate environmental control. Meanwhile, the collected data helped the researchers to understand the conditions when occupants provided certain feedback (i.e., interact with building components) and for other research purposes. Sensors installed for monitoring the indoor and outdoor environment include thermocouples, temperature sensors, humidity sensor, light sensors, illuminance sensors, and pyranometers, and so on. Extra sensors such as and pyroelectric infrared detectors (PIR) were for detecting occupancy, and infrared receivers were for capturing remote controllers' signals. In the developed system, there were two controlled objects – shading systems and mini-split air conditioner. In the future, its scope would be expanded to other common building components in the spaces.

The processing unit was the medium of sensors, controllers, and database. For gathering environmental data from sensors, we used two types of systems (sensors + processing unit) in this study. The low-cost ones were there for the targeted system and data collected through this system was directly used for control. The high-end sensors and processing unit (mainly DAQ system) were set up in order to validate the readings collected by low-cost sensors. Both systems were integrated into the overall system frame, and the data was sent to a cloud database.

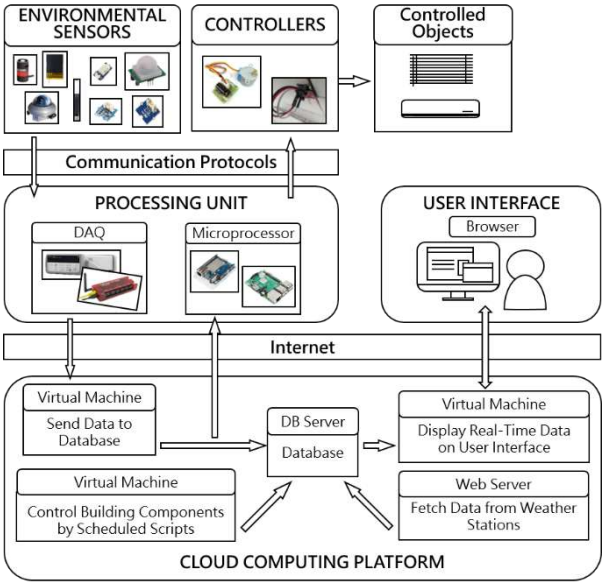

Figure 1. The overall system structure of developed building management platform

For low-cost data gathering, we chose Arduino and Raspberry Pi microcontroller boards as our processing unit. Both boards were capable of decoding communication protocols such as UART, I^2C, Modbus, and other communication protocols, which allowed better flexibility. Both boards supported Wi-Fi, which was critical to the existing space. Although communication through physical wires might be more reliable, it would increase the overall installation cost and workload. The data gathering program was running on

the boards directly. After gathering the reading from sensors, it sent POST requests with the readings to a cloud server running a custom database and PHP application.

High-end system's processing units consisted of several different data acquisition systems which connected to sensors with voltage outputs, current outputs, etc. Instead of installing a program into the packaged DAQ system, the data gathering was running on the cloud server which sent signals to communicate with the DAQ system while the DAQ system communicates with sensors through its internal protocol. The data collected by the cloud server were sent and stored in the database directly.

Some microprocessors served for control purpose. The details would be present in 3.2 and 3.3. The typical way to interact with components in daily life were kept while the occupants' action being recorded. The web-based user interface also allowed engineers and occupants control the system remotely and to set up more complicated control algorithm.

The user interface of our system is web-based. The website present real-time information such as temperature, humidity from weather stations and sensor data, components' status, and occupancy status. We can also download CSV data for a customized period from the website.

The cloud computing platform was the core of the system. It was set up on the cloud instead of on-site to increase the computational efficiency, and to save the cost and space and can be accessed by people with access right from anywhere. Tasks hosted by cloud computing platform include hosting database, hosting PHP server that passed data to the database, performing data gathering programs, fetching data from weather stations, hosting user interface websites, and running control scripts on the virtual machines. New control algorithms would be deployed from the cloud computing platform. The expandability of the platform would give us the flexibility to add more functions and to add more computational capacity to the system in the future.

3.2 Thermal Environment Control

The section describes how our system control the thermal environment for the targeted space according to occupants' actions or control algorithm commands while capturing occupants' feedback. The structure of how the system executes thermal environment control is shown in Figure2.

The air conditioner demonstrated, in this case, was a mini-split system. Typically, it was controlled by occupants through the factory remote controller. However, it did not keep when and the conditions when occupants took a control action. The developed system kept the original way to control and added a web-based user interface that allowed both users and system to control the air conditioner from outside of the space. The original factory controller communicated with air conditioner through infrared signals, so we installed an Arduino Yun microprocessor with infrared receiver right next to the air conditioner signal to capture and decode the infrared signal sent by the controller in order to record occupants' actions. The remote controller sent out a specially timed sequence of pulses to transmit data. The infrared sequence consisted of a set of marks and spaces referred to as a "frame" of data. The receiver captured the whole sequence and determined critical time intervals (space) to decode the set point temperature and wind speed the controller was trying to tell the air conditioner. For realizing the control from outside of the space, an infrared transmitter and a WEMOS D1 mini pro microprocessor with a built-in web server were set up and aimed to the receiver in order to pass the infrared signal according to users' command through the website instead of factory remote controller. One of the most challenging parts was to decode the signals before setup the extra receiver and transmitter. In order to differentiate from the signals sent from the factory remote controller and signals sent by the website, we altered the small part of the signal.

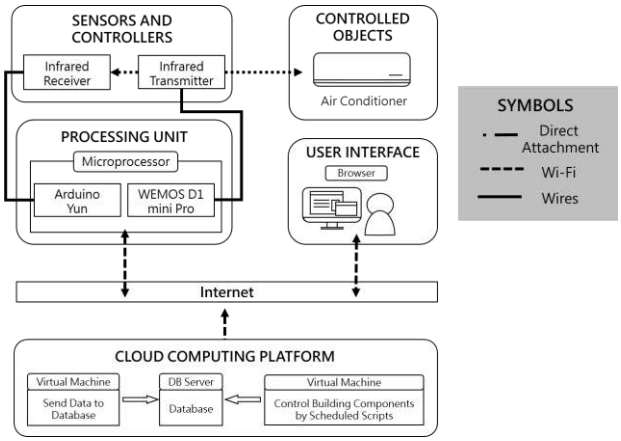

Figure 2. The system structure of thermal environment control

The user interface displayed the latest air conditioner temperature set point and wind speed. When changes were made, the code will swap out the characteristic time intervals to regenerate the corresponding infrared signal. It then emitted it through the infrared LED transmitter, and the signals were expected to be captured by the air conditioner and the Arduino Yun. After decoding and filtering the signal, the code on Arduino Yun then POST sensor reading to another web server on the cloud computing platform. The targeted website server would execute a PHP code that reads the information containing in the URL string and passed the sensor readings to the

database.

Other than establishing the ability to control from outside of space and gathering occupants' action records, we also deployed multiple thermocouples and other sensors to gather indoor environment data as described before, so we knew what the indoor environmental condition was when the occupants happened to take the actions. The beeper in the air conditioner was replaced with a blue LED to avoid the disturbance caused by automated control.

3.3 Shading Control

The targeted shading system in our study was Venetian blinds which controlled the amount of sunlight entering the environment and controlled the glare by its slats. Venetian blinds system consist of slats, gears, a fixed frame, a drawstring, and a rotating rod. The drawstring's function was for adjusting the height of the blinds. When released, the louver would cover the entire window. In this study, we fixed the blind's height to the full-covered position in order to reduce the complexity of the shading control system. The rotating rod's function was for adjusting the angle of the slats, which would also change the amount of sunlight entering the space. The slats angle was the primary control variable in this system.

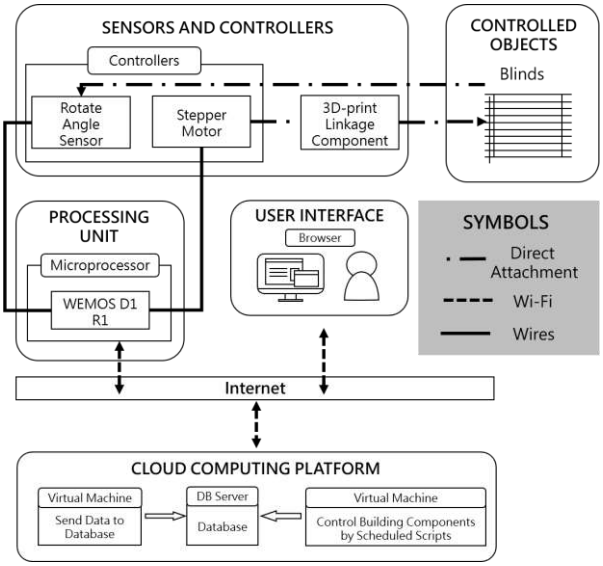

Figure 3. The system structure of shading control

Figure3 shows the system structure of shading control. We connected the rotating rod of the shades to a stepper motor by a customized 3D printed device. Then in the same WEMOS D1 R1 microprocessor, we installed an angle sensor and put it on top of the slats to measure the three axial displacements. The readings from the angle sensors were used to tell the stepper motor when to stop. The slats angle operation procedure is shown in Figure 4.

A web server was also hosted on this WEMOS D1 R1 board. By accessing the web server, the users and the system can control the shading system directly. When a command was sent, WEMOS D1 R1 would execute the code to trigger the motor, and it would stop when the slats reached the desired angle. At the same time, an URL containing the desired angle was POST to the cloud server. An infrared receiver was also installed, and programmed to couple with a remote controller and to provide another control option. Consequently, the shades can be controlled by either infrared signals or web commands.

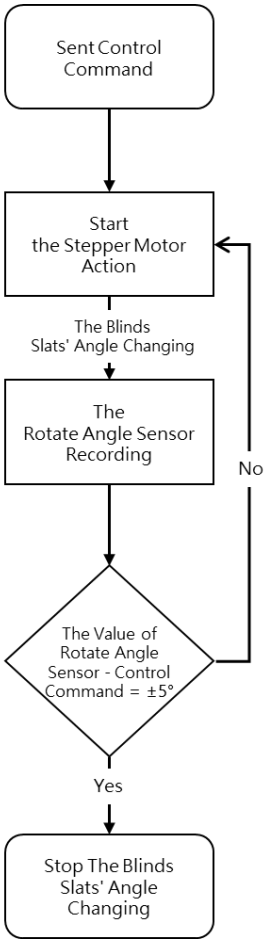

Figure 4. The slats angle operation procedure

4 Case Demonstration

In this section, we demonstrated the system's capabilities by deploying it into an existing space. The following session showcased the function of the current building management platform, the control implementation, and the environmental data and the occupants' feedback can be collected by the system.

4.1 Introduction The Testbed Environment

The testbed was set up in Taipei, Taiwan. The city is located 121 degrees east longitude and 25 degrees north latitude, with an average annual temperature of 23.6 °C and an average annual average relative humidity of 76%. The climatic conditions are classified into a subtropical monsoon climate, which means high temperature and rain in summer and warm and humid in winter than in the same latitude.

Figure 4 presents the configuration of the testbed. The size of the testbed was 6.1 m × 2.4 m × 2.6 m (length × width × height). The testbed had a door (90 × 200cm) and three windows on the west wall and three windows on the east wall. Each window is 110 × 90cm. The window to wall ratio for east wall and west wall is around 18.8%.

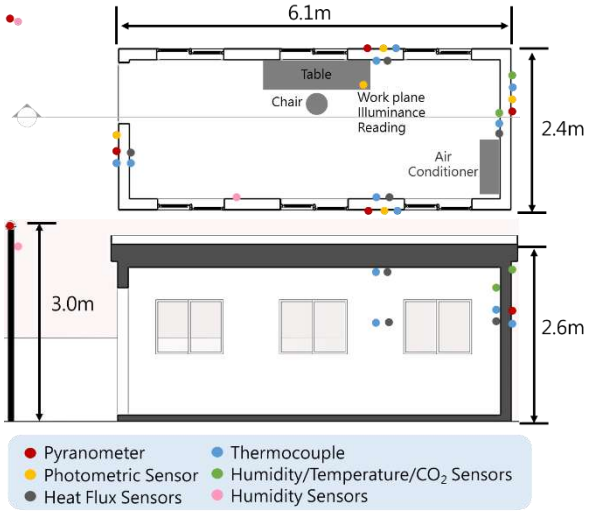

Figure 5. The Testbed Environmental Sensors Arrangement Position

The existing components targeted in this study were a split air conditioner and Venetian blinds. Only the west side of windows and blinds can be altered, while the shades on the east side were all closed during the experiments period in order to simulate the situation of a typical individual office. The table for the occupant was placed in front of the middle west window, and there was a photometric sensor to read work plane illuminance on the table.

We recruited several occupants to test the environmental comfort in the testbed. In order to observe the occupants' activities and actions, we maintained testbed's starting conditions similarly before the occupant entered the testbed by automated control. For this purpose, we set up a virtual machine program to execute the control sequence at 01:00 am every day, so the Venetian blinds would be fully open, and the air conditioner would be off when occupant entered the room. Before the test, we told the occupant that we gave him/her the full control of targeted building components.

4.2 Occupant's Behavior Related Thermal Comfort

We designed a test to gather occupants' response to the changes in the indoor environment and to demonstrate the system's capability to control from outside of the space. Figure 6 shows a comparison between a day with the air conditioner on (top) and a day with the air conditioner off (bottom). The vertical axis on the left side indicated the temperature, and the vertical axis on the right side indicated the passive infrared (PIR) sensor - value 0 indicates occupant was not there, value one indicates occupant was in the space. In the case with the air conditioner on, it was evident that the air conditioner is hunting the set point in comparison to the case with the air conditioner off – which has a smooth curve. Therefore, sometimes we do not need action response sensors to capture occupant behavior. The virtual sensor can be developed by analyzing the data.

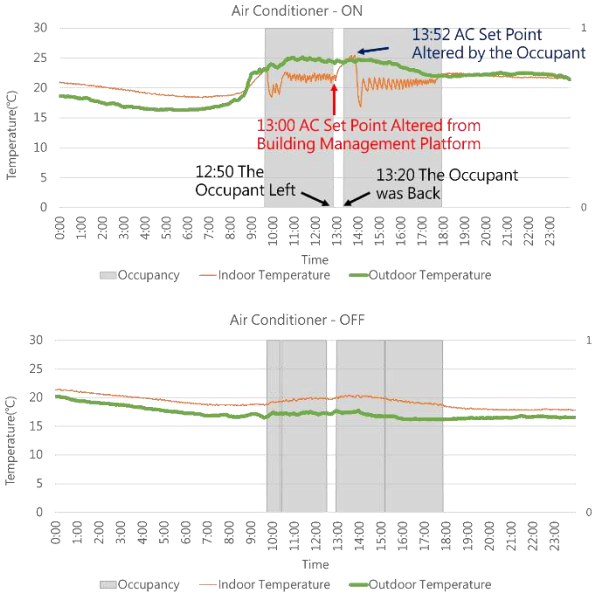

Figure 6. Occupant and Air Conditioner Interactions

The test process was to adjust the temperature setpoint while the ambient temperature is stable in order to recognize their thermal tolerance and to develop energy-saving strategies. Figure 6 (top) shows that the adjustment was sent at around 13:00 when occupant left for lunch but forgot to turn off the air conditioner. The system raised the set point by 4 degrees. The occupant was not happy about this adjustment. While when the occupant came back, the temperature set point of the air conditioner was not immediately adjusted, the occupant decided to lower the setpoint 30 minutes after entering the room. From the case where the air conditioner was off, we can find that the occupant's preferred temperature

range is approximately between 21 and 23 degrees. The energy-saving adjustment, unfortunately, caused the occupant discomfort and resulted in occupant's unexpected action by adjusting the set point to somewhere even lower than the set point before adjustment. The presented result was a compelling case that the control algorithm developer should pay attention to. It also demonstrated the importance of building management system and its remote control function.

4.3 Occupants' Behavior Related to Visual Comfort

This session demonstrates the capability of the system's shade adjustment and feedback from occupants. Figure 7 shows the results of shade status and occupant's behavior on a sunny day and a cloudy day. The vertical axis on the left is the illuminance level, and the vertical axis on the right is the slat angle. The gray block was the interval that the occupant was in the space.

In the sunny day case, the system read the report from weather prediction and knew that the day was sunny beforehand. It then adjusted the slat angle to 40 degrees in advance through the management platform before the occupant entered the testbed for capturing the occupant's reaction. Note that: the slat angle is zero degrees when the slat is horizontal, -70 degrees when it rotated towards the ground and 70 degrees when it rotated towards the sky.

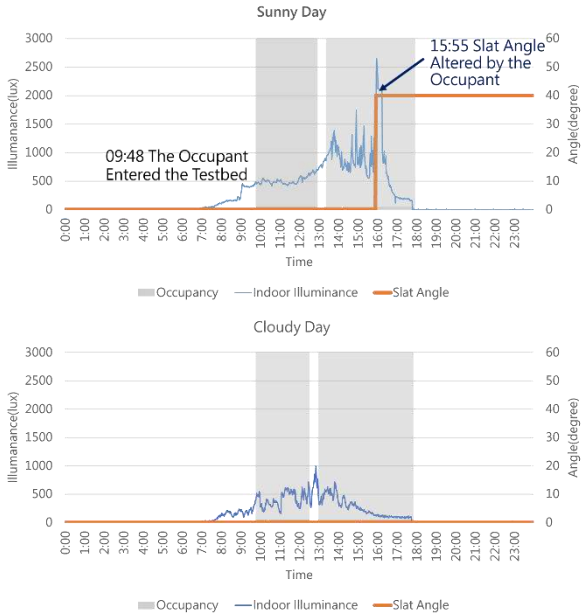

Figure 7. Occupant and Air Conditioner Interactions

From Figure 7, we knew that once the occupant entered the space, the occupant found that the indoor light is insufficient. The good news is that instead of turning on the light, this occupant chose to change the slat angle to 20 degrees. The occupant adjusted the slat angle again at 15:55 to reduce the amount of light coming in and maintain visual comfort because it is the time when direct light can transmit through the gap between the slats from what we found in Figure 7. Unfortunately, the sensor here was placed on the work plane instead of the vertical plane. It was a lesson learned from testing and can be used to adjust the set up for control.

5 Discussion

Although this system is designed to be easy to build and easy to use, there are still some challenges to overcome when adapting our system to other cases.

We need a knowledge base for setting up remote and automated control for different existing building components. There are many different types of building components with different communication protocols and different shapes, and the component with the same communication protocol might adopt different ways to decode the signal. For example, the infrared signals differ from one air conditioner to another air conditioner. 3D printed adapter for connecting step motors and rod also needs to be redesigned for different rod shape.

After all, we are looking forward to expanding our system to include more building components such as fans, stand-alone heaters, etc. The industry standard should be established in the future, and a more natural way to build accessories such as 3D printed adapter should be studied. We also need to find a more efficient way to deploy the control logic that requires less experiencing on programming.

6 Conclusion

We built a building management platform in an existing space to verify the feasibility and effectiveness of the overall system structure. The preliminary results and demonstration provided a crucial foundation for the subsequent implementation of intelligent systems and equipped a testbed that can be used for other behavior studies and control studies in the future.

The building management platform is composed of many different hardware devices and software services. The low-cost sensors and microprocessors were selected to reduce the implementing cost. The demonstration showed that the low-cost hardware devices could be used as a good terminal device for intelligent systems and carefully designed and commissioned devices could achieve good stability and accuracy. The low-cost concept would benefit buildings that are in the operation and maintenance phase, and make the system more acceptable in the market.

The concept of getting feedback from occupants can help the manager and research communities understand occupants' need better. The continuous monitor of the indoor environment can help the managers check if the building components such as air conditioner and the blind system can achieve designed service level. The cloud-based platform makes the commission process and other services more flexible.

In the past, the control of the building environment and the management and maintenance of building components strongly depend on the experience of the building managers, which usually led to an unnecessary waste of energy and increased the difficulty to deploy new control algorithms. This study showed that we have the potential to learn more and occupants and to run advanced energy saving control logic by introducing the cloud-based building management platform into the existing building space.

Abstract –

This paper presents an approach to classifying spatial categories of space objects using their textual properties in IFC data. As a standardized data format of building information, IFC enhances the data interoperability between the heterogeneous domain software. However, there are some problems that required information is omitted due to the technical translation error or mistake by users. The other problem is that some semantic information cannot be defined in the IFC data scheme. Manually checking and modifying this information requires an amount of time and labor. The intelligent information enrichment system can facilitate the application of BIM. In this regards, this research tried to address the interoperability problems with a machine learning-based method by automatically enhancing the semantic information of the BIM model. In this paper, we focused on the semantic enrichment of space objects by using textual data in the IFC. We implemented the NLP-based classification training model, which employs the word embedding techniques. As an early phase of research, this paper conducted training experiments with variable input properties, name and area of space, from space object in Korea school buildings. The accuracy of the classification model with a single feature (name) is measured at 85.9%, which is higher than multi feature (name and area). The suggested model can be expanded to more variable properties and target objects as a part of the semantic enrichment system.

Building information modeling (BIM), Spatial information enrichment, Natural language processing (NLP), Industry foundation classes (IFC)

1 Introduction

The adoption of building information modeling (BIM) contribute to enhancing the efficiency of architecture, engineering, and construction (AEC) industry by generating and managing building information with a computational model. BIM enables the automation of variable processes such as code compliance checking, design analyses [1]. Industry Foundation Class (IFC) standard supports the data interoperability of BIM, which aims to maximize the advantage of BIM.

However, several problems still remain in terms of practical applications of BIM. Some basic analysis processes can be driven by quantitative data from IFC, but the practical analysis requires more complex and domain-specific data that are not defined in IFC scheme. The semantic information required for specific analysis tasks can be easily obtained by a human who has domain-specific knowledge. Domain experts reason the semantic information about building objects using various types of data, such as text, images or quantity values. In order to intelligently automate these reasoning process by a computer, there have been some researchers to implement the automated information inference system. The research area, called semantic enrichment, addressed the interoperability of semantic BIM data by employing rule-based or machine learning methodologies [2, 5-8]. This research is also a part of them, which tried to implement the semantic enrichment system focusing on a space object instance. In this paper, we propose the utilization of textual values to intelligently inference the semantic information of space objects, as domain experts.

As machine learning and deep learning technology have been dramatically developed, natural language processing (NLP), which is sub-domain of artificial intelligence, also has made an amount of progress [3]. Machine learning-based NLP enables the computer to learn the semantic meaning of natural languages by itself. Word embedding technique helps to represent the semantic meaning of words in numerical vectors, which make a breakthrough in variable NLP tasks. In this research, the NLP techniques including word embedding are employed to implement the classification model. The approach to NLP-based feature generation and spatial category classification model are depicted in this paper. The results of training experiments with spaces in Korean school buildings are also described for validations. The overview of this research and scope of this paper are illustrated in Figure 1.

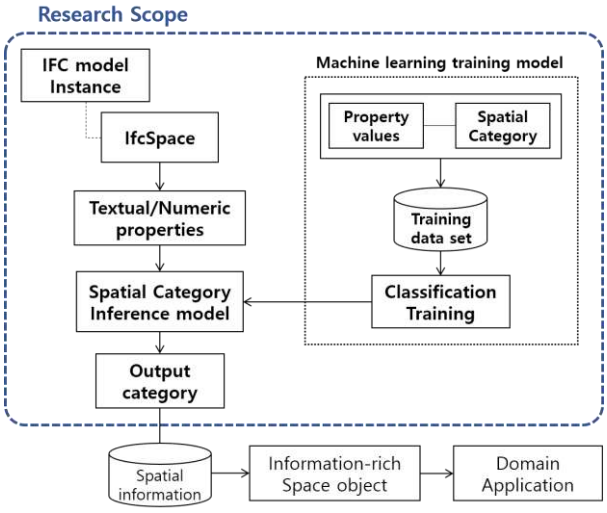

Figure 1. An overview of the suggested spatial information enrichment system and scope of this paper

2 Background

2.1 Semantic information of building objects for domain-specific application

As a standardized data specification, IFC is meant to support data interoperability between the different BIM platforms, however, there have been some studies reported practical problems of IFC [3]. Domain-specific applications require higher levels of semantic information and the required information is different for each domain task. Model View Definitions (MVDs) was suggested to define a subset of IFC required for domain-specific applications. However, MVD approach has a limitation on practical applications since it has to be defined respectively for every application.

Recent studies in code compliance checking, building analysis, and BIM model query tried to develop a system to supplement the semantic information. Solihin et al. suggested FORNAX platform for code compliance checking system, which supplements the semantic attributes of building objects with pre-defined FORNAX objects [5]. Lee et al. developed space database and mapping algorithms that provides the standard information of space object instances [6]. Belsky et al. proposed a Semantic Enrichment Engine for BIM (SEEBIM) which is a rule-based inference system for classifying components of bridge models [7].

Tanya and Rafael suggested machine learning-based inferencing method for semantic enrichment of space objects. Using the single features and pairwise features of space objects, the machine learning algorithm is trained to classify the type of room [2]. Koo et al. utilized support vector machines, which is one of the machine learning algorithms, to classify the building objects and check the semantic integrity of them [8]. These studies tried to switch the rule-based inference method into machine learning-based method, and showed the potential of the approaches.

2.2 Spatial category classification

Space is one of the critical elements in the computer-based information system for the concept design, construction process, and facility management process [5, 8]. As a functional element where human activities are performed, space is used as a unit of design or building analysis.

Traditional 2D CAD system only represents space object with surrounding physical objects and labels. BIM application is based on the objects-based modeling, which represents space object dependent on their

Table 1. Classification of spatial categories and training labels for Korean school buildings [11, 12]

physical boundaries. This approach enables AEC industry stakeholders to manage and utilize required information of space objects.

Although, BIM provides rich-information about space objects, there are limitations on the interoperability of space objects in the domain application. Space instance can be classified differently, according to the applications. In some analysis, several spaces can be defined in a single zone, which is an aggregation of spaces. These characteristics hinder the utilization of space objects and their associated information. As an early phase of research to address the classification problems, we propose an approach to automated spatial category classification for space instance in the BIM model using machine learning algorithms. The motivation of this research is based on the research of Lee et al [6], which used space name data for classifying spatial categories.

3 Spatial categories classification of space objects for school buildings in Korea

The environmental comfort of educational facilities, which primarily depends on the building design, can affect the work or study productivity [10]. In this regards, many countries make efforts to establish more comfortable and effective facilities for both students and teachers. The Korean government also tries to improve the education environment with advanced facilities. The standard area for each student and classroom is specified in design regulations. In addition, the Korean ministry of education tried to introduce subject classroom system, which requires classrooms for each subject [11]. The design plans of school buildings have to follow these guidelines. In terms of subject classroom system, classifying the spatial categories of spaces is critical for the design and assessment of school building.

The fundamental features for spatial category classification is a name and area. The problem of utilization of name property is that the computer cannot understand the textual semantics of the space names written by different naming conventions. Figure 2 shows a simple example of naming convention problems. The floor plans of each project have a different naming convention for the same subject classroom.

In this paper, we focused on the functional usage of space object among the spatial categories. The classification of usage is listed in Table 1. Omniclass Table 13: Spaces by Function [12] and Classification system in Subject Class Operation Guidelines in Korea [11] are considered for the space classification system. The concept of high-level categories is borrowed from Omniclass and detailed training labels referenced the classification in Korean guidelines.

4 Development of NLP-based spatial category classification model

4.1 Property Extraction from IfcSpace object

The classification model in this research is based on a supervised learning method, which requires input features and corresponding label of objects. The input feature is a critical factor for machine learning since the model is trained to capture the patterns of input features and use the patterns for classification. The property values of IfcSpace objects are extracted for generating input feature of the usage classification model. The extracted property values of each IfcSpace instance object are expressed in a single vector as an input of the classification model.

Table 2. A list of IfcSpace properties

Attribute /Pset	Property name	IFC entity	Data type
Attribute	LongName	IfcLabel	String
	Name	IfcLabel	String
	GlobalId	IfcGolbally UniqueID	String
	Description	IfcText	String
	...	...	...
Property set	Department	IfcText	String
	Occupant	IfcText	String
	Area	IfcArea Measure	Numeric
	Unbounded Height	IfcLength Measure	Numeric
	...	...	...

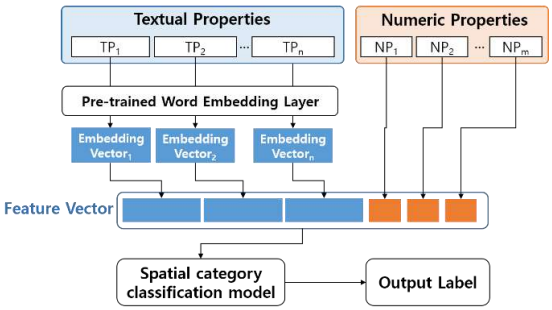

Figure 3. Feature extraction from space object properties

Table 2 shows a snippet list of IfcSpace properties. The IfcSpace object has attributes and property set which express the information of a space. Each property has a specific data type suitable for expressing the information. The feature generation is proceeded with converting property values in a suitable form. Numeric or Boolean data can be simply converted into input features. In order to translate textual data in a numeric form, word embedding techniques are applied. The details of utilization of word embedding are described in the next section. In this paper, we use the values of space name and area among the listed properties for classification.

4.2 Feature generation with NLP techniques

Neural network-based word embedding techniques become a prominent method for representing text data into the numeric form. In order to help the computer to understand and process the natural language, there have been variable methods to encode text in numeric format. The count-based representation approach has a limitation for representing the semantics of each word. Distributed representation makes a breakthrough by predicting the possibility of co-occurrence of words or phrases and encoding their features into vector format [13]. The concept of distributed representation is recently implemented with neural network-based models, which can handle the amount of text data. In this research, we obtained word vectors with word embedding model named fastText developed by Facebook's AI Research (FAIR) lab. The fastText model uses subword information for obtaining word vectors, which enables a model to represent the words that did not appear in the training data set [14].

We train the 100-dimensional word embedding model with 356,010 sentences from Korean Act sentences collected with an Open API data of National Law Information Center (law.go.kr). The 100-dimensional word vectors can be used for classification alone or concatenated with other numeric properties (Figure 3). Other numeric properties are obtained from the property value of given space object, with IFC parsing tool such as IfcOpenShell or it can be simply derived from the room schedule exported from BIM authoring tool. An approach to the explicit representation of relational properties such as connection, inclusion, adjacency is also another important issue for utilizing the information to machine learning or deep learning training.

4.3 Classification training and inference model

The classification model is implemented with a feed-forward network composed of three hidden layers. Each hidden layer contains 50 nodes respectively and the size of the output layer is 22 which is same as the number of output labels. ReLU (Rectified Linear Unit) function is used for activation function of each layer. The cross-entropy loss function and the stochastic gradient descent algorithm are employed to calculate the loss of training and optimize the model. The neural network model is implemented with the PyTorch framework [15]. The inference model makes an inference for new input data with a classifier of the trained model.

5 Training experiments and results

5.1 Training experiments

The training data set is collected from the best practice examples of educational facilities in Korea, provided by Education Facilities Research & Management Center (EDUMAC). EDUMAC provides design proposals of school buildings which include floor plans and space programs. In this research, 7 buildings are selected by the author, and 598 space data are collected for training. Training data is randomly separated in 80:20 ratio for training data and validation data, thus 478 spaces are used for training and 120 spaces are used for measuring the accuracy of trained data.

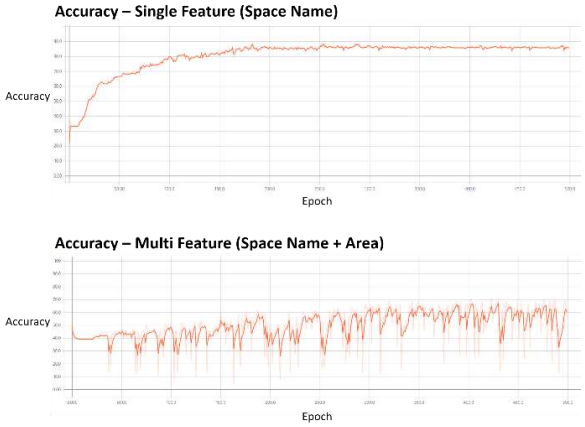

Figure 4. Training accuracy of each training

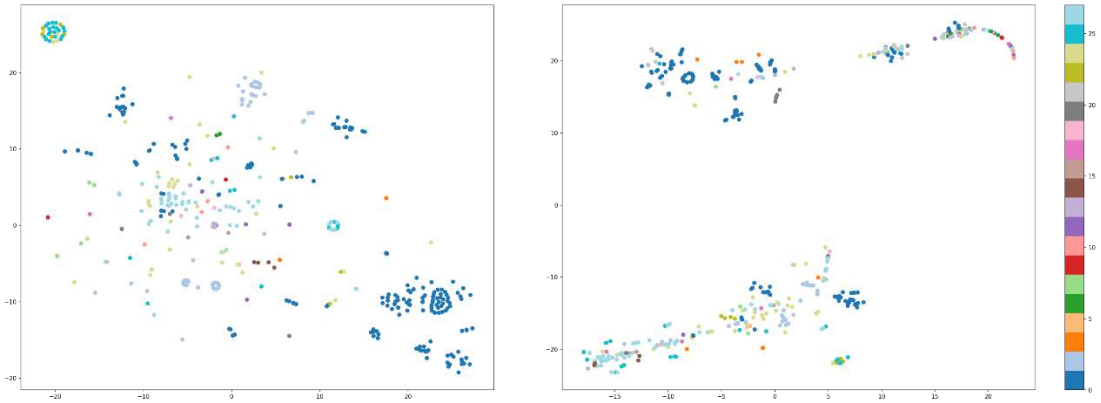

Figure 5. t-SNE Visualization of input feature vectors; Left: 100-dimensional vector (word embedding vector), Right: 101-dimensional vector (concatenated vector of word embedding and space area)

Training experiments are conducted with two scenarios. The first training is proceeded with a single feature, in this case, word embedding vectors of space name. In the second training experiment, the multi feature, which is a concatenated vector of word embedding vector and the value of the space area, are inputted to a training model. The training model and the number of training epoch are used for training, to compare the results.

5.2 Training results

The training results of each training model with 500 iterations are illustrated in Figure 4. Figure 4 illustrates the plot of training accuracy of single feature training model in the above graph and multi feature training model below. As shown in the above graph, there are no advances in training after 350 times of iteration for the single feature training result. The final training accuracy is measured by 85.9%. The training accuracy of second training experiment with multi feature is measured lower than the former one, measured to 60%. This result shows one single feature - space area in this case - can affect the training outcome by changing the input values and even produce worse results.

Figure 5 is a t-SNE (t-distributed Stochastic Neighbor Embedding) visualization [16] of input feature vectors. t-SNE visualization is a visualization tool for high dimensional data, which capture the similarity between the points and tries to express them in a lower dimension. By visualizing data in 2D or 3D space, the user can easily figure out the distributed pattern of data. In Figure 4, Left one is a 2D scatter plot of the 100-dimensional vectors with a single feature and the right one is the plot of 101-dimensional vectors with the multi feature. The color of dots represents the usage label of each observation. The clusters of data are more easily identified in left scatter plot than the right one. In other words, the computer can easily figure out the patterns and classify input observations of single feature vectors than multi feature.

This result can be attributed to the design plan of school building based on the unified spatial module. Most of the spaces in school buildings have a similar area and geometric feature regardless of functional features. They are partitioned to a certain size which is mostly based on the size of the general classroom. Whether the functional usage of space is laboratory classroom or teacher office, most of them have very similar, even almost the same, geometric features to the general classroom. In the training experiment from this research, the area value acts as a noise to lower classification accuracy since they cannot show the pattern to distinguish the usage. In the future work, other geometric properties and relational properties of space object can be appended to the input features for validation of the proposed approach.

6 Conclusion

This research proposes a spatial category classification method utilizing name and area of space objects. The spatial category classification is based on a neural network model, which use the word embedding techniques for processing textual data. The results of training experiments show that deep learning model can classify the space object by their name. However, deciding which properties to be utilized as training features is critical for training output.

The contribution of this research is to expand the utilization of textual data that is one of the important values for inferencing the semantic information of space object. In the proposed classification model, machine learning-based NLP techniques are employed, which can help the computer to understand the semantic meaning of natural languages. The machine learning-based model

can deal with the lexical problems, such as acronyms, omissions, which are difficult to handle in the rule-based algorithm.

This research could be expanded in terms of input features and target objects. Input features can be expanded with other textual data or numeric data. If there is more information about occupants or department of space, these textual properties could be converted into the feature vector of training models. Additionally, the other geometric properties and relational properties also can be applied to training. Utilization of variable properties are expected to be more independent to the requirements of input properties; Even if some information is missing in the BIM model, the trained model may infer the semantic information about the space objects. The target of the classification also can be expanded to variable objects including building itself.

Abstract

Commissioning (Cx) of heating, ventilating, air conditioning (HVAC) systems has emerged as an effective sustainable practice to ensure high performance of these systems during operation. According to a DOE report, HVAC systems used 62% of the energy consumed by buildings in the US in 2011. It was also reported that controls related issues resulted in wastage of 50% of the HVAC energy consumption in 2011 (around 10% of total building energy consumption). Incorrect implementation of controls is a very common issue that can be traced back to improper representation of design intent of controls in the sequence of operations (SOOs). SOOs are currently represented through textual narratives that cannot be completely and accurately interpreted for comparison against the implemented controls during Cx. As a result, incorrectly implemented controls may remain undiagnosed, resulting in inefficient operation, energy wastage or both.

Currently, there is no guideline that can be used to identify the information to be included in SOOs. ASHRAE GPC 36 provides SOOs for 13 AHUs and ASHRAE Guideline 13 provide one sample SOOs, but they both do not list specific information to be included in SOOs. OpenBuildingControl is a research project to automatically implement the SOOs from ASHRAE GPC36 and simulate them through Spawn of EnergyPlus (SOEP) simulation engine. Even with all these efforts, there is still a need for a generalizable approach for identifying the information to be included SOOs for any AHU configuration, including the ones not included in ASHRAE GPC36. This paper describes a generalized way of identifying information items to be listed in SOOs. This approach incorporates functional and topological reasoning mechanisms to identify all temperature and flow related control processes within an air handling unit (AHU) and all components that influence each control process in a generalized way, regardless of the configuration of specific AHU.

Keywords –

HVAC Controls Commissioning, HVAC Controls Design Intent, HVAC Controls Information Requirements, HVAC Sequence of Operations, Building Information Modeling

1 Introduction

Commissioning of heating, ventilating, air conditioning (HVAC) systems is a formal step by-step process of verifying that a building is designed, constructed, and operated according to an owner's project requirements. From the energy performance perspective, commissioning of HVAC systems is important to ensure that these systems are installed to meet the heating/cooling needs of interior spaces and use energy optimally. Traditional commissioning of HVAC systems verifies a given design through various project phases and ensures that the correct system components are installed and are operational according to design documentation.

The documentation of HVAC controls is traditionally done through textual narratives called, sequence of operations (SOOs). A previous study related to this research identified several categories of challenges in accurately interpreting the design intent of controls from these narratives [12]. The identified challenges were classified into five categories: 1. Missing controlling/controlled parameters; 2. Missing set points; 3. Missing control logic; 4. Inconsistent values from multiple information sources; and 5. Missing information items. Due to these challenges, it may not be possible to accurately interpret the design intent of HVAC controls for verification during commissioning. And HVAC controls, which are not commissioned properly, will

likely result in energy wastage, occupant discomfort or both.

This paper presents an approach to generate a customized list of all control processes related to air flow and air temperature within an AHU. Further, a list of all components that influence each control process that need to be described in SOOs is also generated to support commissioning. The reasoning mechanisms rely on a building information model (BIM) of a given AHU and identify all control processes related to air flow and air temperature using the types of sensors and actuators in the model. Further, the developed approach reasons with the inherent control function of components (like temperature controlling components, flow controlling components, etc.) and their topological sequence to identify all components that influence each control process. At the end, it outputs a checklist that states all control processes along with a list of all AHU components that influence each control process.

These reasoning mechanisms were implemented in a prototype that takes the BIM of an AHU as an input and generates a checklist of all temperature and flow related control processes with the AHU and all components that influence each control process. The paper provides the results of the initial experiments conducted over a case study project.

2 Background

The primary function of an AHU control system is to maintain ambient parameters of a space at pre-determined set points. These parameters such as temperature, flowrate, etc. controlled by an AHU are called controlled variables. A component like valve, damper, etc. that reacts to a signal is a controlled device. A series of actions, induced by controlled devices to manipulate controlled variables related to air or water, is called a control process. The role of controlled devices within a system depends on their inherent functionality. The roles of AHU components relevant to this study are - to enable movement of air/water through the system (flow-moving); to control the movement of air/water through the system (flow-controlling); and to enable transfer of energy between two different air/water streams in a system (energy-conversion). Each controlled device may also influence more than one control process within a system through its interactions with other system components. For example, a hot water pump next to a heating coil influences the control of hot water flowrate through the pump directly and indirectly influences the control of air temperature due to its interaction with the heating coil. This study emphasizes the interdependence of a component's inherent functionality and its impact on other control processes due to its topological relations relative to other components in the system. To ensure that the controls are accurately verified during commissioning, this information about each components' inherent functionality and indirect impact on other control processes needs to be captured in SOOs. The following sections summarize various points of departure for this study.

2.1 Previous research related to information requirements of HVAC SOOs

2.1.1 Standards and Guidelines

While no industry standard exists in identifying information requirements for HVAC SOOs, there are several guidelines published by ASHRAE that provide guidelines to generate SOOs.

ASHRAE Guideline 13, 2014 [2]:
Summary: This guideline provides suggestions in developing specifications for Direct Digital Controller (DDC) systems for HVAC control applications and provides guidance system architecture, input/output structure, communication, program configuration, system testing and documentation.
Gaps in standard/guideline: 1. This guideline does not assist mechanical designers in verifying the completeness of SOOs; 2. It does not guide mechanical designers to identify information items to be included in SOOs.

SOOs for common HVAC systems, ASHRAE, 2005[3]:
Summary: This document includes a set of 28 SOOs for various AHU configurations. Each SOOs has text version, control schematic diagram, object lists and control model summary for the AHUs.
Gaps in standard/Guideline: 1. It does not provide guidance about adapting the SOOs for other types of AHU configurations; 2. Only focuses on SOOs for AHUs and no other components of HVAC systems; 3. Does not provide guidance of testing the implemented controls based on these SOOs.

ASHRAE RP-1455 SOOs (ASHRAE GPC-36, 2018) [1]:
Summary: This specification contains a set of 13 SOOs for air distribution and terminal variable volume systems. The document contains: (a) list of hard-wired points; (b) control diagrams; (c) sequence of operations; (d) programming parameters, settings and variables for the systems.
Gaps in standard/guideline: 1. It does not provide information of the approach used to identify the information items represented in the document for extending the document to other types of systems; 2. It does not provide guidance for testing the implemented controls based on these SOOs; 3. The findings of this research project were not validated to be generalized.

2.1.2 Previous research studies

Several researchers acknowledged many challenges

involved in interpreting HVAC controls' design intent from SOOs and addressed various aspects of these issues. Using the Function-Behavior-Structure (F-B-S) framework proposed by [7], the information requirements of SOOs from the past research was categorized and summarized in Table 1. Examples of information items for each category of the F-B-S framework according to previous researchers are listed in bold in the second column in Table 1.

Table 1. Information requirements of SOOs based on Function-Behavior-Structure framework

Category	References
Functional requirements	**E.g.: Be time efficient, Provide comfort, etc.**
Static information items	[4] [9] [15] [16]
Behavioral requirements	**E.g.: Heat absorption rate, response time, etc.**
Run-time information items	[10] [11]
Energy performance related information items	[10] [11]
Structural requirements	**E.g.: Geometrically interconnected components, Logically and physically interconnected components, etc.**
Relational information items	[9] [13] [15]
Constraints and heuristic information items	[5] [8]

It is required that the SOOs narrate about all control processes and relevant controlled variables and controlled devices to clearly convey the controls' design intent. Currently, as there is no formal approach to identify all the information items to be included in the SOOs, the mechanical designers are unable to verify the completeness of SOOs effectively. Hence, there is a need for a generalized approach to identify all the information items to be included in SOOs of a given HVAC system to validate the completeness of SOOs. The following sections describe the proposed research approach and reasonings that were developed to address this need.

3 Research Approach

Since the reasoning mechanisms and data representation are interdependent, all data schemas that are currently used in the industry to represent HVAC controls design information were analyzed. Table 2 presents the coverage of data schemas to represent various controls related information items that were identified under each category listed in Table 1.

Table 2. Analysis various data schemas related to HVAC controls to represent SOOs related information items

	Information items identified under each category listed in Table 1	**IFC4***	**COBie***	**HVACie***	**BAMie***	**BRICK**	**EnergyPlus**	**gbXML***
Static information items								
1	Type of controlled variables / devices	X		X	X	X	X	X
2	Sensor unique id	X			X	X		
3	Component unique id	X		X	X		X	X
4	Control set points and schedules	X			X	X	X	X
5	Functional role of a controlled device							
Run-time information items

2	Efficiency and capacity	X		X	X		X	X
Relational information items								
1	Topological relationships	X		X	X	X		
2	Functional relationships						X	X
Constraints and heuristic information items								
1	Impact of components on all control processes							
2	Performance limitations						X	X

**IFC4 – Industry Foundation Classes 4; COBIE: Construction Operations Building Information Exchange; HVACie – HVAC Information Exchange; BAMie – Building Automation Modeling Information Exchange; gbXML – Green Building XML schema*

As can be driven from Table 2, none of the data schemas that are currently used in the industry represent all information items to be included in the SOOs to enable automated controls Cx. This study specifically focuses on identifying all components influencing each temperature and flow control process in an AHU. This can be achieved by determining the functional role of all controlled devices in the AHU. Although none of the data schemas can currently be used to represent the functional role of components within an AHU, reasoning with other static information items can help determine this. Other static information items required to be represented in HVAC SOOs are mostly represented by IFC4 and BAMie schemas. BAMie is a model view definition of the IFC4 schema, i.e. it is a sub-set of IFC4 schema. Hence, the reasoning mechanisms to identify the functional role of components were developed for an input file represented in IFC4 format. The subsequent sections present the vision and reasoning mechanisms that were developed.

3.1 Proposed Approach

The developed approach, which automates the process of determining the identification of components that directly or indirectly impact temperature and flow control processes in an AHU, consists of two major steps as shown in the shaded boxes in Figure 1. The approach takes an AHU represented in IFC4 format with all enumerations of sensor types and distribution system types as an input and outputs a list of all control processes and all components that directly and indirectly influence each control process. For example, the hot water heating coil in the AHU shown in Figure 3 directly influences supply air temperature and the hot water pump indirectly influences the air temperature by maintaining the hot water flow.

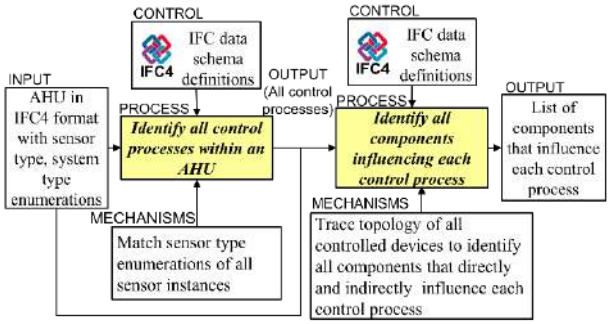

Figure 1. Proposed envisioned reasoning mechanisms

IFC4 schema has classes defined for sensors, controllers and different controlled devices. The two steps in the proposed approach rely on the sensor type enumerations, system type enumerations, component inherent functionalities and topological relationships of all components defined in the input IFC4 format file to identify each control process and components that directly and indirectly influence it. Figure 2 presents a flowchart showing the various reasonings that were developed in this study. The flowchart shows some sample results in bold-italics.

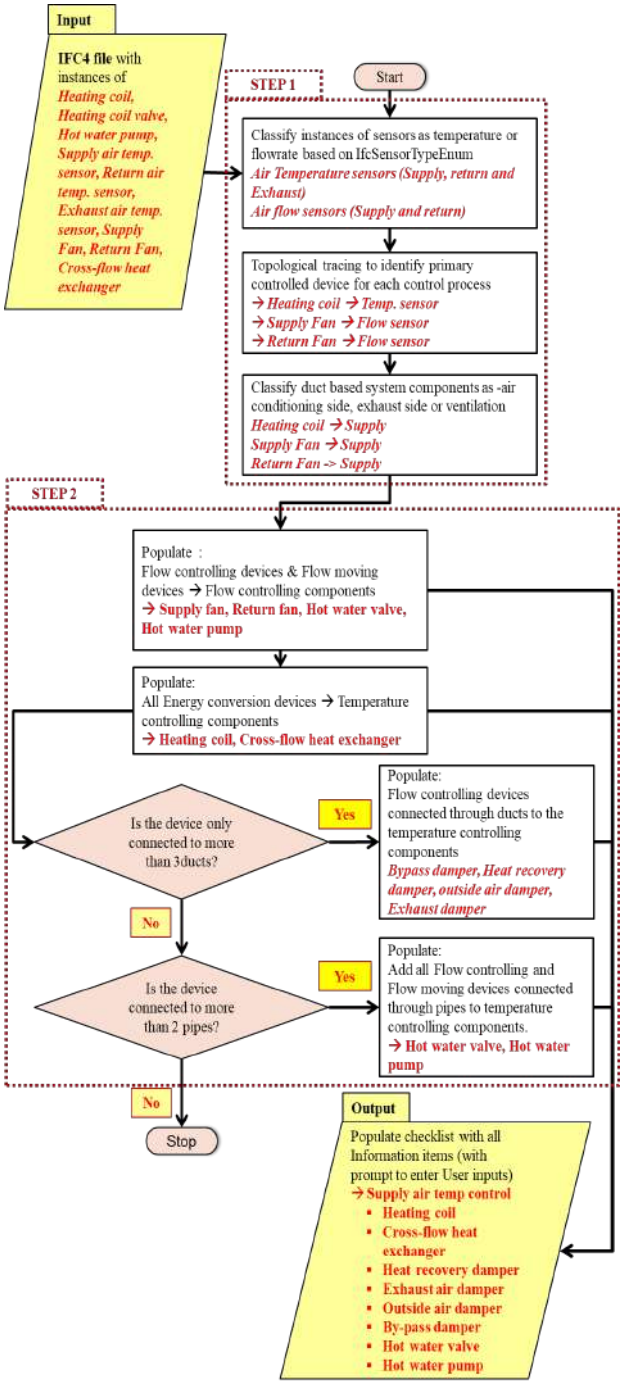

Figure 2. Flowchart showing the proposed reasoning mechanisms implemented in the prototype

Currently, many of the existing BIM authoring tools do not directly allow defining these enumerations. For the purpose of this study, enumerations of all components (IfcDistributionSystemTypeEnum, IfcFlowDirectionEnum and IfcSensorTypeEnum) within the testcase were manually populated. Figure 3 shows the AHU that was used as the test-case for this study.

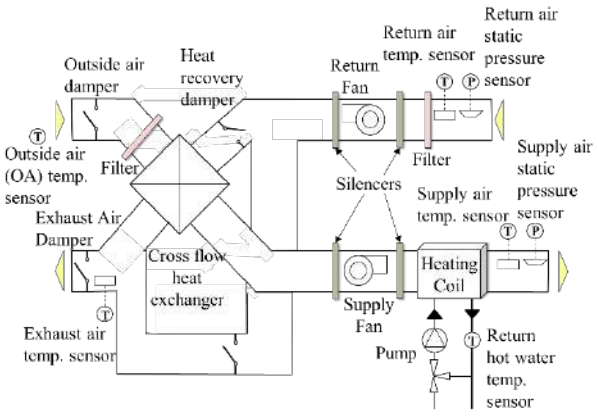

Figure 3. An AHU used as a test case for the study

3.1.1 Step 1: Identification of all temperature and flow related control processes

The first step in the proposed reasoning mechanisms is to identify all the control processes within the system. This step also involves the identification of the primary controlled devices influencing the control process and its relative location within the system to determine if it indirectly influences other control processes. For example, the supply air temperature sensor in the test case in Figure 3 is determined based on its sensor type enumeration (TEMPERATURESENSOR). Due to the relative location of the heating coil and the cross-flow heat exchanger occurring before the supply air temp sensor, it is determined to primarily impact supply air temperature control process. The reasonings are explained below:

Step 1a – Matching of sensor type enumerations for each sensor instance to identify control process types:

According to the principal of design for closed loop control systems, each control process uses the measurements from sensors at the end of a control sequence to send feedback to the controller about the controlled variable. The functioning of a controlled device is adjusted based on the feedback until the desired measurement is received from the sensor. Hence, knowing the types of sensors defined through the IfcSensorTypeEnum class helps in identifying the types of the control processes in a system. Since the scope of this study is limited to air temperature and flow related control processes, an instance of a sensor with FLOWSENSOR enumeration can be used to identify flow related control process and an instance of a sensor with TEMPERATURESENSOR enumeration can be used to identify temperature related control process. These two enumeration definitions for IfcSensorTypeEnum class are listed in Table 3.

Table 3. Enumerated item definitions for IfcSensorTypeEnum class relevant to this study in IFC4 schema

Enumeration	Definition	Reasoning
FLOWSENSOR	a device that senses or detects flow in a fluid	Match enumeration to flow control process
TEMPERATURE SENSOR	a device that senses or detects temperature	Match enumeration to temperature control process

Step 1b – Topological tracing to identify primary controlled devices associated with each sensor:

Further, knowing the topological location of the sensor with respect to other system components can help in identifying the specific control process, whose output is being measured using the sensors. This step involves tracing the sequence of AHU components to identify the energy conversion devices preceding temperature sensors and flow moving devices immediately preceding the flow/pressure sensors in an AHU. Since sensors can only measure the impact of preceding components in a control sequence, the proposed reasoning only looks for components preceding the sensors in a given AHU configuration. Also, all components are connected to each other through flow-fittings like ducts, pipes or cables. Since these flow-fittings do not directly influence the control processes, if a flow-fitting is directly preceding a sensor, the next preceding energy conversion device or flow moving device are identified respectively. The sequence of components in the AHU can be determined by the component's ports that connect to the adjacent component. IFC4 schema defines four different types of ports using IfcFlowDirectionEnum. Table 4 presents the definitions that were used in this study. SOURCE port corresponds to the outlet and the SINK port corresponds to the inlet of any component. The flow direction of air and thereby the sequence of AHU components is determined by the connections of source of a component to the sink of the adjacent component. For example, the supply air temperature sensor in Figure 3, has a duct connected to its source port. Further, the sink port of the heating coil is connected to the source port of the duct. Hence, the air flows through the heating coil to the duct to the sensor.

Table 4. Enumerated item definitions for IfcFlowDirectionEnum class in IFC4 schema

Enumeration	Definition	Reasonings
SOURCE	A flow source, where a substance flows out of the connection	Component connected to SOURCE port occurs prior in the sequence
SINK	A flow sink, where a substance flows into the connection	Component connected to SINK port occurs after in the sequence

Step 1c – Matching of distribution system enumerations and topological tracing to identify all control processes:

For each control process, once its type and the controlled devices primarily associated with it are determined, its context within the AHU (i.e., if it belongs to the supply side, return/exhaust side) is identified by matching the enumeration of the abstract class IfcDistributionSystem for each primary controlled device identified. This is required as the same type of control process can occur on the supply and the return side. For example, air flow is controlled by both the supply and return fans. All components that can be connected to ducts (since this study only involves AHU components) have three possible enumerations, based on the definitions in IfcDistributionSystemEnum. All control processes associated with components with AIRCONDITIONING or VENTILATION enumeration are classified as supply side control processes. All control processes with components with EXHAUST enumeration are classified as return / exhaust side control processes. Table 5 presents the enumerations for IfcDistributionSystemEnum class for duct-based systems used in this study.

Table 5. Enumerated item definitions for IfcDistributionSystemEnum class for duct-based systems in IFC4 schema

Enumeration	Definition	Reasonings
AIR CONDITIONING	Duct-based systems with this enumeration are meant to maintain temperature range within one or more spaces;	Match enumeration as supply side components
EXHAUST	Duct-based systems with this enumeration are meant to remove air from or more spaces;	Match enumeration as return / supply side components
VENTILATION	Duct-based systems with this enumeration are meant to either exchange or circulate outside air to spaces in a building;	Match enumeration as supply side components

3.1.2 Step 2: Identification of all components that influence each control processes

The second step of the reasoning mechanism is to identify all components that influence each identified control process in Step 1. This involves determining the inherent functionality of all components within the input IFC4 file through abstraction. For example, the supply fan is represented by an instance of IfcFan. The super-class of IfcFan is IfcFlowMovingDevice. All instances of sub-classes of IfcFlowMovingDevice influence flow related control processes based on the defined inherent functionality in IFC4 schema. Further, it is important to understand the interaction between control processes related to air flow and air temperature within an AHU. Temperature related control processes may involve direct heat transfer, air-to-air heat transfer or water/refrigerant-to-air heat transfer. While no additional components are involved for direct heat exchange, components that influence air temperature control for air-to-air and water/refrigerant-to-air heat exchange are identified through classification of component types and analyzing their configuration. The reasonings for step 2 are explained below:

Step 2a: Identification of inherent control functionality of all components through abstraction to associate with the identified control processes:

Inherent control functionality of HVAC components is defined at superclass level in IFC4 schema. Various control functionalities of components are defined as sub-classes for IfcDistributionFlowElement class. Instances of subclasses (e.g., IfcFan, IfcPump) of IfcFlowMovingDevice are used to define components that initiate the movement of fluids within an AHU. Instances of sub-classes (e.g., IfcDamper, IfcValve) of IfcFlowController are used to define components that regulate the flow of fluids through a system. All components that are instances of sub-classes of IfcFlowMovingDevice and IfcFlowControllingDevice define the occurrence of a device to control or enable flow of fluids through a system. All instances of sub-classes of IfcEnergyConversionDevice influence temperature related control processes based on their inherent functionality as defined in IFC4 schema. The other sub-classes of IfcDistributionFlowElement (e.g., IfcFlowFitting, IfcFlowTerminal, etc.) are not relevant for this study as their inherent functionality as defined by their abstract class do not influence air flow and

temperature within an AHU. Figure 4 shows the relevant class hierarchy at which the inherent functionality of various components can be determined.

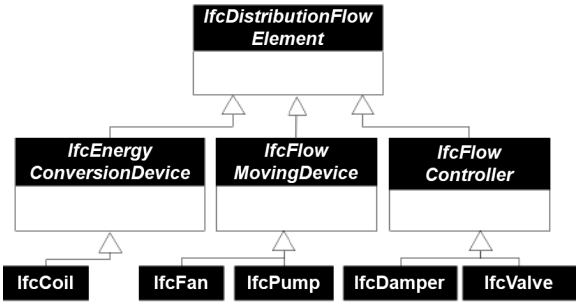

Figure 4. Subtypes of IfcDistributionFlowElement in the IFC4 schema relevant to this study

Step 2b: Identification of components influencing temperature control processes involving air-to-air heat transfer:

Air-to-air heat transfer resulting in air temperature related control processes can be identified based on the number of ducts connected to the instance of energy conversion device. Energy conversion devices can be classified as air-to-air heat transfer devices if they are connected to more than three ducts at their ports. The configuration of one air stream through an energy conversion device can have a maximum of three ducts – entering, leaving and exhaust (optional for pressure release). Hence, energy conversion devices with more than one air stream passing through them would have more than three ducts connected to them. Flow controlling devices immediately next to these air-to-air heat transfer energy conversion devices help modulate temperature of air. For example, the cross-flow heat exchanger in the test case modulates the flow air supply and return air streams. Dampers adjacent to the cross-flow heat exchanger are also used to control the supply and return air, but their purpose is to control the temperature by modulating air streams through a heat-exchanger.

Step2c: Identification of components influencing temperature control processes involving water/refrigerant-to-air heat transfer:

Water/refrigerant-to-air heat transfer resulting in temperature related control processes in an AHU can be identified if an energy conversion device is configured to be connected to a maximum of three ducts that correspond to one air stream and at least two pipes connected to it that correspond to one water or refrigerant stream. These correspond to an air stream and another stream of water/refrigerant through pipes. The first flow moving device and first flow controlling device connected to the pipe immediate after the water/refrigerant-to-air energy conversion device help modulate the temperature of air through the component. For example, the hot water heating coil in the test case enables water-to-air heat transfer to control the supply air temperature. The hot water valve and the hot water pump immediately next to the coil modulate to influence the control of temperature of air through the coil.

3.2 Prototype development and discussion

The described reasoning mechanisms were developed with the aim of identifying all temperature and flow related control processes within an AHU. Further all components that influence each control process are identified in a customized way through abstraction, classification and configuration analysis of each component. A prototype was developed with the proposed reasonings to identify the contextual functions of components in an AHU.

The prototype was created and the reasonings were verified using the test-case AHU shown in Figure 3 to see if it captured all the temperature and flow control processes and the components that directly and indirectly influence each identified control process. Table 6 presents the results identified by the prototype. Since no components precede the return air temperature sensor, no components were identified for the control process.

Table 6. Control processes and the components directly and indirectly influencing them identified by the reasoning mechanisms in the prototype

Control process identified	Components identified to directly and/or indirectly influence the control process
Supply air temp control	Heating coil, heat exchanger, heat recovery damper, outside air damper, by-pass damper, hot water valve, hot water pump
Return air temp control	-
Exhaust air temp control	Heat exchanger, outside air damper, heat recovery damper, by-pass damper
Supply air flow control	Supply fan, outside air damper
Return air flow control	Return fan, heat recovery damper, bypass damper, exhaust air damper

As a summary, reasoning mechanisms to identify components that directly and indirectly influence air temperature and flowrate in an AHU were developed and verified using a testcase. Future research in this study will focus on determining components that directly and indirectly influence other types of control processes within an AHU like humidity, CO2 level, etc.

4 Conclusion

This paper highlights the information items that need to be included in SOOs for HVAC systems based on the Function-Behavior\-Structure (FBS) ontology structure. FBS ontology structure is a proven robust descriptor of designs and designing process [7]. Reasoning mechanisms were developed based on function and structure ontology to identify temperature and flow related control processes within an AHU. Also, the components that influence each control process through abstraction, classification and their configuration analysis. Future research in this study will be extended to other control processes within an AHU such as humidity, CO2 level, etc. Also, future work will extend data schemas and reasoning mechanisms to enable automated extraction of all information requirements for HVAC SOOs identified in this paper.

A Chatbot System for Construction Daily Report Information Management

J. Cho[a] and G. Lee[a]

[a]Department of Architecture and Architectural Engineering, University of Yonsei, South Korea
E-mail: jkun86@naver.com, glee@yonsei.ac.kr

Abstract –

Consistently updating, analyzing, and managing construction-related information is one of the key success factors in project management. Quite a few construction projects have recently started to utilize instant messaging (IM) applications such as Slack, WhatsApp, and WeChat as a communication channel among project participants to share daily construction information due to easy accessibility. However, general contractors are still required to manually extract and integrate the data from instant messages to compose daily reports. This is because the data inputted by subcontractors through IM applications are usually in an unstructured form and the IM application is not normally interoperable with the systems database especially developed for construction management. To solve this problem, this study proposes a chatbot-assisted construction daily report data management system. The chatbot in the proposed system collects and processes the required information through conversations with subcontractors, and automatically generates and shares a daily report for general contractors. A prototype system has been designed and implemented to prove the concept.

Keywords –

Construction daily report; Chatbot; Instant messaging application

1 Introduction

Consistently collecting and analyzing construction management related information, such as the schedule and cost, is very important for successful project results due to the inherent risks and uncertainty of the construction industry. Therefore, a systematic communication plan or process between the general contractor and subcontractors needs to be defined for efficient data collection.

However, it can be problematic if all participants do not utilize a unified communication channel or if a low level of technical understanding about the system prevents them from using it. Nevertheless, the use of everyday instant messaging (IM) applications at construction sites has been on the rise as a channel of information exchange. There are many advantages to using popular IM applications, such as interoperability with external systems, searching for information, and exchanging files.

In addition, chatbot technologies can be deployed. A chatbot is a service that provides a communication interface with users based on rules or artificial intelligence (AI). An AI-based chatbot answers based on the understanding the intentions of texts from users using natural language processing (NLP), while rule-based chatbot can answer only when detect predefined expressions[1]. When using chatbot technologies that understand intent and context from a user's utterances, and provide the necessary information through an interactive interface, there is the potential to support the user's efforts to collect and unify information. Therefore, this study presents a chatbot system model that collects construction daily report data through conversations with users, such as general contractors and subcontractors, and automatically generates daily report.

This paper is organized as follows. First, the requirements of the chatbot system are defined through the literature review. Then, the system architecture and dialog model for the two main functions of data extraction and report generation are explained. Finally, the functional feasibility was validated through the development of prototypes.

2 Literature Review

2.1 Limitations of Previous Studies on Construction Daily Report Systems

Many studies have suggested a system model for troubleshooting time-consuming and inefficient processes performed each day for collecting data and creating construction daily reports.

Russell et al. emphasized the importance of readily and reliably collecting data while presenting an early model of the computing system [2]. However, even with

the advantages of storing and utilizing information, the proposed early system model was not able to relieve the burden on the business because the manager still had to input all the information at construction field. In a case study lead by Yan-chyuan et al., a system model in which a daily report module extends its functionality by incorporating the estimation, pricing, and accounting system to enable cost management [3]. However, it was also not clearly defined for the main body to enter the necessary report data.

Subsequently proposed system models were designed to allow subcontractors to enter construction daily report data. The system model designed by Chin et al. would reduce a manager's tasks and enable plan-completion management by entering detailed level of work items by subcontractors [4]. More recently, a number of BIM-based cloud computing software programs, such as BIM360 and Procore, allow for effective construction project management by reflecting the system model explained above.

However, while this software provides strong management functionality, it has a major issue in that the systems require users to have a high level of technical understanding. Several factors, such as lack of education programs and low levels of subcontractor technical expertise, have been cited as the main cause of the problem with regards to using a unified platform [5].

2.2 Possibilities and Limitations in Current Use of IM Applications for Daily Report Information Collection

Recently, participants of quite a few construction projects have communicated using IM applications originally developed for nonbusiness purposes [6].

IM applications can provide better management capabilities when coupled with external management systems, such as a BIM-based construction management system explained above. However, due to the lack of connectivity, managers are currently required to spend additional time reformatting, integrating, and re-entering the same information.

This study proposes a "chatbot" as a solution to such redundant and manual data-input problems. In the construction domain, NLP has been mainly used for analysis of documentations for checking code compliance [7], retrieving similar project cases [8], and managing safety factors [9]. However, there are no studies utilizing NLP for construction daily report related data management.

In order to automatically manage information related to the construction daily report through communications with the chatbot, the specific model of the chatbot system needs to be designed to understand the messages from the users, to automatically extract the necessary information or store it in the database, and to automatically generate relevant documents for users.

3 Requirement and Coverage Definition of the System

3.1 Requirement of the System

The system requirements defined through the literature review are as follows:

1. The chatbot system should be able to extract the information related to the daily report from the messages or through the conversation with the chatbot and automatically store it in a linked database.
2. The chatbot system should be able to generate reports automatically based on information from the database.

With respect to the first requirement, it is necessary to define which types of information should be handled by this system. In this research, information types are defined based on prior research by Song [6]. Song has analyzed conversations that have taken place using IM applications on seven actual construction projects. Through the analysis, "date," "name of company," "types and number of labor," "types and number of equipment," and "work items" have been defined as primarily shared information types through IM applications. Figure 1 is an example message for daily reporting, including the five information types used in construction projects.

With respect to the second requirement, automatically created documents are defined as including "project name," "date," "total number of units per labor type," "total number of units per equipment type," and "work item list" as shown in Figure 2.

In order to calculate the total number of laborers and equipment used, the sum of the numbers entered by different subcontractors must be determined.

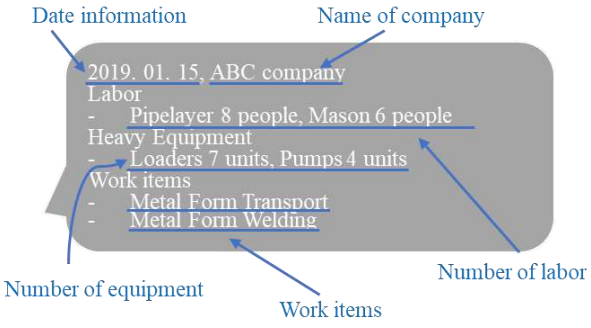

Figure 1. Mainly shared information types in an example user message for daily reporting

3.2 Coverage of the Defined Information Types in the System

In the case of labor and equipment, it has been determined that it is generally entered in a structure that follows the order of "type," "quantity," and "unit name," such as "Mason 6 people" in Figure 1. Therefore, in this study, a regular expression (regexp) approach is applied to detect the types "number of labor" and "number of equipment."

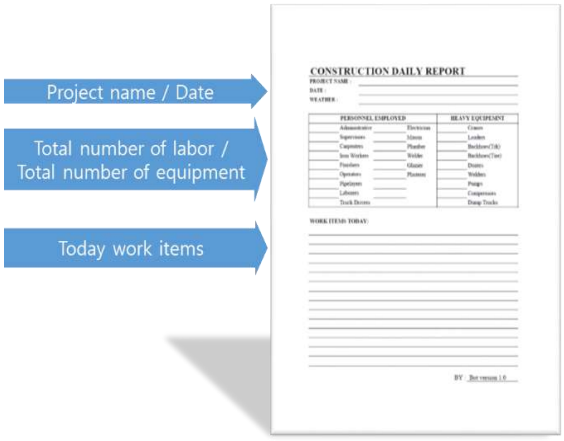

Figure 2. defined report format and included information types

In defining the regular expression for the "number of labor" and "number of equipment," because the detailed items of both types may vary depending on the breakdown structure applied, the items in Table 1 are temporarily defined as labor and equipment items that the system deals with.

Table 1. Temporary breakdown structure of labor and equipment covered by the chatbot system

Labor types		Equipment types
Carpenter	Electrician	Crane
Supervisor	Mason	Loader
Ironworker	Plumber	Backhoe
Glazier		Dozer
Operator		Welder
Pipelayer		Pumpcar
Truck driver		Compressor
Plasterer		Dump Truck

Individual input about work items for the day is designed to be made through a dialog with the chatbot because it is determined that a phrase about work items for the day follows a declaration expression such as "work item" in Figure 1 and is not entered in a structured form.

The architecture of the chatbot system to meet the defined requirements will be explained in the next section.

4 Design of the Chatbot System

The architecture of the system to meet the above requirements is designed as shown in Figure 3. This system consists of a web application, a chatbot module, and a back-end module that connects to IM applications.

The web application receives the text input from the user through the IM application and transfers it to the chatbot module. The chatbot module then analyzes the messages from the users and generates a responding sentence or call using several functions of the web application and utilizing the back-end module.

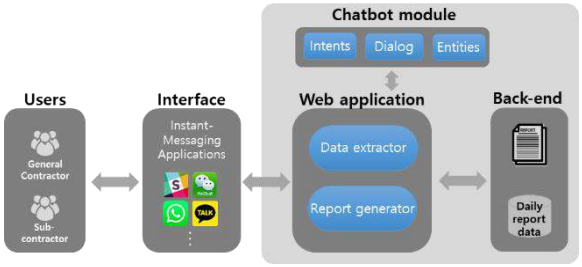

Figure 3. The architecture of the proposed system

The chatbot is an AI module based on Natural Language Processing (NLP) and it plays a role in understanding sentences that are received from users and then producing appropriate responses. The chatbot module is composed of "intent," "entity," and "dialog." Intent represents the purpose of the input by a user. All types of requests users made by users are defined as intent.. Entity means a term or object related to intent. Entity is used to provide a specific context for intent. Dialog is a branching conversation flow that defines responses to the defined intents and entities.

The web application consists of a "data extractor" and "report generator." Both modules are activated by function calls derived from the analysis results of chatbot modules.

The back-end system includes a database for storing extracted daily construction information obtained through message analysis and a file system for managing daily construction documents that are generated automatically upon user request.

In the following section, the design of the dialog model, intents, and entities for information input and report generation in the chatbot module are explained.

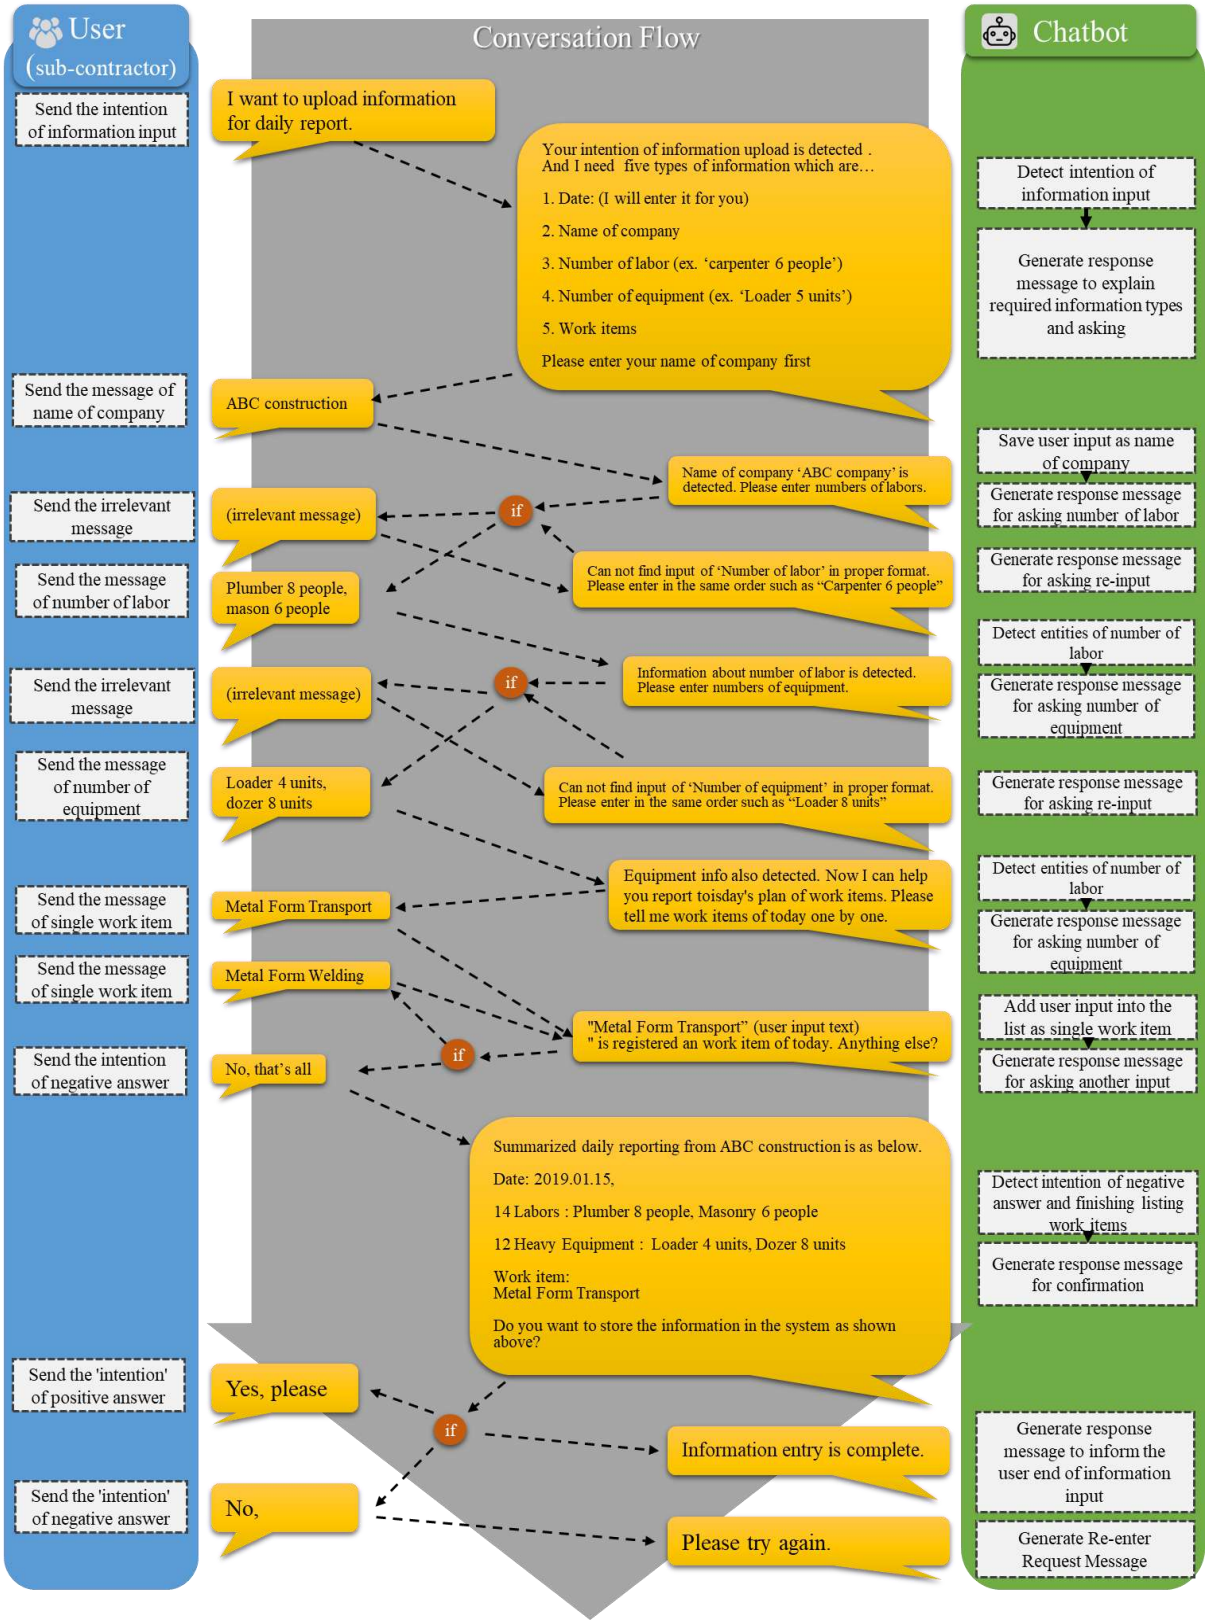

Figure 4. Dialog design for information input

The dialog model includes example messages between the user and the chatbot. Messages from the chatbot are generated by detecting one of the predefined "intents" and "entities" based on the context of the dialog.

4.1 Chatbot Module Design for Information Extraction

First, the dialog model for information extraction has been designed as illustrated in Figure 4.

The conversation begins with the chatbot detecting a message, representing the intention of the user to input information. Subsequent conversation flows are designed for chatbot to ask users for information in the order of labor, equipment, and work item. Finally, it is designed for the user to receive a final confirmation message generated by summarizing the information.

Table 2. Defined intents and examples of user utterances

Intent	Example expressions
Information input	"I want to upload information for the daily report" "Information input for daily report"
Positive answer	"Yes, please," "Great"
Negative answer	"No, it isn't," "No"

The types of intent to cover the dialog model defined above are given in Table 2. All the example expressions from users are necessary for the NLP training of the AI chatbot. The intent "information input" is designed to start a conversation process about information extraction with the chatbot. The "positive answer" and "negative answer" are designed for the confirmation step in the last part of dialog.

Table 3. Defined entities and value types

Entity	Value type	Structure description
Date	Patterns	Combination of year, month, and day
Name of company	Synonyms	Synonym from predefined list
Number of labor	Patterns	Combination of type, number of quantity, name of unit (Figure 5)
Number of equipment	Patterns	

The types of entity are defined in order to detect the types of information and extract them from the user messages as designed in Table 3. The remaining four information types were defined as "entities" for this dialog model, except for the non-structural form of work item mentioned previously.

The intent type "date" borrowed the most common form of structure, and the intent type "name of company" is defined as matching the text within a list of company names.

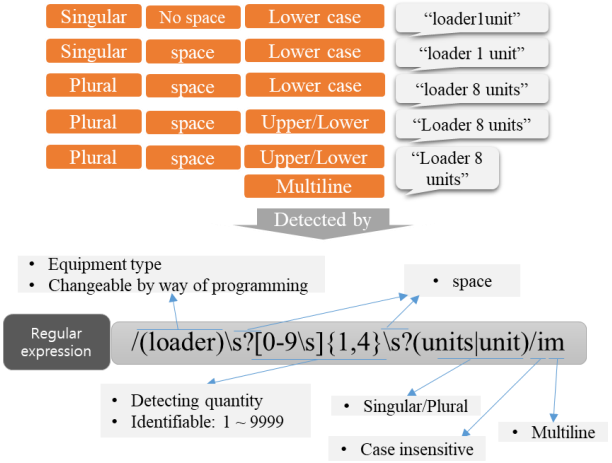

Figure 5. Designed regular expression approach for entity detection

Intent types "number of labor" and "number of equipment" takes the identical approach with regards to the pattern. Figure 5 describes the structure design of the regular expressions for recognizing the example text for the number of equipment. The pattern structure consists of "equipment type," "number of quantity," and "name of unit." The regular expression structure also includes consideration for "singular and plural form," "existence of space," "upper case and lower case," and "multiline" for the text from users.

Although Figure 4 explains the longest possible flow of conversation, based on the defined types of entities, it is also possible to have a scenario in which the chatbot module extracts all of the information for each of the four types from a single message sent by the user.

4.2 Chatbot Module Design for Report Generation

The dialog model for daily report generation has been designed as illustrated in Figure 6. The conversation begins with the chatbot detecting a message representing the intention of the user to request a document. Subsequent conversation flows are designed for the chatbot to ask for the user's e-mail address to send the generated document. The conversation is finished when the user receives an e-mail with the generated daily report.

This dialog model is designed for short conversations; only one type of intent "requiring document" is designed. Several example expressions, including the message

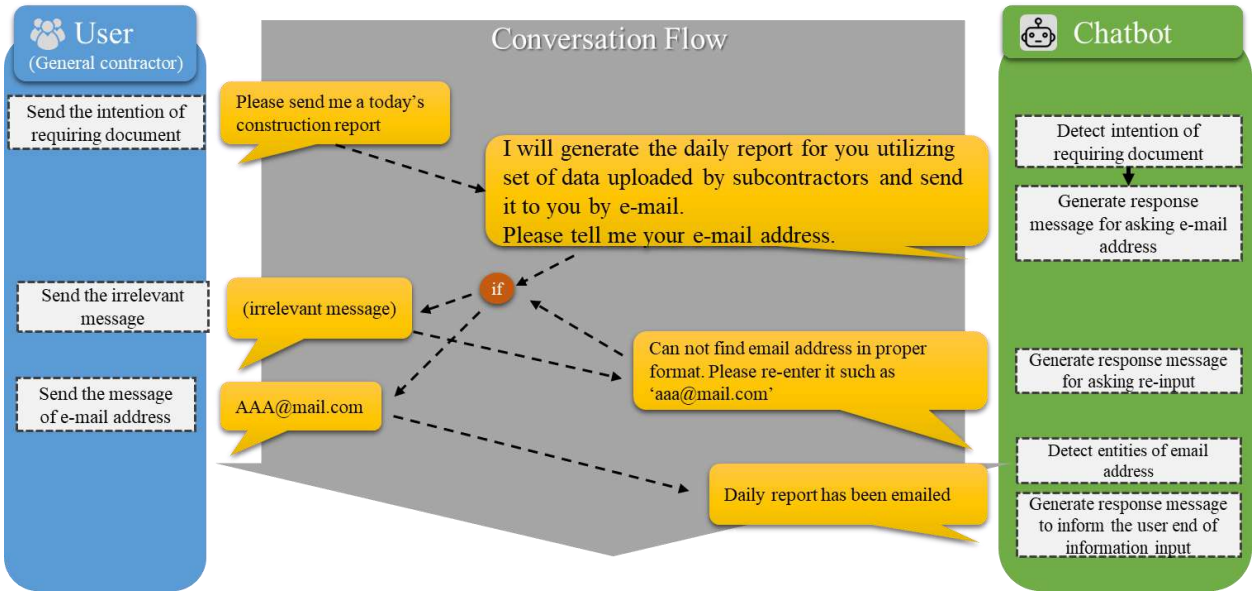

Figure 6. Dialog design for daily report generation

"Please send me today's construction report," are required for AI training as shown in Figure 6.

A single entity type is defined to obtain an e-mail address from a user in regular expression pattern.

It is also possible to skip this dialog in actual system implementation because once the system saves the email address, or has alternative information such as a phone number, the chatbot can automatically generate the documents and send them to the user on a regular basis at a defined time.

5 Prototype Implementation

5.1 Configuration of the Prototype System

A prototype of the proposed system as depicted in Figure 7 was developed to check the functional feasibility to determine how well it satisfies the requirements identified in the requirements analysis phase of system development.

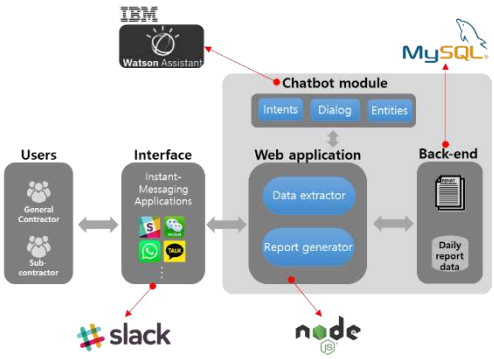

Figure 7. Configuration of the system prototype

First, the collaborative platform Slack, a well-established IM application, has been utilized for connecting users and the chatbot system.

The chatbot module has been implemented with Watson Assistant, which is an AI as a Service (AIaaS) provided by IBM for designing and implementing chatbots.

The web application has been implemented as a Node.js application. Node.js is an open source development platform for executing JavaScript code server-side. In the development of the Node.js web application, several packages shared through NPM (Node Package Manager) are included as dependencies of the system as explained in Table 4.

Table 4. Utilized packages for Node.js web application in the prototype

Name	Role
botkit	Integrating IM application and chatbot service
Express	Providing web application framework
Node-MySQL	Handling database
XLSL	Generating and updating excel file
Nodemailer	Sending e-mail

The "botkit" package has been utilized to integrate

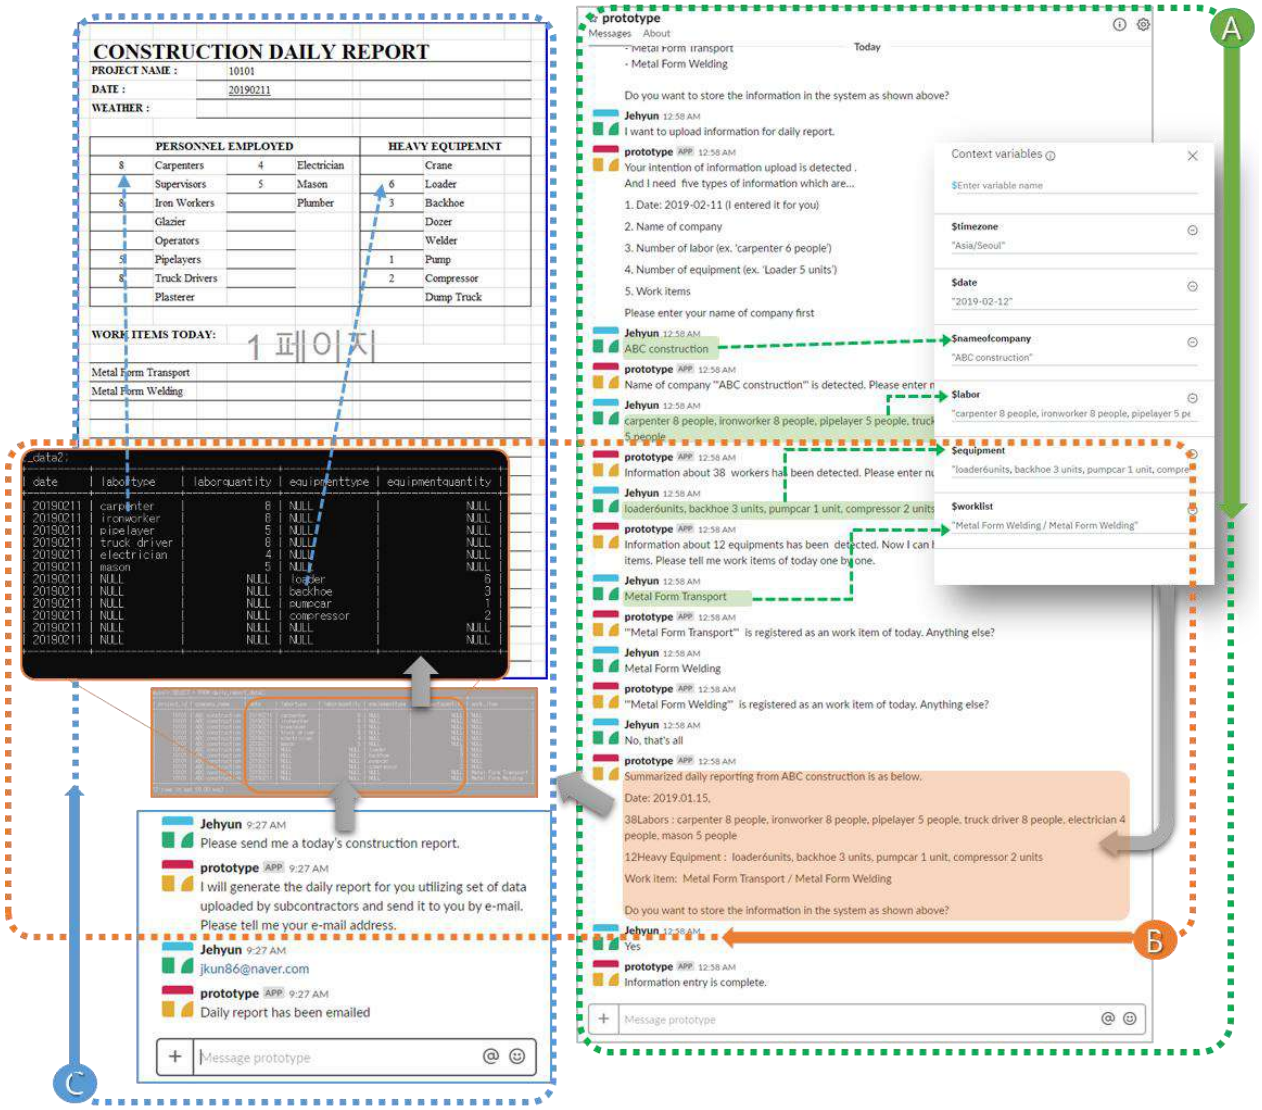

Figure 8. Implementation of the dialog models in the prototype system

the IM application and the chatbot service, which are Slack and Watson Assistant in the prototype. The "Express" package has been utilized for operating the server. The "Node-MySQL" package has been utilized for handling the database. The "XLSX" package has been utilized to generate and update the Excel file for the daily report. The "Nodemailer" package has been utilized to send emails to users.

The database system has been implemented with MySQL, which is a popular open source database.

5.2 Implementation of the Designed Dialog Model in a Prototype System

Data collection and automated report generation were tested using the prototype system based on predefined dialog models.

First, as depicted in area A of Figure 8, it is confirmed that, except for the "date" information, information related to the "name of company," "number of labor," "number of equipment," and "work items" was properly extracted from user messages, saved in the form of context variables during the process of conversation, and finally utilized for generating confirmation message.

Following this, as described in area B of Figure 8, user-confirmed data was parsed and stored by the web application as multiple rows in the database. In the case of "number of labor" and "number of equipment," quantity information was extracted and stored separately from the structured text such as "8" in the example "Carpenter 8 people,".

Finally, as shown in area C of Figure 8, a document was automatically generated by the web application by entering the information from the database into the

report's Excel form, which is predefined in advance when requested by the user.

5.3 Discussion

Through the experiments, the chatbot system has been identified as a functional and feasible system model that is expected to provide the following benefits:

- It can serve as a basis for enhancing management functions because IM application data is no longer volatile; it is now part of the system environment.
- This system model is beneficial to both user groups. The subcontractors do not require any special courses in the system input process, and the burden of data collection and documentation is reduced for the general contractors.

Nevertheless, the proposed system model has some problems to overcome at the current level.

- In the case of labor and equipment, the structure of text was borrowed from a previous study. However, for the "work items," because each subcontractor has a different work breakdown structure (WBS) and the text of the message is mixed with information about the work location in an unstructured form, it needs to incorporate a cognitive approach based on standardized WBS and LBS (Location Breakdown Structure).
- Due to the nature of the interactive interface, compared to the visual user interface, it is necessary to extend the dialog model in terms of convenience to meet various user scenarios. For example, it may be possible to modify only some of the total information entered, or to re-check the information entered.

6 Conclusion

This study presented a chatbot system model that automatically extracts information related to the construction work daily report exchanged in IM applications and automatically generates the construction daily report. The proposed system model includes a chatbot module, web application, and database. Several types of "intents" and "entities" are defined as needed for the conversation between users and the chatbot, along with dialog models. Detected information through the conversation between the user and chatbot could be utilized by the web application for data extraction and document generation using a database.

The prototype was developed and validated to determine whether the chatbot system can perform functions related to the requirements of data extraction and document generation.

The proposed system is expected to provide benefits for subcontractors in terms of ease of use and for general contractors with regards to reducing the effort to collect and document information. In addition, studies required for structural recognition of work items and functional range extensions for other management purposes, such as schedule and cost management, are further expected.

Abstract –

Conventional demolition approaches of razing a building at the end of its life-cycle generate a large amount of mingled debris, which is difficult to reuse and recycle. Compared to demolition, deconstruction involves disassembling a building systematically and it is a more environmentally friendly alternative. Recent research studies have focused on the transition from demolition to deconstruction to minimize the amount of generated waste and maximize the amount of recycling and reusing material. However, due to tight schedule requirements, extra labor cost, and the lack of drawings and design information, it is difficult for an owner to estimate the cost and duration of deconstruction ahead of time. 3D imaging technologies, such as laser scanning and image-based 3D reconstruction, provide an opportunity to obtain data about as-is conditions at a job site and hence can potentially help in identifying quantities of materials that will be recycled. Existing 3D imaging workflows have two primary limitations: visibility and appearance ambiguity. First, 3D imaging can only capture visible objects before a deconstruction process starts. Also, data captured before deconstruction or at different times during deconstruction can only include a subset of all building components. Second, building components with similar appearances can be made from different materials, resulting in misclassification and errors in quantity estimation. Only a few case studies have discussed how visibility and appearance ambiguity can affect the usage of 3D imaging in deconstruction waste management. In this paper, the authors aim to illustrate the application of 3D imaging during a small-scale deconstruction project in Pittsburgh. Specifically, the authors documented the waste generated during deconstruction manually and by using two different 3D imaging technologies: laser scanning and image-based registration. We then quantified the number of invisible objects and objects with ambiguous appearances at different stages of deconstruction. Through the comparison between the quantity takeoffs from 3D imagery and the ground truth, the paper aims at providing insights on the following questions: 1) How accurate are the quantity estimation and documentation of two 3D imaging technologies (laser scanning and imagery) compared to the actual waste generated? 2) Does 3D imaging capture all components of interest during deconstruction?

Keywords –

3D Imaging; Demolition; Deconstruction; Waste Management; Laser Scanning; Image

1 Introduction

The paper starts with an introduction of challenges encountered in deconstruction projects and review how previous research aimed to address these limitations.

1.1 Background

The demolition projects in the US generated over 547 million tons of demolition debris in 2015, which had tripled compared to the 170 million tons of debris in 2005 [1]. Over 30% of demolition debris had become landfill without being adequately recycled [2]. Demolition often generates mingled waste, which might contain hazardous materials, such as asbestos, lead, PCBs and medical waste [3]. With the concerns mentioned above, several researchers have proposed utilization of deconstruction instead of demolition to systematically disassemble a building into reusable components [4–7]. As governments all over the world publish stricter waste management and landfill regulations and guidelines, such as [8], deconstruction is becoming an important alternative to conventional demolition approaches.

Many barriers need to be overcome for a successful transition from demolition to deconstruction. For example, deconstruction projects often require a longer period and extra labor cost compared to demolition ones and such extra time and cost deter owners from adopting deconstruction approaches [9]. Deconstruction planning also requires a more accurate quantity takeoff than demolition. First, the feasibility of a deconstruction

project heavily depends on the value of salvaged material. Therefore, owners need an accurate quantity takeoff to support an economic assessment for a deconstruction project [10]. Second, deconstruction allows for preservation of a reusable component to maximize its value, such as keeping a reusable door rather than a 30-pound wood [11]. In a demolition project, waste quantity is usually estimated by using waste index inferred from historical data [12] and quantities from related deconstruction databases [13,14] of materials, which cannot satisfy the two requirements mentioned above.

Deconstruction projects also require prior knowledge of an existing building to facilitate planning and selection of disassembling procedures [10]. For example, a deconstruction project manager needs prior information of a building to estimate how long a project will take, how many workers are needed during deconstruction, and how much material can be recycled. However, as-built documents are often not available for buildings to be deconstructed. For example, 169 out of the 433 buildings demolished in Portland in 2016 had no as-built drawings information while the rest of buildings had drawings that were obsolete and hence were not reliable for deconstruction planning [15].

Another challenge when shifting from demolition to deconstruction is the need for detailed documentation of removed components. In a demolition project, the amount of recycled material is often measured by landfill diversion rate, which measures how much waste has been diverted from landfills and can be conveniently calculated using landfill receipts [16]. In comparison, documentation during deconstruction requires to record categories, quantities, and specifications of each component to support future recycling and potential tax reporting [5].

Several researchers have proposed many approaches, such as Building Information Model (BIM)-based deconstruction planning, reality capturing, and design for deconstruction, to address the limitations above [6,10,17]. The section below overviews these related research works and discusses their strengths and limitations.

1.2 Previous research

Previous research on obtaining information to support deconstruction waste management can be broadly categorized into two groups: 1) retrieving information from as-designed documents and 2) retrieving information from as-captured data. For instance, many researchers have been using Building Information Model (BIM) to facilitate the planning and waste management during demolition and deconstruction [5,6,17,18]. With an up-to-date BIM, it is convenient to generate an accurate quantity takeoff and a detailed deconstruction plan [19]. However, BIM is usually not available for most buildings to be deconstructed as mentioned in Section 1.1, which generates extra labor and time cost for manually creating a BIM for a deconstruction project.

Reality capturing through 3D imaging, such as laser scanning and RGB-D images, have become an active research topic in the Architectural, Engineering, and Construction (AEC) industries to capture the as-is status of a building [20]. For instance, Scan-to-BIM approaches that convert point clouds captured by a laser scanner to an integrated BIM are widely used for progress monitoring, as-designed and as-is comparison, and facility management [21–23]. Structure-from-Motion methods that reconstruct a 3D model from images are also well studied in the past ten years [24,25].

Previous case studies on using 3D imaging in deconstruction projects have focused on reconstructing a BIM from point clouds captured before deconstruction begins and generating quantity takeoffs from the reconstructed model [26,27]. However, many concerns exist about the possibility of using existing reality capturing approaches in deconstruction projects. The first concern is related to occlusion. For instance, Liu et al. reported that a data collection event with three laser scans for each room could only capture about 40% of the total components [28]. Most facility components are invisible due to occlusion before deconstruction begins, which will affect the completeness and accuracy of quantity estimation. While using progressively-captured data during deconstruction can possibly mitigate the occlusion problem, it raises new concern about the balance between data collection frequency and component coverage rate. Another issue is around identifying which 3D imaging technology would be more suitable for supporting deconstruction projects, especially due to the need for efficiency. This paper aims to provide insights on these issues through a case study of a deconstruction project.

2 A case study of using 3D imaging in a deconstruction project

Section 2 will first provide an overview of motivating problems associated with the case study, and then briefly introduce the project settings.

2.1 Problem statement

As mentioned in Section 1.2, existing reality capture approaches are faced with many challenges when used for deconstruction projects. This paper introduces the application of two types of 3D imaging - laser scan and imagery – in a small deconstruction project and examines the following questions in detail:

- Completeness: What portion of a building can be captured through 3D imaging at different stages of a deconstruction project and how will it affect the

quantity estimation?

- Quantity Estimation Accuracy: Can 3D imaging technologies provide accurate geometric information to support quantity estimation?
- What is the cost of using a 3D imaging in a deconstruction project, including labor hours, data collection, data processing, and data storage?

2.2 Project information

The case study was conducted on a two-story house job site with an area of 500 ft^2, consisting of a living room, a kitchen, a restroom, a bedroom, and two mechanical rooms. Figure 1 shows the exterior look of the building to be deconstructed.

Figure 1. The front view (left) and back view (right) of the building to be deconstructed

The goal of the deconstruction project is to reuse most structural and facility components in a new construction project, including but not limited to interior oak, roof panels, appliances, doors, windows, solar thermal systems, decking and lumbers. There are 125 groups of components to be recycled in total. Table 1 shows an example list of components.

Table 1. Example list of components to be recycled

Category	Components
Structure	Cypress plywood
	Cedar exterior cladding
	Laminated Veneer Lumber
	Structurally Insulated Panels
Doors and Windows	Fixed window
	Awning window
	Metal door frame
	Door wood
Appliances	Light fixtures
	Hand sink
	Solar photovoltaic panels
HVAC	Air diffuser
	Flex duct
	Insulated piping

The deconstruction of the building was mostly conducted manually with the help of a crane for lifting only. Since the building was designed for research purpose, it has a full set of design drawings and a 3D model, which provided useful information for pre-deconstruction planning. In the actual deconstruction process, the deconstruction team identified all components to be recycled from drawings and the 3D model first, created a detailed deconstruction plan, and then performed the actual disassembly. Figure 2 shows the interior disassembly plan for structural components. There are corresponding deconstruction plans for mechanical rooms, appliances, and exterior structural components respectively. A crew with about 20 students was involved in deconstruction activities. During deconstruction, once a component is removed from the building, the deconstruction team documents the component and uses the record as ground truth to evaluate the 3D imaging approaches discussed later.

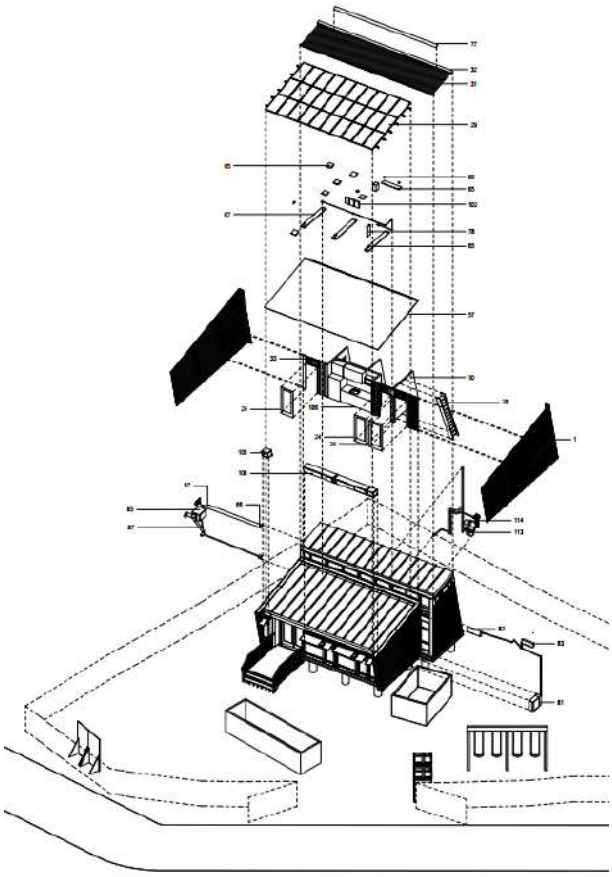

Figure 2. Interior disassembly plan for structural components (Figure generated from the 48-719 Architecture Design Studio: AECM UDBS course material taught at CMU during Fall 2018)

2.3 Application of 3D imaging technologies in the deconstruction project

Two 3D imaging technologies were used in this

project to collect data for the purpose of quantity estimation and documentation. One is terrestrial laser scanning which captures point clouds at different locations on site and the other one is unstructured images captured by cameras at fixed locations and hand-held cameras together. Below, we will introduce the details of how each technology was used in the deconstruction project.

2.3.1 Laser scanning

In this project, we used a Faro Focus3D S120 laser scanner to capture point clouds of the building. The laser scanner can capture 5 million points per scan with a view angle ranging from 0 to 360° horizontally and 30 to 330° vertically. In addition, the laser scanner also captures a panorama image to facilitate visualization and point cloud registration.

Figure 3. Point clouds captured at different times during the project: (a) before deconstruction, (b) after removing furniture and exterior walls, (c) after removing door and window frames, (d) after lifting the roof

Since laser scanning requires dedicated time for data collection to avoid possible occlusions from moving workers and equipment, we conducted 4 data collection events during the period of deconstruction, each consisting of 6-12 scans covering both interior and exterior of the building. The first scan event was conducted before deconstruction, the second was conducted right after removal of exterior panels, the third was after removal of door and window frames, and the fourth was after lifting of the roof. Figure 3 shows an example data captured from the laser scanner.

2.3.2 Imagery

Images captured by RGB-D cameras, DSLR cameras, and smartphones are also used for supporting deconstruction documentation. Before deconstruction began, we used an Intel Realsense D435 RGB-D camera to capture a set of images around the building. During deconstruction, two DSLR cameras were set up in the front of the building to record time-lapse image sequences. There were also 4-6 cameras moving around the job site to capture working progress and components being removed. At the end of the deconstruction project, there were more than 5,000 images available. Figure 4 shows example images captured during deconstruction.

Figure 4. Example images captured during deconstruction (Top: exterior; Bottom: interior)

2.4 From progressively-captured 3D imaging to quantity takeoff

The goal of using 3D imaging in a deconstruction project is to obtain a quantity takeoff consisting of important entries for cost estimation and activity planning, such as component categories, quantities, dimensions, materials, and recyclability. In this case study, we will focus on extracting categories and quantities from 3D imageries as a primary result. We used following methods to generate a component list and compared it with the manually-calculated ground truth. For laser scans, we manually identified and annotated objects in registered point clouds and measured their dimensions. Figure 5 shows an example of window frame annotations in the captured point cloud.

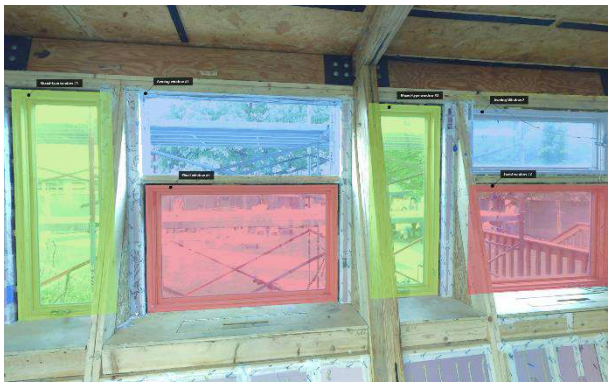

Figure 5. Component annotation from laser scans (red: fixed window, blue: awning window, green: mix-type window)

For images, since there are much more images (~5,000) compared to laser scans (6-12 scans per data collection), it is laborious to annotate objects on images to obtain the number of components. Therefore, for the purpose of evaluation only, we used the ground truth component information extracted from drawings to help identify objects presented on images. A component presented in the digital model is marked as found if at least one image captures the object on site. Similarly, a component presented in a digital model is marked as missing if there is no image captures the object. Figure 6 shows a concatenation of images covering all components of the mechanical room.

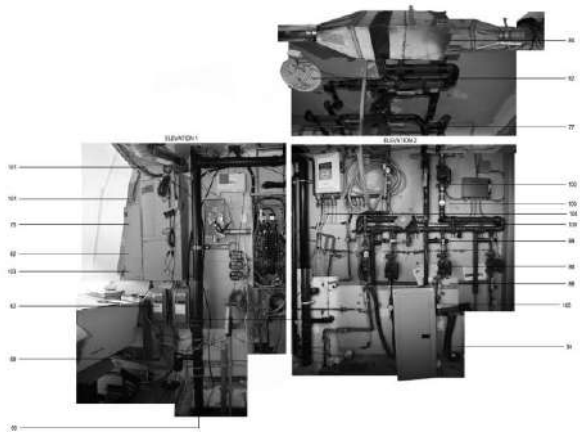

Figure 6. Components identified on images of the mechanical room (Numbers indicate the index in quantity estimation)

Table 2 below shows an example list of quantity takeoff in this case study. In the complete table, we also documented whether a component is recycled, labor hours for removing a component, and whether a component is seen on laser scans and images respectively. The quantity takeoff will be used for evaluation in the next section.

Table 2. Example list of a quantity takeoff

Component	Dimension	Quantity	MasterFormat
Hardwood boards	4’-4’’-2’’	9	061300
Plywood	4’-1’-3/4’’	3	061626
Door track	10’ - 10’’	4	083513
Glass door	8’-3’	1	081710
Structurally insulated panels	12’-9’	6	036866
Cabinets	2’-2’-1’	2	060000
Wash sink	-	1	-

3 Evaluations

In this section, we first define the metrics employed for evaluating the application of various 3D imaging approaches into a deconstruction project. Next, the results are analyzed to demonstrate the benefits and limitations of each 3D imaging technology.

3.1 Metrics

As mentioned in Section 2.1, this case study aims to address multiple concerns of using a 3D imaging approach in deconstruction projects, including completeness, capability of dimension measurement, labor time, and amount of data generated. Below we will talk about the metric used for the evaluation of each perspective.

- Completeness: The completeness of quantity estimation is defined as shown below where the number of identified components is calculated by counting the components that are captured during data collection and the number of total components is determined based on on-site documentation logs. We use the completeness to measure the accuracy of quantity estimation.

$$\text{Completeness} = \frac{\#\ of\ identified\ components}{\#\ of\ total\ components}$$

- The capability of dimension measurement: This metric indicates how well a 3D imaging approach supports dimension measurement, which is critical for quantity estimation. For example, if a user conducts a measurement on the captured data, obtaining a real-size measurement and an up-to-scale measurement that requires correction make a significant difference in quantity estimation.
- Time: We measured the time used for data collection, data processing, and component annotation to evaluate the efficiency of a 3D

imaging method.

- Amount of data generated: This metric measures the space needed to store the captured data.

In the primary experiments below, we ignore two important metrics for the moment: identifiability and dimension error. Identifiability indicates whether a 3D imaging method can distinguish objects with similar appearances. Since in this case study all components are annotated manually, we will leave the evaluation of identifiability after automating the quantity estimation process using 3D imaging. Also, for the metric dimension error which shows how much a measurement on length, area, or volume deviates from its ground truth, we will leave the evaluation for further experiments whose measurements are not performed manually.

3.2 Results and analysis

In this section, we will present the evaluation of two 3D imaging technologies using the metrics mentioned above. In our evaluation, we didn't include all the components listed in the as-designed documents. Small and unimportant components, such as woodscrews and assorted wires, are ignored when evaluating 3D imaging technologies. After selection, we have 1,041 components from 123 categories.

Table 3. Evaluation of using 3D imaging for quantity estimation in the deconstruction project

Metric	Laser Scanning		Imagery	Manual
Completeness	1	54%		
	2	19%	100%	100%
	3	11%		
	4	2%		
	Total	86%		
Dimension	Real-size		Up to a scale	Real-size
Data collection	16 hours		4.5 hours	48 hours
Annotation	20 hours		-	0 hour
Storage	13 GB		2.2TB	22kb

Table 3 shows the evaluation results for each 3D imaging technologies in comparison with documenting quantities manually. There are several interesting points worth discussing:

3.2.1 Completeness

The results indicate that with four laser scanning events, we can capture about 86% of the total components that need to be recycled. Specifically, the first data collection event consisting of 12 scans can only capture 54% of the components of interest, indicating that directly using scan-to-BIM approaches to estimate quantities is not very accurate.

Through inspection of the missing objects, we found that the incompleteness of data captured by laser scanning comes from two sources: 1) occlusions, 2) the temporal gap between two laser scans.

Occlusion refers to the problem that some components are invisible until other components are removed. The comparison between the completeness of the progressively-captured data and the one of data captured before deconstruction indicates that capturing data progressively during deconstruction can mitigate the occlusion problem. Figure 7 Metal studs behind the kitchen region are invisible in Scan 1 (left) but become visible in Scan 2 (right)shows how progressively captured data can address occlusions presented in a scene.

Figure 7. Metal studs behind the kitchen region are invisible in Scan 1 (left) but become visible in Scan 2 (right)

If an invisible object in a previous scan is removed before the next round of data collection, it will be missing in the quantity estimation. In our case study, there were 30 solar panels installed on the roof which cannot be captured by a terrestrial laser scanner in the first scan. After lifting the roof, these solar panels were removed between the third and the fourth scan, resulting in one of the primary errors in our quantity estimation.

In comparison, images captured by handheld cameras and time-lapse cameras can cover all objects of interest. Though in this case study we captured more imagery data than usual, the result shows that with enough crowd-sourced image data, it is possible to generate a complete quantity takeoff without missing components.

3.2.2 Dimension measurement

Point clouds intrinsically support measurements and can achieve a low dimension error of ~2-5 mm as reported in previous research [25]. Image-based approaches cannot provide the functionality of measurement unless all images are well calibrated, which limits its application in quantity estimation.

3.2.3 Time efficiency

Table 3 also shows the time used for data collection and annotation to obtain a quantity estimation. For data collection, we only counted the dedicated labor hours in our calculation. Therefore, crowd-sourced images captured during deconstruction activities require the least time to collect. However, when it comes to annotating objects to generate a quantity estimation, it is quite difficult for human beings to annotate over 5,000 images, which originates the need for either reconstructing a 3D model from images or recognizing components automatically. For point clouds, annotating objects manually also took a significant number of hours. Therefore, automation in identifying components of interest will benefit both laser scanning-based approaches and image-based approaches.

4 Conclusions

This paper presents a case study of using two different 3D imaging technologies to support quantity estimation and documentation in deconstruction projects. Through the evaluation of completeness, the capability of dimension measurement, and time efficiency, we highlighted the importance of capturing data progressively during deconstruction and automating the process of annotating components from 3D imaging data. In addition, despite that we have a deconstruction schedule, planning when and where to perform data collection is still challenging during deconstruction. It is necessary to develop an approach to plan progressively data collection events during deconstruction. Also, though imagery data covers all recyclable objects during deconstruction, the amount of data is enormous. Therefore, the next step of our study will be to develop an automated approach to process progressively-captured data from 3D imaging to support deconstruction planning and documentation.

5 Acknowledgement

We would like to acknowledge and thank Professor John Folan, all staffs and students participating in the course 48-719 Architecture Design Studio: AECM UDBS taught in Fall 2018 at Carnegie Mellon University for their help during deconstruction, data collection, and data analysis.

Abstract –
Large construction projects generate thousands of documents that require a careful management. The classification of documents is an important step in document management and control. Construction documents are generated in different formats, many of which are unstructured and contain drawings and images, which makes the task of document classification and control even more challenging. In this paper, a dataset of 5000 documents is used as a case study. Optical Character Recognition (OCR) bounding boxes are applied to extract text from the set of documents. In the next step, two classification methods are applied. One based on a predefined set of keywords and another based on deep learning long short-term memory (LSTM) network. The challenges of the proposed approaches are discussed in relation to OCR bounding box locations with different document layout and how to obtain a set of representative key words for each class. Initial results of the study are encouraging and show that OCR technique combined with text classification is a powerful method for construction documents' control and can reach an accuracy of 92%.

Construction document; Text detection; Classification; Data mining; Optical Character Recognition (OCR); Deep Learning

1 Introduction

Many construction documents are complex and include text, images and drawings, which represent a vital source of information and knowledge regarding a construction project.

Text in construction documents includes important information such as title and number, which can be used to manage and classify construction document. However, not all documents are digitized or machine readable. Therefore, we need to create an image file of any printed document for text analysis. In this case, text is presented as an image in the file. Then, we can use OCR software to convert the scanned text and image into a machine-readable document. Also, it is one of the most used extraction techniques for documents and images [1]. In this paper, the research of OCR in construction industry is reviewed. In the second step, text detection and classification of construction documents are described, then two classification methods are applied on the case study. First classification is based on a predefined set of keywords and the second one is based on deep learning long short-term memory (LSTM) network. Finally, we compared and analyzed the effectiveness of the two classification, and the research results are presented.

2 Related studies

The literature review shows that previous researchers used OCR in construction document for different purposes. Berkhahn et al., (2008) used OCR and Kohonen neural network in construction drawings, in order to extract information about the dimensions of construction parts and inscription texts. Their model checks out all the dimension line points and construction element points to extract the dimension number and text. However; the user needs to check the result and correct the errors [2]. Banerjee et al., (2016) used OCR system to hyperlink engineering drawing documents. They created a hyperlink based on the extracted information, as a result the engineers can quickly navigate between different files. They

achieved more than 94% accuracy on automatic hyperlinking [3]. Also, Banerjee et al., (2017) used OCR engine in (Architecture, Engineering & Construction) AEC industry drawing documents for detection of Elevation Datum (ED) name, and graphical shape of ED, also they used experimental analysis to validate the ED name. The result of their research shows they achieved overall accuracy of 95% for ED detection and accurate destination document text recognition [4]. Another research of Banerjee et al., (2017) used OCR engine for extraction of alphabetic code and text of reference document, for that purpose of creating automatic navigation among architectural and construction documents. Their result shows the OCR has more than 91% accuracy on character level recognition [5]. Seraogi et al., (2017) used OCR engine in AEC to find the correct orientation of the documents based on the information of extracted texts and graphical shapes. They used mixed text/image drawings as their case study and achieved more than 99% accuracy on automatic orientation [6]. Gupta et al., (2018) used OCR engine in AEC to extract the title of the documents. In their method, OCR engine is scanning the information table only to extract the title. Also, they used historical data to increase the accuracy of their model. However, the extracted title should be reviewed by user to achieve 100% accuracy [7].

3 Related software and applications

Several commercial software packages are using OCR technology to extract the document information. Procore is a construction project management software that is using OCR on pre-defined template to extract drawing number, drawing discipline and drawing title. Drawing block text should be on the bottom right of drawing with specific size and location, then the Procore can automatically pre-populate the fields [8]. Docparser is another software which is using OCR engine to extract the text from any document. The user must define the specific locations inside the document and rules to apply on the all documents. Then Docparser will train to find the location of each field. Finally, this software will extract the text from pre-defined location based on regular expressions and pattern recognition [9]. Microsoft Azure is a computer application which is using variety of technologies such as OCR engine for text analysis. It can extract the text from images and documents, which can be used for label recognition, key phrase extraction and enable searching. Microsoft Azure is also using computer vision algorithms for image classification. The user must provide the labeled images to train a custom vision algorithm and create a model, which can classify new images [10]. The biggest problem of existing software is that they are not suitable for documents with variety of templates and their accuracy will significantly decrease in such situations.

4 Methodology

4.1 Dataset preparation

10 different document types and 500 documents from each document type (in total 5000 documents) was selected for case study analysis. All documents were in PDF format, which should be converted to image format for the purpose of using OCR text detection. Adobe Acrobat Pro DC was used to convert PDFs to PNGs. Since the information we want to extract is usually on the first page of each document, only the first page of each document was selected for future text analysis.

4.2 Pre-processing steps for improving image quality

The case study includes different sizes of documents, with different qualities. The resolution of images should be at least 300 DPI for a better text detection result. The first step is to resize all the documents to A4 size (8.27*11.96 inch) which will affect the resolution of images. In the second step, *Matlab*'s image processing toolbox is used for improving the quality of images. It has different function and filters that can be applied to modify the images. *rgb2gray* filter is used to convert documents to grayscale images. *Imadjust* filter is applied to increases the contrast and brightness of the output image and

Median filter is used to remove the noise from the grayscale pictures [11]. Figure 1 shows an original image and the enhanced images using *Matlab*'s image processing toolbox.

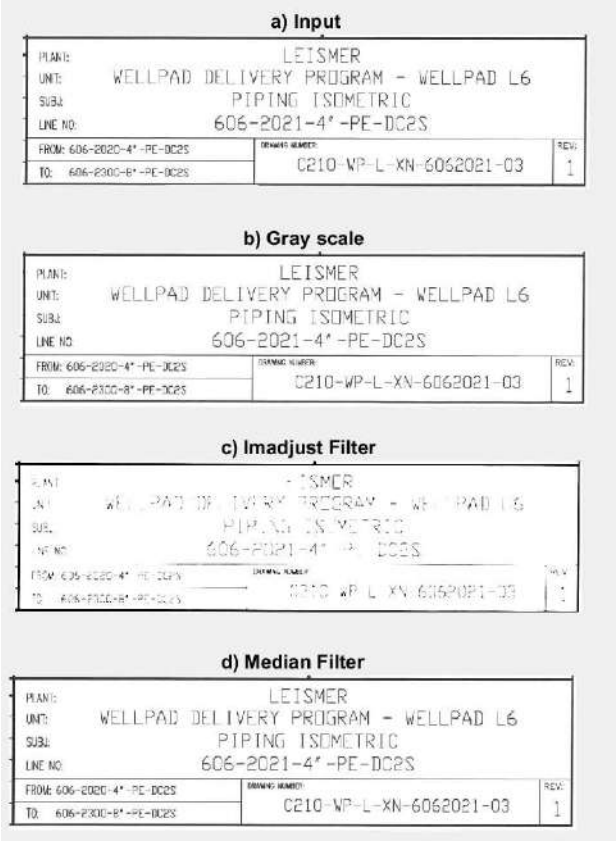

Figure 1: Original image and enhanced images using *Matlab* image processing

4.3 Layout analysis

Layout analysis such as page segmentation and region classification have an important role in text detection. Different regions such as texts, images, and tables should be identified in order to extract the text correctly. Layout analysis defines the possible location of text that needs to be extracted which can increase the OCR accuracy and extract more useful text from each document [12]. As figure 2 shows the dataset has different layouts which needs to classify to text and non-text segmentations.

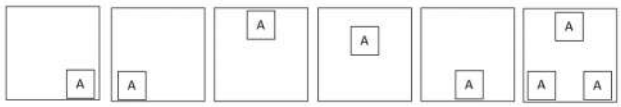

Figure 2: Possible locations of text in dataset

For the case study, connected component analysis was used to classify text and non-text segmentations. Non-text segmentation involves table, image, and lines. In the next step all the text segmentations will be processed through *Matlab*'s OCR in Computer Vision System Toolbox™. Figure 3 illustrates the layout analysis and text extraction in next section.

4.4 Text extraction from Construction Document

Different OCR engines were tested for text detection. The best result for case study was achieved via *Matlab* OCR in Computer Vision System Toolbox™. As figure 3 shows, the following steps were applied [13]:

- Resize the image if needed
- Binarize image (creates a binary image from image)
- Connected component analysis
- Detect text regions using MSER algorithm
- Remove non-text regions
- Provide region of interest (ROI) around the text
- Expand bounding boxes around words
- Dilate image to make letters thicker
- Apply OCR to find as much text as possible in no specific order, even if they are embedded in images.
- Store the detected text in text file format

Matlab OCR can provide the word confidence and character confidence for extracted result. To have a better accuracy, we only accept more than 80% confidence level.

Figure 4. Text extraction steps

4.5 Classification based on predefined set of keywords

In order to process text categorization, we need to provide a list of keywords before classification. The keywords can either be determined by experts in the specific domain of the application or based on historical documents. In case study experiment, we program a *Matlab* tool box to find the keywords in the text files and then assign the appropriate classes to the documents. Based on our case study experiment, we analyzed 5000 documents for text categorization from 3 different construction projects. The accuracy of classification is tested based on 100 documents for each class and it was between 73% to 85% for different classes. However, in this method each document can be assigned to more than one class since each document can contain the keywords of more than one class. The other challenge of this method is reliability of accuracy. The accuracy of classification for a new project that we do not have any samples is questionable. To increase the reliability of the pre-defined keywords, text mining was applied via *Matlab*'s Text Analytics Toolbox™. The purpose of this method is analyzing the most repeated words in each document type, and then unique words were added to the keywords, which can be another option instead of pre-defined keywords for any new project. In this step, the accuracy of classification has increased between 85% to 92%.

4.6 Classification based on deep learning long short-term memory (LSTM) network

Recurrent neural network (RNN) is a class of artificial neural network which is developed during the 1980s [14]. RNN is a repeating model of neural network with different loops to connect the previous information to the present task. When there is a gap between relevant information and output, the RNN is unable to connect the information. A long short-term memory (LSTM) network is a type of RNN which is designed to fill the gap and avoid the long-term dependency problem. LSTM network will take three decisions about the information: decide about the useless information which should be removed, decide about the new information which should pass to the next layer, and decide about the output of each layer [15]. Recently, LSTM is increasingly used to classify text data. Text data is naturally sequential, and LSTM can learn sequences from the training data [16]. Several researchers reported the high accuracy of their text classification result base on LSTM, such as [17], [18], [19]. We used *Matlab*'s Deep Learning Toolbox™ to test LSTM network with a word embedding layer on our dataset. The dataset was imported to the toolbox in .CSV format and it contains two columns: The first one is label of document types and the second column contains the text of each document. In the next step, each word converted to numeric sequences to be use as an input in LSTM network. The LSTM model was defined by hidden layers, and word embedding layer. Table 1. shows the architecture of LSTM network used in our case study. The training model partitioning is: 70% training, 15% validations, and 15% test observations. The maximum number of epochs is 10 and initial learn rate is 0.01. The validation accuracy of classification is between 75% to 83%.

Sequence input layer	1 dimension
Word Embedding Layer	100 dimensions and 87106 unique words
LSTM layer	180 hidden units
Fully connected layer	Number of classes, 10 layers
Softmax layer	softmax
Classification Output layer	Number of outputs, 10 classes
Loss function	Cross entropy

Table1. LSTM architecture

5 Results and conclusion

Document text detection and classification is a challenging task especially for construction documents which includes text, images and tables. The result of case study on construction documents confirmed that OCR is a feasible tool for text detection and the result of that can be used for classification of construction documents. We conducted experiments on large-scale datasets consisting of 5000 construction documents. The first classification was based on predefined set of keywords and most repeated words in each document. The accuracy of this classification was between 85% to 92%. The second classification

was based on LSTM network and the accuracy was between 75% to 83%. The evaluation demonstrated that predefined set of keywords has more accurate result. however, the layout of documents and texts should be analyzed in advance which is time consuming and expensive. LSTM has a better accuracy on new sets of data, and it does not require data analysis. The result of classification can improve if we can increase the accuracy of OCR text detection.

The paper shows that deep learning algorithms such as LSTM has potential benefit to be use in construction documents classification. However, other deep learning algorithms need to be tested. In this paper, we consider the experiments as preliminary result and more data and algorithm should be test in future research.

6 Acknowledgments

The authors would like gratefully to acknowledge the PCL company for providing case study material for this project and their support.

Abstract –

Emergency management can benefit from advanced information and communication technology (ICT), since it can support officers in charge of emergency management to deal with urgent decision within a really short deadline. Further enhancement can derive from the application of holonic systems, which typically deal with the unexpected. In fact, unexpected events may prevent the application of emergency plans, e. g. evacuation of people outside of a building in fire through a network of pre-determined paths.

The holonic emergency management system, proposed in this paper, guarantees the shift to a contingent approach, leveraging the flexibility and adaptability to changing scenarios deriving from the holonic theory. Last but not least, the BIM integration provides all the building's topological information. Such a technology can exploit general data to automatically detect unconventional ways out and arrange rescue operations in real-time. The developed system has been applied to the fire safety management of a large building in a university campus. The BIM model of the case study has been imported in a game environment where an unconventional pathfinding has been experienced.

Holonic System; Emergency Management; Fire Safety; BIM.

1 Introduction

1.1 Building Management System

Building automation systems (BAS), also known as building management systems (BMS), denote a wide range of computerized building control systems, from special-purpose controllers, to standalone remote stations, to larger system including central computer stations. A BAS comprises several subsystems which are connected in various ways to form a complete system. The system has to be designed and engineered around the building itself to serve the services systems for which it is intended. Consequently, although the component parts used may be identical, no two systems are the same, unless they are applied to identical buildings with identical services and identical uses [1]. BMS, with their typical hierarchical structure, are usually able to reach their goals in an efficient way and with no faults, whereas they fail to stick to pre-determined targets in the presence of disturbances. In fact, traditional systems cannot pursue the assigned task if any unforeseen events occur. Their rigid structure makes it very difficult to tackle unexpected scenarios. As low-level modules have to consult higher hierarchy levels in case of a disturbance, their reactivity becomes weak. Furthermore, global decision-making is often based on obsolete information [2]. Building services include HVAC systems, electrical systems, lighting systems, fire systems, security systems and lift systems. In industrial buildings they may also include the compressed air, steam and hot water systems used for the manufacturing process [1].

In this paper, fire and security systems for the emergency management will be studied in depth in order to overcome the limits of the traditional BMS. Emergency management, since directly affects safety of people, represents a relevant issue in each phase of building lifecycle, from a foresighted design of buildings and infrastructures to the elaboration of emergency plans according to specific regulations. Emergency scenarios are even more relevant as case studies, if the high frequency of unexpected events affecting them is considered. The traditional approach to the emergency management is based on a deterministic forecast of main scenarios. The emergency plan resulting from them has a key role, although it does not consider the totality of possible scenarios. As a consequence, it is regardless of contextual, changing and unexpected events that may happen and seriously affect the effectiveness of emergency measures.The limits of such a knowledge-based approach are confirmed by several examples of

complications in the emergency operations. To name one, during the emergency response to the September 11, 2001 attack on the World Trade Centre, commanders on the scene were unable to communicate to '911' Public Service Access Points (PSAP) that people should evacuate the building [3]. As a result, PSAP operators complied with New York City's standard operating procedure for hi-rise fires and advised callers to stay in impacted buildings. The '911' system was inadequate for handling a major disaster and could not adapt to the emergency. The final death toll 2749 may have been substantially reduced if the PSAP's were adaptive in coping with the overload. Moreover, commanders trying to evacuate fire fighters from the north tower during the World Trade Centre disaster were seriously hampered by ineffective radio communications; the final death toll 343 of New York fire fighters may also have been substantially reduced if the system controlling the radio communications was also adaptive [3]. To name another example, the Grenfell Tower fire produced a high number of victims not only for technical reasons, due to the employment of a not proper cladding system and to a lack of separated fire boxes into the building, but also to a mistake in the emergency evaluation [4]. The "stay put" strategy, led by a tardive declaration of the situation as a major incident with the consequent delay of one hour in the evacuation process, has revealed as a fatal mistake in the rescue operations [4]. Furthermore, a traditional emergency plan does not facilitate the operational use. In fact, it remains as a plain-text document which is difficult to consult during an excited situation due to an oncoming danger. In other words, a way out plan hung on the wall cannot help incisively to find a viable exit route. The fire in the Rhode Island station club represents an example of how a not profound knowledge of the building in which people were located affected the evacuation process: a study has demonstrated that people did not use alternative ways out since they ignored their presence [5]. While the main exit doors were obstructed by the smoke presence, there were no indication to use alternative paths to escape from the building; therefore, the evacuation process was affected by a fatal delay [5].

Starting from this shortcomings, the current research proposes a contingent approach which exploits a BIM-based holonic technology to overcome the limits of the traditional BMS. The developed holonic management system integrates a building digital model, which provides all the necessary data for the real-time detection of ways out. This paper is organized as follows. Section 2 provides a description of the system architecture. Section 3 describes the Virtual Reality Platform. Section 4 provides a description of the Bayesian Selector. Section 5 describes the generation of Multi-Target Partial Plans for the considered case study. Section 6 provides a description of the Combiner and shows the simulations results. Section 7 is devoted to conclusion.

1.2 Holonic Theory

The holonic concept, which is the basis of holonic management systems, is the key enabler to tackle unexpected events and overcome the limits of the traditional BMS. The holonic theory was introduced in 1967 by Koestler [6] to explain the evolution of biological and social systems. Likewise, in the real world, where almost everything is at the same time a part and a whole, each holon can be part of another holon [2]. In fact, the word holon is the combination of "holos", which in Greek means "whole", and the suffix "on", which suggests a part [7], [8], [9]. In the manufacturing field, holons are autonomous and cooperative building blocks, since they can both control the executions of their own strategies and develop mutually acceptable plans [2]. Furthermore, holons consist of an information-processing part and often a physical-processing part [2], [7], [8]. The former is responsible for high-level decision making, collaborating and negotiating with humans and other holons, while the latter is a representative of its linked physical component and responsible for transferring decisions and instructions to it [7]. According to Koestler, a holonic system or holarchy is then a hierarchy of self-regulating holons that function (i) as autonomous wholes in supra-ordination to their parts, (ii) as dependent parts in subordination to control at higher levels, and (iii) in coordination with their local environment [2], [6], [9]. Therefore, holonic architecture combines high and predictable performance, which distinguishes hierarchical systems, with the robustness against disturbances and the agility typical of heterarchical systems [8]. In this way, systems' resilience is guaranteed. Holonic management systems, which have been successfully applied in the manufacturing field, can constitute a novel technology to tackle unforeseen scenario variations. Indeed, the autonomy and cooperation of their elementary units, the holons, makes it possible to avoid the rigid structure of hierarchical systems and therefore respond quickly to disturbances [2].

2 System Architecture

The architecture of the developed holonic system, depicted in Figure 1, supports fire emergency management and rescue operation, detecting the most effective way out. Its aim is not to substitute the actual approach foreseen by regulations, rather to enhance the standard emergency plan, detecting unconventional path to exit the building, if an unexpected event occurred. The architectural principles are shortlisted as follows:

- *Real-time effectiveness*: it must regard both the information flow and the decision making process.

Since the system is continuously evolving, especially in complex scenarios like emergencies, it is not feasible to represent all the changing status it assumes, in order to provide the proper solution to the occurring situations. Moreover, the response of the system must be sufficiently reactive in order to result effective to face the situations that are in place.

- *Proactive and unconventional problem solving*: on the basis of the information gathered in a real-time manner, the system, in order to be sufficiently resilient, must be capable to extract the information useful to reach its objectives also by general data, as well as to provide escape solutions with the employment of unconventional means.
- *Resilience*: the system must be reactive and adaptive to the new possible configurations that may occur, without compromising its primary function of managing the emergency scenario. Failure, interruptions, damages to the standard communication backbone systems, as well as injuries or obstructions to the usual evacuation means, must not impede the main objective of keeping people safe during emergencies.
- *Emergent cooperation*: the system architecture embodies the capability of the holons to cooperate in temporary associations, namely the holarchies, introducing the "emergent cooperation". This concept can be described using a metaphor: the behaviour of these agents is similar to the one belonging to the birds of a flock; no one is able to manage flock's shape and dimension, but everyone takes care of maintaining flock's trajectory, flock's speed and minimum distance from its fellows. Although no one of the birds has a complete view of the scene, the behaviour described above is the result of an "emergent collaboration". This kind of cooperation is not so onerous for birds because it is supposed to be integrated within their DNA and, therefore, instinctive. The same functioning characterizes the agents inside the developed architecture.

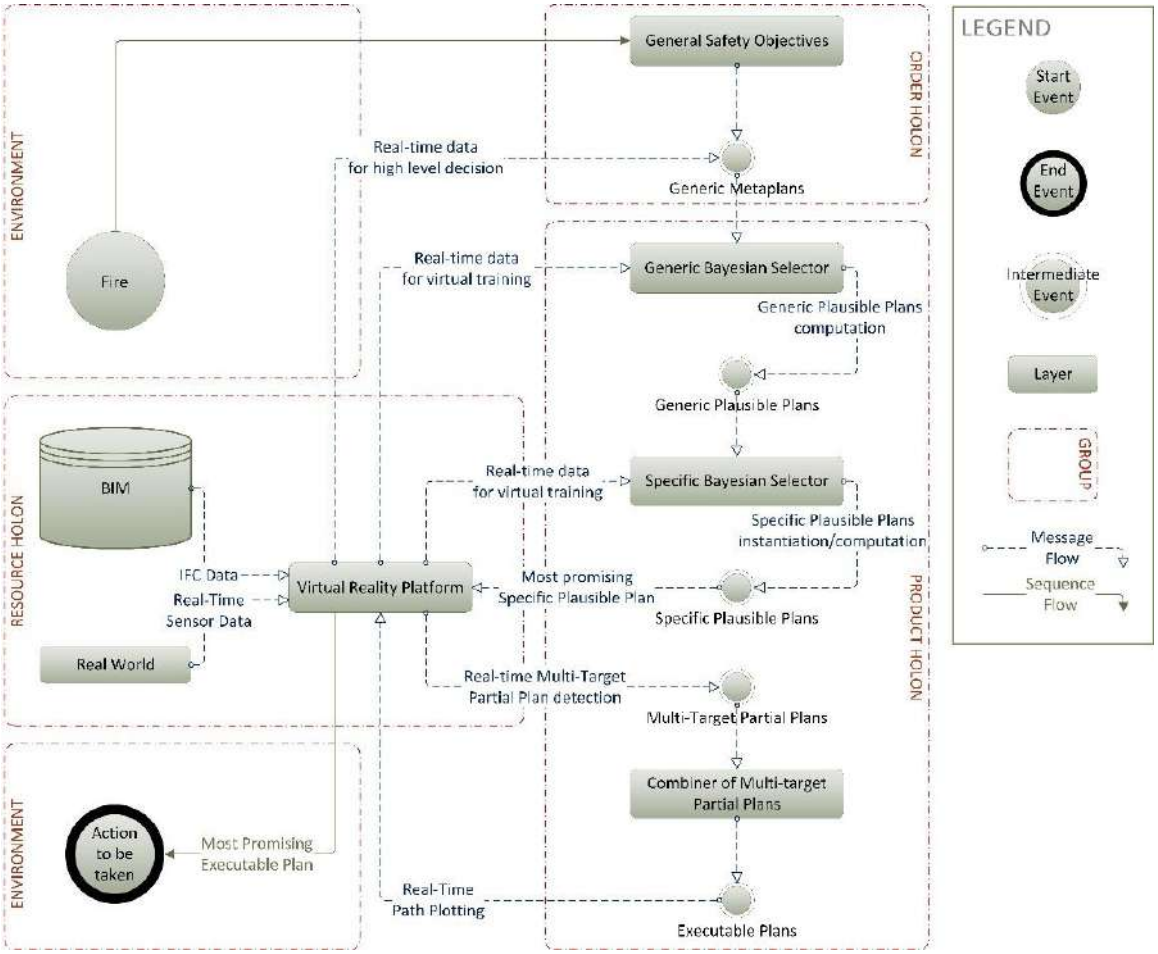

Figure 1. System architecture of the developed holonic management system

The system architecture in Figure 1 is composed by different layers interacting each other according to a publish/subscribe scheme, whose central concept is the notion of *topic*: each node/layer of the architecture subscribes and some other publishes information on the *topic*. In other words, the *topic* is simply the database content itself without intermediate language adapters: the unique language is the database language and its queries. Hence, the architecture layers behave like a human being that only subscribes to interesting events/information and publishes relevant events/information, which are specifically useful for the occurring situation, complying to the actual needs [10].

The different layers can be clustered by function according to the PROSA reference architecture [2], a conceptual architecture for manufacturing control, that has shown great potentialities to be applied also in different context. The acronym PROSA stands for *product-resource-order-staff architecture* and refers to the different types of holons. Three basic types of holons can be distinguished: product holons, resource holons, and order holons. Staff holons are optional and can be added to provide the other holons with expert knowledge [2]. In PROSA, the holons' physical part belongs to the world of interest, that is the part of reality which falls within a certain scope relevant for the application [8]. In Figure 1, the PROSA analogy is highlighted identifying resource, product and order holons. Finally, the environment is the real world scenario where the holons operate, namely the fire occurring and the countermeasures to be taken at the end of the elaboration process.

The highest architecture layers, namely the General Safety Objectives and the Generic Metaplans (see Figure 1), correspond to the order holon, which in the manufacturing system represents a task that needs to be executed, for example the delivery of a package [2]. The General Safety Objectives represents the always valid target: "Save all the people inside the building". As a consequence, the Generic Metaplans are triggered and fed with real-time data from the Virtual Reality Platform. The output of this elaboration are the general processes to be executed, which may be represented by the generic instruction "Stay in/go out" and are published to the following layer. Thanks to the generality of the high level setting, the resilience architectural principle is guaranteed and the resulting system is applicable for every building, without the need to configure it manually every time. This is a key feature that distinguishes the developed architecture from classic BMS.

3 Virtual Reality Platform

The Virtual Reality Platform (VRP) is the heart of the resource holon, which in the logistic context corresponds to resources like all transport means and material handling equipment [2]. In the developed system, the VRP is implemented using the Unity 3D game engine. It has been selected as the most suitable tool because of the following characteristics:

- high interoperability with other software, including the capability to integrate several functional mockups afferent to different engineering disciplines;
- presence of a physics engine that provides physical behaviour to the components of the scene, basically the correct acceleration and the affections by collisions, gravity and other forces, making the simulation of a great likelihood with the real world;
- possibility to introduce artificial intelligence by scripts, based on C# or Java programming languages, or by means of visual programming.

In other words, Unity 3D offers an extremely realistic environment to simulate a fire emergency scenario of the case study and building occupants' behaviour using artificial intelligence. The VRP constitutes a dynamic hub able to collect IFC data from BIM and real-time data from pervasive sensors distributed in the real world. The interconnection with the BIM software Autodesk Revit has been established through an IFC Loader, based on the IFCEngine DLL Library [11]. This component makes it possible to import contextual, geometrical, material properties from the BIM, once exported in IFC format. The interconnection with sensors, which has not been tested in this research step, is one of future developments. The technological solution to this issue is ASP.NET Core SignalR, an open-source library that simplifies adding real-time web functionality to apps. Real-time web functionality enables server-side code to push content to clients instantly [12]. The building digital model, coherently updated during the whole lifecycle, provides in real-time accurate topological information, that goes further beyond the static and poor information usually contained in emergency plans. In this environment, the Unity 3D asset A* Pathfinding Project Pro (A*PPP) [13], applying the A* algorithm, detects the most effective way out. If the usual escape route is obstructed by smoke, fire, collapsed building elements or other kinds of accidents, the A* algorithm can detect unconventional ways out through internal doors. Moreover, BIM is proposed not only as a comprehensive provider of the main building properties, but it is subjected to a proper semantic enhancement: some building elements can be exploited in an unusual way in respect of their main purpose and become evacuation means in an unconventional manner. This contribution appears even more relevant, if we consider the possibility to have random visitors inside building, affected by a poor awareness of the spatial distribution. As depicted in

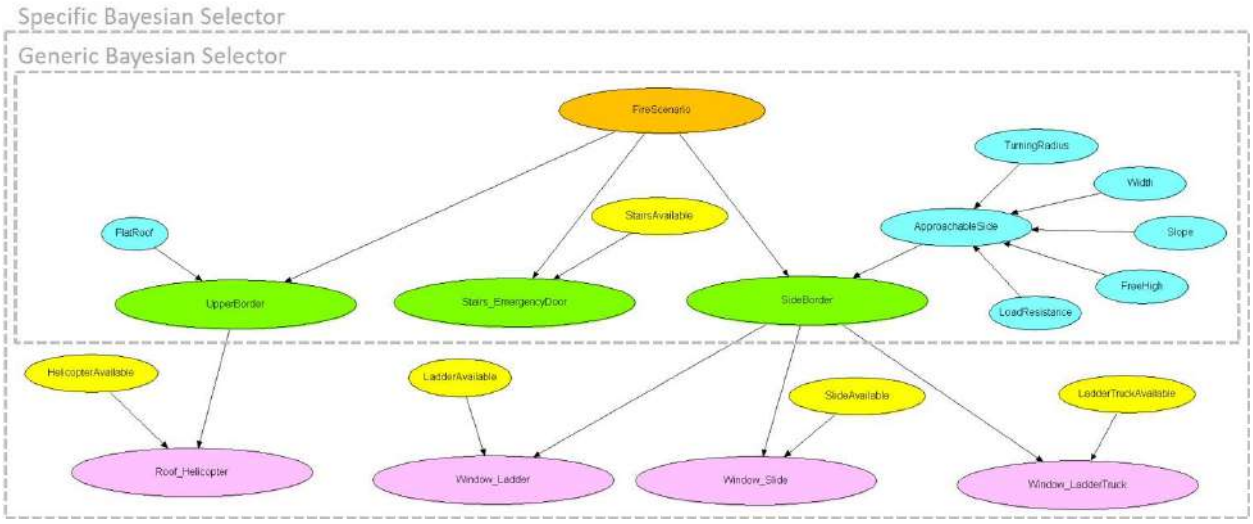

Figure 2. Bayesian Selector

Figure 1, the VRP acts as a collector of heterogeneous data and represents the proper environment where the required knowledge can be produced and published. In this way, real-time data are available for each subscribing layer of the architecture.

4 Bayesian Selector

The Bayesian Selector (BS) is conceived as the translation into a Bayesian network of an expert's knowledge. Bayesian networks, which constitute a powerful mean to represent phenomena affected by a high level of uncertainty, are a probabilistic graphical model that uses Bayesian inference for probability computations. They aim to model conditional dependence, and therefore causation, by representing conditional dependence by edges in a directed graph. Through these relationships, one can efficiently conduct inference on the random variables in the graph through the use of factors [14].

In the fire emergency management, the BS, fed by real-time data from the VRP, detects which strategy or plan is probabilistically the most effective to exit safely the building in fire. As shown in Figure 1Figure 2Figure 1, it is composed by a generic part and a specific one, respectively linked to Plausible Plans and Multi-Target Partial Plans. The Generic Bayesian Selector suggests the most effective preliminary escape strategy (called also Generic Plausible Plan) amongst those ones valid for any building. The Specific Bayesian Selector detects the most promising escape plan (called also Specific Plausible Plan), instantiated for the analysed building. All these layers, according to the PROSA analogy, constitute the product holon, which contains the knowledge on how instances of a specific task type (represented by order holons) can be executed by the resources [2].

4.1.1 Generic Bayesian Selector

The Generic Bayesian Selector subscribes data deriving from Generic Metaplan and is trained by real-time data published by the VRP; as output, the most effective Generic Plausible Plan is computed (see Figure 1). In details, when the "Fire Scenario" (see orange node in Figure 2) is activated by the alarm, the Bayesian network computes which Generic Plausible Plan (see green nodes in Figure 2) should be analysed in depth in order to find a viable exit route. The "generic" attribute means that the Generic BS is applicable for every building. As a matter of fact the green nodes in Figure 2 represent the possibilities to exit any building:

- "Stairs and Emergency Door" represents all the exit routes which exploit stairs and emergency doors. They comprise not only the standard exit route suggested by the emergency plan, but also alternative and unconventional ways out through internal doors connecting adjacent rooms.
- "Upper Border" and "Side Border" represent the building's frontiers where rescue teams could pick up and save endangered people. They comprise only the unconventional ways out, detected when an unexpected event voids the standard emergency plan.

Finally, blue nodes represent building's features (for example "Flat Roof", in Figure 2, stands for "Is the building's roof flat?") whereas yellow ones represent resource availability (for example "Stairs Available", in Figure 2, stands for "Are the building's stairs available/viable?").

4.1.2 Specific Bayesian Selector

The Specific Bayesian Selector integrates the generic one adding the Specific Plausible Plans (see purple nodes in Figure 2). It subscribes data deriving from Generic BS and is trained by real-time data published by the VRP. On the base of these data, the technology described in [15] and [16] is able to instantiate in real-time the Specific Plausible Plans for the emergency management of the considered building. As output, the most promising Specific Plausible Plan is detected (see Figure 1). In Figure 2, four Specific Bayesian Plans, instantiated for the building case study, are reported as examples:

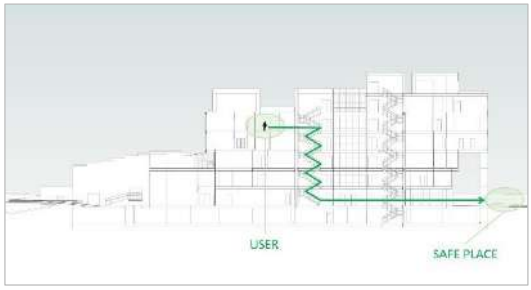
- "Roof and Helicopter" which stands for "Lead people to the roof and pick up them by a helicopter";
- "Window and Ladder" which stands for "Lead all people to the window and pick up them by a normal ladder";
- "Window and Slide" which stands for "Lead all people to the window and use a slide";
- "Window and Ladder Truck" which stands for "Lead all people to the window and pick up them by a ladder truck".

5 Multi-Target Partial Plan

5.1 Description of the case study

In order to implement and test the developed architecture, the mixed-use building "Eustachio", located in Ancona (Italy), has been chosen. The building belongs to a major complex of edifices occupied by the Faculty of Medicine of Polytechnic University of Marche. This eight storeys-building presents a quite regular shape with two major blocks on the north and south side, containing spaces devoted to heterogeneous scopes: classrooms, scientific laboratories, administrative offices for students, a library, books storage rooms, services. The two main blocks are connected by two double stairwells, which present a separate reinforced concrete envelope that makes these parts separated from the block for seismic reasons. The choice has fallen on this edifice for its characteristic of public building with several uses that may involve variable flow of different people inside it: estimated between 100 and 2320 individuals and characterized by several age ranges and, more specifically, owning a different level of knowledge of the building. Finally, the presence of inflammable substances in several laboratories leads to simulate the fire scenario in this building, since this is one of the most common and disruptive emergency situation, often affected by unexpected events and mistakes in the management of the evacuation process.

a.



b.

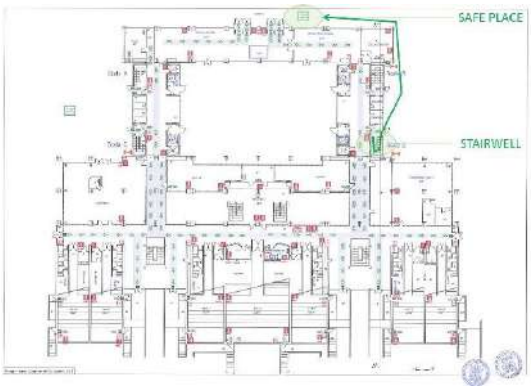


Figure 3. Example of exit route according to the Eustachio's emergency plan: section view (a.) and ground floor plan view (b.)

5.2 Strengths of the system

The traditional approach to the emergency management is based on a deterministic forecast of a finite number of main scenarios. Unfortunately, unexpected events could prevent the effectiveness of the pre-determined paths defined by the standard emergency plan. According to the Eustachio's one, as shown in Figure 3.a. and Figure 3.b.Figure 4, a user, in whatever floor he is, should reach the closest stairwell, go downstairs until the ground floor and, finally, exit the building. It may not be the best solution to run away from a building in fire, especially if an unforeseen event occurs and the usual escape route is unviable. In other words, the obstruction of a path by operators in charge of operation and maintenance or the collapse of non-structural components, like ceilings, may have tragic consequences during a fire. The developed holonic system detects alternatives and unconventional ways out in real-time, overcoming the limits of an a-priori plan. Hence, officers in charge of emergency management can benefit of the proposed system's computing capability and nimbly coordinate rescue operation.

5.3 Generation of Multi-Target Partial Plans

The developed holonic system, as mentioned before, can tackle unexpected events, providing in real-time unconventional paths outwards. More in details, the pathfinding, carried out in the VRP by means of the A* algorithm (see Section 3), detects the Multi-Target Partial Plans (see Figure 4). Given the most promising Specific Plausible Plan, the A*PPP detects automatically all the possible routes towards intermediate points. For example, assuming that the Bayesian Selector has classified "Window and Ladder Truck" as the most effective Specific Plausible Plan, the VRP by means of A*PPP provides the following Multi-Target Partial Plans:

- all the shortest paths (see blue lines in Figure 4) from the endangered user towards all the building's windows, assumed as intermediate points and identified by their GUID (Globally Unique Identifier);
- all the shortest paths (see red lines in Figure 4) from the rescue team, represented for example by the ladder truck, towards the building's windows.

6 The Role of the Combiner Unit

The Combiner of Multi-Target Partial Plans, along with the connected plans (see Figure 1), completes the product holon largely discussed in Section 4. The role of the Combiner is to find the fastest escape route outwards, composed of only one path for each of Multi-Target Partial Plan. Following the example discussed in Section 5 (see Figure 4), the Combiner detects the path composed by the fastest route that leads the user to that window which can be reached and approached in the shortest time by the ladder truck. The detected Executable Plan is then plotted into the VRP and notified both to the endangered user and the rescue team. In this way, both of them can act coordinately towards the same intermediate point, exploiting the emergent collaboration and speeding the rescue operation. Assuming the user and the rescue team starting moving at the same time, the rescue operation lasts as the slower one. For this application path data about Multi-Target Partial Plans are exported into Excel (see Figure 5) to be elaborated. Obviously this process can be automated within the VRP in order to directly detect the viable Executable Plan.

7 Conclusions

The holonic management system, described in this paper, improves the usual emergency management approach, supplying more updated and significant information and investigating unusual solutions for rescue purposes in case of unforeseen events. In fact, the connection with BIM and sensors from the real world provides, in real-time, building's topological information and contextual data. Furthermore, the resilient system, based on the holonic theory, makes it possible to tackle unexpected events by means of unconventional escape routes and support the standard rescue operations.

The developed system architecture, tested in a large mixed-use public building, shows its potentiality through the contribution given to officers in charge of emergency management. The detection of unconventional solutions in real-time helps, in an emergency scenario, to deal with urgent decision within a really short deadline.

Abstract –

Upgrading building envelopes with fully prefabricated 2D modules requires high accuracy during the manufacturing process with tolerances lower than 1 mm. In the research described in this paper, computer designed and accurately manufactured objects have been assembled with robotic arms. However, in previous phases, it was detected that during the assembly process, the placement differed from the planned location due to undesired deviations of the object while being grasped and placed by the robotic tool. The experiments presented in this paper imply correcting this deviation by localizing the grasped object's position and recalculating the path and final pose of the assembly process. For localizing the deviated grasped object's location, an intermediate pose was planned. During this pose, the location of the grasped object was estimated by two different means. For the first solution, visual markers have been placed on a known corner of the objects and these have been recognized with a camera. For the second solution, the coordinates of the objects were measured by a digital theodolite. The location of the deviated object was calculated and compared to the planned location so the robot could divert from its original path. The measurable parameter in the experiments was the assembly accuracy. The results in the two experiments have been analyzed and compared. According to the results, the solutions could be implemented not only in the factory, but at on-site processes as well.

Deviation; Localization; Estimation; Adjustment

1 Introduction

The existing building stock's envelope capabilities need to be upgraded in order to achieve zero-energy consumption [1]. In an ongoing research project named BERTIM [2], timber based prefabricated 2D modules with embedded renewable energy sources (RES) are fixed onto existing building façades in order to improve the insulation of the building and generate energy. According to the objectives of the research project, these 2D modules should be fully prefabricated, which means that no rework should be necessary after fixing the modules onto the façade. As a consequence, on-site installation time is reduced. These fully prefabricated modules need to achieve waterproof and airtight conditions while ensuring fitting ducts [2]. This requires an accurate manufacturing of the modules with very low tolerances of up to 1 mm. In 2D module manufacturing with timber-frames, traditional off-site techniques [3] don't fulfil the demanded accuracy, where tolerances can reach up to 10 mm. In brief, current marketed processes are based on precut studs and beams, which are placed in a carpentry bench according to their position. Afterwards, studs and beams are nailed and the frame is compiled. In the next step, OSB boards are placed and nailed onto the timber-frame and, finally, the OSB boards are cut by a CNC bridge crane.

There are several reasons for such inaccuracies that were pointed out in previous phases of the research [3]. As a solution to these inaccuracies, it was proposed that all the objects of the prefabricated modules should be contoured in a CNC machine and then robotically assembled to create a façade module as shown in Figure 1. In this sense, there is experience in the manufacturing process of CNC routed timber objects [4]. Moreover, there are some experiences that link the design and the robot thanks to parametric design tools [5]. However, besides some exceptions [6], the assembly of studs and boards is mainly achieved manually. The robotic assembly of prefabricated modules is still a process which faces some challenges related to accuracy as well. The remainder of this paper is to define and test a solution related to overcome accuracy issues with the robotic assembly processes.

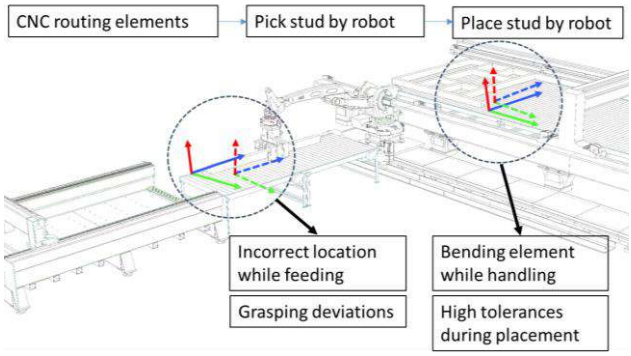

Figure 1. Scheme for a fully robotized assembly of prefabricated timber frames

In Figure 1 it is shown an scheme based on CNC routed elements that are robotically placed into an automated multi-function bridge for the assembly. In previous phases of the research, it was detected that deviations occur mainly while grasping and placing the timber elements by the robot.

2 Challenges of robotic assembly of fully prefabricated (timber-framed) modules

30 years ago, Kodama et al. [7] reported deviations during the grasping and placing of construction blocks while building a wall. These blocks were specially designed for facilitating the assembly process following the robot oriented design (ROD) concept [8]. However, the deviation of the wall built was considerable. Gambao et al.[9] also faced similar issues during the erection of a wall with robots during the ROCCO project. In more recent research projects, ordinary bricks were used to build parametrically designed walls. Bonwetsch [10] reported deviations of up to 10 mm compared to the desired location. Similar deviations happened in a research project that assembled timber profiles for building structures and, for this case, Willmann et all [6] suggested sensor feedback mechanisms in order to allocate the grasped object as well as the assembled module. In the researches explained by Willmann and Bonwetsch [6, 10], the objects to be assembled don't present any special joining system such as ROD, which in turns does not facilitate the allocation of the parts or elements with each other. On the other hand, some timber-framing machine builders offer the possibility of robotizing the assembly process of boards (not timber frame elements such as studs and mullions). However, as can be seen in reference [11], the grasped object tends to bend, which jeopardizes the exact placement of the object.

Therefore, it can be stated that the current robotic tools aren't as precise as desired in the assembly process of prefabricated modules. The accuracy of the robot's grasping is not guaranteed. This lack of precision increases especially when working in unstructured environments where the grasped objects aren't placed in a known location. Besides, the variety of design of the prefabricated modules hinders an automated programming of the robot's grasp and path planning.

During the research project explained in this paper, some tests were already achieved before [12]. A simulation was defined and some problems were intercepted (see also Figure 1):

- Incorrect placement of objects during feeding
- Deviations while grasping the objects
- In the case of some objects, especially boards, the object tends to bend and, therefore, the final position might not be adjusted
- Tolerances due to robotic arms calibration and accuracy during placing

As stated previously, it is necessary to recognize the location of the grasped or handled object to be assembled. In this sense, robotic assembly in construction can take advantage of concepts such as measurement assisted assembly (MAA). Maropoulos et al. [13] determined a solutions that enable a more predictive and flexible assembly process by using active tooling and closed loop control. This concept was mainly developed for complex and large-scale assembly processes such as in the aviation industry, but it can be used for the construction industry as well. Following these ideas, Druot et al. [14] applied the MAA for high accuracy aerospace assembly with robots with optimal results.

During the assembly process with robots, an adjustment of the robot's path is necessary. There is already literature where robots' paths can be adjusted depending on the feedback that the robot receives from different data acquisition and sensing devices and there are also some experiences in robotic assembly that can be found in the literature. Nottensteiner et al. defined a system to recognize objects and plan the assembly process by using two robotic arms [15]. In the research carried out by Feng et al. [16], markers were used for localizing objects and defining a plan for the assembly of parametrically designed walls. Finally, Lundeen et al. [17] used optical marker on top of the end effector to estimate the pose of articulated excavators.

2.1 Objective

The main research objective presented in this paper is to adjust the robotic assembly path depending on the location of the grasped element. Subsequently, the research question is if element location recognition and object path adjustment improve the deviations and displacements generated while grasping the object during

the assembly processes. The objective is to increase accuracy on the final pose for achieving the assembly of a timber-frame with CNC routed elements. For achieving that goal, it has been necessary to use visual systems that recognize the position of the grasped element and accordingly correct the deviation by adjusting the path of the robot.

3 Tests in laboratory environment

The works carried out during the experimentation phase consisted on assembling a mockup that resembled a timber-frame. The objects of the mock-up were made or fabricated by a 3D printer (German RepRap X400©) using PLA filament (Polylactide PLA from German RepRap ©) as an additive material. The objects were dovetailed as can be seen in Figure 2 in order to facilitate the placement by the robot.

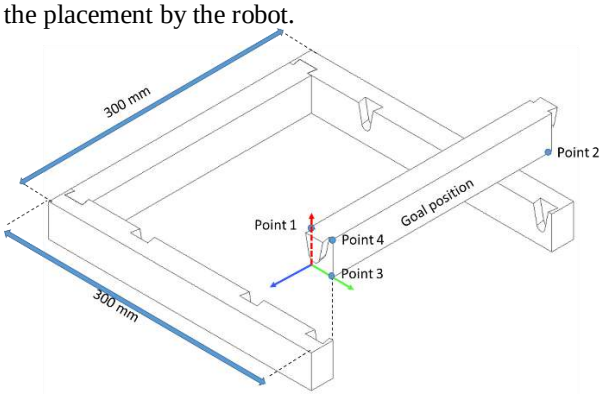

Figure 2. Prefabricated module mockup used for the assembly in laboratory environment experiments

The robot was placed in a referenced/known location with respect to the assembled module. The objects were also in known locations. The size of the mock-up was 300mm*300mm*35mm, which is about ten times smaller than a conventional prefabricated timber-frame module.

Figure 3. Assembly process carried out by the Kinova Jaco® robotic arm

The robot used for the assembly process was a Kinova Jaco® (six Degrees of Freedom) robotic arm (see Figure 3). It is noteworthy that the scale of the mock-up and the functionalities of the robot don't appear to reflect the reality of the assembly of the prefabricated module or that of the building industry. However, the materials and the robot used for the test reflect a worst-case scenario regarding deviations. On the one hand, the accuracy of the end-effector (hand type) of the Kinova Jaco® is not appropriate for grasping cubicle objects and, therefore, the deviations are considerable and appear exaggerated when compared to a gripper that is more adequate for such conditions. These "large" deviations are "good"; it is assumed that the robot and the mockup are suitable for this test and carrying out the adjustment of such grasping inaccuracies while picking and placing objects. In Table 1, the materials and devices used during the experimentation are defined.

Table 1. Equipment, materials and resources used

Computer processor	Intel CORE i7 8th Gen
Robotic arm	Kinova Jaco®
Controller	ROS
Path planning	MoveIt!
Camera	Logitech C170©
Digital theodolite	Leica 3D Disto©
Light source	LED lamp

The protocol for the experimentation follows a linear process. This linear process is included in a broader integrated workflow that spans from the data acquisition of the existing building to the assembly process of the prefabricated modules (it must be recalled that the prefabricated modules are conceived for building renovation [3]). The protocol for this experimentation starts by gathering the information that parametric software named Dynamo© [18] generates, which is a list with the coordinates of the location of each of the objects. In ROS-MoveIt! environment, the robot reads the list and plans the motion and starts executing the plan. During the execution of the planned operations, there is a pause in the path. This paused pose's objective is to facilitate the recognition of the location of the grasped element. Three tests were carried out during the experimentation phase. The first test was achieved without applying any deviation correction. The second test was achieved by the use of ArUco markers for localizing the grasped object's place. The third test was achieved by using a digital theodolite or total station for localizing the key point coordinates of the object. Each test was repeated five times. Once the grasped object's location was determined, the robot modified its position in order to get closer to the planned location of the object. All three tests finalized with a goal position where the location of the grasped object was measured in order to define the accuracy

obtained in each test. Four points were measured as it is shown in Figure 2 and Table 2: point 1, point 2, point 3 and point 4.

Table 2. Planned location for point 1, 2, 3, and 4(mm)

Name	Position X	Position Y	Position Z
Point 1	0.0	25.0	0.0
Point 2	0.0	25.0	37.5
Point 3	0.0	0.0	37.5
Point 4	-250.0	25.0	0.0

In all tests, the robot was positioned with respect to a reference coordinate, in other words, the position of the robot was independent of the location of the assembly module.

The deviation of positions is obtained by the equations as follows:

$$r_i = \sqrt{(x_{ni} - x_0)^2 + (y_i - y_0)^2 + (z_i - z_0)^2} \quad (1)$$

$$\bar{r} = \frac{\sum_{i=1}^{N} r_i}{N} \quad (2)$$

$$\sigma_k = \sqrt{\frac{\sum_{i=1}^{N} (r_i - \bar{r})}{N}} \quad (3)$$

where N is number of trials, (x_0, y_0, z_0) is the planned location and (x_i, y_i, z_i) is the accomplished location during the i number of trials. The accuracy of the test is shown by the equation as follows:

$$\delta_k = \sqrt{\frac{\sum_{i=1}^{N} r_i}{N}} \quad (5)$$

3.1 Test without any deviation correction

This experimentation was carried out in order to determine the benchmark or the "normal" capabilities of the robot. The protocol is a process without any iterative step as shown in Figure 4, and no correction or adjustment was applied.

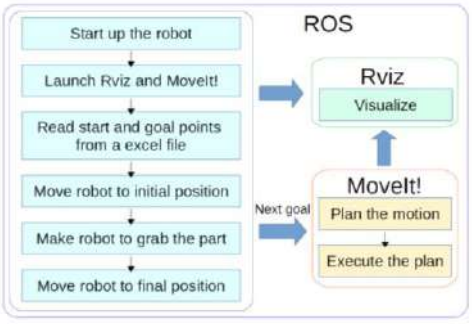

Figure 4. Protocol of the assembly process for the test without any deviation correction

The path planning and the grasping was determined in advance by the data generated for the parametric software. In Figure 5, the five different localitions of the object on the final pose of the robot are shown in red. In green, the planned location of the object are shown. In Table 3, the average point coordinates of the five different locations can be seen.

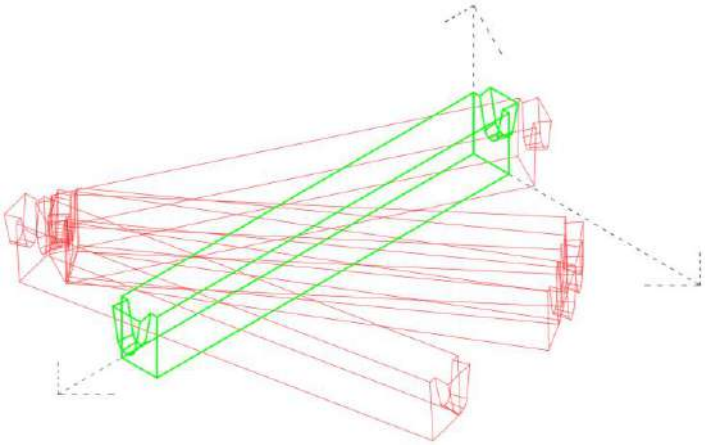

Figure 5. Goal position results without using any deviation adjustment

The results of the pose without any pose deviation, as expected, show a high deviation in comparison to the planned location of the object, where distances reach up to 136,86 mm in Point 2.

Table 3. Absolute location in the test without any deviation correction and distance from planned location (mm)

Name	Position X	Position Y	Position Z	Distance
Point 1	-65,20	-106,50	14,90	147,53
Point 2	-47,70	-94,10	-10,10	136,84
Point 3	-47,10	-93,00	-1,80	111,41
Point 4	-188,60	99,20	-22,60	98,93

As can be observed in Table 3, the results are considerably poor and impede the assembly of the mock-up with deviations higher than 100 mm. Therefore, these results show a worst-case scenario regarding deviations that need to be improved upon in the next two tests.

3.2 Test with Open CV and ArUco markers.

This test was based on the capabilities of Open CV [19] for recognizing the so-called ArUco markers. It states on their official website [19] "*OpenCV (Open Source Computer Vision Library) is an open source computer vision and machine learning software library*". In this test, two types of markers were used according to their functionality. First, a set of markers was placed onto the grasped element so that the pose of the center of it could be obtained if any of the markers were detected. The other marker was fixed on the working table as a reference for the coordinates of the robot and the

assembled module. The marker on the working table was used as a reference for the positioning.

During this test, an iterative step was defined in order to check and correct the deviation as explained in Figure 6. This iterative step improved the adjustment of the goal position. The camera was calibrated by using OpenCV and the chess board square placed in front of the Jaco robot. The corner of this square was used as a Reference coordinate, as it is shown in Figure 7.

The detection of the markers was not without issues e.g. it was affected by insufficient lighting. Furthermore, the occlusion of the markers caused the grasped object to not be recognized. When the markers were inclined too much away from the camera, it was difficult to detect them. In addition, z-axis flipping sometimes occurred [20]. This problem was prevented by using several markers and by accepting the majority decision.

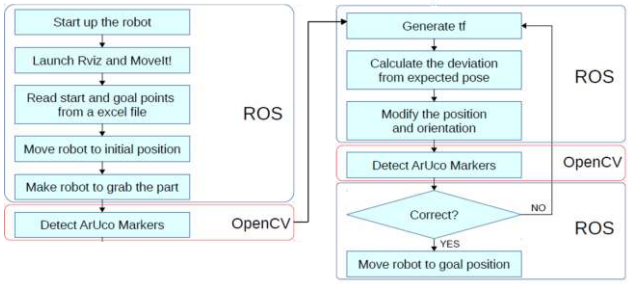

Figure 6. Protocol of the assembly process for the test with the ArUco markers

However, due to specific conditions such as grasped point or brightness, only one marker was detected and z-axis flipping was found to occur occurred.

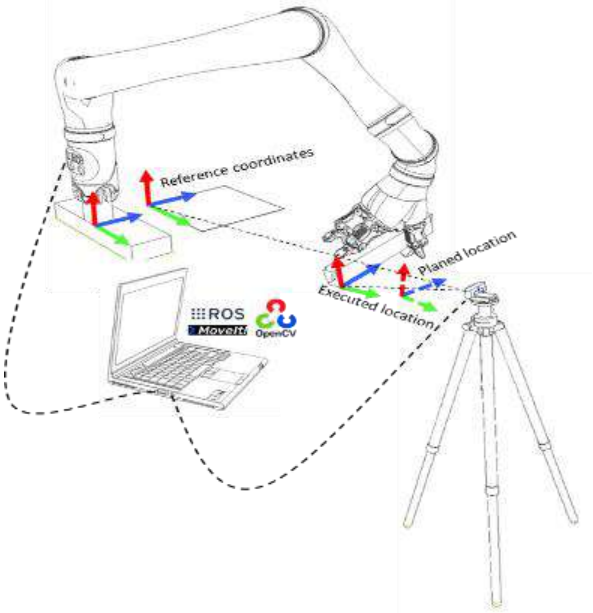

Figure 7. Scheme of the recognition of the grasped object by using the ArUco markers

In Figure 7, the scheme on the left shows the relative simplicity of the system. The camera needed to be placed on the point where the markers on the object and the reference marker can be seen at the same moment. The results; however, improve the final position location considerably.

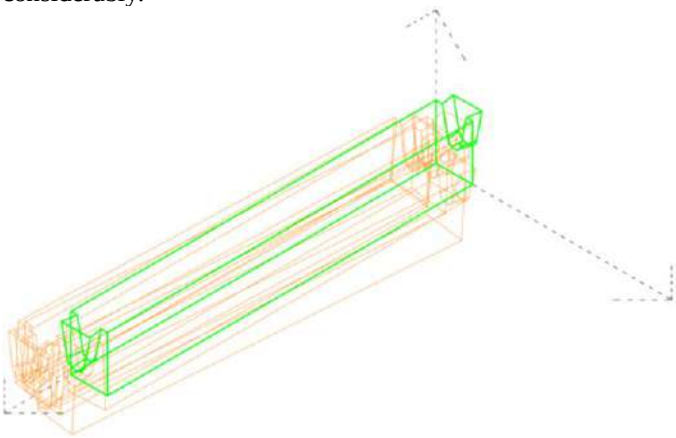

Figure 8. Goal position results using markers

In Figure 8, the five different locations of the object on the final pose of the robot are presented in orange. In green, the planned location of the object is shown.

Table 4. Absolute location in the test with the markers and distance from planned location (mm)

Name	Position X	Position Y	Position Z	Distance
Point 1	11,50	11,80	9,40	19,87
Point 2	11,40	10,10	1,90	40,24
Point 3	13,20	-10,30	28,20	19,15
Point 4	-238,10	18,10	-14,20	19,77

In Table 4, the results show deviations smaller than those that were presented in the test in sub-chapter 3.1. Similar to the test in sub-chapter 3.1, in Table 4, the average point coordinates of the five different locations are shown.

3.3 Test with the digital theodolite.

In this test, during the intermediate pose, the objects were recognized by localizing three points of the object. This test further requires that a human operator recognizes the location of the grasped object points by the Leica 3D Disto©.

During this test, an iterative step was defined as well as in the previous test, in order to check and correct the deviation as explained in Figure 9. In all five tests, the same three points of the element's corner were measured in the same order.

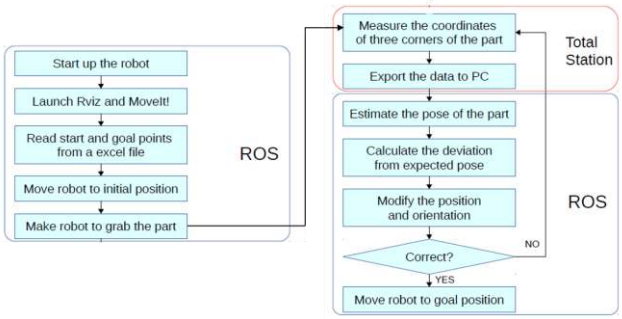

Figure 9. Protocol of the assembly process for the test with the digital theodolite

For calculating the necessary robotic pose adjustment depending on the element's position, a series of algorithms were used, which is explained as follows.

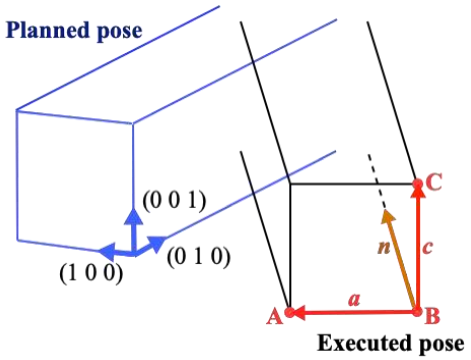

Figure 10. Deviation between the planned pose and the executed pose

From the three points (in Figure 10, A, B, and C), two vectors of the object were calculated ($\boldsymbol{a}$ = A − B, $\boldsymbol{c}$ =C−B). Then, the cross product of the two vectors was the same as the normal vector of them:

$$\boldsymbol{n} = \boldsymbol{a} \times \boldsymbol{c} \tag{6}$$

The unit vectors of the three vectors were calculated by dividing by the magnitude of themselves:

$$\boldsymbol{u}_a = \boldsymbol{a}/\|\boldsymbol{a}\| \tag{7}$$

$$\boldsymbol{u}_c = \boldsymbol{c}/\|\boldsymbol{c}\| \tag{8}$$

$$\boldsymbol{u}_n = \boldsymbol{n}/\|\boldsymbol{n}\| \tag{9}$$

Then, the following equation was established:

$$(\boldsymbol{u}_a \quad \boldsymbol{u}_n \quad \boldsymbol{u}_c) = \boldsymbol{R}_z\boldsymbol{R}_y\boldsymbol{R}_x \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix} = \boldsymbol{R}_z\boldsymbol{R}_y\boldsymbol{R}_x \tag{10}$$

where $\boldsymbol{R}_x$, $\boldsymbol{R}_y$, and $\boldsymbol{R}_z$ are the rotation matrices about x-, y-, and z-axis respectively. When the angles about each axis are α, β, and γ;

$$\boldsymbol{R}_z\boldsymbol{R}_y\boldsymbol{R}_x = \begin{pmatrix} C\beta C\gamma & S\alpha S\beta C\gamma - C\alpha S\gamma & C\alpha S\beta C\gamma + S\alpha S\gamma \\ C\beta S\gamma & S\alpha S\beta S\gamma + C\alpha C\gamma & C\alpha S\beta S\gamma - S\alpha C\gamma \\ -S\beta & S\alpha C\beta & C\alpha C\beta \end{pmatrix} \tag{11}$$

where $C\theta$ means $\cos\theta$; $S\theta$ means $\sin\theta$.

Thus, $\boldsymbol{u}_a$, $\boldsymbol{u}_n$, and $\boldsymbol{u}_c$ were defined as follows:

$$(\boldsymbol{u}_a \quad \boldsymbol{u}_n \quad \boldsymbol{u}_c) = \begin{pmatrix} u_{a_x} & u_{n_x} & u_{c_x} \\ u_{a_y} & u_{n_y} & u_{c_y} \\ u_{a_z} & u_{n_z} & u_{c_z} \end{pmatrix} \tag{12}$$

α, β, and γ were calculated by using the following equations:

$$\alpha = \tan^{-1}\left(u_{n_z}/u_{c_z}\right) \tag{13}$$

$$\beta = \tan^{-1}\left(-u_{a_z}/\sqrt{{u_{n_z}}^2 + {u_{c_z}}^2}\right) \tag{14}$$

$$\gamma = \tan^{-1}\left(u_{a_y}/u_{a_x}\right) \tag{15}$$

On the other hand, the coordinates of the center of the object P were calculated by the following equation:

$$\mathrm{P} = \mathrm{B} + (\boldsymbol{a} + \boldsymbol{c})/2 + l\boldsymbol{u}_n/2 \tag{16}$$

where l is the length of the object.

Then, the deviation of the position and orientation between the planned pose and the executed pose was obtained.

As shown in Figure 11, the robotic system is not complex. However, the interfaces with the digital theodolite were not robust and therefore time consuming.

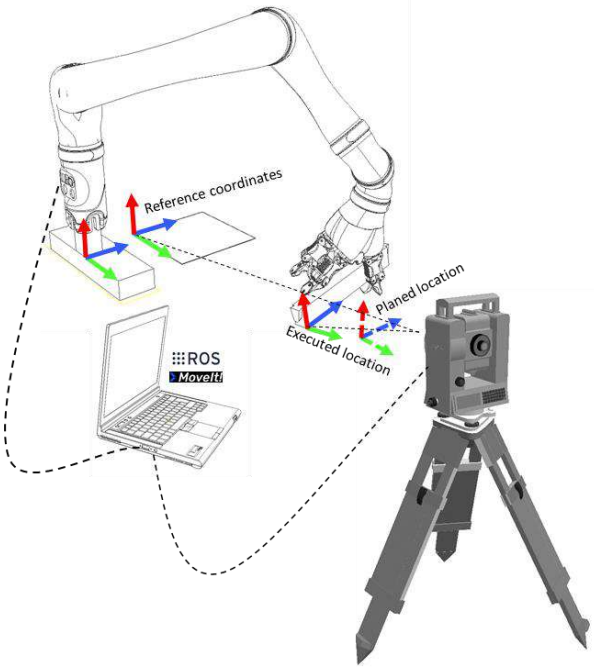

Figure 11. Scheme of the localization of coordinate recognition by using a digital theodolite

Similar to the test explained in sub-chapter 3.2, there were some issues while estimating the position of the grasped element. The points in this test were selected manually, and therefore the obtained coordinates were subject to errors.

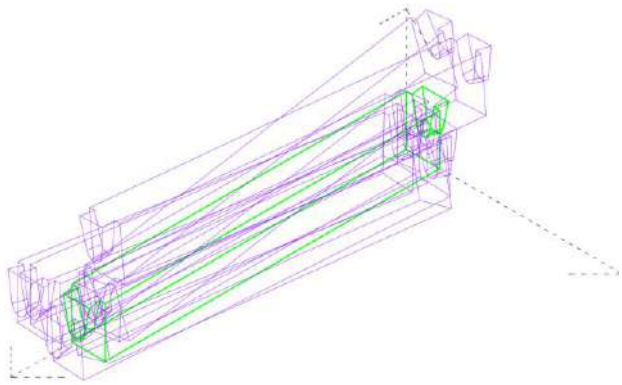

Figure 12. Goal position results by using digital theodolite

In Figure 12, the five different localizations of the object on the final pose of the robot are shown in purple. In green, the planned location of the object is presented. Table 5 shows the average point coordinates of the five different locations.

Table 5. Absolute location in the test with the digital theodolite (mm) and distance from planned location

Name	Position X	Position Y	Position Z	Distance
Point 1	-6,10	10,60	6,90	17,09
Point 2	-7,90	-18,60	40,70	44,43
Point 3	-6,40	6,00	43,80	10,80
Point 4	-254,40	26,00	5,40	7,04

3.4 Discussion

The results differ considerably during the three tests. On the first test (without any deviation adjustment), the final pose deviations are too high to accomplish any type of assembly tasks. On the two tests carried out with adjustment operations, the final localization of the object improves considerably, as an average, around 70 mm. The experiments achieved with the guidance of the markers show the best and most accurate results compared to the final desired location of the object. The tests achieved by the coordinate's localization with the digital theodolite present higher deviations than the results gathered with the ArUco markers.

Among the methods presented in this paper, the third test (recognition of coordinates) requires more attention from the human operator. However, it is not necessary to stick a marker on the object to be assembled which, in complex assembly processes where there are many parts, may be advantageous. Human-robot cooperation environments could benefit from this approach as the human worker could mark the necessary points. A specific interface for processing the data gathered with the digital theodolite and linking it with the ROS controller would reduce the time necessary to complete the processing.

Regarding the assembly of large-scale and bended objects such as plaster boards, the markers may be a better solution because the object moves while being handled. This means that the object recognition and its adjustment must be achieved once the object is close to the rest of the assembly.

The results show that, depending on the robotic system's accuracy, there should be consequences in the design of the objects to be assembled. This means that the openness of the joinery system in particular must be dependent on the accuracy of the robotic system. Therefore, in the timber-frame industry, it would be necessary to find the optimal CNC machining and routing geometries of the objects depending on the robot's assembly accuracy.

4 Conclusions

The main problems of assembly processes in fully or partially unstructured environments such as the prefabricated module industry are the inaccuracies associated with the picking and placing of objects. The grasping of objects typically requires structured environments and accurate grasping end-effectors. However, due to the variety of objects, shapes, sizes, and weights in the construction industry, this premise might not always be possible to achieve. In other words, due to the high variety of randomized products and objects in construction and particularly in building renovation, it is difficult to generate a fully structured environment. Therefore, the CNC machined elements of timber-frames need to be recognized before placing them in the module or in the construction site.

In the research outlined in this paper, two techniques have been tested for resolving such inaccuracies. As a conclusion, it can be stated that the objective of the research has been accomplished, which was to adjust the deviations of the grasped objects by recognizing their location. However, future work is necessary to create a more robust solution. Moreover, future experiments will be carried out using 3D laser scanners for localizing the grasped objects' deviations and linking the object with CAD or possibly BIM information.

The procedures executed in this research can be applied to the on-site installation of fully prefabricated modules as well. The pick and place prefabricated modules at the construction site is a task that could benefit from the methods described in this paper.

Abstract -

Robot assisted construction processes in the architectural domain which include assembly are uncommon due the size difference of the robot with respect the scale of the output. In order to extend the workspace of industrial robots, these can be mounted on top of a mobile platform. However industrial mobile robotics currently focuses on the utilization within clearly defined and structured production environments. Nevertheless, due to increasing product variety, a paradigm shift away from repetition of static task towards dynamic human robot collaboration is noticeable. Especially mobile robots face very specific challenges such as inaccuracy, dynamic on-site adaptability and predictability of whether the design is producible within the constraints of the robot. In this paper we discuss these challenges encountered due to onsite construction through a built project and illustrate the solution taken forward to address these challenges. In this research we propose a new methodology for on-site construction of non-standard components using mobile robots. The demonstrated project comprises of complex space frame timber system where every component of the structure is unique in its shape and size. For this we combine pre-planning of design with human-robot collaboration for on-site adaptation. The approach utilizes force torque sensors embedded within the robot in combination with haptic fiducials, in order to improving accuracy of the robotic fabrication and allow for human-robot collaboration within assembly. Employing the a-priori design knowledge the robot places the work-piece at the correct angle, while allowing for human adaptation of the path in order to increase accuracy. The paper illustrates the various optimization techniques developed to predict design manufacturability including potentially necessary adaptions. The research envisions a safe and automated large-scale construction methodology for complex systems and opens to new gateways for construction, allowing the collaboration between human workers and mobile robots within unstructured environments.

1 Introduction

Low level automation is becoming common practice for pre-fabrication of building elements in construction industries. Simultaneously concepts from Industry 4.0 allow for more and more custom production specifically in fabrication of individualized elements. However, construction industry still struggles to develop effective techniques for onsite construction processes especially for assembly due to the limited working envelope of a stationary robot as well as limited adaptability in robotics in order to handle raw material with high tolerances. But with the advent of mobile robotics, the possibility of onsite construction seems promising. However, there are several factors which limit the use of these tools.

One critical factor is the design being developed independently of fabrication process constraints of these complex machines. Hence the designer does not realize the limitations of the fabrication setup while developing complex designs. This results in fabrication difficulties or even non-manufacturable designs. In a commercial practice, the designer typically sends the design directly to a fabricator, who tries to find quick solutions and intuitively fabricates by experience which results in a one-off solution for each design. But in case of mass production of individualized components an automated workflow is necessary. In the project developed by Aarhus School of Architecture, Israel Institute of Technology and the ETH Zurich [1], which has proved the value of integrating topology optimization for direct realization in the digital process. The research pavilion, 2011 of ICD Stuttgart further demonstrates the use of structural optimization for the full-scale fabrication of plated timber structures using bespoke robotic milling. Current robotic fabrication methods carried out at ETH Zurich under the Robotic Timber Construction group [2], as well as the Digital Urban Orchid by IAAC [3] achieve

similar output. However, these projects do not address the direct influence of fabrication process and its parameters towards the design, as well as the potential of a reciprocal relationship between fabrication and design. Similarly, the Wood Chip Barn project by Hooke Park [4] although harvesting the inherent structural form of the timber fail to automate the challenges of using a limited size robot for oversized workpieces (tree forks). At the time of writing, there are no existing design methods in timber construction where the machine and fabrication workspace parameters and its constraints are integrated into the digital design process which informs the design.

To overcome the gap between design and fabrication, we introduce a novel concept of design which is driven by a continuous production feedback and the integration of fabrication constraints. The fabrication constraints are addressed within the domain of robot's reachability for the given design. This methodology is demonstrated through 'The Twisted Arch' project (Figure.1). The potentials and limitations of each fabrication resource are analyzed through design and construction of a 1:1 scale prototype of complex space frame timber structures by employing a mobile robotic setup and a bandsaw cutting process for fabrication, as well as human robot collaborated assembly. The outcome of the research results in the creation of an intelligent computational program, which provides visual guidance for the user during the design process. The project was first introduced in [4].

Another critical factor to be considered while using mobile robots is the inaccuracies encountered due to the movement of the mobile platform which could be caused due to uneven floor, dirt, etc. This requires an additional element which compensates the accumulated errors of all elements in the structure. In our research, a construction feedback method is implemented where the inaccuracies of fabrication of each workpiece is automatically measured using haptic sensors and the errors are then compensated in the subsequent assembly of the structure. Thus, avoiding errors accumulation within the process establishing a continuous design and process feedback loop.

Figure 1. 'Twisted Arch' Project

2 Concept and Workflow

The general workflow and concept of our approach, as illustrated within Figure 2 based on our demonstrator project, consists of the following elements:

- Global Design (the overall structure to be fabricated)
- Assembly workspace analysis based on the global design ensuring reachability and collision free assembly, as well as structural stability
- Extraction of a single work pieces informed by the global design
- Fabrication workspace analysis to ensure manufacturability with feedback into the global design
- Execution of design to fabrication workflow with dynamic calibration resulting in feedback to the workpiece design
- Execution of design to assembly workflow with human-assisted adaption resulting in feedback to the global design

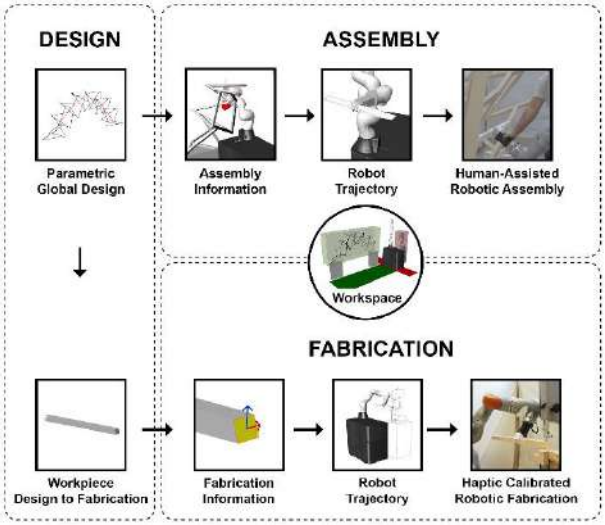

Figure 2. Process Overview

Within the following this workflow will be discussed in detail based on 'The Twisted Arch' project. Therefore, a first proof of concept is introduced, which illustrates the potential of bidirectional feedback between design, fabrication and assembly both in the context of work-piece fabrication as well as global structural design. Within [6] a first approach to transfer workspace constraints towards human-robot collaboration within assembly was introduced, specifically through the integration of constraint models within the robot controller and the term haptic programming was coined. The architectural impact of this workflow, with specific focus on the continuous design and process feedback loop, will be further discussed in section 10.

3 Global Design

The design of the prototype is based on a simple catenary arch comprising of a complex triangular space frame system made of timber elements. To test the process' influence on design, a complex timber space frame design connected by simple butt joints which follows a user-defined curve, is developed parametrically in a CAD environment. The parameters which include span, height, and offset of the catenary arch are optimized to test the workspace of the mobile robotic assembly process within the limits of structural stability of the design. The optimization in turn radically changes the space frame design and subsequently changes the length and angle of the cut of each element while still maintaining the configuration of the system. The maximum reach of the robot is verified to generate the working envelope and subsequently the robot's workspace. This data is continuously fed to the designer through custom visualization to make an informed choice for an ideal design. The entire interface is developed in the Rhinoceros3D and Grasshopper3D environment. The algorithms are custom plugins to check the functionality of the process developed by the authors. The design is initially simplified using the centerlines of the components and system for easier computation.

Another algorithm informs the design towards structural stability with the help of Karamba, a third-party plugin in grasshopper developed by Clemens Preisinger. The plugin integrates timber properties, in this case beech as part of the structural simulation. Irregularities like rot, cracks, etc. are not considered in process. The displacement of potential designs is then visualized to allow the designer to make an informed choice for the ideal design. The space frame is generated along the Cantenary arch allowing the design to choose different space frame variations, which are in turn used to generate solid geometries from the structural centerlines. Both algorithms simultaneously, inform the user to evaluate the design in terms of fabricability and structurally (Figure.3).

The design is evaluated every time to identify the non-manufacturable components through another iterative algorithm. The algorithm uses inverse kinematic solver, namely KUKA|prc [8], which checks for reachability, collisions, and singularities of the robot simulation. Nevertheless, after a series of optimization procedures, there are instances where the robot is still not able to manufacture the components (for example if the workpiece exceeds the fabrication limitations such as workpiece length, the angle of cut or a combination of both). The algorithm then highlights the geometries which cannot be manufactured in red. This visual illustration informs the designer whether the design can be fabricated or not, throughout the design process. The design can be continuously altered by the designer through quick modifications of the curve until all components are manufacturable. The designs generated are recorded and analyzed to understand deviation of the manufacturable design from the one intended by the designer.

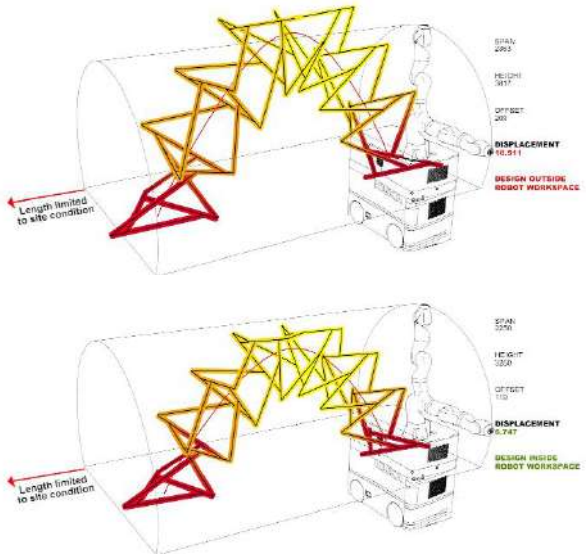

Figure 3. Optimization of the Design guided by the robotic workspace and structural constraints

This process establishes a new methodology in the field of architecture where every design decision is continuously informed and controlled by the parameters of fabrication. The process results in multiple options where every design is completely manufacturable but with slight modifications in its overall appearances from the one initially envisioned by the designer. The biggest drawback of this method is that the algorithm does not indicate which exact parameters are to be modified and by how much to achieve a manufacturable design. Although the constraints are identified and parameterized in this research, the next step is to develop an interface which would result in providing the above-mentioned feedback to the designer. The next steps are also to develop an algorithm to find the best suitable robot position, tool position and orientation of end-effector. This would result in an alternative approach where an optimal machine setup is generated based on the design created which otherwise would be a local solution for a given setup.

4 Workpiece: Design to Fabrication

After several iterations an optimized design is finalized, and an algorithm creates simple butt joinery between connecting components from the centerlines of the space frame system. Butt joinery is generally used to

connect two more timber pieces when the ends are cut flat at specific angles where they meet. The flat faces of the butt joints are fastened using timber screws. The butt joinery results in compound angles at certain connections due to complexity of the design. The sectional dimensions of the timber stock are 35x35mm. To avoid loss of the strength considering the limited sectional size of the timber, each timber component is restricted to only one connection at each end. The output from the algorithm is the final geometry which needs to be fabricated from the given stock material.

The length of each component is limited to a certain size depending on the maximum reach of the robotic arm or the robots working envelope. This is ensured to avoid collision between the timber material and the robotic arm or the environment. As the timber is gripped by the robot only at the center, the lengths of the timber pieces are limited to avoid extensive vibrations are the end of the stock material.

As the entire workflow is based on the centerline information and the local design (joinery) is automatically developed from it, this method allows transfer of the global design (timber framing drawing) made by another designer into the fabrication process. The centerlines of the connecting members in a design are required for the cad data.

5 Demonstrator Process Overview

Within the Twisted Arch project, the fabrication and assembly process flow consists of the following steps:

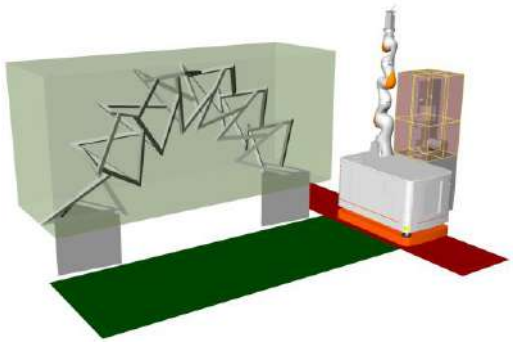
- Gripping of a square timber pieces from a supply station are manual handover.
- Optimization of the mobile robot's position towards the bandsaw with regard to reachability
- Haptic measurement adaption of the bandsaw plane to reduce the positioning error of the mobile platform
- Reorientation of the timber piece towards the bandsaw blade
- Cutting of the timber piece according to the compound angle
- Reorientation of the timber piece towards the band sawblade with the second side
- Cutting of the second side of the timber piece according to its compound angle
- Moving the piece away from the saw workstation
- Movement of the mobile platform towards the assembly station
- Movement of the cut timber piece towards the assembly position
- Manual adaption of the timber piece position to reduce inaccuracies
- Robot-assisted assembly
- Movement of the arm away from the assembly
- Movement of the mobile platform towards the bandsaw work station
- The assembly process is continued by retrieving the next timber piece.

6 Workspaces

The setup consists of a KUKA iiwa with 14kg payload and maximum reach of 840mm which has a gripper as an end effector, the robot is mount KUKA Mobile Robotic (KMR) platform, a standard workshop bandsaw with a maximum cutting depth of 110mm. Due to the limited reachability of the robot two boxes which provide the base on either ends of the arch at a raised height of 500mm is constructed.

The major challenge of using stationary robot is developing a successful robot path devoid any collisions. In this process the challenge is amplified due to continuous repositioning of the mobile robot base. For mobile robots a dynamic workspace is considered, unlike in stationary robots with a static workspace. The actual workspace is dependent on the setup and therefore requires the superposition of various workspaces, such as robot, fabrication, assembly workspace and its surrounddings taking into consideration within ever-changing and unstructured construction environments.

Before we begin to understand the fabrication and assembly processes, one needs to consider the setup and various workspaces involved in production (Figure.4). To comprehend and implement the parameter space within which fabrication and assembly can be successfully carried out, the effective workspace of each production resource (machine, tool, material) is analyzed. These analytical results are combined to create a process model that considers the interrelationship between all parts of the fabrication process. The fabrication workspace is a combination of robot, end effector (gripper) and tool workspace (bandsaw).



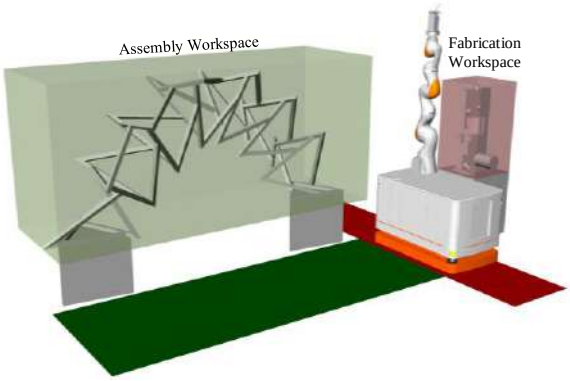


Figure 4. Workspaces

The robot workspace is the functional workspace which differs from working envelope of robot because the workspace takes the robots TCP (Tool Center Point) into account [7]. To determine the robot workspace an iterative algorithm is developed with the help of a genetic solver (namely Galapagos a Grasshopper3D plugin), which in turn generates some material and additional design constraints, such as timber section length and possible cutting angles. With the minimum and maximum reach known we can determine the three-dimensional robot workspace.

The bandsaw workspace can be described as a collection of robots TCP positions for cutting. The intersection of the robot with end-effector and bandsaw workspace defines the fabrication workspace. By establishing this fabrication workspace, it is easier to test the manufacturability of a component. Comparative studies are conducted between various robot and tool positions to understand their impact on the workspace.

The intersection of robot with end-effector with various TCP positions for assembly of all components in the prototype define the assembly workspace. The sequential assembly order of the timber components must be considered and understood so that the robot workspace does not collide with assembly workspace of the surrounding components. Each process is clearly defined by the boundaries of fabrication and assembly workspaces which are placed orthogonally to each other so that the mobile platform is allowed to freely operate to resolve reachability issues without any collisions.

7 Robot trajectory optimization for fabrication process

While manually cutting timber using a bandsaw, tremendous amount of forces is exerted by the bandsaw blade on the workpiece. Therefore, the workpiece is ensured to rest on the bandsaw table so that the forces are mostly absorbed by the table. This allows the fabricator to easily guide the workpiece at the required direction and angle without experiencing much of the forces. Similarly, while using the robot, in order to ensure least amount of forces are transferred to the robotic arm, the workpiece is required to rest on the bandsaw table during the cut (Figure.5). This prerequisite becomes a major robot trajectory challenge as the robot not only has to place the workpiece at the required orientation and position but also ensure the workpieces rests on the bandsaw table.

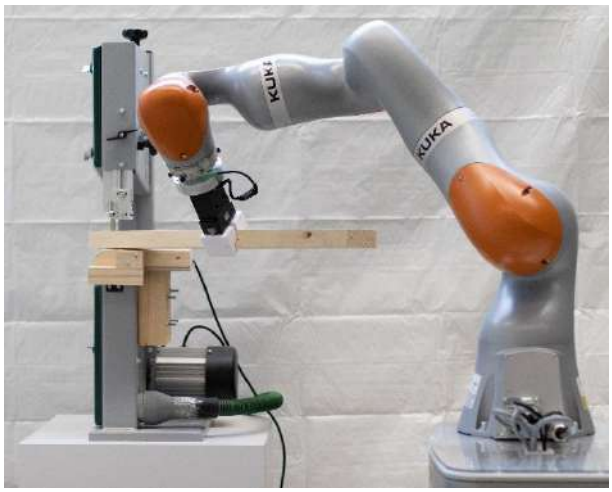

Figure 5. Resting the workpiece on the bandsaw table using the robot during fabrication

Hence, to achieve robot reachability for the above complex trajectory devoid of any collisions, a series of optimizations are executed. While using a stationary robot, a suitable gripping position from any of the four available directions of the workpiece is used to ensure reachability. Unfortunately, due to gripping and regripping of the workpiece every time for each cut of the workpiece, severe inaccuracies are encountered. To rest the workpiece on the bandsaw table, the workpiece geometry is rotated around the cutting surface until at least one edge (in case of compound angle cut) or a flat surface (in case of a simple angle cut) aligns with the table. However, in the current process to resolve this problem, we move the KUKA mobile platform, which in turn changes the base position of the KUKA iiwa and therefore enables different axis configuration in the robotic arm movement (Figure.6). This automatic optimization is conducted until a suitable trajectory is obtained which is free from collisions and well within the reach of the robot.

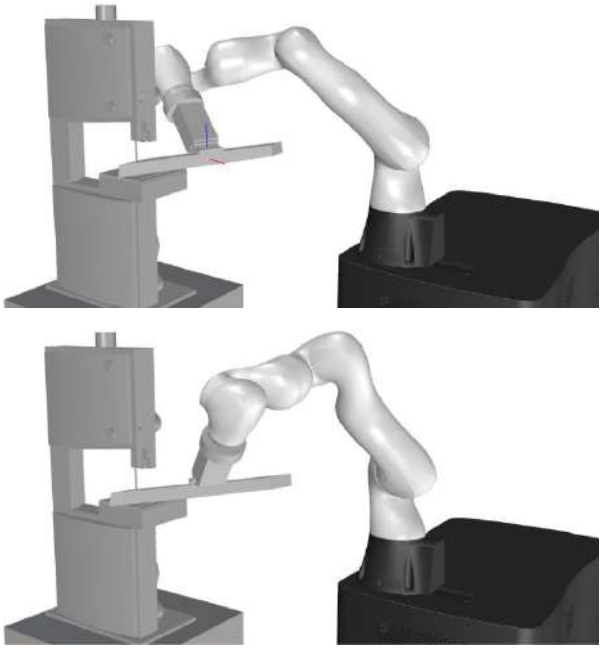

Figure 6. Optimizing the workpiece position to the robot and machine workspace

While the movement of the robotic arm is highly accurate the movement of the mobile platform is not. While it is possible to create a full map of the environment using the mobile platforms laser scanners this is however a very static process that does not allow for a dynamically changing environment as is often the case within construction. We compensate the inaccuracies within the process through haptic feedback for dynamic adaptivity on top of the statically planned fabrication process from design. In order to create dynamic adaptivity within the fabrication process, the robot is moved to a pre-calibrated position employing a haptic fiducial, before the cut is processed (Figure.7). Using the force torque sensors inbuilt in the robot, the robot dynamically calibrates the deviation between the haptic fiducial and the pre-calibrated position. By calculating this deviation, the cutting position is automatically updated to a corrected position in accordance with the real-world placement of the bandsaw thus providing an accurate cut. The pre-calibrated plane on the haptic fiducial serves as the primary reference point for the entire fabrication and assembly setup. All robot movements are referenced to it.

Without the haptic feedback for accuracy, the fabrication process observed an error over serval centimeters. The inaccuracies was inconsistent to evaluate as the mobile robot moved to various position depending the angle and size of the cut. But on an average the inaccuracies was found to be 20-30mm. With the haptic feedback the accuracy improved with an error less than 2.5mm.

Figure 7. Haptic Feedback using the custom built fiducial

8 Robot trajectory optimization for assembly process

Current workflows consider design informed fabrication the construction of complex assembly however requires more consideration for sequence planning as well as adaptation towards on-site deviations. Within assembly deviations between pre-planned design and real-world construction increase with every layer. Similar to fabrication, to resolve reachability issues during assembly the mobile platform is moved closer to the position of the component (Figure.8), however while creating the structure there are no available haptic fiducials on or closer to the prototype to increase the mobile platforms accuracy.

There are instances where the robot is still unable to reach the target position. Since the geometry plane is placed along the centreline of the geometry, we can rotate it into four different configurations which leads the robot gripping the part from 4 different directions. This also changes the robot's configuration while keeping the geometry in the same place. In order to compensate for these deviations, the robot connects the assembly component to the existing butt joint of its predecessor.

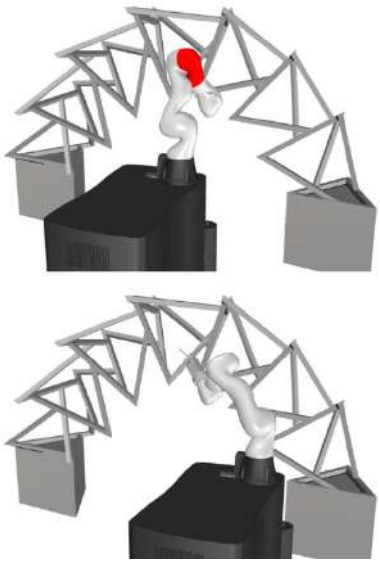

Figure 8. Optimizing the mobile robot position for reachability

However, the final assembly is conducted through human robot collaboration where the robot orients the workpiece in position while the human co-workers adapts the timber piece position in order to connect it correctly to the already fabricated space frame system (Figure.9). During assembly the robot is therefore set to an adaptive compliance mode, meaning the robot is in soft mode that allows the human co-worker to move the workpiece to a certain degree. If the deviations between planned target position and real-world position become too high the robot increases its stiffness and cannot be moved further of track. The components should be assembled in order so that they do not interfere with the assembly of its nearby components.

Figure 9. Human Robot Collaboration

9 The IDAA Framework

This leads to a reciprocal communication strategy between human co-worker and robot. This movement is easily guided by a user with its respective joinery to compensate the inaccuracies encountered during fabrication and transition, while simultaneously allowing the identification of construction errors that would lead to high deviations between design and assembly. The Production Immanent Design concepts of KUKA|prc which allow for a direct motion planning based on parametric design are therefore redefined and extended within the IDAA System, which was first introduced 2016 in [9] and further detailed in [5] for a stationary KUKA iiwa robot. However, within this paper the reciprocal relationship between the mobile platform and robotic arm movement is detailed.

In general, this system allows the integration haptic interaction primitives and concepts for dynamic configuration and path adaptation on-site, which is especially valuable for mobile robotics. The IDAA system does not rely on computer vision, which is unreliable in environments with dynamic lighting conditions but creates new means of communication between design and assembly through haptic feedback, not only for fully automated processes but also for human-robot collaboration.

Figure 10. Robotic Assembly

The design of adaption and control strategies can be challenging especial for users without expertise in robotics. In order to allow for the use of haptic feedback for adaptation in fabrication as well as assembly, or even extending these control strategies with other sensory input, a superposition between the geometrically planned

path and control strategy needs to be created.

Similar to skilled based robot programming [10] a catalogue of operations is created allowing the designer to link between geometric positioning and the execution of complex operations, such as dynamic recalibration of the robotic base frame at a haptic fiducial within fabrication. Such operations need to be accessible to designers but also create reusable descriptions of each operation. The IDAA Framework therefore allows for the extension of the operation catalogue in a combined approach the data interface to each operation is given by the geometric but localized path description, based on this the fitting control strategy can be chosen in a clearly defined setting.

1 Architectural Impact

The research illustrates how a single mobile robot can be resourcefully used for complex onsite construction processes and for multiple applications (including fabrication and assembly) and through efficient material handling in the 'Twisted Arch' project. Thus, demonstrating in what manner designers can thoughtfully develop design considering the parameters of the construction thereby yielding maximum efficiently from minimal resources. The research social impacts tangibly, by realizing the downsides of current technology and shows how human senses can be used sensibly for collaborative processes. Within the larger context of construction, the workflow establishes a new methodology in architectural design where the designer is always informed not only during design process but also during the construction process. One such example is the machinic inaccuracies encountered which is addressed through continuous designing and redesigning during the construction process. Thus, this methodology also allows the designer to have complete control throughout the process.

2 Synopsis

Within this work we illustrated the use of an adaptable mobile robot for onsite construction. By establishing a continuous design and process feedback loop the integration of a wide variety of fabrication and assembly tasks becomes, as well as individualized production becomes feasible. In order to make this approach applicable to other construction task further development is however necessary.

Within future work we will therefore focus on the automatic modelling of superimposed workspaces. By allowing for the representation and transfer of the necessary parameter space both from a production point of view as well as intended design adaptation can be optimized to adhere to the existing constraints from both viewpoints. While feedback from onsite production is possible this is still not fully integrated.

Furthermore, the used system is not suited for the rough environments of the construction site. The transfer to different systems and processes is still a major challenge and requires further research and development.

Abstract –

Safety in the construction industry remains a major challenge despite the technological advancements made in recent years. In recent years, ontologies are applied to give a formal structure to the knowledge in different domains. Ontologies also facilitate the integration of various domain knowledge and thus allow for better cross-functional developments (e.g., operator support systems that consider safety and productivity at the same time). The authors have previously developed a comprehensive Earthwork Ontology (EW-Onto). However, there has been no linkage between safety regulations and EW-Onto. Therefore, this research aims to: (1) develop a formal representation of earthwork safety regulations knowledge, and (2) integrate this knowledge with EW-Onto. A case study is developed to validate the integrated ontology. It is shown that the integrated ontology can be used to bridge the gap between high-level safety regulations and task-level instructions.

Keywords –

Earthwork; Ontology; Regulations; Safety

1 Introduction

Worker and equipment safety is a critical issue in the construction domain. Numbers from construction sites show that hazards in workzones affect projects at different levels. According to OSHA [1], in 2016, 21.1% of fatalities in the private industry are related to construction. Ignoring the safety rules, not following safety regulations, weather, and reckless equipment operators are the main factors that lead to accidents on construction sites. Accidents in construction sites are the main reason for the loss of life, which in turn affects schedules, productivity, costs, and the reputations of construction firms. In earthwork domain, excavation, especially trenches, are recognized as the most hazardous construction operation that can lead to serious accidents, such as cave-ins, toxic atmospheres, and falls [1]. *Job Hazard Analysis* (JHA) from OSHA [2], is a technique used for identifying, evaluating, and controlling these types of hazards. This technique is one of the different methods used for checking if the variables that are related to workers, tools, equipment, and the environment meet the associated regulations and rules. The data collected from construction sites using different technologies can enhance construction site productivity and safety. Moreover, combining human (e.g., workers, operators, designers, and coordinators) experience and best practices that are gained from previous similar projects is another method to avoid accidents in workzones. However, it is necessary to link the related hazards at the different levels of the project with other entities on the site (e.g., products, equipment, and the surrounding environment) in order to have better decision making. In recent years, ontologies are applied to give a formal structure to the knowledge in different domains. Ontologies also facilitate the integration of various domain knowledge and thus allow for better cross-functional developments (e.g., operator support systems that consider safety and productivity at the same time). The authors have previously developed a comprehensive Earthwork Ontology (EW-Onto). However, there has been no linkage between safety regulations and EW-Onto. Therefore, this research aims to: (1) develop a formal representation of earthwork safety regulations knowledge, and (2) integrate this knowledge with EW-Onto.

The rest of this paper is organized as follows: Section 2 discusses the related works on the safety regulations in construction. The methodology considering the different hazards in earthwork are presented in Section 3. Section 4 discusses the implementation of the ontology. Section 5 presents the conclusion and future work.

2 Related works

2.1 Safety Checking Methods and Techniques in Construction

Providing and performing safety procedures in workzones are a major factor for the success of the construction industry. These procedures should be followed by everyone involved in the business, which, in turn, saves lives and reduces the costs of business. Safety checking, which is the main part of safety management, aims to identify potential hazards before they occur on construction sites. Different methods and techniques are used to perform safety checks on construction workzones. The most efficient method is JHA, which defines the relationships between jobs, tools, workers, and the surrounding environment and provides a list of procedures and resources that are needed to prevent or reduce these hazards [2]. *Occupational Risk Assessment* (ORA) [3] is a process that is performed on the construction site to gather information from different sources to build better knowledge about hazards [4]. Check-list [5] technique is used to perform ORA on construction sites to define the safety issues at early stages of the work. Zhang, et al. [6] outlined a framework for early hazards identification in the construction model by integrating the *Building Information Model* (BIM) and safety regulations. Thus, the related hazards and the corresponding prevention procedures can be automatically identified and applied. 4D-BIM technologies connect the safety activities, construction planning, and visualizing the safety arrangements at any time [7]. Thus, the safety personnel and the designer with less knowledge about safety can use BIM-based friendly software to organize the *Safety Knowledge* (SK) and to improve occupational safety.

2.2 Ontological Modeling in Construction

Ontologies aim to represent the implicit knowledge in a domain in an explicit way through an organized structure of related concepts and relationships. Gruber [8] defined the ontology as "an explicit specification of a conceptualization."

Different studies use ontology and combine it with modeling techniques (e.g., BIM) [6][9]. Lee et al. [9] proposed an ontological approach for quantity take-off using BIM as a data source. The developed ontology is then used to infer the suitable items based on the estimated cost. Zhong et al. [10] provided an approach to integrate construction processes with regulation, which are related to quality compliance.

Zhang et al. [11] described an approach to store and re-use the safety management knowledge in construction. This approach links three main models, which are represented as ontology (i.e., product model, process model, and safety model). Ding et al. [12] proposed an approach to combine BIM with ontology to semantically organize construction risk knowledge. Wang and Boukamp [13] created a framework to improve access to the company's JHA. The framework uses the ontology to organize knowledge about activities, jobs' steps, and the related hazards.

Earthwork operations are a common part of construction projects. These operations include excavation, hauling, dumping, scraping, and grading. Earthwork operations account for 20% of the total cost of road building projects [14]. Using advanced information technologies in earthwork operations to improve safety and productivity is a major concern for researchers. Vahdatikhaki et al. [15] proposed the application of *a Multi-Agent System* (MAS) as a means to support fleet-level coordination for earthwork operations. Ontologies are one of the advanced technologies that have been used in construction to facilitate not only the human-to-human but also machine-to-machine communications by formalizing the information exchange scheme [16]. Taher et al. [16] proposed a framework to develop *Earthwork Ontology* (EW-Onto) to support and enhance the communication and data exchange between different stakeholders in earthwork projects.

2.3 Ontology Development Methodologies

The foundation Ontology (FO), also known as top-level or upper ontology, is an ontology that describes the most general terms across the domains. Zhou et al. [17] explained that certain studies might include some steps from the previous methodologies for developing their ontologies. In the 1990's, some methodologies for developing ontologies have been outlined. Skeletal methodology [18], and METHONTOLOGY [19] are examples of general methodologies used to build ontologies. IDEF5 is an ontology capture method and one of the Integrated DEFinition (IDEF) family languages that support the analysis and design of models [20]. Other methodologies or approaches are used to build the ontologies by re-using the existing ontologies or integrating two or more ontologies.

Description Logics (DL) is a language to formalize the knowledge representation that provides high-level descriptions of the world to be used in intelligent systems [21]. DL delivers syntax to describe the knowledge by expressions, which are built as atomic concepts, atomic roles and role constructors. DL is separated into three formalism components: Terminological Component (TBox), Assertion Component (ABox), and Role Axiom (RBox). TBox axioms describe the general properties of concepts and contain the intensional knowledge in the form of taxonomy or terminology such as concept inclusion. ABox axioms contain the assertional knowledge for specific individuals in the domain.

Whereas RBox refers to the properties of roles, such as role equivalence axioms and role inclusion [22].

3 Proposed Framework

The framework used to develop EW-SKB follows the approach of METHONTOLOGY for the following reasons: (1) it is application-independent and mature; (2) it is well-documented and has clear development activities; (3) it is based on the experience acquired from developing ontologies for many domains [19]; and (4) it has an integration step, which facilitates reusing EW-Onto as the main base of EW-SKB.

3.1 Main Steps to Develop EW-SKB

The best practices and knowledge in the earthwork domain and the related safety issues are used in EW-SKB development. Figure 1 illustrates the main phases of developing EW-SKB as explained in detail below.

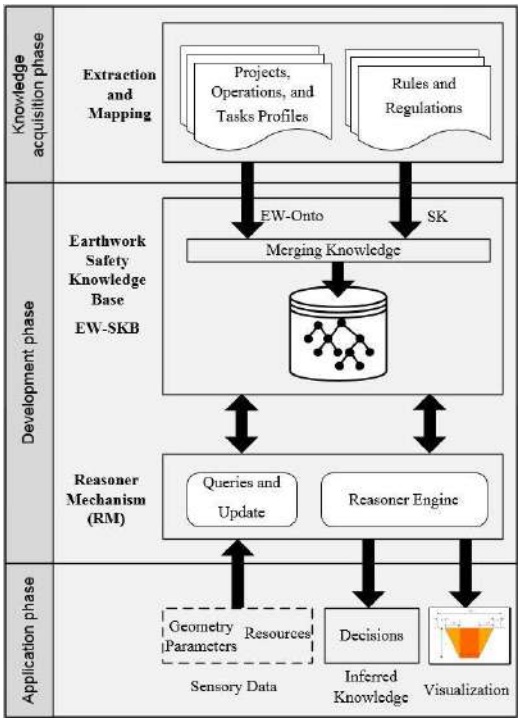

Figure 1. Proposed framework

3.1.1 Knowledge Acquisition Phase

The initial phase of the proposed framework, i.e., the knowledge acquisition phase, consists of defining the scope of the EW-SKB and defining concepts and taxonomies based on the requirements. The requirement data (e.g., terms and properties) are collected from various sources, such as textbooks and online resources (e.g., OSHA). EW-SKB should address the *Competency Questions* (CQ), such as: Why do we need to develop or extend the ontology? What are the domains and the scope of the ontology? Who are the users of the ontology? Answering these questions addresses parts of the requirements in the earthwork safety domain. Also, it helps to clarify what should be included in the developed ontology, and to which level of detail it should be developed. Furthermore, the basic concepts and relationships of EW-SKB structure is defined at this phase. The concepts, terms, properties, and instances are parts of the *Glossary of Terms* (GT). Developing the GT becomes easier when the specifications are clear.

3.1.2 Development Phase

In this phase, safety knowledge is added to the EW-Onto. SK includes the related concepts and relationships that link EW-Onto, related hazards, and related rules and regulations. The development phase includes the steps to add the SK to EW-Onto. The formalization of EW-SKB starts with transferring the conceptual model into the formal model using DL. Table 1 illustrates some examples of the conceptual components represented as terminology, assertion, and rules axioms, which define the concepts, individuals, and relationships, respectively. These components are added to the EW-Onto to link the concepts to soil types, product hazards, and equipment hazards. *The Reasoning Mechanism* (RM) or reasoner engine is the mechanism that represents the inferred knowledge and performing the queries over the explicit knowledge in the ontology. The RM checks the consistency of the developed ontology and validates the update of the relationships to ensure that there is no conflict.

3.1.3 Application Phase

This phase consists of any changes and updates of EW-SKB. The assumption here is that the ontology receives the sensory data from the site, including geometry data and resources data. Geometry data is more about the terrain model and the products (e.g., depth, width). Resources data includes data about the different types of resources in the earthwork domain including equipment (e.g., hoes, trucks), and materials (e.g., soil) from the workzones. The decisions are then generated based on the received data and the rules in EW-SKB. The visualization mechanism is not included in this paper and will be considered in future work.

3.2 Earthwork Related Hazards

In earthwork operations, there are a variety of hazards that affect the earthwork project at different levels. In this research, and as one of the main steps to map the concepts in the first phase, hazards in earthwork operations are classified into three main categories: material hazards, product hazards, and equipment hazards.

Table 1. Examples of TBox, ABox, and RBox components related to soil classification, product hazards, and equipment hazards

Axiom	Explanation	Examples
TBox	Express the terminological knowledge	SoilType_A, HazardWorkzone, ProtectionSystem, SlopingSystem, CaveIn, Path, Segment, Intersection, ExcavationZone, DumpingZone, IntersectionZone, WarningRange
ABox	Express the knowledge about the individuals	Soil1, Soil2, Workzone1, TrenchBox1, Slop1, Path1, Segment3, IntersectionPointT1, ExcavationZone
RBox	Describe the properties of the roles	hasStructure, hasTexture, hasType hasSiltAndClayPercentage, hasSoilType, hasHazard, hasSlopAngle, hasSpeed, hasLocation, hasCollisionWarning, hasToStop, hasDirection

It should be noted that products (e.g., trench) and materials (e.g., soil) are linked to each other. Product hazards are the result of the geometry of the product (e.g., length, width, and depth). Whereas, soil hazards are linked with the properties of the soil. Different actors who share and perform the processes and tasks (e.g., equipment operators, and on-feet workers) need to avoid hazards during the project at any level. To make the situations at the site more practical, the excavations and trenches are divided into workzones. Thus, each trench is composed of some workzones that may be different in their properties (e.g., soil type, depth, or other nearby workzones). Moreover, at each workzone, the tasks are performed by one individual or a team of different equipment and workers.

3.2.1 Material Hazards

In this research, and since the earthwork operations are linked to soil, the hazards related to soil are considered. These hazards are related to the different materials that are used in the project in different earthwork operations, such as cleaning and grabbing operations, excavation operations, and compaction operations. In some earthwork projects, explosive materials could be used in cleaning and grubbing operations, which affect the soil (e.g., the stability).

Soil classification plays a vital role in safety regulations, where each type of soil has its own structure and properties, which affect soil behavior under different circumstances. Soil classification can be obtained based on different values of the properties [23], which directly affect the stability of the excavation and the choice of suitable safety procedures and resources. OSHA standard number 1926 Subpart P Appendix A [24] provides examples of the guidelines that can be applied to classify the soil based on various properties. In EW-SKB, the quantitative properties are used to write the classification rules, which are: the structure of the soil (i.e., cohesive, granular, or granular cohesionless); the percentage of silt and clay in the soil, this percentage can be less or more than 15%; and the *Unconfined Compressive Strength value* (UCS), which is a result from the soil lab test and signifies the consistency and measures shear strength.

Different OSHA standard rules are translated to Semantic Web Rule Language (SWRL) to integrate them into the developed ontology. The next paragraph lists examples of SWRL in EW-SKB to classify the soil based on these quantitative properties. In addition, the pseudocode illustrates the logical steps to apply the rule. Soil classification is used to link to other rules related to the product hazards

Rule 1. This rule uses the structure of the soil, the clay percentage, and the UCS value to classify the soil and determine the soil texture.

Start
Input: The soil structure, the Silt and Clay percentage (scp), The value of (ucs)
Output: Soil classification, The soil texture
For each Soil sample **do**
If Soil has structure = "Cohesive" and scp > 15% and ucs >1.5 and **has** plasticity and **is** fissured
Set soil **has** type (A)
Set soil **has** texture (clay)
end if
end
End

Soil(?s)^hasStructure(?s,"Cohesive")^hasSiltAndClayPersentage(?s,?scp)^swrlb:greaterThan(?scp,0.15)^hasUnconfinedCompressiveStrengthValue(?s,?ucs)^swrlb:greaterThan(?ucs,1.5)^hasPlasticity(?s,true)^isFissured(?s,false)->Soil_Type_A(?s)^ hasType(?s,"A")^hasTexture (?s, "Clay")

3.2.2 Products Hazards

Products hazards describe the hazards that are linked to the final or intermediate outcomes of the processes and tasks, such as trenches, excavations, and holes. The focus here is on the trench-related hazards and how to improve the safety level in this type of earthwork.

OSHA rule number 1926.652, subpart P [25] is related to requirements for protective systems for

excavation. This clause specifies in general the rules related to trench shields. OSHA regulation (1926 Subpart P App B) [26] states the angle of slope for each type of soil. Based on these regulations, the following examples of SWRL rules link the workzones, the type of the earthwork operation, the type of the soil, the expected hazards, and how hazards can be avoided by performing certain procedures.

Rule 2. This rule checks the depth of the workzone. If the depth is more than 153 cm, then this workzone is classified as hazard workzone. The rule determines the type of hazard that this workzone has and which safety resources are needed to make it safer. As a result, the excavation operation is classified as hazard operation.

Start
Input: The workzone depth (d)
Type of the earthwork operation (exc)
Output: The potential hazard
The safety resource needed
Classification of the workzones
For each excavation operation **do**
For each workzone in the operation **do**
If d > 152 cm
Set workzone **has** hazard (CaveIn)
Set workzone **needs** safety resource (ProtectionSystem)
Set workzone **is** hazard workzone
Set excavation operation **has** hazard
end if
end
end
End

ExcavationOperation(?exc)^ProtectionSystem (?ps)^ CaveIn(?ca)^swrlb:greaterThan(?d,152)^has Depth (?w,?d)^hasWorkzone(?exc,?w)^Workzone(?w)-> hashazard(?w,?ca)^needSafetyResource(?w,?ps)^ HazardWorkzone(?w)^has (?exc, Hazard)

Rule 3. This rule classifies the earthwork operation based on the range of the depth and the soil type. If the depth of the operation in the range between 365 cm and 609 cm, and the soil type is A, then this operation is classified as hazard operation. The hazard type of this operation is Cave In hazard. Thus, this operation needs a safety procedure, which in this case is making a slop with 53˚.

Start
Input: The workzone depth (d), Type of Soil, and
Type of the earthwork operation (exc)
Output: The potential hazard, The safety procedure needed, Classification of the earthwork operation
For each excavation operation **do**
If d > 365 cm and < 609 cm and Soil Type = A
Set excavation operation **needs** safety procedure (Trench Slop)
Set excavation operation **needs** slop Angle 53˚
Set excavation operation **has** hazard (CaveIn)
Set excavation operation **is** hazard operation
end if
end
End

SlopingSystem(?ss)^Workzone(?w)^Excavation Operation(?exc)^hasWorkzone(?exc,?w)^ hasType (?s,"A")^CaveIn(?ca)^hasDepth(w,?d)^swrlb:greater Than (?d,365)^swrlb:lessThan (?d,609)^hasSoilType (?w,?s)^Soil(?s)-> needSafetyProcedure(?exc,?ss)^ needSlopAngle(?exc,53)^hashazard (?exc,?ca)^Hazard Operation (?exc)^has(?exc,Hazard)

The steps to identify the hazards in the earthwork workzones and equipment are illustrated in Figure 2. The algorithm considers the hazards in workzones, which are a combination of soil and product hazards.

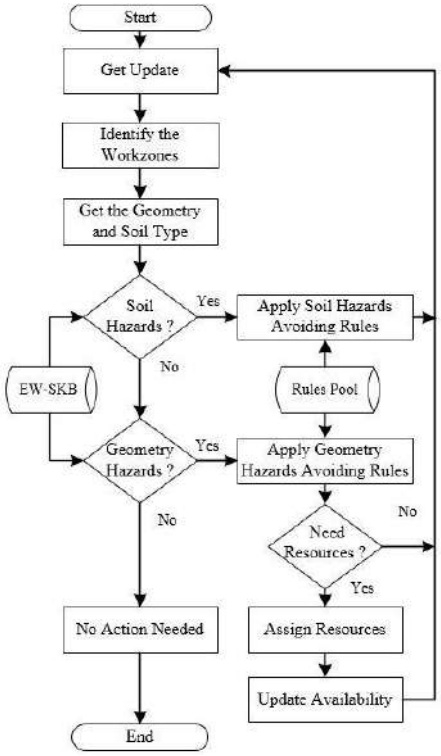

Figure 2. Material and product hazard identification

The steps begins with retrieving an update of a particular workzone. The type of workzone is identified (e.g., excavation or trench), followed by retrieving the geometry and soil type of the workzone. Then, the type of hazards are recognized based on applying the rules of the ontology. In the case that resources are needed to avoid the hazard (e.g., trench boxes), the assigned resources are used to update the availability of resources.

Then, an update is applied to ensure that the safety rules will not be triggered again.

3.2.3 Equipment Hazards

Several types of equipment (e.g., trucks, scrapers, dozers and hoes) are used in earthwork sites because of their ability to perform different tasks. These pieces of equipment are usually working together as a team to achieve the work. Equipment hazards could be called the operation hazards, where the risks are higher when several teams of equipment perform different tasks in parallel in a congested site. For equipment hazards, trucks are considered as sources of hazards when they are moving from one location to another. There are a variety of hazards related to trucks, which can increase the potential hazards of accidents and collisions, such as exceeding the maximum load or speed on roads and paths, and right-of-way regulations. Uncontrolled paths in construction sites pose high potential hazards to equipment and workers. Intersections have more complex traffic situations, which are influenced by a variety of safety rules, such as the permitted and prohibited directions and different priorities for equipment crossing the intersection at the same time. Moreover, the hazard level is raised when the equipment is operated by reckless drivers or poorly-trained operators. However, using a decision-support mechanism can help the operators in improving their safety.

Figure 3 illustrates how the hazards related to equipment are identified after retrieving the update of sensory data from the site.

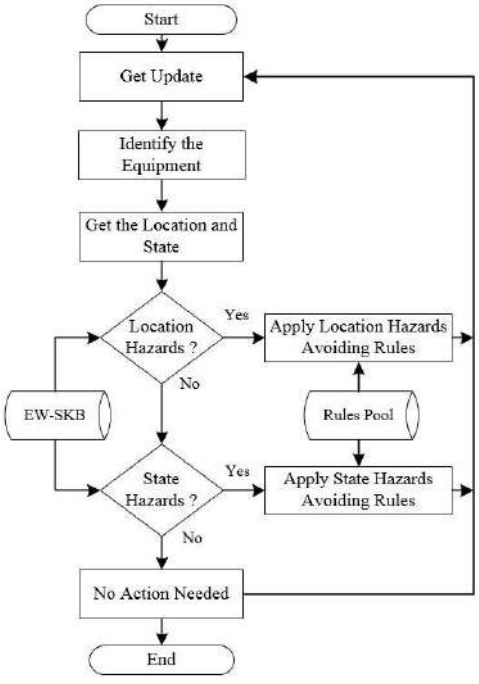

Figure 3. Equipment hazards identification

Generally, the equipment hazards are divided into two main categories, namely hazards related to equipment location and hazards related to the equipment state. Hazards related to equipment location are the result of changes in locations while the equipment is preforming a task (e.g., a truck or scraper moving between excavation and dumping area) or equipment relocation (e.g., a hoe moving from one workzone to another). Whereas the hazards related to the equipment state are the result of performing the tasks (e.g., a hoe swinging to the digging area). The hazards related to the equipment state are beyond the scope of this paper.

Data properties can obtain their values from sensors attached to the equipment (e.g., truck) and/or located on the paths and intersections. *locatedAt*, *movingFrom*, *goingTo*, *isOn*, *isUnder*, and *isToward* are object properties linked the individuals. Figure 4 shows a hazards situation where a group of three trucks performs their tasks (i.e., hauling and return from the dumping zones).

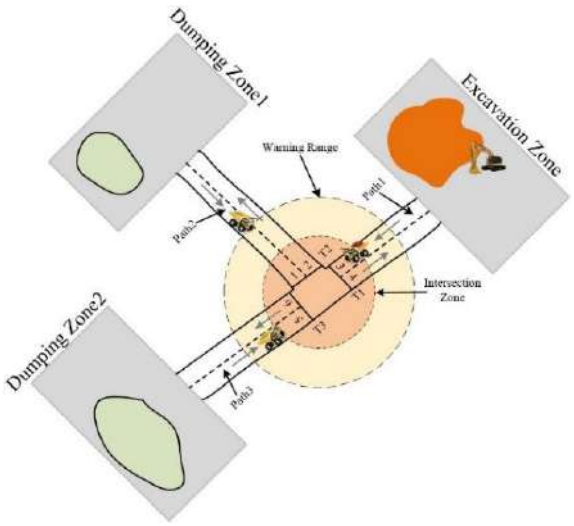

Figure 4. The case study scenario of the uncontrolled intersection

The trucks equipment are located near an uncontrolled intersection. This scenario simulates the hazards related to the equipment locations. Figure 4 shows the simulated scenario. Trucks on paths (1, 2, and 3) are moving in different directions. Each truck is labeled based on its direction and its path. SWRL is used to link the above-mentioned concepts with other concepts and entities in EW-Onto. SWRL is also used in EW-SKB to infer the safety decisions and create a safe driving environment, such as the right-of-way, sending a warning, order to stop, or order to slow down. The next SWRL rules are examples that formularize the knowledge about truck hazards at an uncontrolled intersection.

Rule 4. This rule illustrates an example of the orders that

trucks are received based on the situation of truck with the priority. In this rule, Truck1 has the priority, its direction is straight, and is located at the intersection. Thus, Truck3, which its direction is left receives the order to stop in case it is under the warning ranges.

Start
Input: The location, The direction, Truck name
Output: The order to stop or slow down
For each Truck do
If label = "Truck1" and location= isLocatedAt (IntersectionPointT1) and direction= "GoingStraight"
If label= "Truck3" and direction= "GoingLeft" and location =isUnder (Warning_Range)
Set Truck3 **has** Order (Stop)
end if
end if
end
End

Truck(?tr1)^hasLabel(?tr1,"Truck1")^isLocatedAt(?tr1, IntersectionPointT1)^hasDirection(?tr1,"GoingStraight")^Truck(?tr3)^hasLabel(?tr3,"Truck3")^hasDirection(?tr3,"GoingLeft")^isUnder?tr3,?wr)^Warning_Range(?wr) -> hasToStop(?tr3, true)

4 Implementation and Case Study

As mentioned in Section 1, EW-Onto is used as the main part of EW-SKB. In this paper, Protégé, 5.0.2 [27] is used to edit EW-Onto by adding the related concepts and relationships using a set of graphical plugins. Moreover, SWRL rules can be added and edited using Protégé. The verification is done by checking whether EW-SKB can answer the CQ or not. Furthermore, the consistency of EW-SKB is checked using a reasoner (HermiT reasoner). Figure 5 illustrates an example of using the reasoner engine based in Rule 1 to define the soil type.

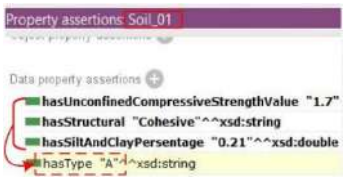

Figure 5. Reasoning engine result for soil classification

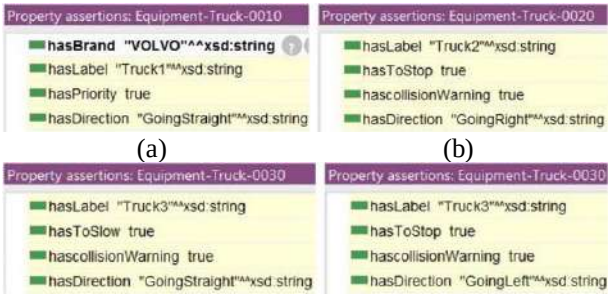
Thus, *Soil_01* is soil type A based on the values of this sample. Figure 6 provides examples of hazard related to workzone and excavation operation based on the Rules 2 and 3. Excavation-100-01 has inferred a hazard because it has an instance of workzone (i.e., Workzone001), and has soil type A.

A simulated case study is conducted to verify the developed implementation. As demonstrated in Figure 4 and based on Rule 4, Figure 7(a) shows the simulated scenario. Truck1 *isOn* Path1, and *isToward* the intersection. This truck gets the priority (*hasPriority: true*) because it is located in the intersection area and is loaded (*isLoaded: true*).

(a) (b)

Figure 6. Reasoning engine results for workzones (a) and for excavation operation (b)

The other trucks (Truck2 and Truck3) are ordered to stop or slow down. The messages to the other trucks are based on their locations and directions. For example, as shown in Figure 7(a), Truck1 is moving in a straight direction. Thus, Truck2 received the order to stop (*hasToStop=true*) as in Figure 7(b) and Truck3 received the order to slow down (*hasToSlow=true*) because its direction is also going straight (*hasDirection"GoingStright"*) as shown in Figure 7(c). Whereas the order will be changed to stop (*hasToStop=true*) if Truck3 direction is going left (*hasDirection" GoingLeft"*) as shown in Figure 7 (d).



(a) (b)

(b) (d)

Figure 7. Reasoning engine results in EW-SKB for trucks at an uncontrolled intersection.

5 Conclusion and Future Work

In this paper, the previously developed earthwork ontology (EW-Onto), has been augmented by adding safety knowledge base (EW-SKB). EW-SKB is a combination of essential knowledge related to the safety issues in earthwork, which can contribute to improving safety decision-making. Knowledge associated with safety is integrated with EW-Onto to link the different concepts in EW-SKB. EW-SKB has the added value of integrating different entities (e.g., equipment, trench, and

soil) in construction sites with safety regulations. The potential benefits of the developed ontology are combined from the scalability nature and the automatic inferring decisions that can be taken based on data collected from actual projects. The future work will focus on developing an approach to visualizing the decisions and combining soil and sensor ontologies, which will add a more robust base to extend EW-SKB. Thus, more comprehensive representation of the concepts and relationships will be included in the resulting ontology.

Combining Deep Learning and Robotics for Automated Concrete Delamination Assessment

E. McLaughlin[a], N. Charron[a], and S. Narasimhan[a]

[a]Department of Civil and Environmental Engineering, University of Waterloo, Canada
E-mail: em3mclau@uwaterloo.ca, ncharron@uwaterloo.ca, snarasim@uwaterloo.ca

Abstract –

Computer vision and robotics present tremendous opportunities for automating routine inspections of reinforced concrete bridges. One of the most critical aspects of these inspections is delamination assessment, as delaminations present immediate safety concerns due to falling concrete. Current methods of delamination assessment include hammer sounding and chain dragging, which are time consuming and difficult when accessibility is limited. Infrared technology presents an alternative method of assessing delaminations. In this work, a novel inspection method is proposed that uses an infrared camera combined with a convolutional neural network to automatically assess delaminations in infrared images. MobileNetV2 is implemented as an encoder with Deeplab V3 to perform pixel-wise segmentation in infrared images of delaminations.

The results show 74.5% mean intersection over union (mIoU) for predicting delaminated areas, which is comparable with the performance of this network architecture on benchmark data sets. Reviewing the predicted delamination areas also shows that the results accurately predict delamination locations, and accuracy limitations primarily exist in the fine outline details of the delamination. The automated delamination assessment method was also tested by mounting an upward facing thermal camera on a mobile ground robot to perform a bridge soffit inspection. The robotic scanning data set yielded a mIoU of 79.5% for delamination assessment. The increase in mIoU is likely due to the image data being better structured in the robotic images. This displays the ability to combine infrared imagery, convolutional neural networks, and unmanned mobile robots to meet case-specific accessibility needs for more accurate and time-efficient delamination assessment.

Convolutional neural network; Pixel-wise segmentation; automation; Delamination assessment; Bridge inspection

1 Introduction

Modern technologies in computer vision and robotics enable automation of routine tasks, with potential for improved efficiency in large-scale work. Routine concrete bridge inspection is one task where these technologies could provide great benefits [1]. In North America, there is demand for improved bridge inspections to more efficiently allocate the resources invested in bridge management. Routine inspections are performed by qualified inspectors following standardized guidelines (e.g., OSIM [2]). These inspections can be cumbersome and fraught with human error when access is limited due to long spans, water bodies, traffic conditions, and safety requirements. In addition, the results of routine inspections can be subjective and variable between inspectors [3].

One of the most important defects assessed during routine concrete bridge inspections is delamination. Concrete delamination can be described as a subsurface void in a concrete structure, which is caused by excessive internal stresses. The surface concrete next to the void is referred to as the delaminated concrete. Delaminations are critical, as they pose multiple safety hazards. The immediate hazard is that the mass of concrete below the void is likely to eventually fully detach and fall. This hazard is especially dangerous for bridges over high pedestrian or vehicular traffic areas.

In addition to being critical defects, delaminations are also one of the most difficult defects to assess during routine visual inspections because they are a subsurface defect that can seldom be detected by human vision. Currently, delaminations tend to be detected by manual process of hammer sounding or chain dragging to listen for hollow sounding concrete. These current sounding methods are time-consuming, inaccurate, and often not performed due to accessibility limitations. This makes delamination assessment a good candidate for an automated inspection method.

Infrared cameras combined with mobile robotic technologies present the opportunity for an efficient method of delamination assessment. The first step

towards developing this method is to use hand-held infrared cameras to assess delaminations. Delaminations can be identified in infrared images of concrete [4], as the delaminated concrete heats and cools at a different rate than the surrounding concrete. This occurs because the internal void acts as an insulating layer, making the delaminated concrete an independent, small mass [5]. This phenomenon makes delaminated areas often appear as a hot or a cold spot in an infrared image, depending on the time of day and environmental conditions. Detecting delaminations in infrared images is based on relative differences in thermal readings, so the absolute temperature of the delaminated areas is not critical for this study. Figure 1 shows examples of both hot and cold delaminations in infrared images of concrete bridge soffits.

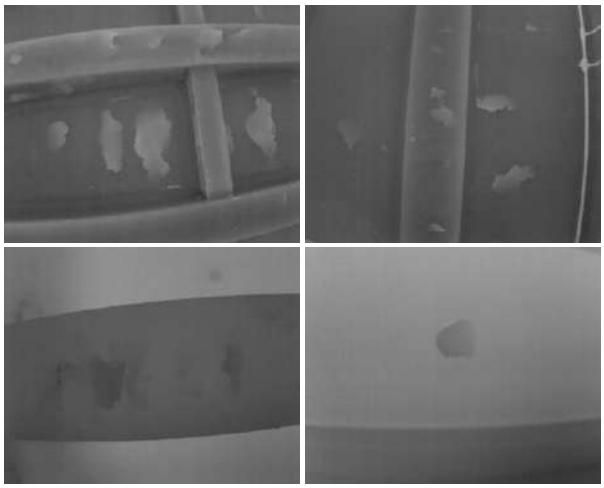

Figure 1. Examples of white-hot (top row) and black-cold (bottom row) delaminations in infrared images of concrete bridges.

Another advantage of using infrared cameras to detect delaminations is that this creates new possibilities for easy access to hard to reach bridge components. Many existing infrared cameras come in compact forms, ready to be mounted on an unmanned mobile robotic vehicle. This has the potential to eliminate many accessibility issues, as an infrared camera can be deployed on various vehicle types (aerial, ground, water) to account for the specific limitations of any bridge environment. For example, a bridge over water could have an upward facing infrared camera on a water vehicle to collect images. This proposed vision based infrared and robotic delamination assessment procedure provides a reasonable alternative in situations where traditional methods (e.g. hammer sounding) are not economically feasible due to special equipment and/or traffic control requirements.

Of all the advantages, perhaps the most useful advantage of using infrared imagery to assess delaminations is the ability to detect and localize the delaminations automatically using computer vision. In the computer vision community, there are two types of approaches that are used to automatically process image data for detecting objects of interest (delaminations being the objects of interest in this work): knowledge-driven methods and data-driven methods.

Knowledge-driven methods are based on the known characteristics of the object of interest. For example, this knowledge may include known colours and shapes of the objects of interest in the images. Knowledge based methods will often include human inputted rules for determining which features in images correspond to which objects. The second approach is data-driven methods, which rely on large quantities of labelled image data to train deep prediction networks. Once these networks have been trained to detect and localize the objects of interest based on the inputted data, they can then be used to detect and localize those objects on new data sets. These methods require large labelled data sets and significant processing resources to train the networks. Data-driven methods have become the method of choice for many computer vision based object recognition. These methods have consistently dominated computer vision competitions since a data-driven network first won the ImageNet challenge in 2012 [6].

For the assessment of concrete delaminations, knowledge-driven methods are difficult to implement successfully as delaminations have no definitive shape, and can show as a hot or cold area in the image depending on environmental conditions. This makes it difficult to determine a set of rules that will work across various delamination cases. Little research has been done to automatically assess delaminations using knowledge-driven methods, but some algorithms exist to automatically detect delaminations using a simple data-driven method (e.g., k-means clustering [7]). These existing methods are limited to specific bridge environments and often require some expert supervision.

Alternatively, convolutional neural networks (CNN) present an opportunity to use data-driven methods for fully automated detection. CNNs are considered state-of-the-art in computer vision as they currently dominate benchmarks such as [8], and can be leveraged to detect and localize objects of interest within images. Thus CNNs not only allow detection of images that show delaminations, but also provide the location of delaminated areas within each image. CNNs have yet to be applied to concrete bridge delamination assessment, but present a viable opportunity to improve upon existing results for delamination detection. This work proposes a CNN for semantic pixel-wise segmentation of delaminated areas within an infrared image of a reinforced concrete bridge.

The work presented herein can be divided into three main contributions. First, a versatile image labelling methodology is presented. This methodology fosters rapid pixel-wise labelling of concrete bridge defects in images to accelerate dataset building. Second, a novel approach is taken to concrete delamination detection and localization using infrared imagery combined with a convolutional neural network. Lastly, the described delamination detection methodology is demonstrated on a mobile ground robot. This final demonstration proves that the method presented herein can alleviate accessibility constraints in many bridge inspections. The methodology can be extended to aerial robots as well.

2 Related Works

Research work combining computer vision with concrete bridge inspection has primarily focused on automated crack detection and localization in visible spectrum images [9,10]. Some research has also been done on spall/delamination detection [11,12], but to a far lesser extent. With regards to delamination specifically, automated assessment via computer vision is still significantly limited. Since this work is focusing on delamination detection on concrete bridges using a CNN, this section will briefly present the work done to date on automated delamination detection as well as a the use of CNNs for general defect detection.

Automated detection of delaminations is fairly novel, as computer vision techniques applied to infrared imagery is required. Omar et al. [7] presented an automated procedure for detecting delaminations in concrete bridge decks using infrared thermography. They first created a thermal mosaic of the entire bridge deck from individual enhanced thermal images using a stitching algorithm. They then segmented the mosaic and identified objective thresholds using a k-means clustering method, to be able to identify delamination locations based on changes in heating patterns. This algorithm results in a condition map that effectively identifies delaminations within bridge decks.

A convolutional neural network (CNN) is a type of feed-forward neural network that utilizes the convolution operator in place of typical fully connected network layers. These CNNs are commonly applied to analyze inputs that have a grid-like data structure (e.g. pixel structure of images) [13]. Many practical computer vision applications require localization information within an image in addition to classification. Localization in this context means identifying which pixel areas in an image belong to a specific class (e.g., which pixels are part of a delamination). There are currently two CNN-based methods to achieve this: region based CNNs (R-CNN) and CNNs for semantic pixel-wise segmentation of images (semantic segmentation CNNs). R-CNNs improve on classification by adding a bounding box around the detected object to provide location information. Semantic segmentation CNNs provide structured grid-like data output, which provides pixel-level location accuracy within the image. Some researchers have begun to implement CNN algorithms for detection and/or localization of structural defects, and have shown promising results. However, much work is yet to be done for bridge inspections to incorporate the level of CNN technology that is currently available.

Region based CNNs (R-CNN) have been used more frequently than semantic segmentation CNNs. Cha et al. [14] developed a R-CNN algorithm for detecting cracks in high-resolution images. This method is computationally inefficient, as it uses a 256x256 pixel sliding window approach to classify each region as cracked/not cracked. The algorithm reported a high accuracy, but results were only tested on images of similar locations with a consistent background. This method was not proven to generalize to varying environments. Cha et al. [15] also used Faster R-CNN [16] for assessing five defect types (four types of steel defects and concrete cracking). This algorithm is efficient and showed promising test results for concrete cracks, but was limited to images of two bridges and a building complex. In addition, this study primarily focused on steel bridges rather than reinforced concrete bridges. Kim et al. [17] proposed a R-CNN as part of a complete bridge inspection solution. They used an unmanned aerial vehicle to collect images and combined it with a R-CNN for data processing and damage analysis. This work only studied visual images for crack assessment and did not investigate thermal defect analysis.

Zhang et al. [18] proposed a semantic segmentation CNN called CrackNet. CrackNet automates crack detection on 3D asphalt surfaces and maintains the shape of the original input image for pixel-wise classification/localization. This algorithm was successful for pixel-level detection of cracks but the results are only tested on asphalt. In addition, the algorithm is limited to crack labelling using 3D images from a high-quality PaveVision3D road inspection system. As a result, it is expected that this system cannot generalize to structural bridge inspections.

3 Methodology

The delamination assessment method proposed in this work uses a data-driven CNN for semantic pixel-wise segmentation. The first step to the proposed implementation is to collect a training data set large and diverse enough to provide high detection accuracy on a variety of concrete bridges. The following sections will

elaborate on the data collection and the labelling process. Finally, the implementation of the CNN will be presented in detail.

3.1 Image Data Set

A data-driven image segmentation approach is highly dependent on the size and quality of the image dataset provided. Therefore, collecting an adequate dataset to train, validate, and test a neural network is a critical step to the success of this method. There exist few public online data sets containing infrared images of delaminations, and no data sets where these images are labelled at a pixel-level to indicate delaminated areas. As a result, it is essential that a new infrared image data set be created and labelled appropriately.

The data set collected for this research consists of 500 infrared images taken of four reinforced concrete bridges in the cities of Kitchener and Waterloo, Ontario. The four selected bridges were in variable conditions. Images were taken at varying times of day, on different days, and under different weather conditions to ensure a variety in the data set. Of the 500 images, 261 contain some delamination, and 239 show no delamination in the concrete. All images were collected using a FLIR VUE Pro thermal camera. This camera can be mounted on small robots, including on unmanned aircraft systems, and can be remotely controlled. The camera has a 512x640 pixel resolution, and has a 7.5-13.5 micrometer spectral band. The images for this study were taken using the 'white hot' thermal camera setting (i.e., hot areas appear white in images, as shown in Figure 1).

The images that make up the dataset were collected in two ways: (1) manually and (2) automatically via unmanned ground robot. The manual method was used for the majority of the images in the dataset. In this case, the inspector held the camera. When the inspector suspected an area as delaminated, images were captured of that area using the FLIR camera phone application. The automatic image collection was done by mounting the FLIR camera in an upward facing configuration on a Husky unmanned ground robot (manufactured by Clearpath Robotics). Figure 2 shows this configuration including the robot and other sensors integrated into the system. This configuration allows the images to be captured at precise intervals and be synchronized with the other images taken on-board the robot. Furthermore, the exact position that the images were taken from can be determined based on the known coordinates of the robot.

The second collection method not only proves the additional benefits of integrating this defect detection method with other robotic sensors (e.g., GPS and visible spectrum cameras) but it also shows that this methodology can be used on any generic unmanned robot. As a result, this approach is suitable to address

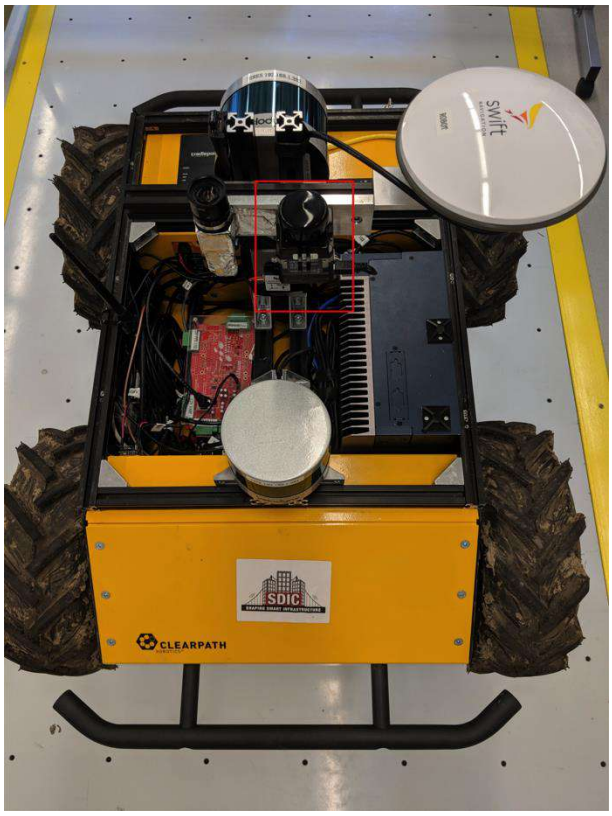

Figure 2. Husky unmanned ground vehicle with upward facing thermal camera.

the accessibility problems with delamination assessment by utilizing the mobility of aerial, ground, and surface robotics.

3.2 Image Labelling

To train the proposed CNN to detect objects in images at a pixel level, each training image needs all the pixels to be labelled as one of the classes. In this case, only two classes are used: (1) sound concrete, and (2) delamination. Semantic pixel-wise image labelling is a tedious task, even with only two classes. To help with the labelling, a labelling graphical user interface (GUI) was created using MATLAB [19]. The goal of this GUI is to be generic enough that it can be used to label image pixels for any number of defect types on concrete bridges. This GUI makes use of basic image processing techniques to provide an initial estimate of the defect locations, and then provides tools to manually fine-tune the labelling.

Figure 3 shows the process used to provide the initial estimate of the pixel labels, prior to manual editing. First the image is converted to grayscale. This is required as grayscale thresholding is used to generate the initial delamination segmentation estimate. Even though most of the images used for this dataset were

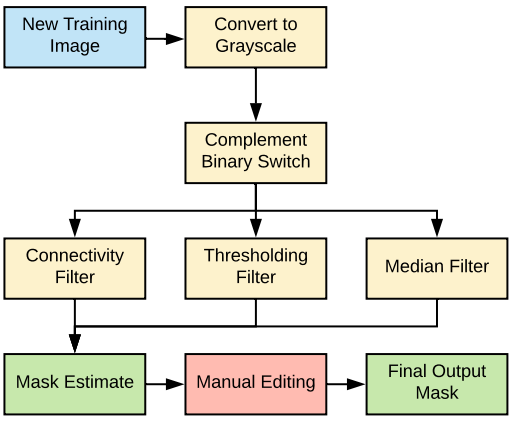

Figure 3. Flowchart of the image processing techniques used to simplify pixel-wise labelling.

collected in grayscale, this approach would generalize to any visible spectrum image or infrared images that use coloured heat gradients. The second step is to perform a complement binary switch (if required) to ensure the delamination consistently appears as back in the image mask. The three filters can then be applied including the thresholding, connectivity, and median filters. Each of these filters is applied using a sliding adjuster to allow easy editing of the three filters' sensitivities. Finally, a manual editing tool is used to remove unwanted areas or add missing areas.

Figure 4 shows the two main steps of the graphical interface for the image labeller. The top image shows the sliding filters. The bottom image shows the interface used for manually editing the initial mask.

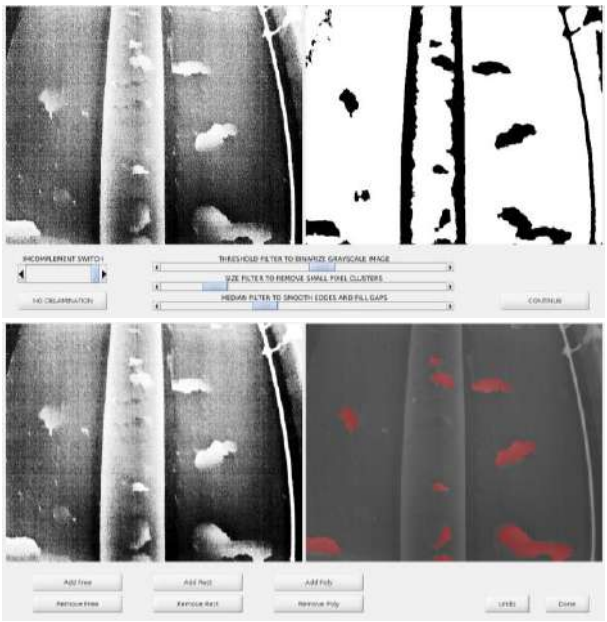

Figure 4. Image processing sliders to adjust delamination mask estimate (top) and GUI tools to manually adjust image mask (bottom).

These image processing techniques provide a good pixel-wise estimate of delaminated locations, but have several shortcomings. First, there tend to be other artifacts in the image that will be included during thresholding and cannot be removed by other filters. For example, girder edges tend to also heat/cool quicker than the surrounding concrete, giving them similar thermal patterns to a delaminated area. These edges are an example of an object requiring manual removal from the mask. Second, there can be some small gaps in the detected delamination area that cannot be fixed by the connectivity or median filters. This is an example of areas required to be manually added to the mask.

The described labelling approach allows for accurate, time-efficient labelling, which is necessary to be able to generate an adequate, well labelled data set. This approach has also been tested for labelling cracks, spalls, corrosion stains, and exposed reinforcement in concrete structures.

3.3 CNN Implementation

In order to properly assess delaminations in infrared imagery, both detection and pixel-level localization of the defect is required. In other words, it is not sufficient to say there is a delamination in the image, as the location of the delamination in the image is essential. The current state-of-the-art method for achieving this is a CNN algorithm. Many CNN algorithms exist to perform semantic pixel-wise segmentation, and often report exceptional results on standard segmentation data sets, such as Pascal VOC [8] or Cityscapes [20]. These datasets contain more classes, and more variable images compared to a dataset for delamination detection. Thus a similar quality of results should be expected when applied to delaminations, since the complexity of the data does not increase.

The network chosen for this application is MobileNetV2 [21] as a feature extractor with Deeplab V3 [22] to perform semantic pixel-wise segmentation. This network architecture was developed for mobile deployment, where time-efficiency is considered more important than accuracy. This is preferable as certain applications may benefit from real-time delamination assessment. For example, an inspector benefits more from real-time viewing of detected delamination locations on site than obtaining higher-resolution localization information about the exterior-boundary of the delaminated area.

The main building blocks of the network are from [21,22]. However, minor modifications were made to suit this specific application of this network to delamination assessment. The network input size is adjusted to be 512x640 to match the infrared image size. The last layer of the delamination prediction network is programmed to be a pixel-wise softmax activation layer,

which is given by the equation,

$$softmax(x)_i = \frac{\exp(x_i)}{\sum_{j=1}^{n} \exp(x_j)} \quad (1)$$

where x_i represents the network's calculated output score for a given class and n represents the number of classes [9]. In this case, $n = 2$ and the softmax activation is applied to predict each output pixel individually. This activation function restricts the output scores of each pixel to be between 0 and 1 so that the model can be trained using the categorical cross entropy (CCE) loss function, given by the equation,

$$J(\theta) = -\sum_{i=1}^{n} y_i \log(P(\theta)_i) \quad (2)$$

where θ represents the network weights, n is the number of possible classes, y_i is a binary classifier if the pixel does ($y_i = 1$) or does not ($y_i = 0$) belong to class i, and $P(\theta)_i$ is the network predicted likelihood that the pixel belongs to class i [9]. This combination of softmax output layer and CCE loss was used as it is generally considered best practice for multiple-class single-label classification. For this case it is also possible to use a sigmoid activation function with a binary cross entropy loss function, but this algorithm is intended to be scalable to include more defect classes in the future so the binary method was not preferred.

The network was trained using stochastic gradient descent [9], with a learning rate of 0.005, momentum of 0.9, and weight decay of 0.005/number of epochs. Image augmentation was used during training help prevent overfitting. Before each epoch, random transformations were applied to the training images only. These randomized image transformations include: flip horizontal, flip vertical, rotation, width and height shift, and zoom. This data augmentation ensured that the network would highly likely not see the exact same image twice during training.

4 Results

The collected 500 image data set was split into two main structures. The first structure consisted of randomly sorting the images into a 400 image training set, 50 image validation set, and 50 image test set. This yields a 80/10/10 dataset split. The second structure separated the images into a validation set consisting of images that were taken from the ground robot (Figure 2) under a bridge, and the training set consisted of all other images. This data split will be referred to as the robotic scanning split, where 62 images taken from a robot were used in the validation set and 436 of the remaining 438 images were used in the training set. Two images were left out to keep the number of training examples divisible by four (the desired batch size for this application).

The CNN algorithm for delamination assessment was reviewed for accuracy using the CCE loss (Equation 2) and mean intersection over union (mIoU) metrics. IoU is a common metric to compare segmentation results on benchmark datasets and is given by the equation,

$$IoU = \frac{TP}{TP + FP + FN} \quad (3)$$

where TP is true positives, FP is false positives, and FN is false negatives. In this application, positive is considered predicting a delamination and negative is considered predicting no delamination. CCE and mIoU were calculated and tracked at the end of each epoch for both the training and the validation set. Figure 5 shows the results of training on both dataset splits and Table 1 summarizes the final results.
